IMPROVEMENTS ON THE CANTOR-ZASSENHAUS FACTORIZATION ALGORITHM

Michele Elia, Torino, Davide Schipani, Zürich

(Received May 21, 2013)

Abstract. The paper presents a careful analysis of the Cantor-Zassenhaus polynomial factorization algorithm, thus obtaining tight bounds on the performances, and proposing useful improvements. In particular, a new simplified version of this algorithm is described, which entails a lower computational cost. The key point is to use linear test polynomials, which not only reduce the computational burden, but can also provide good estimates and deterministic bounds of the number of operations needed for factoring. Specifically, the number of attempts needed to factor a given polynomial, and the least degree of a polynomial such that a factor is found with at most a fixed number of attempts, are computed. Interestingly, the results obtained demonstrate the existence of some sort of duality relationship between these two problems.

Keywords: polynomial factorization; Cantor-Zassenhaus algorithm

MSC 2010: 12Y05, 12E30

1. Introduction

The Cantor-Zassenhaus polynomial factorization algorithm [5] is an efficient (polynomial-time) probabilistic algorithm for factoring polynomials over a finite field $\mathbb{F}_{p^m}$ which are the product of irreducible polynomials with common degree s and multiplicity one. When the multiplicity is above 1, the factors can be separated by computing the greatest common divisor of the given polynomial and its formal derivative. If the irreducible polynomials have different degrees, the factors are separated by computing the greatest common divisors with polynomials of the form $x^{p^{mr}-1}-1$, starting from $r=1$, so as to obtain the product of all irreducible factors of degree

The research was supported in part by the Swiss National Science Foundation under grants No. 126948 and 132256.

$r = 1, 2, \ldots$ (see e.g. [1]). Thus standard methods can be used to reduce the problem to the above case.

First, we will introduce the Cantor-Zassenhaus factorization algorithm, providing a non-standard description that will be the basis for the rest of the paper. In Section 2 we will discuss a more agile version of the algorithm, with more favorable estimates of its complexity and success rate. Further, the new description leads us to consider a deterministic version of the algorithm, so that in Section 3 we will deal with the problem of establishing how many attempts are needed in the worst case to obtain a factor. Lastly, in Section 4, we will consider a kind of dual problem, namely, what is the least degree of a polynomial such that a factor is found with at most a fixed number of attempts.

1.1. Preliminaries and notation. Let $f(z)$ be a polynomial of degree t over $\mathbb{F}_{p^m}$ which is the product of irreducible polynomials of degree s. We take first the case $s = 1$, and suppose that the trivial factor z does not divide $f(z)$. We first deal with the case $p = 2$, and following [5] we assume that m is even, otherwise we would consider a quadratic extension solely for the computations. If α is a known primitive element of $\mathbb{F}_{2^m}$, we define $l_m = (2^m - 1)/3$ and $\varrho = \alpha^{l_m}$, which is thus a primitive cubic root of unity in the field $\mathbb{F}_{2^m}$.

Let $c(z)$ be a non-constant polynomial over $\mathbb{F}_{2^m}$ of degree less than t, and let

$$a(z) = c(z)^{l_m} \bmod f(z),$$

which is again a polynomial of degree at most $t - 1$. Furthermore, we have

$$(c(z)^{l_m} + 1)(c(z)^{l_m} + \varrho)(c(z)^{l_m} + \varrho^2) = c(z)^{2^m - 1} - 1.$$

Now, either $\gcd(c(z), f(z))$ is nontrivial (and thus we already have a factor of $f(z)$) or else $c(z)^{2^m-1} - 1 = 0 \bmod f(z)$. In this latter case, if we write $c(z)^{2^m-1} - 1 = u(z)f(z) + r(z)$ and specialize it into the roots $\{z_i\}$ of $f(z)$, we see that $r(z)$, which is a polynomial of degree $t - 1$, takes the value 0 for all t roots, as $b^{2^m-1} - 1 = 0$ for any $b \in \mathbb{F}_{2^m}^*$. This implies that $r(z)$ is identically 0. Thus we can write

$$(c(z)^{l_m} + 1)(c(z)^{l_m} + \varrho)(c(z)^{l_m} + \varrho^2) = (a(z) + 1)(a(z) + \varrho)(a(z) + \varrho^2) = 0 \bmod f(z).$$

Since every factor of the product $(a(z)+1)(a(z)+\varrho)(a(z)+\varrho^2)$ has degree less than t, at least two of them must have a common nontrivial factor with $f(z)$, unless $a(z) = 1$, ϱ, ϱ^2. In this latter case, the Cantor-Zassenhaus algorithm considers another random polynomial instead of $c(z)$, and reiterates the procedure until all factors have been found.

Notice that $a(z) \equiv 0$ never occurs, since $c(z)$ has degree less than $f(z)$, so that at least one root of $f(z)$, say b, is not a root of $c(z)$; then substituting b in the identity $c(z)^{l_m} = v(z)f(z) + a(z)$, we get $a(b) \neq 0$, therefore $a(z)$ is not identically zero (this holds even if the roots of f were not in the field of the coefficients, as in the original description of the algorithm).

For the case $p > 2$, the procedure is similar: we consider $l_m = (p^m - 1)/2$ and $\varrho = \alpha^{l_m} = -1$, where α is a primitive element of $\mathbb{F}_{p^m}$. Here we compute $a(z) = c(z)^{l_m} \bmod f(z)$ and then factor as soon as $a(z) \neq \pm 1$.

Let us now consider the case $s > 1$. One option is to look at $\mathbb{F}_{p^{sm}}$, where the polynomial fully splits into linear factors: once a factor $z - b$ is found, it can be multiplied by the factors $z - b^{p^{mi}}$, with $1 \leqslant i \leqslant s-1$, to obtain an irreducible factor of degree s. A second option is to apply the algorithms over $\mathbb{F}_{p^m}$ ([2], [5]), to directly find the irreducible factors of degree s over $\mathbb{F}_{p^m}$. If $p = 2$, the argument follows as above: either $\gcd(c(z), f(z))$ is nontrivial, or $\gcd(c(z), f(z)) = 1$, in which case

$$(c(z)^{l_{sm}}+1)(c(z)^{l_{sm}}+\varrho)(c(z)^{l_{sm}}+\varrho^2) = (a(z)+1)(a(z)+\varrho)(a(z)+\varrho^2) = 0 \bmod f(z).$$

Since every factor of the product $(a(z) + 1)(a(z) + \varrho)(a(z) + \varrho^2)$ has degree less than t, at least two of them must have a common nontrivial factor with $f(z)$ in $\mathbb{F}_{2^m}$, unless $a(z) = 1$, ϱ, ϱ^2. In this latter case, the Cantor-Zassenhaus algorithm considers another random polynomial $c(z)$, and reiterates the procedure until all factors have been found.

For the case $p > 2$, the procedure is similar: we consider $l_{sm} = (p^{sm} - 1)/2$ and compute $a(z) = c(z)^{l_{sm}} \bmod f(z)$ and then factor as soon as $a(z) \neq \pm 1$.

In the next section we will present a variant of the Cantor-Zassenhaus algorithm, according to the description given above, and then deal with probabilistic as well as deterministic considerations about its success rate.

2. Variations of the algorithm

We focus first on the case $s = 1$ and show that it is enough, and indeed convenient, to choose $c(z) = z$ as the initial test polynomial, and to choose $c(z) = z + b$, for some random $b \neq 0$, as a further test polynomial, and to continue by choosing random b's different from the previous ones until a factor is found.

We then consider the case $s > 1$, where polynomials of degree 1 or s will be involved as test polynomials in order to obtain bounds on the number of attempts to find a factor.

More deterministic aspects of the algorithm will be postponed to Sections 3 and 4.

We notice that a similar approach was already presented in [2], [11], but only for the case of odd characteristic and factors of degree 1; also, the analysis was of a different type, with focus on the expected number of operations used by the algorithm.

2.1. Case $s = 1$. Suppose $f(z)$ is over $\mathbb{F}_{2^m}$ and $z^{l_m} = \varrho^i \bmod f(z)$, $i \in \{0, 1, 2\}$. Now, any element in $\mathbb{F}_{2^m}^*$ can be written as α^{k+3n}, with $k \in \{0, 1, 2\}$: we define $\mathcal{A}_0 = \{\alpha^{3i} \colon\ i = 0, \ldots, l_m - 1\}$, that is the subgroup of the elements of $\mathbb{F}_{2^m}^*$ that are cubic powers, and let $\mathcal{A}_1 = \alpha\mathcal{A}_0$ and $\mathcal{A}_2 = \alpha^2\mathcal{A}_0$ be the two cosets that complete the coset partition of $\mathbb{F}_{2^m}^*$. If we substitute α^{k+3n} for any root z_i of $f(z)$ in $z^{l_m} - \varrho^i = Q(z)f(z)$, we obtain $\varrho^k - \varrho^i = 0$, which implies $k = i$. This means that if $z^{l_m} = \varrho^i \bmod f(z)$, then all the roots of $f(z)$ are of the form α^{i+3n}, that is they belong to the same coset. When this situation occurs, we consider another test polynomial $c(z) = z + b$, which is equivalent to testing $c(z) = z$ for the polynomial $\varsigma(z)$ whose set of roots is $\{z_i + b\}$. The test succeeds as soon as we find a b such that the roots $z_i + b$ do not all belong to the same coset.

The next step is to determine an upper bound to the number of attempts needed in the worst case scenario, or on average, until a factor is found.

Let us first consider the simple case $t = 2$: suppose that z_1 and z_2 belong to the same coset; then we look for a b such that $z_1 + b$ and $z_2 + b$ are in different cosets. For the worst case scenario, we need to know how many pairs $(z_1 + b, z_2 + b)$ have both elements in the same coset. This is equivalent to knowing the number of ways in which $z_1 - z_2 = z_1 + b - (z_2 + b)$ can be written as the sum of two elements in the same coset. This number is actually $(2^m - 1)/3 - 1$, as can be deduced from [18], Theorem 1, specialized with $i = 0$ and χ the cubic character. So at most with $(2^m - 1)/3$ attempts we can factor a polynomial of degree 2. Clearly, at each test we can factor with a probability of $2/3$, so that the expected number of attempts is 1.5.

If $f(z)$ is a polynomial over $\mathbb{F}_{p^m}$, $p > 2$, then the maximum number of attempts is $(p^m - 1)/2$, by similar reasoning: we again use some additive properties of residues ([9], [10], [12], [18]). At each test we can factor with a probability of $1/2$, so that the expected number of attempts is 2.

The remainder of this paper will be devoted to establishing both the probabilistic estimates and the deterministic bounds on the number of attempts needed to successfully factor, for a generic t. A first deterministic, though very loose, bound is the following:

Proposition 2.1. *Let $s = 1$. The maximum number of attempts needed to find a factor is upper bounded by l_m (that is $(2^m - 1)/3$ or $(p^m - 1)/2$ for $p = 2$ or p odd, respectively). In particular, in the Cantor-Zassenhaus algorithm it is sufficient to consider only linear polynomials as test polynomials $c(z)$.*

P r o o f. In characteristic 2, if a root z_i belongs to a given known coset, we can test all the l_m elements of that coset, until we obtain z_i itself: $z_i + z_i$ adds to 0, which does not belong to any coset. Thus we will succeed with at most l_m attempts. In characteristic p greater than 2, it is sufficient to add all the elements of the coset multiplied by $p - 1$.

That it is enough to consider all the p^m monic linear polynomials is anyway clear, since computing $\gcd\{z - b, f(z)\}$ for all b in $\mathbb{F}_{p^m}$ would be enough to find all the factors. □

R e m a r k 2.1. The above argument implies that, if the first attempt fails, we know which coset the roots belong to, and can restrict our choice of b to that coset.

R e m a r k 2.2. Alternatively, the upper bounds of the proposition follow from the above remarks about $t = 2$: clearly, if t is greater than 2, then a degree-2 polynomial is anyway a factor of the t-degree polynomial, so that the maximum number of attempts cannot exceed the number needed to factor this degree-2 polynomial.

R e m a r k 2.3. In the original version of the Cantor-Zassenhaus algorithm, $\gcd(a(z), f(z))$ is computed when searching for a factor of $f(z)$, corresponding to the case when $\gcd(c(z), f(z))$ is nontrivial. Our version of the algorithm avoids this computation, since it is sufficient to evaluate $f(z)$ in b with any efficient polynomial evaluation algorithm; this can be done before elevating to the power l_m.

R e m a r k 2.4. If q is a prime factor of $p^m - 1$, then we may consider the exponent $l_m = (p^m - 1)/q$: in this case the probability of success is $(q - 1)/q$ and the corresponding expected number of attempts is $q/(q - 1)$, which is close to 1 already for small primes like 5 or 7; the drawback is that, if q is large, in the worst case we must check q greatest common divisors, namely $\gcd(a(z) + \zeta_q^j, f(z))$, for $0 \leqslant j \leqslant q - 1$, where ζ_q is the q-th primitive root of unity.

R e m a r k 2.5. It is interesting to assess the probability of factoring with the above method. Given that the set of $\{z_i + b\}$ for some b is made up of elements each belonging to a given coset $\mathcal{A}_i$ with probability $1/3$ (or $1/2$ in the case $p > 2$), the probability that they all belong to a common coset of the three is $3 \cdot 1/3^t$ (and $2 \cdot 1/2^t$ in case of the two cosets in $\mathbb{F}_{p^m}^*$, $p > 2$). Therefore the expected number of attempts to obtain a factor is $1/(1 - 1/3^{t-1}) = 1 + 1/(3^{t-1} - 1)$ or $1 + 1/(2^{t-1} - 1)$ and so decreases exponentially with the degree of the polynomial, so that the probability of factoring with one test is close to 1 when the degree is large enough. Clearly, once a factor is found, the polynomial splits into two parts, to which we can re-apply the previous computation if we are interested in a complete factorization, until all linear factors are obtained.

2.2. Case $s > 1$. If $s > 1$, either we look for linear factors in $\mathbb{F}_{p^{ms}}$, and the analysis is the same as in the case $s = 1$, or we choose the direct method, as explained in the previous section. In this latter case, by a similar argument as above, the algorithm succeeds as soon as $c(z_i)$, z_i being the roots of $f(z)$, are not all in the same coset. This is equivalent to requiring non conjugate roots to be not all in the same coset, as

$$c(z_i^{p^m})^{l_{sm}} = ((c(z_i))^{p^m})^{l_{sm}} = ((c(z_i))^{l_{sm}})^{p^m} = (c(z_i))^{l_{sm}}$$

by the properties of the Frobenius automorphism $\tau(z) = z^q$.

Let us examine this more precisely, describing in detail the case $p = 2$, while a similar argument applies in the case of odd primes. Let $f(z)$ be, as above, a polynomial of degree t over $\mathbb{F}_{2^m}$, which is the product of t/s irreducible polynomials $f_i(z)$ of degree s over the same field $\mathbb{F}_{2^m}$, where it is not restrictive to assume even m. According to the Cantor-Zassenhaus algorithm, a polynomial $c(z)$ over $\mathbb{F}_{2^m}$, relatively prime with $f(z)$, separates $f(z)$ into two polynomials of smaller degree if $a(z) = c(z)^{l_{sm}} \bmod f(z)$ is different from 1, ϱ, ϱ^2: at least two factors $f_i(z)$ are in two distinct greatest common divisors between $f(z)$ and $a(z) + 1$, $a(z) + \varrho$ and $a(z) + \varrho^2$, respectively.

Lemma 2.1. *With the above hypotheses and definitions, a polynomial $c(z)$ over $\mathbb{F}_{2^m}$ separates $f(z)$ into two polynomials, one containing the factor $f_1(z)$, and the other containing the factor $f_2(z)$, if and only if $c(z)^{l_{sm}} \bmod f_1(z) \neq c(z)^{l_{sm}} \bmod f_2(z)$. Equivalently, $f_1(z)$ and $f_2(z)$ are separated if and only if $c(z_1)$ and $c(z_2)$ belong to different cosets $\mathcal{A}'_h$ of $\mathbb{F}^*_{2^{sm}}$, where z_1 and z_2 are roots of $f_1(z)$ and $f_2(z)$, respectively.*

P r o o f. The polynomial $f(z)$ can be written as a product of three polynomials, i.e., $f_1(z)$, $f_2(z)$, and $f_r(z)$ which collect the remaining factors, thus $a(z)$ can be decomposed, using the Chinese Remainder Theorem (CRT), as

$$a(z) = a_1(z)\psi_1(z) + a_2(z)\psi_2(z) + a_r(z)\psi_r(z) \bmod f(z),$$
$$\psi_1(z) + \psi_2(z) + \psi_r(z) = 1,$$

where $a_1(z) = c(z)^{l_{sm}} \bmod f_1(z)$, $a_2(z) = c(z)^{l_{sm}} \bmod f_2(z)$, and $a_r(z) = c(z)^{l_{sm}} \bmod f_r(z)$.

If $a(z) = 1$, ϱ, ϱ^2, the uniqueness of the CRT decompositions implies that $a_1(z) = a_2(z) = a_r(z)$.

If $a(z) \neq 1$, ϱ, ϱ^2, then $c(z)$ separates $f(z)$ into two polynomials of smaller degree, and we distinguish two cases: 1) $a_1(z) \neq a_2(z)$: the polynomials $f_1(z)$ and $f_2(z)$ are in different factors because, if both of them were in the same factor, they would both

divide the same polynomial $a(z)+\varrho^h$, thus $a_i(z)=a(z)=\varrho^h$ modulo $f_i(z)$, $i=1,2$, contrary to the assumption.

2) $a_1(z)=a_2(z)$: $f_1(z)$ and $f_2(z)$ are in the same factor; if we suppose they are not, then $a_1(z)=a(z)=\varrho^{h_1} \bmod f_1(z) \neq a_2(z)=a(z)=\varrho^{h_2} \bmod f_2(z)$, yielding a contradiction.

Also, since $a(z)=c(z)^{l_{sm}} \bmod f(z)$ and $a(z)=a_i(z)=\varrho^{h_i} \bmod f_i(z)$, we have that $c(z_i)^{l_{sm}}=\varrho^{h_i}$, $i=1,2$, which means that $c(z_i)\in\mathcal{A}'_{h_i}$, hence it follows from the first part of the lemma that $c(z)$ separates $f_1(z)$ and $f_2(z)$ if and only if $c(z_1)\neq c(z_2)$. □

Now, as in the case $s=1$, we are interested in upper bounds for the number of attempts, and we can limit the choice of $c(z)$ according to our convenience. For example, if we know at least one primitive polynomial $m(z)$ of degree s, we can choose the polynomials $c(z)$ within the set of monic irreducible polynomials of degree s, so that we get directly p^{ms}/s as an upper bound. If we have no primitive polynomial of degree s, that is, we have no means of obtaining and drawing from the pool of irreducible polynomials of degree s, then we can choose the polynomials $c(z)$ within the larger set of monic polynomials of degree s, and we have the looser bound p^{ms}. Somewhat surprisingly, we show next that again it is usually actually sufficient to consider linear polynomials.

Let $\chi'_3(x)$ be a nontrivial cubic character over $\mathbb{F}_{2^{sm}}$, namely χ'_3 is a mapping from $\mathbb{F}^*_{2^{sm}}$ into the complex numbers defined as

$$\chi'_3(\alpha^h\theta)=\zeta_3^h, \quad \theta\in\mathcal{A}'_0,\ h=0,1,2,$$

α being a primitive element of $\mathbb{F}^*_{2^{sm}}$, ζ_3 a primitive complex cubic root of unity, and $\mathcal{A}'_0$ the coset of cubes in $\mathbb{F}^*_{2^{sm}}$. Moreover, we set $\chi'_3(0)=0$ by definition.

If z_1 and z_2 are roots of two distinct irreducible polynomials of degree s, we denote by $N_2^{(m)}(z_1,z_2)$ the number of monic polynomials $c(z)=z+b$ with $b\in\mathbb{F}_{2^m}$ such that $\chi'_3(c(z_1))=\chi'_3(c(z_2))$.

Proposition 2.2. *Let $s>1$. The maximum number N_A of attempts needed to find an irreducible factor of degree s, using monic linear polynomials as test polynomials, is upper bounded by $(2^m/3)(1+(4s-2)/\sqrt{2^m}+1/2^m)$ if $p=2$, or by $(p^m/2)(1+(2s-1)/\sqrt{p^m})$ if p is odd. In particular, linear polynomials are sufficient to find a factor if $(4s-2)/\sqrt{2^m}<2$ or $(2s-1)/\sqrt{p^m}<1$, respectively.*

P r o o f. In the case of characteristic 2, N_A is upper bounded by the maximum of $N_2^{(m)}(z_1,z_2)+1$ taken over all distinct pairs of roots z_1 and z_2 of distinct irreducible polynomials of degree s. Thus an upper bound for $N_2^{(m)}(z_1,z_2)$ independent of z_1 and z_2 is also an upper bound for N_A-1.

Consider the indicator function

$$I_{\mathcal{A}'_h}(c(z_i)) = \frac{1 + \overline{\zeta}_3^h \chi'_3(c(z_i)) + \zeta_3^h \bar{\chi}'_3(c(z_i))}{3}, \quad i = 1, 2,$$

which is 1 if the cubic character of $c(z_i)$ is ζ_3^h, and is 0 otherwise, if we suppose $c(z)$ relatively prime with $f(z)$.

Therefore, for a given $c(z)$ we have a coincidence whenever the product $I_{\mathcal{A}'_h}(c(z_1)) \cdot I_{\mathcal{A}'_h}(c(z_2))$ is 1. Thus,

$$\sum_{h=0}^{2} I_{\mathcal{A}'_h}(c(z_1)) I_{\mathcal{A}'_h}(c(z_2)) = \frac{1}{3}(1 + \chi'_3(c(z_1))\bar{\chi}'_3(c(z_2)) + \bar{\chi}'_3(c(z_1))\chi'_3(c(z_2)))$$

is the coincidence indicator for a fixed polynomial $c(z)$. Summing over all monic linear polynomials $z + b$ over $\mathbb{F}_{2^m}$, we get the total number $N_2^{(m)}(z_1, z_2)$ of coincidences

$$N_2^{(m)}(z_1, z_2) = \frac{1}{3} \sum_{b \in \mathbb{F}_{2^m}} (1 + \chi'_3(z_1 + b)\bar{\chi}'_3(z_2 + b) + \bar{\chi}'_3(z_1 + b)\chi'_3(z_2 + b)) - \frac{2}{3},$$

where $-2/3$ comes from excluding the polynomials $z + b$ having z_1 or z_2 as a root. For its computation, the summation is split into three summations: the first is simply 2^m, and the second and third are complex conjugated, thus it is enough to evaluate only

$$C = \sum_{b \in \mathbb{F}_{2^m}} \chi'_3(z_1 + b)\bar{\chi}'_3(z_2 + b).$$

This summation is hard to evaluate in closed form, thus we content ourselves with a bound. Namely, as χ'_3 can be viewed as the lifted character of a nontrivial character χ_3 over $\mathbb{F}_{2^m}$ ([7], [8]), we can write

$$C = \sum_{b \in \mathbb{F}_{2^m}} \chi_3(N_{F_{2^{ms}}/F_{2^m}}(z_1 + b))\bar{\chi}_3(N_{F_{2^{ms}}/F_{2^m}}(z_2 + b)),$$

where $N_{F_{2^{ms}}/F_{2^m}}(x) \doteq x x^{2^m} \dots x^{2^{m(s-1)}}$ is the relative norm of x.

Since $N_{F_{2^{ms}}/F_{2^m}}(z_i + b)$, $i = 1, 2$, are polynomials of degree s in b, and $\bar{\chi}_3 = \chi_3^2$, we can then use the Weil bound ([15], Theorem 2C′; cf. also [17], Lemma 2.2) to obtain

$$C < (2s - 1)2^{m/2}.$$

In conclusion, we obtain N_A bounded as

$$N_A < \frac{2^m}{3}\Big(1 + \frac{4s - 2}{\sqrt{2^m}} + \frac{1}{2^m}\Big). \tag{2.1}$$

The same argument holds similarly for p odd, and making the appropriate changes the conclusion is

$$N_A < \frac{p^m}{2}\Big(1 + \frac{2s-1}{\sqrt{p^m}}\Big). \tag{2.2}$$

□

3. Deterministic splitting I: fixed t

In the following we analyse the algorithm in greater detail from a deterministic point of view; in particular we will show that the maximum number of attempts to obtain a factor is usually very small, so that the algorithm, which is probabilistic in nature, can often be considered deterministic. In order to simplify the subsequent analysis, we will assume from now on that $s = 1$.

If we use the proposed variant of the Cantor-Zassenhaus algorithm, the tightest upper bound for the number of attempts necessary to split a polynomial $f(z)$ of degree t over F_{2^m} is equal to

$$M_2(t) \doteq 1 + \max_{z_1 \neq z_2 \neq \ldots \neq z_t} N_2(t),$$

where $N_2(t)$ is the number of solutions b of a system of t equations in $\mathbb{F}_{2^m}$ of the form

$$\begin{cases} \alpha^j w_1^3 + b = \alpha^k y_1^3, \\ \alpha^j w_2^3 + b = \alpha^k y_2^3, \\ \qquad\vdots \\ \alpha^j w_t^3 + b = \alpha^k y_t^3 \end{cases} \tag{3.1}$$

where $\alpha^j w_1^3, \alpha^j w_2^3, \ldots, \alpha^j w_t^3$ are given and distinct (i.e. they are the roots z_i of $f(z)$), whereas the y_is must be chosen in the field to satisfy the system, and the three values $\{0, 1, 2\}$ for k and j are all considered. However, we may assume $j = 0$ (and $z_i = w_i$), since dividing each equation by α^j and setting $b' = b\alpha^{-j}$ and $k' = k - j \bmod 3$, we see that the number of solutions of the system is independent of j. If the system is unsolvable, then the number of attempts is 1.

To evaluate $N_2(t)$, we define an indicator function of the sets $\mathcal{A}_u$ using the cubic character, namely for every $x \neq 0$

$$I_{\mathcal{A}_u}(x) = \frac{1 + \zeta_3^{2u}\chi_3(x) + \zeta_3^u\bar{\chi}_3(x)}{3} = \begin{cases} 1 & \text{if } x \in \mathcal{A}_u, \\ 0 & \text{otherwise,} \end{cases} \qquad u = 0, 1, 2$$

(where the bar over χ denotes complex conjugation). Then, given a z_i we can partition the elements $b \neq z_i^3$ in $\mathbb{F}_{2^m}$ into subsets depending on $k \in \{0,1,2\}$ so that $\chi_3(b+z_i^3) = \zeta_3^k$. Therefore, a solution of (3.1) for a fixed k and $j = 0$ is singled out by the product

$$\prod_{i=1}^{t} I_{\mathcal{A}_k}(b+z_i^3) = \frac{1}{3^t}\left[1 + \sum_{i=1}^{t} \sigma_i^{(k)}\right],$$

where each $\sigma_i^{(k)}$ is a homogeneous sum of monomials which are products of i characters of the form $\chi_3(b+z_h^3)$ or $\bar{\chi}_3(b+z_h^3)$. Thus

$$N_2(t) = \sum_{\substack{b\in\mathbb{F}_{2^m} \\ b\notin\{z_i^3\}}} \left[\prod_{i=1}^{t} I_{\mathcal{A}_0}(b+z_i^3) + \prod_{i=1}^{t} I_{\mathcal{A}_1}(b+z_i^3) + \prod_{i=1}^{t} I_{\mathcal{A}_2}(b+z_i^3)\right]. \tag{3.2}$$

The roots z_i in the sum need not be considered, since in any case they are not solutions ($z_i^3 + z_i^3 = 0$ cannot be in the same coset as $z_i^3 + z_j^3$ if $i \neq j$).

Similarly, in characteristic greater than 2, the tightest upper bound for the number of attempts necessary to split a polynomial $f(z)$ of degree t is equal to

$$M_p(t) \doteq 1 + \max_{z_1\neq z_2\neq\ldots\neq z_t} N_p(t),$$

where $N_p(t)$ is the number of solutions b of a system of t equations in $\mathbb{F}_{p^m}$ of the form

$$\begin{cases} \alpha^j w_1^2 + b = \alpha^k y_1^2, \\ \alpha^j w_2^2 + b = \alpha^k y_2^2, \\ \qquad\vdots \\ \alpha^j w_t^2 + b = \alpha^k y_t^2 \end{cases} \tag{3.3}$$

where $\alpha^j w_1^2, \alpha^j w_2^2, \ldots, \alpha^j w_t^2$ are given and distinct and the two values $\{0,1\}$ for k and j are considered. Again, we may assume $j = 0$ and we can define an indicator function of the sets $\mathcal{B}_u$ using the quadratic character, where $\mathcal{B}_0$ is the set of squares and $\mathcal{B}_1$ the complementary set in $\mathbb{F}_{p^m}^*$: namely, let χ_2 be the mapping from $\mathbb{F}_{p^m}^*$ into the complex numbers defined as

$$\chi_2(\alpha^h\theta) = (-1)^h, \quad \theta \in \mathcal{B}_0,\ h = 0,1.$$

Again, we set $\chi_2(0) = 0$.

The corresponding indicator function is thus

$$I_{\mathcal{B}_u}(x) = \frac{1+(-1)^u\chi_2(x)}{2} = \begin{cases} 1 & \text{if } x \in \mathcal{B}_u, \\ 0 & \text{otherwise,} \end{cases} \qquad u = 0, 1.$$

Given a z_i we partition $\mathbb{F}_{p^m} \setminus \{z_i^2\}$ into subsets depending on the value of k, so that $\chi_2(b+z_i^2) = (-1)^k$. Therefore, a solution of (3.3) for a fixed k is given by the product

$$\prod_{i=1}^{t} I_{\mathcal{B}_k}(b+z_i^2) = \frac{1}{2^t}\Big[1 + \sum_{i=1}^{t} \sigma_i^{(k)}\Big],$$

where each $\sigma_i^{(k)}$ is a homogeneous sum of monomials which are products of i characters of the form $\chi_2(b+z_h^2)$. Thus $N_p(t)$ is

$$N_p(t) = \sum_{\substack{b\in\mathbb{F}_{p^m} \\ b\notin\{-z_i^2\}}} \Big[\prod_{i=1}^{t} I_{\mathcal{B}_0}(b+z_i^2) + \prod_{i=1}^{t} I_{\mathcal{B}_1}(b+z_i^2)\Big]. \tag{3.4}$$

The following subsections deal with computations of $N_p(t)$ for small values of t, then with general bounds on $N_p(t)$.

3.1. Computations for small t. In the following computations, we will use some properties of nontrivial characters that we briefly mention: $\sum_{x\in\mathbb{F}_q} \chi(x) = 0$; if $b \neq 0$, then $\sum_{x\in\mathbb{F}_q} \chi(x)\bar{\chi}(x+b) = -1$ ([14], [18]). Moreover,

$$\sum_{x\in\mathbb{F}_{2^m}} \chi_3(x)\chi_3(x+1) = G_m(1,\chi_3) = -(-2)^{m/2},$$

with $G_m(1,\chi_3)$ being the Gauss sum [14].

We will start with the case $p = 2$. First we compute $N_2(2)$, already found above by another technique, then analogously $N_2(3)$.

▷ *Case* $p = 2$, $t = 2$: Setting $x_i = b + z_i^3$, we have

$$\prod_{i=1}^{2} I_{\mathcal{A}_h}(x_i) = \frac{1}{9}\big(1 + \sigma_1^{(h)} + \sigma_2^{(h)}\big), \quad h = 0, 1, 2,$$

where

$$\sigma_1^{(h)} = \zeta_3^{2h}\chi_3(x_1) + \zeta_3^{h}\bar{\chi}_3(x_1) + \zeta_3^{2h}\chi_3(x_2) + \zeta_3^{h}\bar{\chi}_3(x_2),$$
$$\sigma_2^{(h)} = \zeta_3^{h}\chi_3(x_1)\chi_3(x_2) + \chi_3(x_1)\bar{\chi}_3(x_2) + \bar{\chi}_3(x_1)\chi_3(x_2) + \zeta_3^{2h}\bar{\chi}_3(x_1)\bar{\chi}_3(x_2).$$

Since $\sigma_1^{(0)}+\sigma_1^{(1)}+\sigma_1^{(2)}=0$ and $\sigma_2^{(0)}+\sigma_2^{(1)}+\sigma_2^{(2)}=3(\chi_3(x_1)\bar\chi_3(x_2)+\bar\chi_3(x_1)\chi_3(x_2))$, the sum of the three products $\prod_{i=1}^{2} I_{\mathcal{A}_k}(x_i)$ is $(1/3)(1+\chi_3(x_1)\bar\chi_3(x_2)+\bar\chi_3(x_1)\chi_3(x_2))$, and thus the sum over b in the whole field $\mathbb{F}_{2^m}$, with the exclusion of $b=z_1^3$ and $b=z_2^3$, is

$$N_2(2)=\frac{1}{3}\biggl(2^m-2+\sum_{b\neq z_1^3,\,z_2^3}\bigl(\chi_3(b+z_1^3)\bar\chi_3(b+z_2^3)+\bar\chi_3(b+z_1^3)\chi_3(b+z_2^3)\bigr)\biggr).$$

Let S denote the above summation, then S can be evaluated in closed form: by the substitution $b=z_1^3+\eta$, since χ_3 is a nontrivial cubic character, we have

$$S=\sum_{\eta\neq 0,\,z_1^3+z_2^3}(\chi_3(\eta)\bar\chi_3(\eta+z_1^3+z_2^3)+\bar\chi_3(\eta)\chi_3(\eta+z_1^3+z_2^3))=-2,$$

as the summation of each of the two parts gives -1 ($z_1^3+z_2^3\neq 0$ by hypothesis). In conclusion,

$$N_2(2)=\frac{1}{3}(2^m-4),$$

so that we have

Proposition 3.1. *$M_2(2)=(2^m-1)/3$.*

▷ *Case $p-2$, $t=3$*: In this case

$$\prod_{i=1}^{3} I_{\mathcal{A}_h}(b+z_i^3)=\frac{1}{27}(1+\sigma_1^{(h)}+\sigma_2^{(h)}+\sigma_3^{(h)}),\quad h=0,1,2,$$

where

$$\begin{aligned}
\sigma_1^{(h)}&=\zeta_3^{2h}\chi_3(x_1)+\zeta_3^{h}\bar\chi_3(x_1)+\zeta_3^{2h}\chi_3(x_2)+\zeta_3^{h}\bar\chi_3(x_2)+\zeta_3^{2h}\chi_3(x_3)+\zeta_3^{h}\bar\chi_3(x_3),\\
\sigma_2^{(h)}&=\zeta_3^{h}\chi_3(x_1)\chi_3(x_2)+\chi_3(x_1)\bar\chi_3(x_2)+\bar\chi_3(x_1)\chi_3(x_2)+\zeta_3^{2h}\bar\chi_3(x_1)\bar\chi_3(x_2)\\
&\quad+\zeta_3^{h}\chi_3(x_2)\chi_3(x_3)+\chi_3(x_2)\bar\chi_3(x_3)+\bar\chi_3(x_2)\chi_3(x_3)+\zeta_3^{2h}\bar\chi_3(x_2)\bar\chi_3(x_3)\\
&\quad+\zeta_3^{h}\chi_3(x_3)\chi_3(x_1)+\chi_3(x_3)\bar\chi_3(x_1)+\bar\chi_3(x_3)\chi_3(x_1)+\zeta_3^{2h}\bar\chi_3(x_3)\bar\chi_3(x_1),\\
\sigma_3^{(h)}&=\chi_3(x_1)\chi_3(x_2)\chi_3(x_3)+\bar\chi_3(x_1)\bar\chi_3(x_2)\bar\chi_3(x_3)+\zeta_3^{2h}\bar\chi_3(x_1)\chi_3(x_2)\chi_3(x_3)\\
&\quad+\zeta_3^{2h}\chi_3(x_1)\bar\chi_3(x_2)\chi_3(x_3)+\zeta_3^{2h}\chi_3(x_1)\chi_3(x_2)\bar\chi_3(x_3)\\
&\quad+\zeta_3^{h}\bar\chi_3(x_1)\bar\chi_3(x_2)\chi_3(x_3)+\zeta_3^{h}\chi_3(x_1)\bar\chi_3(x_2)\bar\chi_3(x_3)+\zeta_3^{h}\bar\chi_3(x_1)\chi_3(x_2)\bar\chi_3(x_3).
\end{aligned}$$

We thus have

$$\begin{aligned}
\sigma_1^0+\sigma_1^1+\sigma_1^2&=0,\\
\sigma_2^0+\sigma_2^1+\sigma_2^2&=3(\chi_3(x_1)\bar\chi_3(x_2)+\bar\chi_3(x_1)\chi_3(x_2)+\chi_3(x_2)\bar\chi_3(x_3)\\
&\qquad+\bar\chi_3(x_2)\chi_3(x_3)+\chi_3(x_3)\bar\chi_3(x_1)+\bar\chi_3(x_3)\chi_3(x_1)),\\
\sigma_3^0+\sigma_3^1+\sigma_3^2&=3(\chi_3(x_1)\chi_3(x_2)\chi_3(x_3)+\bar\chi_3(x_1)\bar\chi_3(x_2)\bar\chi_3(x_3)).
\end{aligned}$$

In the summation over b of the sum of the three products, the values of $b = z_1^3, z_2^3, z_3^3$ should be excluded. Thus we must compute

$$N_2(3) = \frac{1}{9}\Big(2^m - 3 + \frac{1}{3}\sum_{b\neq z_1^3,z_2^3,z_3^3}[(\sigma_2^0+\sigma_2^1+\sigma_2^2)+(\sigma_3^0+\sigma_3^1+\sigma_3^2)]\Big).$$

Therefore, two types of summations must be evaluated, namely

$$S_2 = \sum_{b\neq z_1^3,z_2^3,z_3^3}\chi_3(b+z_1^3)\bar{\chi}_3(b+z_2^3) \quad \text{and} \quad S_3 = \sum_{b\neq z_1^3,z_2^3,z_3^3}\chi_3(b+z_1^3)\chi_3(b+z_2^3)\chi_3(b+z_2^3),$$

the remaining ones being obtained by symmetry or complex conjugation. Considering S_2, and defining for short $y_1 = z_2^3 + z_3^3$, $y_2 = z_1^3 + z_3^3$, and $y_3 = z_2^3 + z_1^3$, we have

$$\begin{aligned} S_2 &= -\chi_3(y_2)\bar{\chi}_3(y_1) + \sum_{b\neq z_1^3,z_2^3}\chi_3(b+z_1^3)\bar{\chi}_3(b+z_2^3) \\ &= -\chi_3(y_2)\bar{\chi}_3(y_1) + \sum_{x\neq 0,y_3}\chi_3(x)\bar{\chi}_3(x+y_3), \end{aligned}$$

thus $S_2 = -\chi_3(y_2)\bar{\chi}_3(y_1) - 1$. Considering S_3 we have

$$S_3 = \sum_{b\neq z_1^3,z_2^3,z_3^3}\chi_3(b+z_1^3)\chi_3(b+z_2^3)\chi_3(b+z_3^3) = \sum_{x\neq 0,y_2,y_3}\chi_3(x)\chi_3(x+y_3)\chi_3(x+y_2),$$

thus, with the change of variable $x = 1/z$, since the character is cubic we obtain

$$\begin{aligned} S_3 &= \sum_{z\neq 0,1/y_2,1/y_3}\chi_3(1+zy_3)\chi_3(1+zy_2) \\ &= \sum_{X\neq 1,0,1+y_3/y_2}\chi_3(X)\chi_3\Big(X\frac{y_2}{y_3}+1+\frac{y_2}{y_3}\Big), \\ S_3 &= \chi_3(y_2)\bar{\chi}_3(y_3)\sum_{X\neq 1,0,1+y_3/y_2}\chi_3(X)\chi_3\Big(X+1+\frac{y_3}{y_2}\Big) \\ &= -1+\chi_3(y_2)\bar{\chi}_3(y_3)\sum_{X\neq 0,1+y_3/y_2}\chi_3(X)\chi_3\Big(X+1+\frac{y_3}{y_2}\Big) \\ &= -1+\bar{\chi}_3(y_2)\bar{\chi}_3(y_3)\bar{\chi}_3(y_1)\sum_{x\in\mathbb{F}_{2^m}}\chi_3(x)\chi_3(x+1). \end{aligned}$$

In conclusion, we obtain

$$\begin{aligned} N_2(3) = \frac{1}{9}[2^m - 11 - (-2)^{m/2}[\chi_3(y_1y_2y_3)+\bar{\chi}_3(y_1y_2y_3)] - (\chi_3(y_1y_2^2)+\chi_3(y_1^2y_2) \\ + \chi_3(y_2y_3^2)+\chi_3(y_2^2y_3)+\chi_3(y_3y_1^2)+\chi_3(y_3^2y_1))]. \end{aligned}$$

Note that, if $z_1 = 0$ (which corresponds to choosing b in one particular coset), then y_2 and y_3 are cubes, and the number of solutions is

$$N_2(3) = \frac{1}{9}(2^m - 13 - [(-2)^{m/2} + 2][\chi_3(y_1) + \bar{\chi}_3(y_1)]).$$

Finally, we focus our interest on the maximum over the z_i and obtain

Proposition 3.2.

$$M_2(3) = \begin{cases} \dfrac{1}{9}(2^m + 2^{m/2} - 2) & \text{for } m/2 \text{ even,} \\ \dfrac{1}{9}(2^m + 2^{m/2+1} + 1) & \text{for } m/2 \text{ odd.} \end{cases}$$

Let us now deal with the case $p > 2$:

▷ *Case* $p > 2$, $t = 2$: In this case, we have

$$\prod_{i=1}^{2} I_{\mathcal{B}_h}(b + z_i^2) = \frac{1}{4}(1 + \sigma_1^{(h)} + \sigma_2^{(h)}), \quad h = 0, 1,$$

where $\sigma_1^{(h)} = (-1)^h \chi_2(x_1) + (-1)^h \chi_2(x_2)$, and $\sigma_2^{(h)} = \chi_2(x_1)\chi_2(x_2)$.

Since $\sigma_1^{(0)} + \sigma_1^{(1)} = 0$ and $\sigma_2^{(0)} + \sigma_2^{(1)} = 2(\chi_2(x_1)\chi_2(x_2))$, the sum over b in the whole field $\mathbb{F}_{p^m}$, with the exclusion of $b = -z_1^2$ and $b = -z_2^2$, is

$$N_p(2) = \frac{1}{2}\left(p^m - 2 + \sum_{b \neq -z_1^2, -z_2^2} \chi_2(b + z_1^2)\chi_2(b + z_2^2)\right).$$

Let S denote the above summation: we evaluate it in closed form by substituting $b = \eta - z_1^2$; since χ_2 is a nontrivial quadratic character, we have

$$S = \sum_{\eta \neq 0, z_1^2 - z_2^2} \chi_2(\eta)\chi_2(\eta + z_2^2 - z_1^2) = -1,$$

the summation being independent of the term $z_2^2 - z_1^2$, which is nonzero by hypothesis. In conclusion

$$N_p(2) = \frac{1}{2}(p^m - 3),$$

so that we have

Proposition 3.3. $M_p(2) = \frac{1}{2}(p^m - 1)$.

▷ *Case* $p > 2$, $t = 3$: In this case

$$\prod_{i=1}^{3} I_{\mathcal{B}_h}(b + z_i^2) = \frac{1}{8}(1 + \sigma_1^{(h)} + \sigma_2^{(h)} + \sigma_3^{(h)}), \quad h = 0, 1,$$

where $\sigma_1^{(h)} = (-1)^h\chi_2(x_1) + (-1)^h\chi_2(x_2) + (-1)^h\chi_2(x_3)$, $\sigma_2^{(h)} = \chi_2(x_1)\chi_2(x_2) + \chi_2(x_1)\chi_2(x_3) + \chi_2(x_2)\chi_2(x_3)$, and $\sigma_3^{(h)} = (-1)^h\chi_2(x_1)\chi_2(x_2)\chi_2(x_3)$.

Since $\sigma_1^0 + \sigma_1^1 = 0$, $\sigma_2^0 + \sigma_2^1 = 2(\chi_2(x_1)\chi_2(x_2) + \chi_2(x_1)\chi_2(x_3) + \chi_2(x_2)\chi_2(x_3))$, and $\sigma_3^0 + \sigma_3^1 = 0$, the summation over b of the sum of the two products, where the values of b equal to $-z_1^2, -z_2^2$, and $-z_3^2$ are excluded, becomes

$$N_p(3) = \frac{1}{4}\bigg(p^m - 3 + \sum_{b \neq -z_1^2, -z_2^2, -z_3^2} [\chi_2(x_1)\chi_2(x_2) + \chi_2(x_1)\chi_2(x_3) + \chi_2(x_2)\chi_2(x_3)]\bigg).$$

We thus need to evaluate only one type of summation, namely

$$\begin{aligned} S_2 &= \sum_{b \neq -z_1^2, -z_2^2, -z_3^2} \chi_2(b + z_1^2)\chi_2(b + z_2^2) \\ &= \sum_{\eta \neq 0,\, z_1^2 - z_2^2,\, z_1^2 - z_3^2} \chi_2(\eta)\chi_2(\eta + z_2^2 - z_1^2) \\ &= -1 - \chi_2(z_1^2 - z_3^2)\chi_2(z_2^2 - z_3^2), \end{aligned}$$

the remainder being obtained by symmetry. In conclusion, we obtain

$$\begin{aligned} N_p(3) = \frac{1}{4}[p^m - 6 - (&\chi_2(z_1^2 - z_3^2)\chi_2(z_2^2 - z_3^2) + \chi_2(z_1^2 - z_2^2)\chi_2(z_3^2 - z_2^2) \\ &+ \chi_2(z_3^2 - z_1^2)\chi_2(z_2^2 - z_1^2))]. \end{aligned}$$

And, if we consider the maximum, we have

Proposition 3.4.

$$M_p(3) = \begin{cases} \frac{1}{4}(p^m - 1), & p = 4k + 1, \\ \frac{1}{4}(p^m + 1), & p = 4k + 3,\ m \textit{ odd}, \\ \frac{1}{4}(p^m - 1), & p = 4k + 3,\ m \textit{ even}. \end{cases}$$

3.2. Bounds. As the number of equations in system 3.1 or 3.3 becomes larger, exact computations become less meaningful for our purpose, as it would then be necessary to consider estimates and bounds of rather cumbersome expressions. We

will thus shift our interest to a general upper bound for the function $N_p(t)$; we will first deal with the case $p = 2$, then the case $p > 2$.

▷ *Case* $p = 2$: Consider equation (3.2) written as

$$N_2(t) = \frac{1}{3^t} \sum_{\substack{b \in \mathbb{F}_{2^m} \\ b \notin \{z_i^3\}}} [\mathfrak{P}_0 + \mathfrak{P}_1 + \mathfrak{P}_2], \tag{3.5}$$

where

$$\mathfrak{P}_k = 3^t \prod_{i=1}^{t} I_{\mathcal{A}_k}(x_i) = 1 + \sigma_1^{(k)} + \sigma_2^{(k)} + \ldots + \sigma_t^{(k)}, \quad k = 0, 1, 2,$$

x_i being $b + z_i^3$, and each $\sigma_j^{(k)}$ is a sum of monomials which are products of the same number j of distinct variables (characters) $\chi_3(x_i)$ or $\bar{\chi}_3(x_i)$, possibly times ζ_3 or ζ_3^2. In particular, the number of addends in $\sigma_j^{(k)}$ is $2^j \binom{t}{j}$.

Define $\sigma_j = \sigma_j^{(0)} + \sigma_j^{(1)} + \sigma_j^{(2)}$ for every $j = 1, \ldots, t$; then σ_j contains fewer addends than any $\sigma_j^{(k)}$, since all monomials multiplied by either ζ_3 or ζ_3^2 are canceled out with monomials multiplied by 1, and the surviving monomials are multiplied by 3 (see also the examples above). In particular, σ_1 is zero; σ_2 is a sum of monomials of the form $\chi_3(x_i)\bar{\chi}_3(x_l)$ (i, l distinct), whose total number is $2\binom{t}{2}$; σ_3 is a sum of monomials of the form $\chi_3(x_i)\chi_3(x_l)\chi_3(x_m)$ (i, l, m all distinct), whose total number is $2\binom{t}{3}$; and σ_4 is a sum of monomials of the form $\chi_3(x_i)\chi_3(x_l)\bar{\chi}_3(x_m)\bar{\chi}_3(x_s)$ (i, l, m, s all distinct), whose total number is $6\binom{t}{4}$. In general, the number of surviving monomials of degree j can be computed by considering that each monomial is a product of n_1 characters and n_2 complex conjugate characters; thus $n_1 + n_2 = j$. Supposing that $\chi_3(x_i)$ are multiplied by ζ_3 and $\bar{\chi}_3(x_h)$ are multiplied by ζ_3^2, the surviving monomial satisfies the condition $n_1 + 2n_2 = 0 \bmod 3$. Therefore, the admissible values of $0 \leqslant n_2 \leqslant j$ satisfy the condition $n_2 = 2j \bmod 3$: if $e = 2j \bmod 3$ and $e \in \{0, 1, 2\}$, the number of surviving monomials is $\binom{t}{j} a_j$, where $a_j = \sum_{h=0}^{\lfloor (j-e)/3 \rfloor} \binom{j}{e+3h}$, with $\{a_j\}_{\mathbb{Z}_{>1}} = 2, 2, 6, 10, 22, 42, 86, 170, 342, \ldots$ matching the sequence A078008 in [16] with the first two terms disregarded. We observe now that the product of j characters, whose arguments are distinct linear functions of b, can be interpreted as a single character whose argument is a polynomial $f(b)$ with j distinct roots: by [15], Theorem 2C′, each sum of these characters is upper bounded by $(j-1)\sqrt{2^m}$, so that

$$N_2(t) \leqslant \frac{1}{3^{t-1}} \left[2^m - t + \sum_{j=2}^{t} a_j (j-1) \binom{t}{j} \sqrt{2^m} \right].$$

The summation above is evaluated as follows, using the expression $a_j = \frac{1}{3}\sum_{h=0}^{2} \zeta_3^{-he} \times (1+\zeta_3^h)^j$ for the sequence a_j as can be found in [3], [6]:

$$\sum_{j=2}^{t} a_j(j-1)\binom{t}{j} = \sum_{j=2}^{t}\frac{1}{3}\sum_{h=0}^{2}\zeta_3^{-he}(1+\zeta_3^h)^j(j-1)\binom{t}{j}$$
$$= \frac{1}{3}\sum_{h=0}^{2}\sum_{j=2}^{t}\zeta_3^{-he}(1+\zeta_3^h)^j(j-1)\binom{t}{j}.$$

Now, observing that $e = -j \bmod 3$ and ζ_3 is a cubic root of unity, we may substitute ζ_3^{hj} for ζ_3^{-he} and write $(\zeta_3^h+\zeta_3^{2h})^j$ for $\zeta_3^{hj}(1+\zeta_3^h)^j$ in the last expression, which we then write as

$$\frac{1}{3}\sum_{h=0}^{2}\sum_{j=0}^{t}(\zeta_3^h+\zeta_3^{2h})^j(j-1)\binom{t}{j}+1$$
$$= 1+\frac{1}{3}\sum_{h=0}^{2}\left(\sum_{j=0}^{t} j(\zeta_3^h+\zeta_3^{2h})^j\binom{t}{j} - \sum_{j=0}^{t}(\zeta_3^h+\zeta_3^{2h})^j\binom{t}{j}\right).$$

Using the binomial sum and its derivative, we finally obtain

$$\sum_{j=2}^{t} a_j(j-1)\binom{t}{j} = 1+\frac{1}{3}\sum_{h=0}^{2}(t(\zeta_3^h+\zeta_3^{2h})(1+\zeta_3^h+\zeta_3^{2h})^{t-1} - (1+\zeta_3^h+\zeta_3^{2h})^t),$$

that is

$$\sum_{j=2}^{t} a_j(j-1)\binom{t}{j} = 1+\frac{1}{3}[2t\,3^{t-1}-3^t],$$

because $(1+\zeta_3^h+\zeta_3^{2h})$ is 3 when $h=0$ and is 0 otherwise. In conclusion

$$N_2(t) \leqslant \frac{1}{3^{t-1}}\left[2^m+\sqrt{2^m}-t+3^{t-2}(2t-3)\sqrt{2^m}\right], \tag{3.6}$$

where we see that, when $3^{t-2}(2t-3)\sqrt{2^m}-t+\sqrt{2^m} \ll 2^m$, roughly $t \ll m/2$, then $N_2(t) \simeq 2^m/3^{t-1}$.

▷ *Case* $p > 2$: In the case $p > 2$, consider equation (3.4) written as

$$N_p(t) = \frac{1}{2^t}\sum_{\substack{b\in\mathbb{F}_{p^m}\\ b\notin\{-z_i^2\}}}[\mathfrak{Q}_0+\mathfrak{Q}_1], \tag{3.7}$$

where

$$\mathfrak{Q}_k = 2^t \prod_{i=1}^{t} I_{\mathcal{B}_k}(x_i) = 1 + \sigma_1^{(k)} + \sigma_2^{(k)} + \ldots + \sigma_t^{(k)}, \quad k = 0, 1,$$

x_i being $b + z_i^2$, and each $\sigma_j^{(k)}$ is a sum of monomials which are products of the same number j of distinct variables (characters) $\chi_2(x_i)$. In particular, only $\sigma_j^{(k)}$'s with even subscripts occur, and clearly they are the elementary symmetric functions of t variables; thus the number of addends in $\sigma_j^{(k)}$ is $\binom{t}{j}$. The same argument used for the upper bound $N_2(t)$ also applies here. In this case, the sum of products of j characters is bounded as $(j-1)\sqrt{p^m}$ by [15], Theorem 2C′, so that

$$N_p(t) \leqslant \frac{1}{2^{t-1}} \left[p^m - t + \sum_{j=2}^{t} (j-1) \binom{t}{j} \sqrt{p^m} \right],$$

which, after some manipulation, can be written as

$$N_p(t) \leqslant \frac{1}{2^{t-1}} [p^m - t + [2^{t-1}(t-2) + 1]\sqrt{p^m}], \tag{3.8}$$

and we see that, when $[2^{t-1}(t-2)+1]\sqrt{p^m} - t \ll p^m$, roughly $t \ll (m/2)\log_2 p$, then $N_p(t) \simeq p^m/2^{t-1}$.

4. Deterministic splitting II: fixed N

This section examines the smallest t such that the algorithm succeeds in at most 1 or 2 attempts: we will call these t_1 and t_2, respectively.

Clearly, $t_1 = l_m + 1$, since there are exactly l_m elements belonging to a given coset; then, if $t > l_m$, the algorithm succeeds at the first attempt.

To evaluate t_2, we must examine the number of representations of a $b \neq 0$ in the field as the sum of an element in a given coset and an element in another (possibly the same) given coset (see also [9], [10], [12]). We then consider the maximum $\mathfrak{M}$ of such numbers, over $b \neq 0$ in the field and over all possible pairs of cosets, so that t_2 is $1 + \mathfrak{M}$. This follows from considering equation (3.1): the worst-case scenario occurs when all roots are in the same coset, and when, by adding a b to all of them, one gets elements again belonging to a common coset.

For the case of the cubic character, $\mathfrak{M}$ can be calculated as

$$\mathfrak{M} = \max_{i,j,b} \sum_{z \neq 0,b} \frac{1 + \zeta_3^{2j}\chi_3(z) + \zeta_3^{j}\bar{\chi}_3(z)}{3} \frac{1 + \zeta_3^{2i}\chi_3(b+z) + \zeta_3^{i}\bar{\chi}_3(b+z)}{3},$$

which is the maximum over i, j, b of the expression

$$\frac{1}{9}[2^m - 2 - \chi_3(b)(\zeta_3^{2i} + \zeta_3^{2j}) - \bar{\chi}_3(b)(\zeta_3^i + \zeta_3^j) - \zeta_3^{2i+j} - \zeta_3^{i+2j} \\ - (-2)^{m/2}(\zeta_3^{2i+2j}\bar{\chi}_3(b) + \zeta_3^{i+j}\chi_3(b))],$$

where we have again exploited the relations $\sum_{x\in\mathbb{F}_{2^m}} \chi_3(x) = 0$, $\sum_{x\in\mathbb{F}_{2^m}} \chi_3(x)\bar{\chi}_3(x+b) = -1$ and $\sum_{x\in\mathbb{F}_{2^m}} \chi_3(x)\chi_3(x+1) = G_m(1,\chi_3) = -(-2)^{m/2}$ ([4], [14], [18]). Then we have

Proposition 4.1. *For the cubic character,*

$$\mathfrak{M} = \begin{cases} \frac{1}{9}(2^m + 2^{m/2} - 2) & \text{for } m/2 \text{ even,} \\ \frac{1}{9}(2^m + 2^{m/2+1} + 1) & \text{for } m/2 \text{ odd.} \end{cases}$$

For the case of the quadratic character, we consider similarly

$$\mathfrak{M} = \max_{i,j,b} \sum_{z\neq 0,b} \frac{1 + (-1)^j\chi_2(z)}{2} \frac{1 + (-1)^i\chi_2(b-z)}{2} \\ = \max_{i,j,b} \Big\{ \frac{1}{4}(p^m - 2 - \chi_2(b)(-1)^i - \chi_2(b)(-1)^j - (-1)^{i+j}\chi_2(-1)) \Big\},$$

hence we have

Proposition 4.2. *For the quadratic character*

$$\mathfrak{M} = \begin{cases} \frac{1}{4}(p^m - 1), & p = 4k+1, \\ \frac{1}{4}(p^m + 1), & p = 4k+3, \ m \text{ odd}, \\ \frac{1}{4}(p^m - 1), & p = 4k+3, \ m \text{ even}. \end{cases}$$

R e m a r k 4.1. It is interesting to notice that $\mathfrak{M}$, which is the maximum t such that it is still possible to fail to split a polynomial of degree t with two attempts, is equal to the maximum number of attempts needed to split a polynomial of degree 3. Similarly, l_m is at the same time the maximum t such that it is possible to fail to split a polynomial of degree t at the first attempt and the maximum number of attempts needed to split a polynomial of degree 2 (cf. also [13]).
