9	
10	In this Supplementary Information section, we derive all equations used in the main
11	article and give an extended discussion of our Methods. It is organized as follows. First,
12	we derive all needed equations. We then provide additional evidence for the validity of our
13	solubility and climate models. Following this, we explain why the averaging method we
14	employ for computing O <sub>2</sub> solubilities as a function of the annually averaged local values
15	for surface temperature and pressure is practical, and underestimates O2 solubilities and the
16	difference between minimum and maximum values. Last, we elaborate on the implications
17	for habitability and potential extant life on Mars, and on how pressure and temperature
18	control solubility, and possibly oxidation, gradients across the Martian surface and shallow
19	subsurface (from here on termed "near-surface").
20	
21	1. Detailed derivation of all necessary equations

To compute the solubility of  $O_2$  in pure water  $[\widetilde{O_2}]_{aq,w}(T, P)$  in mol kg<sup>4</sup>, we start with the equilibrium constant, k(T, P), for a given total atmospheric pressure, *P*, and temperature, *T*, which is defined for an activity coefficient of dissolved  $O_2$ ,  $\alpha$ , and the fugacity coefficient,  $\varphi$ , of  $O_2$  in the gas phase<sup>14</sup>, with  $VMR_{O_2}$  being the volume mixing ratio of  $O_2$  in the atmosphere and the partial pressure of  $O_2$  being  $p_{O_2} = P \cdot VMR_{O_2}$ 

27 
$$k(T,P) = \frac{\alpha \cdot \widetilde{[O_2]}_{aq,w}(T,P)}{\varphi \cdot VMR_{O_2}}.$$
(8)

For Mars, we assume this value to be constant and equal to  $VMR_{O_2} = 0.00145^{\circ}$ . We 28 discuss diurnal, seasonal, obliquity-driven, and atmospheric collapse-related changes in the 29 O<sub>2</sub> mixing ratio in Section 2.2.5 and show that it does not affect our results. Both the 30 31 activity coefficient of dissolved  $O_2$  as well as the fugacity of  $O_2$  in the gas phase are close 32 to unity because of the small concentrations of dissolved  $O_2$  and the small  $O_2$  partial pressures that are relevant to our study (independent of temperature, for  $[\widetilde{O_2}]_{aq,w} \to 0$  and 33  $P \rightarrow 0$ , the definitions for activity coefficient and fugacity demand that  $\alpha \rightarrow 1$  and  $\varphi \rightarrow 1$ , 34 35 respectively<sup>1</sup>). Therefore, Equation 8 simplifies to

36 
$$k(T,P) = \frac{[\widetilde{O_2}]_{aq,w}(T,P)}{VMR_{O_2}}.$$
 (9)

To compute the solubility  $[\widetilde{O_2}]_{aq,w}(T,P)$ , we need to compute the equilibrium constant, k(T,P), which is defined by the change in molar Gibbs potential  $\Delta G^*(T,P)$  between the dissolved and gaseous phases<sup>14</sup>

40 
$$k(T,P) = exp\left(\frac{-\Delta G^*(T,P)}{RT}\right).$$
 (10)

41  $R = 8.3144598 J mol^{-1} K^{-1}$  is the universal gas constant. We compute the molar 42 Gibbs potential through the chemical potential  $\mu(T, P)$  for both the dissolved  $(\mu_{aq,w,O_2})$ 43 and gaseous  $(\mu_{a,O_2})$  O<sub>2</sub> phases

44 
$$G^*(T,P) = \left(\frac{\partial G}{\partial N}\right)_{T,P} = \mu(T,P), \qquad (11)$$

and, hence,  $\Delta G^*(T, P) = \mu_{aq,w,O_2}(T, P) - \mu_{g,O_2}(T, P)$ . Note that the chemical potential is a function of both temperature, *T*, and pressure, *P*. In order to compute the solubility of O<sub>2</sub> in water, we need to know the chemical potential of O<sub>2</sub> in the gaseous and dissolved aqueous phases as a function of temperature and pressure.

We refer to Equations 10-11, where the chemical potential is defined through the molar Gibbs potential, in order to compute  $\mu(T,P)$  in relation to a reference state,  $\mu(T_{ref}, P_{ref})$ , by calculating the differential  $d\mu(T,P)$  from  $(T_{ref}, P_{ref})$  to (T,P)using the entropy, *S*, the internal energy, *U*, and the molar volume, *V*, for both phases

53 
$$d\mu(T,P) = dG^*(T,P) = d(U+PV-TS) = dU + VdP + PdV - TdS - SdT.$$
 (12)

$$53 \quad a\mu(1,P) = aG'(1,P) = a(0 + PV - IS) = a0 + VaP + PaV - IaS - SaI.$$
(12)

54 With the definition of the internal heat

$$55 \quad dU \equiv \delta Q - P dV, \tag{13}$$

56 and the definition for the entropy

57 
$$dS \equiv \frac{\delta Q}{T}$$
, (14)

58 we obtain

59 
$$d\mu(T,P) = \delta Q - PdV + VdP + PdV - TdS - SdT = VdP - SdT.$$
 (15)

60 Therefore, we can rewrite the chemical potential as

61 
$$\mu(T,P) = \mu(T_{ref}, P_{ref}) + \int_{P_{ref}}^{P} V dP' - \int_{T_{ref}}^{T} S(T') dT'.$$
 (16)

62 The entropy, *S*, is a function of temperature and can be related to the specific heat at 63 constant pressure,  $C_P(T)$ , which is more useful (experimentally directly measurable) than 64 the entropy itself, with Equation 14 and  $\delta Q|_P = C_P dT$  we get

65 
$$S(T) = S(T_{ref}) + \int_{T_{ref}}^{T} dS$$

66 
$$= S(T_{ref}) + \int_{T_{ref}}^{T} \frac{C_P(T')}{T'} dT' + \overline{C_P(T) - C_P(T)}$$

$$67 \qquad = S(T_{ref}) - C_P(T) + \frac{\partial}{\partial T} \left( T \int_{T_{ref}}^{T} \frac{C_P(T')}{T'} dT' + C_P(T)}{T' \int_{T_{ref}}^{T} \frac{C_P(T')}{T'} dT' \right).$$

$$(17)$$

Therefore, we replace in Equation 16 the integral over the entropy and obtain in Equation 18 the chemical potential at temperature, *T*, and reference pressure,  $P_{ref}$ , which corresponds to the temperature-dependent function in Equation 2 from our Methods

71 
$$\tilde{\mu}(T) = \mu(T, P_{ref})$$
(18)

$$72 \qquad \qquad = \tilde{\mu}\big(T_{ref}\big) - S\big(T_{ref}\big) \cdot \big[T - T_{ref}\big] + \int_{T_{ref}}^{T} C_P(T') dT' - T \int_{T_{ref}}^{T} \frac{C_P(T')}{T'} dT'.$$

To fully solve for the chemical potential, we need to consider effects by pressure, described by  $\int_{P_{ref}}^{P} VdP'$  in Equation 16. For the gas phase (hence, for  $\mu_{g,O_2}(T,P)$ ), we assume an ideal gas with PV = RT (for one mol) and, hence,

76 
$$\int_{P_{ref}}^{P} V dP' \bigg|_{g} = RT ln \bigg( \frac{P}{P_{ref}} \bigg).$$
(19)

For the dissolved phase, we assume that the molar volume of dissolved O<sub>2</sub>,  $V_{aq,O_2}$ , is smaller than that of water,  $V_w$ , and, hence, we get  $V_{aq,O_2} = \lambda V_w$  with  $0 < \lambda < 1$ . Using this volume estimate with the standard molar volume for water at reference temperature and pressure of  $V_w(T_{ref}, P_{ref}) = 1.8 \cdot 10^{-5} m^3 mol^{-1}$  (water is approximately incompressible for the pressures and temperatures at which we are interested), we find that  $\int_{P_{ref}}^{P} V_{aq,O_2} dP'$ 

- is negligible and would, if included, only increase the solubility of  $O_2$  by about 0.1%.
- 83 Therefore, from relationships in Equations 9-11, 16, 18-19, we obtain Equation 20

84 
$$[\widetilde{O_2}]_{aq,w}(T,P) = \frac{p_{O_2}}{P_{ref}} exp\left(\frac{\widetilde{\mu}_{g,O_2}(T) - \widetilde{\mu}_{aq,w,O_2}(T)}{RT}\right),$$
 (20)

85 which corresponds to Equation 1 in our Methods Section (compare also with other 86 sources<sup>13,4</sup>). Note that the pressure dependence derived here corresponds to Henry's law.

From here, to compute  $\tilde{\mu}_{g,O_2}(T) - \tilde{\mu}_{aq,w,O_2}(T)$ , we need standard values at  $(T_{ref}, P_{ref})$  for the chemical potentials and entropy of gaseous and dissolved  $O_2$  and the specific heat of  $O_2$  in the gas phase,  $C_{P,O_2,g}(T)$ , and dissolved in pure water,  $C_{P,O_2,aq}(T)$ , as a function of temperature. Experiments<sup>6</sup> confirm that  $C_{P,O_2,g}(T) = C_{P,O_2,g}(T_{ref})$ ; all parameters at reference conditions can be found in Table S1.

We examine the choice for the specific heat of dissolved  $O_2$  in pure water and the effects of salts on the solubility of  $O_2$  in the following section and associated subsections.

94

#### 95 2. Extended evidence for the validity of methods

96 2.1. Solubility model

97 In the next subsections, we discuss our solubility model in greater detail.

98

#### 99 2.1.1. Specific heat of dissolved $O_2$ and solubility – tests and robustness of results

Experiments show  $C_{P,O_2,aq}(T)$  increases slightly as temperature decreases from 373-273 K, with no data available below this temperature range<sup>13</sup>. There is reason to expect that the trend of increasing heat capacity continues from 273 K down to ~225-235 K but

possibly also below this limit. Such a steep increase of  $C_{P,O_2,aq}(T)$  is justified by arguing 103 104 that the behavior of the specific heat of water at cooler temperatures below  $\sim 300$  K directly 105 corresponds to the behavior of the specific heat capacity of dissolved O<sub>3</sub>. This assumption 106 can be partially rationalized, as the smooth increase in the specific heat of pure water from 107 300 K into the supercooled water domain down to ~225-235 K can be explained by stronger 108 hydrogen bonds at lower temperature<sup>1</sup>, and, hence, a greater amount of heat being needed 109 in order to increase the ambient temperature. This increase in hydrogen bonding for lower 110 temperatures is expected to similarly affect the dissolved O<sub>2</sub>, which will be partially 111 polarized due to the water dipoles, leading potentially to a similar behaviour of the specific 112 heats of water and dissolved O<sub>2</sub> below 273 K. However, thermodynamics demands that  $\lim_{T\to 0} C_P = 0$ . Indeed, some theoretical predictions find that the specific heat of 113 supercooled water could start to decrease again for T~225-235 K, where potentially a 114 115 liquid-liquid phase transition could occur<sup>3</sup>. We emphasize that experiments to date also 116 allow for the heat capacity to continue increasing into much cooler regions below 235 K. We use for our nominal best estimate (BE) the simplest assumption that  $C_{P,O_2,aq}(T) =$ 117  $C_{P,O_2,aq}(T_{ref})$ , but we also test other reasonable forms of  $C_{P,O_2,aq}(T)$  (all show a similar 118

result), and derive a thermodynamic worst case, which technically cannot be reached –
assuming the validity of Equations 1-2 from our Methods Section.

121 Assuming 
$$\left(\frac{C_{P,O_2,aq}}{C_{P,w}} \sim const.\right)$$
 below 273 K (so that the specific heat of dissolved O<sub>2</sub>  
122 scales with the specific heat of water), and taking the predicted specific heat behavior<sup>4,9</sup> of  
123 supercooled water – consisting of an initial power law increase below 273 K towards a  
124 critical temperature,  $T_{cat}$ , of 225-235 K, below which the heat capacity exponentially decays  
125 towards 0 K, we find that at 140 K, O<sub>2</sub> solubility values are within 20% of our best estimate

126 (BE). Therefore, if the specific heat of dissolved  $O_2$  behaves similar to the theoretical 127 predictions for the specific heat of supercooled water, then our best estimate is an excellent 128 prediction for the solubility of  $O_2$  below 273 K.

129 Alternatively, we examine what happens if we assume that, instead, the specific heat 130 of dissolved O<sub>2</sub> in water behaves similar to the specific heat of a "normal fluid" that does 131 not show anomalous behaviour like water, such as a very salty NaCl brine'. For NaCl-132 brines<sup>o</sup> and many other brines including perchlorates<sup>o</sup>, the specific heat is rather constant 133 but does decay slowly with decreasing temperature. Assuming an unusually strong linear decrease of  $C_{P,O_2,aq}(T)$  by 50% from 293 to 140 K (a few factors to ~1 order of magnitude 134 135 larger than generally found for very salty brines<sup>9,10</sup>), we obtain values for the solubility of 136  $O_2$  at 140 K that are ~3 times lower than our best estimate. Thus, we conclude that, for all reasonable forms of  $C_{P,O_2,aq}(T)$ , the solubility values at 140 K are generally similar to the 137 best estimate assuming a constant heat capacity for dissolved O<sub>2</sub> in pure water. In the next 138 139 section, we derive a thermodynamic lower bound that cannot be reached as our 140 conservative worst-case scenario.

141

### 142 2.1.2. Specific heat of dissolved O<sub>2</sub> and thermodynamic worst case (WC)

143 The solubility of  $O_2$  in mol m<sup>3</sup> in pure water or brine depends on the specific heat of 144 dissolved  $O_2$ ,  $C_{P,O_2,aq}$ , in the following way (see Equations 1 and 3 in Methods Section, and 145 Equations 18 and 20 here in the SI)

146 
$$[O_2]_{aq}(T,\zeta(T)) = F(T)exp\left(\frac{\zeta(T)}{RT}\right),$$

147 with 
$$\zeta(T) = -\int_{T_{ref}}^{T} C_P(T') dT' + T \int_{T_{ref}}^{T} \frac{C_P(T')}{T'} dT'$$
. (21)

The function  $\zeta(T)$  contains all the uncertainties introduced by the behavior of  $C_{P,O_2,aq}(T)$ , whereas F(T) depends only on well-constrained properties, and monotonically increases for lower temperatures. We develop a thermodynamic lower limit for  $\zeta(T)$ , which gives a lower limit for the solubility of O<sub>2</sub> in supercooled water. To achieve this, we need to assess the behaviour of  $\zeta(T)$ .

First, we show that  $\zeta(T_1) > \zeta(T_2)$ :  $\forall (T_1 < T_2)$ , so, independent of the temperature dependence of the heat capacity, solubilities monotonically increase for lower temperatures,

155 with the minimum solubility curve for  $T < T_{min}$  given by

156 
$$[O_2]_{aq}(T,\zeta(T)) > [O_2]_{aq}(T)|_{min} = [O_2]_{aq}(T,\zeta^*) \text{ with } \zeta^*(T) = \zeta(T = T_{min}),$$
 (22)

157 where  $T_{min}$  is the lowest temperature above which we know  $C_{P,O_2,aq}(T)$  sufficiently 158 well. The most conservative worst-case estimate assumes that  $T_{min} = 273 K$  because we 159 have data on  $C_{P,O_2,aq}(T)$  above 273 K; we make this our conservative worst case that is 160 used as the "WC" scenario in the main article.

161 Equation 22 is derived in the following way:  $\forall T: T > 0, C_P(T) > 0$ , and  $T_{ref} > T$  we 162 have T' > T and therefore  $\frac{T}{T_I} < 1$ . Hence, we can establish the following relationships

163 
$$\left\|T\int_{T_{ref}}^{T} \frac{C_P(T')}{T'} dT'\right\| < \left\|\int_{T_{ref}}^{T} C_P(T') dT'\right\|$$
 (23)

164 
$$\int_{T_{ref}}^{T} C_P(T') dT' < 0 \text{ and } \int_{T_{ref}}^{T} \frac{C_P(T')}{T'} dT' < 0.$$
 (24)

165 Therefore, we conclude that

166 
$$\zeta(T) = -\int_{T_{ref}}^{T} C_P(T') dT' + T \int_{T_{ref}}^{T} \frac{C_P(T')}{T'} dT' > 0, \forall (T, C_P(T)).$$
(25)

167 Next, to  $\zeta(T)$  being a positive function, based on Equations 23-25,  $\zeta(T)$  also 168 monotonically increases for lower *T* because:

169 
$$\zeta(T_1) = \zeta(T_2) - \int_{T_2}^{T_1} C_P(T') dT' + T_1 \int_{T_2}^{T_1} \frac{C_P(T')}{T'} dT' > \zeta(T_2), \forall (T_1 < T_2).$$
(26)

170 Finally, with Equation 26, we have a full proof for Equation 22. Our worst case (WC) assuming Equation 22 and  $T_{min} = 273 K$  provides the logic for a conservative lowermost 171 172 bound on  $O_2$  solubility, and it is important to note that the true solution is likely to be much 173 greater and closer to our best estimate (BE) scenario. This is because our WC solution  $C_{P,O_2,aq}(T) = 0$  already for  $T < T_{min} = 273 K$  but 174 indirectly implies that thermodynamics teaches us that this limit of  $C_{P,O_2,aq}(T) = 0$  can only occur at T = 0 K. 175 Compare in Fig. S1 how our worst case is only slightly greater (20 % at 140 K) than a 176 solubility curve assuming  $C_{P,O_2,aq}(T) = 0$  for all temperatures. Please note that we could 177 also reasonably choose  $T_{min} = 225 K$ , where supercooled water is suspected to have a 178 179 turning point for the specific heat to start declining for smaller temperatures<sup>9</sup>. In that case, 180 our solution would follow from 298 K the BE scenario until 225 K instead to just 273 K and would assume  $C_{P,O_2,aq}(T) = 0$  for T < 225 K. This would would lead to a 181 significant additional increase in O<sub>2</sub> solubility curve in comparison to our conservative 182 worst case estimate with  $T_{min} = 273 K$  (see Fig. S1). Also, Section 2.1.1 describes in 183 detail how other reasonable assumptions on  $C_{P,O_2,aq}(T)$  below 273 K would lead to 184 185 solubilities very close to BE.

186

#### 187 2.1.3. Derivation of Pitzer coefficients for perchlorates

We use the experimental results<sup>11-13</sup> on the O<sub>2</sub> solubility in perchlorate brines containing
the salts NaClO<sub>4</sub>, KClO<sub>4</sub>, RbClO<sub>4</sub>, and LiClO<sub>4</sub> to derive the Pitzer interaction coefficients

for the O<sub>2</sub>-perchlorate ion interaction O<sub>2</sub>-ClO<sub>4</sub>, described by  $\lambda_{O_2-ClO_4^-}$  in Equation 4 in our Methods Section. Generally, the temperature dependence of the Pitzer coefficients is negligible, but we examine this in the next section. The O<sub>2</sub>-cation interaction coefficients,  $\lambda_{O_2-c}$ , for the cations c=(Ca<sup>2+</sup>, Mg<sup>2+</sup>) are taken from literature<sup>11</sup>.

We show the results for the salting out coefficient,  $\gamma_{O_2}(X, m_X)$ , for a brine containing 194  $m_X$  mol kg<sup>+</sup> of salt X in Fig. S2 for chlorides and perchlorates (compare with Equation 3 in 195 196 our Methods Section). There are no direct data on O<sub>2</sub> solubility for Ca- or Mg-perchlorates 197 and, hence, there are no data on the secondary Pitzer interaction coefficients describing the 198 interactions between O<sub>2</sub>-cation-ClO<sub>4</sub>,  $\lambda_{O_2-c-a}$ . However, as we explain in the Methods 199 Section, the secondary interaction coefficients are generally negative as they represent the 200 disturbance of the respective cation- $O_2$  and anion- $O_2$  fields, which drive the solubility of  $O_2$ in the liquid. Any reasonable value for  $\lambda_{O_2-c-a} < 0$  would only lead to a reduction of the 201 salting out factor,  $\gamma_{O_2}(X, m_X)$ , and would therefore result in greater solubilities for O<sub>2</sub> in 202 perchlorate brines. Thus, we assume  $\lambda_{O_2-c-a} = 0$  for Ca- and Mg-perchlorate brines—and 203 204 accept that this approach will tend to, if anything, underestimate the solubilities for  $O_2$  in 205 those brines.

206

#### 207 2.1.4. Temperature dependence of Pitzer coefficients

It is commonly found that the Pitzer coefficients introduced in Equation 4 in the Methods Section are only weakly temperature-dependent<sup>14,15</sup> as suggested by experiments<sup>15</sup>. The wide amount of experimental data that we collected and against which we test our results<sup>11,43,45,49</sup> suggest also a slight increase of Pitzer coefficients for lower temperatures. We find that the temperature dependence of the Pitzer coefficients could lead to an additional decrease of the solubility of O<sub>2</sub> in Ca- and Mg-perchlorate brines at 140 K by a factor of 310 (most likely less than 5).

To derive this estimate, we made use of the salting out theory of Tromans<sup>3</sup>. He observes that a salt reduces the solubility of  $O_2$  by reducing the molar volume of water (that is dissolving  $O_2$ ) into an apparent water volume,  $V_{app}$ . He also finds that the change in apparent water volume can be used to infer the salting out factor. Thus, what we do first is to derive the apparent molar water volume as a function of the brine density,  $\rho_{brine}$ , molar concentration,  $m_{X_2}$  of the salt, X, with molecular mass,  $M_{X_2}$  in kg mol<sup>4</sup> and molecular crystalline volume,  $V_{X_2}$ , and the molar mass of pure water,  $M_{w_2}$  leading to Equation 27

222 
$$V_{app}(T) = \left(\frac{1 + m_X M_X}{\rho_{brine}(T)} - m_X V_X\right) M_w(T).$$
 (27)

Equation 27 is easiest to derive by computing the density of the brine,  $\rho_{brine}$ , assuming that water has an apparent volume,  $V_{app}$ , and that the salt preserves its crystalline molecular volume,  $V_X$ , and solving for  $V_{app}$  (for values, see Table S2).

Second, we compute how this apparent water volume in Equation 27 changes during a reduction of temperature from 298-140 K. The temperature dependence for  $V_{app}(T)$ results from the temperature dependence of the brine density and the molar volume of water, but  $V_{app}(T)$  is mainly sensitive to small changes in brine density,  $\rho_{brine}(T)$ . Thus, to compute how  $V_{app}(T)$  changes with temperature, we focus solely on determining how the density of a brine,  $\rho_{brine}(T)$ , changes with temperature when salt and molality are fixed.

There are no data or theoretical predictions for the temperature dependence of the density of perchlorate brines. To obtain an estimate of how much the density changes for Ca- and Mg-perchlorate brines with up to ~4.2 mol of salt per kg water (=  $4.2 \text{ mol kg}^{-1}$ , the 235 concentration at the eutectic for Ca-perchlorate<sup>10,14,2021</sup>, see Table S3 for values) for a temperature change from 298-140 K, we turn towards experimental data<sup>2223</sup> on the density 236 237 of a range of brines of different compositions (i.e., NaCl, MgCl<sub>2</sub>, CaCl<sub>2</sub>, KCl, K<sub>2</sub>SO<sub>4</sub>, MgSO<sub>4</sub>, 238 and  $Na_2SO_4$ ), and examine how their densities change from 373-243 K for various salt 239 concentrations up to 30 weight % (or  $\sim 4.2 \text{ mol kg}^{-1}$ ). We observe that variations in brine 240 density driven by temperature are rather small and would amount to less than a 5-10% 241 increase in density from 298-140 K—assuming a linear increase of the density towards 242 lower temperatures with a gradient determined between 303-243 K. Note, also, that our 243 available data indicate that the density variations decrease for lower temperatures, and one obtains very similar results including data up to 373 K in order to estimate the density 244 245 gradient with temperature.

246 The derivation of the density gradient is illustrated in Fig. S3a, where we plot the 247 density gradient for diverse brines with temperature as a function of molality using density 248 data from 303-243 K. Extrapolating these values would lead to a density increase by less 249 than 5-10% at 140 K in comparison to 298 K (on average about 6% for a random sampling of temperature intervals between 303-243 K). Note that this compares quite well with the 250 251 predicted and measured density variation of NaCl brines between 240-300 K<sup>9</sup>, which would 252 lead to a 5% increase in the NaCl brine density from 298-140 K for a linear extrapolation 253 (which most likely overshoots the density change).

With this approach, we use a density increase of 5-10% for a Ca(ClO<sub>4</sub>)<sub>2</sub> brine from 255 298-140 K to measure the apparent volume changes for a 4.2 mol kg<sup>4</sup> Ca(ClO<sub>4</sub>)<sub>2</sub> brine from 256 298-140 K,  $\frac{V_{app}(\varepsilon \cdot \rho_{brine})}{V_{app}(\rho_{brine})} \approx \frac{V_{app}(140 \text{ K})}{V_{app}(298 \text{ K})}$ , where  $\varepsilon$  is either 1.05 or 1.1 (corresponding to the

we plot the change in apparent water volume as a function of standard brine density for our 4.2 mol kg<sup>-1</sup> Ca(ClO<sub>4</sub>)<sub>2</sub> brine at 298 K. We calculate this density using Equation 27, inverting for the brine density and setting  $V_{app}(298 \ K) \approx V_w(298 \ K)$  as a first order approximation. This leads to an estimated 4 mol kg<sup>-1</sup> Ca(ClO<sub>4</sub>)<sub>2</sub> brine density at 298 of ~1440 kg m<sup>-3</sup>, and thus values for  $\frac{V_{app}(\epsilon \cdot \rho_{brine})}{V_{app}(\rho_{brine})}$  between 0.875-0.935.

We then use the theory of Tromans<sup>3</sup> that can be used to infer how a decrease in 263 264 apparent volume by a factor of 0.875-0.935 affects the increase in salting out coefficient. Adhering to the reference KOH line of Tromans<sup>3</sup> (see his Fig. 7 which shows how the 265 266 salting out factor is a function of apparent volume change), we see that a temperature 267 change from 298-140 K would maximally yield an increase in salting out factor between 268  $\sim$ 3-10 (for the average value of 6% density increase from 298-140 K, it would be a factor of ~5). Therefore, even if we account for a potential temperature dependence of Pitzer 269 270 coefficients, then we would maximally obtain dissolved  $O_2$  concentrations at 140 K that are 271 3-10 (and likely less than  $\sim$  5) times lower than what we observe with our best estimate 272 shown in Figs. 1-4.

273

# 274 2.1.5. Existence of perchlorate brines under Martian conditions and the importance of 275 "near-surface"

For a brine at surface temperature, *T*, and pressure, *P*, to be liquid for limited amounts of time the concentration of salt must correspond to the critical molality,  $m_X(T)$ , at this temperature (see Methods Section) but the pressure must be also above the triple point pressure,  $P_{TP}(m_X)$ , for that specific brine. For pure water, the triple point pressure is ~6.1 mbar, around the average atmospheric pressure on Mars. At this pressure, the melting and boiling temperatures converge, which would limit the time-limited presence of liquid water
to temperatures close to 273 K (this explains the narrow water range in Fig. 2 for Mars).

283 For brines, however, the triple point pressure is significantly reduced. Specifically, for Ca-perchlorate brines, the salt concentrations,  $m_X$ , needed for the brine to be liquid at the 284 285 surface temperatures obtained with our general circulation model (GCM) simulations 286 (below ~230 K, see Table S4) result in triple point pressures at least one order of magnitude 287 below the minimal atmospheric surface pressure of  $\sim 1$  mbar encountered in our GCM. The 288 triple point pressure can be approximately computed as the intersection between the 289 standard "water ice-vapour" phase curve in temperature-pressure space and an isotherm for a given temperature,  $T_{TP} = max(T, T_{eu})$  (with surface temperatures T ranging from 290 ~145-230 K and the eutectic temperature for Ca-perchlorate brines of  $T_{eu} = 198.2 \text{ K}$ ). 291 292 Therefore, the pressure conditions on Mars support the studied Ca-perchlorate brines with 293 salt concentrations  $m_x(T)$ , which we show in Fig. 3, to be liquid for a limited amount of 294 time (atmospheric water vapour limits the time of existence, see below). Moreover, due to 295 the approximate incompressibility of water and brines between  $\sim 1$  bar and  $\sim 1$  mbar, we do 296 not expect any significant change in eutectic temperature from Earth to Mars surface 297 pressures.

Note that for remaining liquid for extended periods of time (so next to stability against freezing and sublimation), the partial vapour pressure will also matter because it determines the stability against evaporation. Here, we look only at the existence of brines and do hence not account for additional effects by the atmospheric vapour pressure at this point in time. We note however that even a thin layer of soil or regolith can effectively prevent

305	
306	2.1.6. Comparison with Earth today
307	It is interesting to note that the Mars-to-Earth solubility conversion factor (= solubility
308	value at the same temperature but changing from an atmosphere of 6.1 mbar with 0.145%
309	$O_2$ to one with 0.21 bar $O_2$ is ~23,742). So, if the solubility of $O_2$ in pure water on Mars at
310	slightly above 273.15 K is $\sim 2 \cdot 10^{-5}$ mol m <sup>-3</sup> , it is, at the same temperature, about 23,742
311	greater on Earth today, or around 0.47 mol m <sup>-3</sup> .
312	The main enhancement factor for dissolved O <sub>2</sub> on modern Mars is the much lower
313	surface temperature in comparison to the Earth.
314	

sublimation, which makes our results especially valid in the shallow subsurface-

exemplifying the choice of focusing on "near-surface" environments in this first study.

#### 315 **2.2. Climate model**

316 In the next subsections, we discuss our climate model in greater detail.

317

303

304

#### 318 2.2.1. Albedo variation with obliquity change

The albedo of the Martian surface and how it changes with obliquity can potentially be a significant control on surface temperatures. For any rotating planet, annually averaged insolation at the poles increases going from zero obliquity to larger values, leading to a warming of cooler regions (poles) and a cooling of warmer regions (low latitudes) as obliquity rises (as seen in Table S4 for annually averaged temperatures for present-day Mars). For a homogenous albedo distribution across the planet's surface, above 54° obliquity, the poles receive more insolation than the equator<sup>34</sup>, and become the 'warmer' regions of the planet (on an annual basis), whereas the tropics become the 'cooler' regionand, therefore, the preferred location for surface ice formation.

The exact timing of how surface ice on Mars evolves with changing obliquity is 328 329 uncertain, as is the exact distribution of tropical surface ice at high obliquity. Different 330 studies alternatively suggest that water ice will condense widely across high topographic 331 and/or high thermal inertia sites on the planet at high obliquity<sup>3</sup>, or only in localized glacial 332 deposits on the flanks of the Tharsis Montes<sup>26</sup>. The impact of the exact distribution on 333 surface albedo on temperature can potentially be significant. For example, during the early 334 phases of an obliquity transition (say, from lower to higher values), ice will likely remain 335 in the polar regions for some time after the obliquity rises because of the multi-kilometre 336 thickness of the polar caps. Albedo, then, may remain relatively high at the poles, while it concurrently increases in the tropics due to the development of ice deposits there as 337 338 obliquity rises. Later in the obliquity transition, though, it is likely that the albedo at the 339 poles will decrease as a darker, dirty sublimation lag forms atop the retreating polar ice cap. 340 The timing of this transition will be gradual and difficult to model precisely.

341 We perform a series of tests of the end-member cases from previous studies<sup>2526</sup>, looking 342 at the effect of their putative ice distributions on the global surface temperatures at high 343 obliquity, looking at different stages of the aforementioned evolution, with bright ice in the 344 poles only, in both the tropics and poles, and in the tropics only. While the annually averaged global surface temperature does decrease with the presence of tropical ice, (which 345 346 covers a larger fraction of the surface with high albedo ice than the poles at low obliquity), 347 the general trend in surface temperatures with obliquity continues regardless of the exact 348 distribution of ice. Differences in surface temperatures between the end members of surface

ice distribution are in the range of 5-10 K while the minimum of the annually averaged surface temperature values varies by up to  $\sim$ 35 K. This behaviour is reflected in the O<sub>2</sub> solubility results in Fig. 4a where, with increasing obliquity, the maximum solubility (corresponding to the lowest annually averaged temperature on the surface) generally decreases.

354

355 2.2.2. South polar ice cap

356 We do not impose any constraints on ice caps for our obliquity calculations; however, 357 on modern-day Mars, observations reveal a perennial polar cap of  $CO_2$  ice in the south 358 (SPC), which global climate models cannot self-consistently reproduce without making 359 specific, ad hoc assumptions. In our GCM calculations, we set the surface temperature to 360 the pressure-dependent CO<sub>2</sub> frost point for all locations poleward of -85°. This GCM model 361 is listed in Table S4 as "25° with SPC" and represents the most realistic climate model for 362 Mars today. We use this model to study modern Mars and to create Fig. 3 in our main 363 manuscript. Mechanisms for forming such a south polar CO<sub>2</sub> cap are not well understood, 364 and, hence, we cannot (and do not) extrapolate it to other obliquities; therefore, we also run 365 a 25° obliquity simulation without the presence of a south polar cap, as shown in Fig. 4. Fig. 4 highlights that the "with SPC" model leads to about one order of magnitude greater 366 367 maximum solubility values on the Martian surface today because of the fixed low temperatures for the southern polar regions. The WC scenario is not much affected by the 368 369 specific assumptions on SPC.

We must emphasize that there is no reason to assume that a SPC should form at different, non-modern obliquities, especially not at higher obliquities where the poles are expected to be much warmer (see Table S4).

373 If we were to arbitrarily enforce a SPC at all obliquities, then this would significantly reduce the secular variation of the maximum value of O<sub>2</sub> solubility with obliquity change. 374 375 This is because, at each obliquity, there would be a small region at the south pole with temperatures at the pressure-dependent frost point of CO<sub>2</sub>, which would only vary with 376 377 pressure changes associated with an evolving obliquity. The secular behaviour of the 378 average values of  $O_2$  solubility would, however, not be changed by assuming an SPC at 379 each obliquity because of the small size of the SPC region. Also, as we show in Fig. 4, the 380 lowest temperatures apart from the SPC do increase with increasing obliquity as the poles start to warm; thus, the highest values outside the SPC for the solubility of oxygen in brines 381 382 do indeed decrease significantly with obliquity, suggesting the robustness of our trends independent of our SPC assumption. 383

384

#### 385 2.2.3. Atmospheric collapse

For obliquities below ~10-15°, we find that, on geological timescales, the atmosphere collapses due to the presence of permanent  $CO_2$  cold traps in the polar regions. This can be seen in Table S4, where we show how the minimum value for the annually averaged surface temperature is at the pressure-dependent  $CO_2$  frost point temperature for lower obliquities. This model scenario is not likely to have occurred in the last twenty million years, might occur rarely in the next five million years (Fig. 4b), but might have occurred more frequently in the deeper past<sup>27</sup>.

Atmospheric collapse will, hence, not significantly affect the time period that we study, but it is interesting to consider what could happen to  $O_2$  concentrations during such an event.  $O_2$  is produced in the Martian atmosphere through photochemical reactions from  $CO_2$  and H<sub>2</sub>O, and subsequent hydrogen escape<sup>38</sup>; hence, in order to understand how  $O_2$  reacts to atmospheric collapse, we need to understand how atmospheric water and  $CO_2$  behave during an atmospheric collapse. See Section 2.2.5, where we explore in detail how the mixing ratios of  $O_2$ ,  $CO_2$ , and H<sub>2</sub>O scale over different timescales.

400

#### 401 2.2.4. Averaging method and extension to daily temperature variations

For practical reasons, we generate climate data of annual averages of temperature and pressure as a function of location on the Martian surface for various obliquities (see details on climate model above). The solubility at each point on Mars' surface is evaluated for this annual average of temperature and pressure. It is important to point out that by doing such time-averaging, the solubility results shown in Figs. 1-4 and the differences between minimum and maximum solubilities shown in Fig. 4 are lower than if we instead compute the annual average of solubility as a function of hourly or daily averages.

With our averaging approach, we underestimate the solubility because  $[O_2]_{aq}$ increases exponentially towards 0 K, hence the gradient  $\left|\frac{\partial [O_2]_{aq}}{\partial T}\right|$  is greater for lower temperatures and the solubility evaluated at the average annual temperature is lower than the solubility averaged over a greater time (and, hence, temperature) interval. The solubility is linear in pressure and, thus, using the annually averaged pressure does represent the precise average for the solubility as a function of pressure. Computing the annual average of the O<sub>i</sub> solubility directly from the non-averaged temperature (daily or hourly) would 416 only increase our  $O_2$  solubility estimates and strengthen the conclusions.

417

#### 418 2.2.5. Variation in the Mars O<sub>2</sub> mixing ratio and timescales of interest

We assume a constant mixing ratio of O<sub>2</sub>, in agreement with currently published 419 measurements<sup>5,29-31</sup>. To explore the validity and possible limitations of this assumption, let 420 421 us briefly revisit how O<sub>2</sub> forms in the Martian atmosphere: CO<sub>2</sub> is the major component in the Martian atmosphere (volume mixing ratio of ~0.96)<sup>5</sup>. CO<sub>2</sub>, being photolyzed by solar 422 UV radiation below 2275 Å ( $2CO_2 + UV \rightarrow 2CO + O_2$ ), is the major source of  $O_2^{28,32-33}$ , 423 with a photochemical lifetime for  $O_2$  of ~30 years<sup>34</sup>. Without catalysts, the recombination 424 of CO and O to CO<sub>2</sub> is much slower than the combination of two O atoms to form O<sub>2</sub>, and 425 426 it is primarily (amongst other factors like the temperature dependence of the CO<sub>2</sub> cross section<sup>28</sup>) the existence of odd hydrogen species ( $HO_x$ , which are mainly formed by the 427 428 photolysis of water vapour) that catalyse the recombination of CO and O into CO<sub>2</sub>, 429 allowing the Martian atmosphere to predominantly consist of CO<sub>2</sub> and have only trace amounts of  $O_2$ , with a modern  $O_2$  mixing ratio of ~0.145%<sup>5</sup>. 430

431 We would expect that the abundance of  $O_2$  is primarily linked to the abundance of 432  $CO_2$  and  $H_2O$  in the Martian atmosphere; hence, in order to explore how the abundance 433 and the volume mixing ratio of  $O_2$  could fluctuate over different timescales, we have to 434 first explore the variability of the abundances of  $CO_2$  and  $H_2O$  over different timescales.

Here, we focus on diurnal and seasonal timescales of  $CO_2$  and  $H_2O$  to study the robustness of our  $O_2$  solubility predictions based on annual averages for a fixed obliquity, and on larger timescales in the order of thousands to millions of years that are relevant to changes in obliquity<sup>27</sup> or thousands of years that are relevant to atmospheric collapse.

#### 439 2.2.5.1. <u>Diurnal and seasonal variability</u>

440 The CO<sub>2</sub> and H<sub>2</sub>O cycles on Mars reflect deposition and sublimation of both species 441 on diurnal and seasonal scales. However, as indicated by work on dry atmospheres<sup>35</sup>, four orders of magnitude variation in the H<sub>2</sub>O abundance affect the O<sub>2</sub> mixing ratio by less than 442 443 a factor of three, and, hence, the diurnal and seasonal variations in water vapour, which are one to two orders of magnitude<sup>36</sup>, do not affect our conclusions—which suggests solubility 444 445 differences of many orders of magnitude over the Martian near-surface. If there is, for our 446 work, any significant variation of the O<sub>2</sub> mixing ratio for annually averaged maps, then this could come from variations in the  $CO_2$  abundance, which can fluctuate by 25% on modern 447 Mars on seasonal or diurnal timescales<sup>5</sup>. The mixing ratio of O<sub>2</sub> should, at first thought, 448 449 increase with a decrease of the  $CO_2$  partial pressure (when  $CO_2$  freezes) on timescales 450 much shorter than the lifetime of  $O_2$  (hence, on seasonal or diurnal timescales). This would, 451 however, only modulate the mixing ratio of  $O_2$  by 25%, which is much smaller than the 452 order of magnitude trends that we observe. However, there are no published data that support such behaviour, which might suggest that the photochemical production rate of O<sub>2</sub> 453 is fast enough to tightly couple the abundance ratio of CO<sub>2</sub> to O<sub>2</sub>. Hence, the mixing ratio 454 of O<sub>2</sub>, as CO<sub>2</sub> is the primary atmospheric component, should, for our purposes, remain 455 rather constant on seasonal timescales. 456

- 457
- 458 **2.2.5.2**.

#### Secular variation timescales

#### 459 **2.2.5.2.1**. *Obliquity change*

460 To infer how the solubility of  $O_2$  could have changed in recent history, we studied 461 how climate changes for different obliquities. Such changes occur over thousands to 462 millions of years<sup>27</sup>. These timescales are much greater than the lifetime of  $O_2$  and, hence,

we expect that the abundance ratio of CO<sub>2</sub>/O<sub>2</sub> remains constant and that the amount of O<sub>2</sub> 463 scales with the amount of CO<sub>2</sub> and, approximately, to total pressure. Moreover, recent work 464 on dry planets<sup>35</sup> illustrate that many orders of magnitude changes in water vapour would 465 only slightly affect the O<sub>2</sub> mixing ratio. Hence, we expect the volume mixing ratio of O<sub>2</sub> 466 to remain rather constant when looking at obliquity variations. 467

468

469

#### 2.2.5.2.2. Atmospheric collapse

470 We find in our calculations that, for low obliquities, atmospheric collapse can occur, where CO<sub>2</sub> and H<sub>2</sub>O fully freeze out. Such events do not seem likely in the timeframe that 471 472 we study; however, we find such events lasting thousands of years, on timescales much 473 greater than the photochemical lifetime of  $O_2$ . The first species to fully freeze out would be H<sub>2</sub>O. This could lead to a full photolytic transformation of CO<sub>2</sub> into CO and O<sub>2</sub>,<sup>28,35</sup> 474 475 with O<sub>2</sub> still being non-condensable at such temperatures—leading to the possibility of a 476 highly oxidizing Mars environment during such times of atmospheric collapse, which might be related to observations of MnO<sub>2</sub> by MSL<sup>37</sup> and redox-stratified ancient lake 477 environments<sup>38</sup>. Nonetheless, in the same timeframe, the CO<sub>2</sub> atmosphere would freeze 478 out, and, hence, to fully answer the question of what really happens to O<sub>2</sub> during times of 479 atmospheric collapse, one would have to study the dynamic aspects of such a transition and 480 481 individual duration of collapse for each species, which is beyond the scope of this paper.

- 482
- 483

#### 2.2.5.3. Conclusion for assuming a constant $O_2$ mixing ratio

Variations of the mixing ratio of O<sub>2</sub> have so far not been conclusively found, but if 484 they occur, then they should modulate our results only by a factor of a few, whereas our 485 486 geographic and obliquity-driven secular change conclusions show differences in O<sub>2</sub>

solubilities by many orders of magnitude. Therefore, our assumption of a constant mixing
ratio for O<sub>2</sub> is reasonable.

489

#### 490 **3.** <u>Life and aerobic environments</u>

#### 491 **3.1. Aerobic environments versus aerobic habitats**

492 We explore Martian brines that could contain enough O<sub>2</sub> to be biologically relevant and accessible by organisms. However, we intentionally study "aerobic environments" and not 493 494 "aerobic habitats". We could well imagine an aerobic habitat (that organisms inhabit) at 495 greater depth (where it is significantly warmer) below an O<sub>2</sub>-rich brine environment accessing the stored O<sub>2</sub>. Hence, although the aerobic environments we explore could be a 496 497 habitat (as we explore in greater depth in the next subsections), such  $O_i$ -rich environments 498 can be also seen as only biologically relevant-making the aerobic environments we 499 explore biologically relevant far below the not-yet-well-constrained lower temperature 500 limit for life (see Section 3.2).

501

#### 502 **3.2.** The lower temperature limit for life and the potential of aerobic habitats

To answer whether the aerobic environments that we explore could be more than just biologically relevant resources and, indeed, be habitats, much more work beyond the scope of this paper will be required, focusing on the habitability of highly saline, likely low water activity fluids, exploring not just the availability of  $O_2$ , but its fluxes and complementary reducing species, and especially studying the low temperature limits to life. The question of what the lower temperature limit to life is sticks out. While the temperatures for high- $O_2$ brines described here are low relative to those typical for life on Earth, no hard, lower temperature limit for life has been established<sup>39</sup>; metabolic activity and cell growth have
been observed at temperatures below -20°C<sup>40</sup>.

512 The lower temperature limit for life is much less constrained than the upper temperature 513 limit for life, and we have to differentiate between the lower temperature limits for survival, 514 life cycle completion (i.e., reproduction), and metabolism<sup>39-42</sup>.

515 The conditions setting the lower temperature limit for life are likely intracellular vitrification at low temperatures<sup>41-42</sup>, where fluids inside a cell start to behave like an 516 amorphous ice of high viscosity (> $10^{12}$  Pa s). Intracellular vitrification occurs for water on 517 the Earth around -20°C and is driven by freezing of the extracellular medium. Note, 518 however, that vitrified cells, although they cannot metabolize, do survive the vitrification 519 520 process<sup>41-42</sup>. However, the Martian brines that we study can absorb atmospheric  $O_2$  exactly 521 because they can remain liquid far below the freezing point of water. As an example, the freezing temperature of Ca-perchlorate brines is around 198 K (-75°C), far below - 20°C. 522 In such a medium (which is not common on the much warmer Earth but should be more 523 524 common in cold, dry environments like the McMurdo Valleys or the Atacama Desert), 525 there would be no freezing of extracellular medium and, hence, no reason for intracellular 526 vitrification. The viscosity of the fluid would also remain rather small (which corresponds 527 to the brine not being frozen or vitrified), allowing vigorous nutrient delivery for metabolic activity. The much lower freezing temperatures for Martian brines and the ability of some 528 529 of them to effectively supercool, even when mixed with soils, are the reasons why we study 530 such brines as materials interesting to life. Hence, the general reason for a lower temperature limit for life, namely extracellular medium freezing and intracellular 531 vitrification, should occur in Martian brines at much lower temperatures than -20°C-532

exemplifying the importance of freezing point reduction for the survival of life at much
 lower temperatures.<sup>43</sup>

In conclusion, if Martian life could adapt to tolerate high salt concentrations such as those in the brines described here, this could lead to a lower temperature limit and access to higher dissolved oxygen concentrations due to the very low freezing points and additional supercooling ability of these systems.

539

#### 540 **3.3. Aerobic habitats on Mars under warmer conditions?**

541 Temperatures above -20°C (and even above the freezing point of water) exist in the 542 Martian near-surface (compare with Figs. 1 and 2 in the main article). We know that (1) at 543 temperatures above  $-20^{\circ}$ C, at least from a temperature perspective, life can survive, grow, 544 and metabolize, (2) above the freezing point of water our model has been validated with experimental data, and (3) at such "warmer" temperatures (above -20°C and even above 545 546 the freezing point of water) our model predicts a dissolved  $O_2$  concentration of ~10<sup>3</sup> mol m 547 <sup>3</sup>, well above the limits of respiration for bacteria<sup>44,5</sup>. Hence, although at very low temperatures the question remains open as to whether aerobic environments can be habitats, 548 549 we know that on modern Mars-from an O<sub>2</sub> availability and temperature perspective-550 near-surface conditions exist that could enable aerobic habitats.

551

#### 552 4. The next steps

#### 553 **4.1. The path towards fluxes and redox gradients**

As we show in Fig. S4, it is primarily temperature and secondarily pressure that determine the potential solubility of  $O_2$  in Martian near-surface environments. The

geographic variations in  $O_2$  content lead to natural gradients in concentrations across environments where waters might naturally flow<sup>46,47</sup>. Areas where spatial gradients (as shown in Fig. S4) in  $O_2$  solubility are largest are observed on Tharsis, across Meridiani, Arabia Terra, and within the Hellas basin.

Next to studying the fluxes of  $O_2$  on Mars, in order to explore the potential for aerobic life, we will also have to explore, in subsequent steps, the fluxes of reducing species, as life needs redox gradients in order to thrive.

563

#### 564 4.2. Distribution, likelihood, and timescales of existence of brines on Mars

The opportunity for oxidative processes involving O<sub>2</sub> during the chemical weathering 565 566 of Mars' crust will reflect a convolution between the availability of water and brines and their O<sub>2</sub> contents. Our results suggest that we should expect a degree of patchiness in 567 568 oxidative chemistry associated with weathering; the same would be true for the potential 569 energetic gradients for aerobic respiration. To fully explore this patchiness, we need to 570 convolve our results with the distribution and the likelihood of brines on Mars: here, we 571 compute how climate impacts the potential for aerobic environments on Mars in 3D (Fig. 572 3), assuming that perchlorate and water are equally available everywhere close to the 573 planet's surface. Naturally, we expect spatial variability in the distribution of water and 574 perchlorates (possibly linked with each other), and, hence, as a next step, it will be 575 inevitable to explore how the distribution of perchlorates and water availability across the 576 Martian near-surface (and also deeper subsurface) might vary, how local vapour pressure 577 and soil thickness affect evaporation timescales (beyond just the potential for existence as 578 addressed here), how ice and surface features might impact the formation and longevity of 579 liquid brines close to the surface, and how these factors would affect our results.

580 Such an extension, however, demands a much deeper insight into the dynamics of 581 brine formation/destruction and gas dissolution processes (connecting subsurface and 582 atmosphere), which is beyond the scope of this first study. For the next steps of our study, 583 it would be informative to know how chlorine and hydrogen concentrations change with 584 depth in the near-surface and ultimately in the deeper subsurface. Unfortunately, currently 585 available data from the Mars Odyssey gamma ray spectrometer reach only down to a few 586 microns in depth, are strongly modulated by dust, and cannot yet see the meaningful depths 587 of the regolith that have daily or seasonal thermal cycles.

590 Fig. S1.

**Thermodynamic lower limit to the solubility of O<sub>2</sub>:** we compare the best estimate (BE, 591 solid blue line) for the solubility curve of O<sub>2</sub> in supercooled water to the thermodynamic 592 worst case (WC, solid red line), which sets the specific heat of dissolved O<sub>2</sub> to zero for 593 594 temperatures below 273 K. Formally, this is only possible for T = 0 K, and thus WC marks a lowermost estimate. We show also a solubility curve assuming  $C_{P,O_2,aq}(T) = 0$  for all 595 temperatures (black dotted line) and one assuming  $C_{P,O_2,aq}(T) = 0$  for T < 225 K (pink 596 dotted line). 597

599 Fig. S2.

600 Salting out coefficients for O<sub>2</sub> in perchlorate and chloride brines: using data on the 601 solubility of O<sub>2</sub> in various chlorides (solid) and perchlorate (dashed) brines<sup>11,13</sup>, we compute 602 Pitzer interaction coefficients at 298 K for Ca- and Mg-perchlorates, describing the salting out factor,  $\gamma_{O_2}(X, m_X)$ , of O<sub>2</sub> as a function of salt concentration. We also plot the salting 603 out factors for other relevant brines (for parameters, see Table S2).  $[O_2]_{aa,X}(T,P) =$ 604  $\frac{1}{\gamma_{O_2}(X,m_X)}$  [ $O_2$ ]<sub>*aq,w*</sub>(*T*,*P*), wherein the salting out factor relates the solubility of O<sub>2</sub> in pure 605 water  $[O_2]_{aq,w}(T,P)$  and in the brine  $[O_2]_{aq,X}(T,P)$ . The salting out factors for Mg- and 606 607 Ca-perchlorates are likely overestimated here, as we neglect electrostatic cation-anion- $O_2$ 608 interactions.

610 **Fig. S3.** 

611 The temperature dependence of salting out factors for  $O_i$  in various brines: (a) the 612 density gradient with temperature as a function of molality using density data from 303-613 243 K. (b) Using an average density variation from 5-10% for a Ca(ClO<sub>4</sub>)<sub>2</sub> brine, we 614 compute how the apparent volume of water changes from 298-140 K for a range of 4.2 m  $Ca(ClO_4)_2$  brine densities at 298 K (our estimated value is ~1400 kg m<sup>3</sup>, see below) by 615 plotting  $\frac{V_{app}(\varepsilon \cdot \rho_{brine})}{V_{app}(\rho_{brine})} \approx \frac{V_{app}(140 \text{ K})}{V_{app}(298 \text{ K})}$ , where  $\varepsilon$  is either 1.05 (red) or 1.1 (blue) (representing 616 the increase in brine density from 298-140 K by 5-10%). The apparent volume depends 617 slightly on the reference brine density at 298 K, which we estimate by using Equation 27, 618 619 inverting for the brine density and setting  $V_{app}(298 K) \approx V_w(298 K)$ , leading to an estimated 4.2 mol kg<sup>-1</sup> Ca(ClO<sub>4</sub>)<sub>2</sub> brine density at 298 K of ~1440 kg m<sup>-3</sup>, and  $\frac{V_{app}(\varepsilon \cdot \rho_{brine})}{V_{app}(\rho_{brine})}$ 620 621 between 0.875 and 0.935. Along the KOH line in the Tromans model<sup>3</sup>, we get an increase

of the salting out factor between  $\sim$ 3-10 (and likely less than a factor of  $\sim$  5).

624 **Fig. S4**.

The predominant factors that control  $O_2$  solubility, and spatial  $O_2$  solubility gradients on modern Mars: this plot shows the  $O_2$  solubilities for modern-day Mars using local annual averages for surface temperature and pressure (top) as well as spatial gradients (bottom) in  $O_2$  solubility. The primary control on  $O_2$  solubility is temperature and secondary modifications result from pressure.

630 Tables:

#### 631 **Table S1.**

**Dissolved oxygen parameters:** all thermodynamic parameters needed to compute the specific heat capacity for  $O_2$  at constant pressure in the gaseous and aqueous phases, essential for deriving the solubility of  $O_2$  in pure water as a function of pressure and temperature in Equations 1-2 in the Methods Section of our main article. The parameters are taken from experiments<sup>1</sup>. The partial volume fraction in the Martian atmosphere is approximately  $VMR_{O_2} = 0.00145^{\circ}$ , and R = 8.3144598 J mol<sup>-1</sup> K<sup>-1</sup> is the universal gas

638 constant.

Thermodynamic parameters for the solubility of O <sub>2</sub> in pure water

657 the maximal supercooling temperature,  $T_{sc}$ , are taken from available experiments<sup>20</sup>.

659 **Table S4.** 

Surface temperatures across obliquities: for the simulated obliquities, the minimum, average, and maximum values on the Martian globe for annually averaged surface temperatures. The annotation "with SPC" is representing modern Mars, where a perennial  $CO_2$  cap at the south pole is assumed. The values [\*] for obliquities of 40°, 60°, and 90° represent climate simulations where the Southern Polar  $CO_2$  cap has sublimated, doubling the average surface pressure to ~12 mbar.

Temperature variation on the Martian surface with obliquity								
Obliquity	Minimum annual	Global annual	Maximum annual					
[°]	average	average	average					
	[K]	[K]	[K]					
5	144.4	205.7	229.7					
10	144.5	205.4	229.5					
15	149.6	205.0	229.0					
20	156.0	204.4	228.3					
25	161.8	203.703	227.413					
25 (with SPC)	144.2	203.651	227.389					
40	172.1 [*175.7]	201.6 [*204.6]	224.1 [*226.9]					
60	179.7 [*183.2]	198.0 [*201.0]	214.4 [*216.8]					
90	177.2 [*179.5]	195.4 [*198.8]	208.8 [*211.9]
