(Received 19 January 2016; published 25 March 2016)

This paper reports the first measurement using the NOvA detectors of ν_μ disappearance in a ν_μ beam. The analysis uses a 14 kton-equivalent exposure of 2.74×10^{20} protons-on-target from the Fermilab NuMI beam. Assuming the normal neutrino mass hierarchy, we measure $\Delta m_{32}^2 = (2.52^{+0.20}_{-0.18}) \times 10^{-3} \text{ eV}^2$ and $\sin^2 \theta_{23}$ in the range 0.38–0.65, both at the 68% confidence level, with two statistically degenerate best-fit points at $\sin^2 \theta_{23} = 0.43$ and 0.60. Results for the inverted mass hierarchy are also presented.

DOI: 10.1103/PhysRevD.93.051104

Neutrino oscillation is a powerful tool for probing fundamental neutrino properties [1–10]. For the case of three-flavor mixing, this process is governed by two independent mass-squared splittings, Δm_{21}^2 and Δm_{32}^2 , and the unitary mixing matrix U_{PMNS} [11]. This matrix, which describes the linear combinations of neutrino mass eigenstates that constitute the neutrino flavor states, is parametrized by three angles θ_{13} , θ_{23} , and θ_{12} , and a CP -violating phase δ_{CP} . θ_{23} has the largest measurement uncertainty of all mixing angles and is consistent with maximal mixing ($\theta_{23} = \pi/4$) within current experimental uncertainties [6–10]. The observation of ν_μ disappearance, as reported here, is used to measure Δm_{32}^2 and $\sin^2 \theta_{23}$. Precise knowledge of θ_{23} is an input into future ν_e and $\bar{\nu}_e$ appearance measurements that may determine whether ν_1

or ν_3 is the lightest mass eigenstate (normal or inverted mass hierarchy, respectively), whether $\theta_{23} > \pi/4$ or $\theta_{23} < \pi/4$, and whether neutrinos violate CP symmetry. This paper reports the first measurement by the NOvA experiment of $\sin^2 \theta_{23}$ and Δm_{32}^2 via ν_μ disappearance.

Neutrinos produced in the NuMI beam line at Fermilab [12] are observed in the NOvA near detector (ND) on the Fermilab site and the NOvA far detector (FD) 810 km from the NuMI target along the Ash River Trail, MN [13]. The 14-kton FD is positioned on the surface, 14.6 mrad off-axis from the NuMI beam. The 290-ton ND, 100 m underground and 1 km from the NuMI target, is also positioned off-axis to allow a measurement of an unoscillated neutrino energy spectrum that closely matches the unoscillated spectrum at the FD. The kinematics of two-body $\pi \rightarrow \mu + \nu_\mu$ decay in the NuMI decay pipe results in a neutrino energy spectrum in the off-axis detectors that peaks close to

*Deceased.

2 GeV, near the first maximum of the ν_μ disappearance probability at the FD. The neutrino energy spectrum has a FWHM of approximately 1 GeV.

The NOvA detectors are functionally identical, segmented, tracking calorimeters. The detectors are designed to provide sufficient sampling of hadronic and electromagnetic showers to allow efficient separation of the ν_e and ν_μ charged current (CC) interaction signals from the neutral current (NC) interaction backgrounds. The basic unit of the NOvA detector is a long liquid-scintillator-filled cell with highly reflective white polyvinyl chloride (PVC) walls and cross sectional size 3.9 cm by 6.6 cm. The liquid scintillator comprises 62% of the fiducial mass of each detector, and a minimum ionizing particle deposits approximately 1.8 MeV of energy for each centimeter traveled in the scintillator of each cell. The PVC cells have a length of 15.5 m in the FD, and 3.9 m in the ND. Each cell contains a Kuraray Y11 wavelength-shifting 0.7 mm diameter fiber [14] that runs the length of a cell, loops, and returns to the readout end where both ends of the fiber terminate on a single pixel of a Hamamatsu avalanche photodiode (APD) [15] operated in proportional gain mode.

Planes of PVC cells with their long axes alternating between horizontal and vertical orientations allow three-dimensional reconstruction of tracks and showers. The FD consists of 896 planes of 384 cells each and is 59.8 m in length. The ND is 15.3 m in length and consists of 192 contiguous upstream PVC planes with 96 cells each. At the downstream end of the ND a muon range stack is formed of 11 pairs of active vertical and horizontal PVC planes, with a 10 cm thick steel plane between each pair. The muon range stack is two-thirds the height of the bulk ND and thus the active horizontal planes have 64 cells rather than 96. The muon range stack is used to improve the containment of muons produced in the upstream active volume of the detector.

The digitization and processing of APD signals is continuous and dead-time-free. The signals produce pulse-height and timing information for any signal above a pulse-height threshold corresponding to approximately 75% of that expected for the passage of a minimum ionizing particle through a detector cell at the end furthest from the APD in the FD. Data are recorded in 550 μs -long trigger windows roughly centered on the 10 μs -long NuMI spills. Additional trigger windows are taken out of time with the beam spill to collect cosmic ray events for calibration and background studies.

The neutrino beam used in this study is generated by colliding 120 GeV protons from the Fermilab main injector onto a 1.2 m graphite target. Two magnetic horns located downstream of the target focus charged particles of one sign along the beam direction and defocus charged particles of the opposite sign. With the horns focusing positive mesons, simulations predict that the NOvA off-axis detectors are exposed to a neutrino beam composed of 97.6% ν_μ ,

1.7% $\bar{\nu}_\mu$ and 0.7 $\nu_e + \bar{\nu}_e$ for neutrino energies between 1 and 3 GeV.

In both detectors, we measure the energy spectrum of muon-neutrino CC interactions, primarily on carbon nuclei. The flavor and energy of the incident neutrino is determined by identifying the lepton flavor in the final state and assigning all the energy deposited by the final state particles to the neutrino. The measured FD neutrino spectrum is fit to a predicted spectrum based on measurements of the unoscillated spectrum in the ND and the effect of neutrino oscillations. Monte Carlo simulations are used to correct for beam flux and acceptance differences between the two detectors.

The simulation of the neutrino flux produced by the NuMI beam line is based on FLUGG [16] which uses the FLUKA [17] and GEANT4 [18] simulations. It includes a full simulation of the production of hadrons by the 120 GeV primary proton beam interacting with the NuMI target and the propagation of those hadrons through the target, magnetic horns, and along the decay pipe. The generation of neutrino interactions in the NOvA detector and surrounding rock is performed using the GENIE simulation [19]. GENIE simulates the primary interaction inside the nucleus, the production of all final-state particles in the nucleus (hadronization), and the transport and rescattering of the final-state particles through the nucleus (intranuclear transport). For this analysis, three charged-current neutrino interaction types categorized by GENIE dominate the signal: quasielastic (QE), baryon resonance production (RES) and deep-inelastic scattering (DIS). The transport, energy loss, interactions and decays of final state particles within the detector volume are simulated by GEANT4. The GEANT4 simulation uses a description of the geometry and material content of the detectors. The simulated energy deposition in the liquid scintillator is converted to a corresponding number of photoelectrons observed in the APD using a model of light production, capture and propagation in the fiber that is based on test-stand measurements. This photoelectron signal is then converted to digitized quantities in the same format as data collected from the detectors using a model of the readout electronics response, also based on test-stand measurements.

The FD data used in this analysis come from an exposure of 3.45×10^{20} protons-on-target (POT). This includes periods during FD construction when a fraction of the detector was live. On average, 79.4% of the detector was live over the data set, which corresponds to a full FD 14 kton-equivalent exposure of 2.74×10^{20} POT. The varying size of the FD is accounted for in the simulation. In addition, data collection in the ND began later than in the FD. The resulting ND data sample, which was recorded with a fully instrumented detector, corresponds to 1.66×10^{20} POT.

The energy response of each channel in the detector is individually calibrated using cosmic-ray muons. The

observed signals for muon energy depositions at different distances along the length of each cell are used to characterize the signal attenuation in the fiber of that cell.

Event reconstruction and characterization starts from calibrated cell data that are grouped into collections based on their proximity in both space and time [20,21]. The cell data in each collection is assumed to arise from the same primary neutrino or cosmic-ray event. The cell energy depositions in these events are then used to reconstruct charged particle trajectories. In this analysis the reconstruction of muon tracks produced in ν_μ CC interactions is performed using an algorithm based on the Kalman filter technique [22,23].

A multivariate analysis implementing a k -Nearest Neighbor algorithm [23–25] is used to identify a muon track in the reconstructed event. The resulting muon identification (ID) is based on the measured dE/dx , amount of multiple scattering along the track, total track length, and the fraction of track planes that have overlapping hadronic activity. The muon identifier was trained separately for each detector using simulated ν_μ interactions. For events with multiple tracks, the primary muon candidate is the track with the highest muon ID. Events are selected as ν_μ CC if the primary track has a muon ID score greater than 0.75. The distribution of the muon identification variable for the primary tracks of contained ND data and simulated neutrino events is shown in Fig. 1.

The reconstructed neutrino events are required to be fully contained in the detectors to ensure an accurate measurement of the neutrino energy, to reject muons produced by

neutrino interactions in the rock surrounding the detectors, and to reduce the cosmic-ray background in the FD. In order to contain hadronic activity, the selection criteria require that the event has no energy depositions in the two cells and planes that are nearest to the detector edge. To ensure that the muon is contained, requirements are placed on the start and end positions of the primary track. In the ND, the forward projection of the track must be 4 or more cell-widths away from the edge of the detector and the backward projection of the track must be 8 or more cell-widths away from the detector edge. A more stringent projection requirement of 10 cells in both the forward and backward directions is applied in the FD, due to the larger cosmic-ray rate for the surface detector. To ensure that the energy resolution in the ND is comparable to the FD, an additional containment requirement is applied in which both the interaction vertex and all but 30 MeV of energy deposited in cells not associated with the selected muon must be upstream of the muon range stack.

The rate of reconstructed cosmic-ray-induced events in the FD is 148 kHz. The corresponding background within the 10 μ s beam window, mostly muons, is reduced using criteria determined from the high-statistics out-of-spill-time data sample and from simulated neutrino interactions. The event containment and muon identification criteria described above reduce this background rate in the FD by a factor of approximately 200. Additional selection criteria based on the primary track angle, which is generally beam-directed for neutrino-produced muons and downwards-directed for cosmic rays, as well as the number of energy deposits in cells in the event, further reduce the background by two orders-of-magnitude. A final three orders-of-magnitude in background rejection, removing the most signal-like cosmic rays, is achieved with a boosted decision tree. This multivariate algorithm utilizes eleven variables, based on the reconstructed tracks (direction, multiple scattering, length, number of tracks, and fraction of cells with energy deposits associated to the muon track), event calorimetry, and general event topology (proximity to detector top and edges).

Approximately 57% of simulated contained ν_μ CC events with less than 5.0 GeV of visible energy pass all of the FD selection criteria, whereas the cosmic background with visible energy below 5.0 GeV is reduced by a factor of 1.2×10^7 . With this level of rejection the cosmic background contributes 4.1% of selected FD ν_μ CC events. The uncertainty on the cosmic background was determined using the out-of-spill data and is negligible for this analysis. The background from contained NC events within the same visible energy range is estimated using simulation to contribute 6% of selected FD ν_μ CC events, which is a 99% reduction. The ν_e and ν_τ CC interactions are negligible backgrounds in both detectors.

In the ND, the selected sample is estimated by simulation to be 98% pure, with 2% NC contamination. Since the ND is underground, the cosmic-ray background is negligible.

FIG. 1. The muon identification variable in the ND for contained neutrino events. For each event only the largest muon ID of all reconstructed tracks is shown. Events with muon ID greater than 0.75 are selected for analysis. The simulated distribution (solid red) and its background component (dashed blue) are also shown. The number of events in the simulated distribution is normalized up for display purposes to remove a 7.2% offset after selection criteria are applied. The shaded band represents the bin-to-bin uncertainties only, suppressing the 20%–30% normalization uncertainties due primarily to neutrino flux and cross sections.

FIG. 2. Reconstructed track length (left) and track angle θ_z relative to the detector longitudinal axis, along the beam direction (right) for the primary muons in selected ν_μ CC interactions in the ND. The simulated distributions follow the conventions of Fig. 1.

Backgrounds from muons produced by neutrino interactions in the surrounding rock are also negligible after containment requirements are applied. After all selection criteria, approximately 500,000 events remain in the ND data sample.

The reconstructed neutrino energy E_ν of a contained ν_μ CC event is given by

$$E_\nu = E_\mu + E_{\text{had}}, \quad (1)$$

where E_μ is the estimated energy of the primary muon track based on its reconstructed path length through the detector and E_{had} is the estimated energy of the hadronic shower based on the sum of all calibrated energy deposition in the event not attributed to the muon [26]. To achieve better E_ν agreement between data and simulation in the ND, the E_{had} calibration scale in data is set 14% higher than that for simulation.

Figure 2 shows the reconstructed muon track parameters for ν_μ CC events in the ND. Figure 3 shows the E_{had}

distribution both with and without the 14% difference in E_{had} calibration scale between data and simulation. A corresponding $\pm 14\%$ uncertainty is assessed on the hadronic energy scale, and is included in all of the uncertainty bands shown. Figure 4 shows the final E_ν distribution. The energy resolution for reconstructed ν_μ CC events is estimated from simulation to be 7%.

The prediction for the FD neutrino energy spectrum is based on the observed ND neutrino energy spectrum, with corrections for acceptance and flux differences derived from simulation. First, the small NC background, estimated from simulation, is subtracted from the ND data spectrum. The resulting background-subtracted spectrum is then converted into a true neutrino energy spectrum via a mapping derived from simulation. This true neutrino energy spectrum is then used to construct a spectrum in the FD by multiplying it by the energy-dependent ratio of FD-to-ND selected events from simulation. Oscillation probabilities for a given set of oscillation parameters are then applied, by energy bin, to the predicted true FD energy

FIG. 3. Reconstructed hadronic energy E_{had} for selected ν_μ CC interactions in the ND, both with (black circles) and without (gray squares) the 14% offset described in the text. The simulated distributions follow the conventions of Fig. 1.

FIG. 4. Reconstructed neutrino energy E_ν for selected ν_μ CC interactions in the ND. The simulated distributions follow the conventions of Fig. 1.

spectrum, which is then mapped to a reconstructed neutrino energy spectrum using FD simulation. The extrapolated ν_μ CC energy spectrum is then combined with beam-induced backgrounds (NC, ν_e CC, and ν_τ CC) predicted from simulation, and the background spectrum measured using events selected from outside of the beam spill window.

Systematic uncertainties in the calibration, flux estimate, cross sections, hadronization modeling, particle-transport modeling and exposure differences between the two detectors are assessed by varying these aspects of the simulation. Because the detectors are functionally identical, many systematic uncertainties largely cancel in the measurements of $\sin^2 \theta_{23}$ and Δm_{32}^2 . The uncertainties and their impact are summarized in Table I.

For the beam-induced backgrounds, which are small, a normalization uncertainty of 100% is assigned. The cosmic background, measured from out-of-spill data, has negligible uncertainty and is therefore not included as a penalty term in the oscillation fit. The neutrino interaction cross section and hadronization uncertainties are determined by altering each cross section and hadronization parameter by its predetermined uncertainties in the GENIE simulation, which vary in size from 15% to 25%, as specified in Ref. [27]. Uncertainties in particle-transport modeling are assessed by comparing alternative hadronic models in the GEANT4 simulation. The beam flux normalization uncertainty in each detector is dominated by beam-line hadron production uncertainties. This uncertainty is approximately 20% near the peak of the spectrum, estimated by comparing simulated pion and kaon yields in the NuMI target to measured yields for interactions of 158 GeV protons on a thin carbon target in the NA49 experiment [28,29]. The detector exposure uncertainty, which accounts for uncertainties in detector mass and periods of data collection when only one detector was operational, is 1%.

The uncertainty in muon energy scale is 2%, driven by detector mass and muon energy-loss modeling. The uncertainty in calorimetric (hadronic) energy scale is 14.9%, the quadrature sum of the 14% uncertainty assigned to reflect

the difference in E_{had} scales used in data and simulation, and 5% derived from comparisons of muon and Michel electron data and simulation. An additional relative 5.2% calorimetric energy uncertainty is taken uncorrelated between the two detectors. The main component of this is a 5% uncertainty derived from muon and Michel electron studies. An additional 1.4% comes from potential differences in E_{had} scale between the ND and FD due to their differing neutrino spectra (primarily due to oscillations). To estimate this uncertainty, the simulated ND kinematic distributions were fit to data by adjusting some or all of the normalizations, hadronic energy scales, and muon energy scales of QE, RES, and DIS events separately in the simulation. The fit results were then applied to FD simulation, and the largest relative energy offset seen between detectors across the ensemble of fits was 1.4%. The largest normalization offset seen was 1%, which is also taken as an uncertainty.

Upon applying the FD event selection criteria to the full data set reported here, a total of 33 ν_μ CC candidate events are observed for reconstructed neutrino energies below 5 GeV. The total expected background is 3.4 events, which includes 2.0 ± 2.0 NC events and 1.4 ± 0.2 cosmic-ray events. In the absence of neutrino oscillations, 211.8 ± 12.5 (syst.) candidate events are predicted. The energy spectrum for the sample is shown in Fig. 5.

Using a three-flavor neutrino oscillation model that includes matter effects, the data are fit for $\sin^2 \theta_{23}$ and Δm_{32}^2 assuming either the normal or inverted mass hierarchy. The fit is a log-likelihood maximization comparing the neutrino energy spectrum of the data to that of the extrapolated simulation over 18 bins from 0.5 to 5.0 GeV. Systematic effects and constraints on all other oscillation parameters are taken into account in the fit with penalty terms. Central values and uncertainties for θ_{12} and Δm_{21}^2 are taken from Ref. [30]. We constrain $\sin^2(2\theta_{13})$ to 0.086 ± 0.005 , a weighted average of recent results [4–6]. δ_{CP} is unconstrained. The resulting allowed region, calculated using the Feldman-Cousins technique [31], is

TABLE I. Impact of the sources of uncertainty on the expected sensitivity of the measured values for $\sin^2 \theta_{23}$ and Δm_{32}^2 evaluated at the test point of $\sin^2 \theta_{23} = 0.5$ and $\Delta m_{32}^2 = 2.5 \times 10^{-3} \text{ eV}^2$.

| Source of uncertainty | Fractional uncertainty $\sin^2 \theta_{23}$ ($\pm\%$) | Fractional uncertainty Δm_{32}^2 ($\pm\%$) |
|---|---|--|
| Absolute calorimetric energy calibration (14.9%) | 4.1 | 2.6 |
| Relative calorimetric energy calibration (5.2%) | 3.4 | 0.6 |
| Muon energy scale (2%) | 2.2 | 0.8 |
| Cross sections and final state interactions (15%–25%) | 0.8 | 0.6 |
| NC and ν_τ CC backgrounds (100%) | 3.0 | 0.6 |
| Particle-transport modeling | 1.5 | 0.6 |
| Beam flux (21%) | 1.3 | 0.3 |
| Normalization (1.4%) | 0.4 | 0.2 |
| Other oscillation parameters | 1.8 | 2.2 |
| Total systematic uncertainty | 6.8 | 3.7 |
| Statistical uncertainty | 17.0 | 4.5 |

FIG. 5. The reconstructed energy for FD selected events. The black data points show the statistical uncertainties. The short-dashed green histogram corresponds to the predicted spectrum in the absence of oscillations. The solid brown histogram corresponds to the best-fit prediction with systematic effects included. The long-dashed red histogram corresponds to the best-fit prediction when the effects from the systematic shifts in the fit are removed. The light-red band represents the systematic uncertainty on the no-systematics (red) prediction. The blue, open-circled points represent the background, mostly NC and cosmic-ray muons.

shown in Fig. 6. One-dimensional 68% confidence level (C.L.) ranges for each of Δm_{32}^2 and $\sin^2 \theta_{23}$ are obtained by maximizing the profile likelihood ratio of each parameter [30].

Assuming the normal hierarchy, we measure $\Delta m_{32}^2 = (2.52^{+0.20}_{-0.18}) \times 10^{-3} \text{ eV}^2$ and $\sin^2 \theta_{23}$ in the 68% C.L. range [0.38, 0.65], with two statistically degenerate best-fit values of $\sin^2 \theta_{23}$ of 0.43 and 0.60. Assuming the inverted hierarchy, we measure $\Delta m_{32}^2 = (-2.56 \pm 0.19) \times 10^{-3} \text{ eV}^2$

FIG. 6. The best-fit (solid black circles) and allowed values (solid black curve) of $\sin^2 \theta_{23}$ and Δm_{32}^2 from this analysis assuming the normal mass hierarchy. The dashed contour lines are results from T2K [10] and MINOS [9].

and $\sin^2 \theta_{23}$ in the 68% C.L. range [0.37, 0.64], with two statistically degenerate best-fit values of $\sin^2 \theta_{23}$ of 0.44 and 0.59. The best-fit parameters in both hierarchies yield a prediction of 35.4 events in the FD.

In conclusion, the first NOvA measurement of $\sin^2 \theta_{23}$ and Δm_{32}^2 through observation of the disappearance of muon neutrinos is reported. The results, based on less than 10% of the planned exposure of the NOvA experiment, are consistent with maximal θ_{23} mixing as well as with current results from [6–10].

This work was supported by the U.S. Department of Energy (DOE); the U.S. National Science Foundation; the Department of Science and Technology, India; the European Research Council; the MSMT CR, Czech Republic; the RAS, RMES, and RFBR, Russia; CNPq and FAPEG, Brazil; and the State and University of Minnesota. We are grateful for the contributions of the staffs of the University of Minnesota module assembly facility and NOvA FD Laboratory, Argonne National Laboratory, and Fermilab. Fermilab is operated by Fermi Research Alliance, LLC under Contract No. De-AC02-07CH11359 with the U.S. DOE.
