ABSTRACT

With Gaia Data Release 2, the astronomical community is entering a new era of multidimensional surveys of the Milky Way. This new phase-space view of our Galaxy demands new tools for comparing observations to simulations of Milky-Way-mass galaxies in a cosmological context, to test the physics of both dark matter and galaxy formation. We present ananke, a framework for generating synthetic phase-space surveys from high-resolution baryonic simulations, and we use ananke to generate a suite of synthetic surveys designed to resemble Gaia DR2 in data structure, magnitude limits, and observational errors. We use three cosmological simulations of Milky-Way-mass galaxies from the *Latte* suite of the Feedback In Realistic Environments (FIRE) project, which offer many advantages for generating synthetic stellar surveys: self-consistent clustering of star formation in dense molecular clouds, thin stellar and gaseous disks, cosmological accretion and enrichment histories, all in live cosmological halos with satellite dwarf galaxies and stellar halos. We select three solar viewpoints from each simulation to generate nine synthetic Gaia-like surveys. We generate synthetic stars assuming that each simulation's star particles (of mass $7070 \,\mathrm{M}_{\odot}$) represent a single stellar population, and we use a kernel density representation to distribute synthetic stars accurately in position and velocity. At each viewpoint, we compute a *self-consistent* dust extinction map, using the gas metallicity distribution in each simulation. Finally, we apply a simple error model to produce a synthetic Gaia-like survey at each solar viewpoint, though we also provide quantities without error convolution. This results in a catalog of synthetic stars, as if measured by Gaia, that includes both observational properties and a pointer to each generating star particle in the simulation. We also provide the complete snapshot-including star, gas, and dark matter particles-at z=0 for each simulated galaxy. We describe data access points, the data model, and plans for future upgrades to ananke. These synthetic surveys provide a tool for the scientific community to test analysis methods and interpret Gaia data.

1. INTRODUCTION

A new generation of observational projects is poised to revolutionize our understanding of resolved stellar populations of the Milky Way (MW) and MW-mass galaxies at an unprecedented level of detail, ushering in an era of precision studies of galaxy formation. In the MW itself, as-

trometric, spectroscopic, and photometric surveys will measure three-dimensional positions and velocities and numerous elemental abundances for stars from the disk to the halo, as well as for many satellite dwarf galaxies. In the Local Group and beyond, the Hubble Space Telescope (HST), James Webb Space Telescope (JWST) and eventually the Wide-Field Infrared Survey Telescope (WFIRST) will deliver pristine views of resolved stellar populations. The groundbreaking scale and dimensionality of this new view of resolved stellar populations in galaxies challenge us to develop new theoretical tools to robustly compare these surveys to simulated galaxies, in order to take full advantage of our

[†] Hubble Fellow

new ability to make detailed predictions for stellar populations within a cosmological context.

Broadly speaking, two classes of modeling tools exist for generating synthetic stellar observations of the MW. One class of tools samples empirically derived density distributions generally assumed to be in dynamical equilibrium, such as the Besançon model (Robin et al. 2003), galfast (Juric et al. 2010), TRILEGAL (Girardi et al. 2005), and GalMod (Pasetto et al. 2018). The other common approach is to re-sample star particles from cosmological simulations of galaxy formation in a manner that preserves phase-space properties, such as the Galaxia¹ implementation of the Bullock & Johnston (2005) mock stellar halos by Sharma et al. (2011) or the resampling of cosmological simulations in Lowing et al. (2015) and later Grand et al. (2018). In the latter case, the phase space density usually is computed using a strategy such as that employed in the publicly available code EnBiD² (Sharma & Steinmetz 2006), which partitions particles and chooses an adaptive smoothing length based on the local Shannon entropy in each dimension, avoiding the need to define a metric for the six-dimensional distance.

While the empirical, equilibrium approach has the advantage of being tied closely to true MW data, it has the disadvantage of requiring a simple analytic, generally equilibrium description of structure, lacking the rich complexity of non-axisymmetric structures like spiral arms in the disk, overdensities in the stellar halo, satellite galaxies, and dark-matter substructure. The N-body resampling approach from cosmological simulations has the disadvantage of not generating a one-to-one match of the MW; however, catalogs generated from N-body simulations can capture the non-equilibrium structures born out of a fully cosmological context.

Mock catalogs generated from such cosmological simulations can serve as valuable aids in characterizing the efficacy of analysis tools to recover "ground truth," from characterizing the underlying potential and dark-matter distribution to recovering the evolutionary history of a simulated galaxy. Thus, while a cosmologically simulated galaxy will not replicate the MW perfectly, it can provide great value as a testbed for discovery and recovery of underlying structural, dynamic, and abundance trends. For example, Grand et al. (2018) recently published two sets of mock Gaia DR2 catalogs generated from 6 cosmological high-resolution MW-mass simulations from the AURIGA project. One set of the mock catalogs were generated using the public SNAPDRAGONS code (Hunt et al. 2015) and the other leveraged the phase-space preserving scheme of the Galaxia code (Sharma et al. 2011) but with a different choice of the smoothing kernel as de-

However, existing mock catalogs of N-body simulations still suffer from some limitations. Previous semi-analytic studies, such as the resampling of Bullock & Johnston (2005) in Sharma et al. (2011) or the resampling of Cooper et al. (2010) in Lowing et al. (2015), are limited by the use of dark-matter-only cosmological simulations as the basis for generating the stellar phase-space distributions. This prevents a self-consistent realization of both the disk-like central galaxy and the accreted halo, and relies on a prescription for translating the phase-space distribution of the dark matter into that of the stars. Such prescriptions can be quite sophisticated, as is the case with Cooper et al. (2010), but cannot self-consistently capture the ongoing interaction between star formation, feedback processes, and the dark matter halos which is of especial importance in the smaller accreted galaxies that eventually form the stellar halo. Neither can these simulations more than approximately account for the contribution of the central galaxy's disk to the tidal destruction of accreted galaxies, which has been shown to be significant especially within the range of Gaia (e.g. Garrison-Kimmel et al. 2017a).

Another limitation of attempts to resample the stellar distributions of cosmological-hydrodynamical simulations, as in Grand et al. (2018), is the choice to use the observed MW extinction map in the synthetic surveys, rather than self-consistently determining the extinction from the metal-enriched gas distribution in the simulated galaxy. This choice can produce both large- and small-scale discrepancies in the stellar density distribution predicted by the synthetic survey: on small scales, the extinction should be correlated with regions where young stars are forming, while on large scales it should be related to the height of the young thin disk and correlated with any spiral features that exist in the simulated galaxy.

To address these limitations, we use the *Latte* suite of simulations of Milky-Way-mass galaxies (Wetzel et al. 2016; Hopkins et al. 2017), run as part of the Feedback In Realistic Environments (FIRE) simulation project. Using these simulations as the basis for generating synthetic surveys allows us self-consistently to incorporate the effects of bary-onic processes in a cosmological context, improving on semi-analytic analyses of dark-matter-only simulations while retaining sufficient resolution to include kinematically cold, single-age, single-metallicity stellar populations, at mass resolution (7070 M_{\odot}) comparable to the masses of (massive) star clusters. Given their spatial resolution (as small as 1 pc

scribed in Lowing et al. (2015). Grand et al. (2018) provides a powerful demonstration of how properties of the stellar halo and young stellar disk can be recovered from these catalogs.

in gas) and tracking of cold (down to 10 K) gas, the simulations start to resolve the formation of giant molecular clouds and thus the clustered formation of young stars. These simulations also self-consistently track the metal enrichment of gas, permitting us to encapsulate all the correlations between (young) stars and gas self-consistently, including the extinction near star-forming regions, assuming a fixed ratio of dust to metal-enriched gas. The result is a self-consistent, extincted synthetic survey of the simulated galaxy that leaves intact important observational relationships between gas, extinction, and stellar populations, as well as the important theoretical relationships between cosmology (dark matter) and galaxy formation.

In this paper we describe a new framework, ananke, for generating realistic synthetic star catalogs and mock stellar surveys from cosmological baryonic simulations, and we present a set of synthetic phase-space surveys created from the textitLatte FIRE-2 simulations that are designed to resemble Data Release 2 of the *Gaia* astrometric survey (Gaia DR2, Gaia Collaboration et al. 2018a). We name this framework for generating synthetic surveys ananke⁴.

We describe the underlying simulations in $\S 2$, the assumptions used to define the solar viewpoint in $\S 3$, the process for creating synthetic stars from star particles in $\S 4$, and the extinction and error models used to create the final synthetic surveys in $\S 5$. In $\S 6$ we present preliminary characterizations of the surveys and describe the data model and access modes for the public versions. In $\S 7$ we provide some guidelines for new users of the surveys, and in $\S 8$ we discuss a few of the many uses of this new resource.

2. SIMULATIONS

2.1. GIZMO code and FIRE-2 model

Cosmological "zoom-in' simulations, which model a selected region at high resolution embedded within a lower-resolution cosmological background (e.g., Katz & White 1993; Oñorbe et al. 2014), now achieve sufficient dynamic range to resolve individual star-forming regions within galaxies, allowing the formation of realistic stellar populations that can connect with detailed observations of the MW. Such cosmological simulations allow one to examine realistic formation histories of MW-like systems—with cosmic accretion, galactic outflows, time-dependent asymmetric gravitational potentials, and orbiting satellites—enabling a self-consistent study of the entire MW system at resolution necessary for detailed stellar modeling.

Hopkins et al. (2017) provides all details of our simulation methodology; we briefly describe the most important aspects here.

We use three cosmological zoom-in simulations of individual MW-like galaxies from the *Latte* suite (Wetzel et al. 2016) of FIRE-2 simulations. We ran these simulations using GIZMO⁵ (Hopkins 2015), a multi-method gravity plus hydrodynamics code. The hydrodynamics are solved using the meshless finite-mass ("MFM") method, a mesh-free Lagrangian finite-volume Godunov method that automatically provides adaptive spatial resolution while maintaining conservation of mass, energy, momentum, and angular momentum. Gravity is solved with an improved version of the Tree-PM solver from GADGET-3 (Springel 2005), using fully adaptive and fully conservative gravitational force softenings for gas (see Hopkins 2015), matching the hydrodynamic resolution.

Our simulations were run with the FIRE-2 physics models from Hopkins et al. (2017). FIRE-2 incorporate radiative cooling and heating from $10-10^{10}$ K, including freefree, photo-ionization and recombination, Compton, photoelectric and dust collisional, cosmic ray, molecular, metalline, and fine-structure processes, explicitly accounting for 11 elements (H, He, C, N, O, Ne, Mg, Si, S, Ca, Fe). This includes photo-ionization/heating from a redshift-dependent, spatially uniform ultraviolet background, including cosmic reionization, from Faucher-Giguère et al. (2009), and an approximate model for local sources and self-shielding. The simulations achieve sufficiently high dynamic range to resolve phase structure of the inter-stellar medium (ISM), allowing gas to condense into resolved giant molecular clouds (Hopkins et al. 2017, Lakhlani et al., in prep.).

Star formation occurs only in self-gravitating gas (following Hopkins et al. 2013) that also is molecular and selfshielding (following Krumholz & Gnedin 2011), Jeans unstable, and exceeds a minimum density threshold, $n_{\rm SF}$ > 1000 cm⁻³. These star-formation criteria naturally produce clustered stellar populations in these simulations (Hopkins et al. 2013; Loebman et al., in prep.). Once a star particle forms, the simulation explicitly follows several stellar feedback mechanisms, including (1) local and longrange momentum flux from radiation pressure (in the initial UV/optical single-scattering, and re-radiated light in the IR), (2) energy, momentum, mass and metal injection from supernovae (core-collapse and Ia), and stellar mass loss (dominated by O,B and AGB stars), and (3) photo-ionization and photo-electric heating. Every star particle is treated as a single stellar population with known mass, age, and metallicity; all feedback event rates, luminosities and energies, mass-loss

⁴ In Greek mythology, Ananke is the primordial goddess of necessity and inevitability; along with Chronos, she marks the beginning of the cosmos. In some versions of Greek mythology, she created Gaia.

⁵ A public version of GIZMO is available at: http://www.tapir.caltech.edu/~phopkins/Site/GIZMO.html

rates, and other quantities are tabulated directly from stellar evolution models (STARBURST99 v7.0; Leitherer et al. 1999, 2014), assuming a Kroupa (2001) IMF.

Supernovae (core-collapse and Ia) and stellar winds generate and disperse metals, which are self-consistently deposited into surrounding gas particles. We adopt nucleosynthetic yields for supernovae Ia from Iwamoto et al. (1999), where the rates follow Mannucci et al. (2006), including both prompt and delayed populations; core-collapse supernovae yields are from Nomoto et al. (2006); yields from stellar winds (AGB and O/B-stars) are from a compilation of van den Hoek & Groenewegen (1997); Marigo (2001); Izzard et al. (2004). We initialize all gas particles with a metallicity floor of $[M_i/H] = -4$ in the initial conditions (to prevent numerical problems in cooling). These simulations also include an explicit treatment for un-resolved turbulent diffusion of metals in gas (Hopkins 2016; Su et al. 2017), which produces more realistic abundance distributions in both the MW-like galaxies (Wetzel et al., in prep.) and in their satellite dwarf galaxies (Escala et al. 2018).

2.2. Initial Conditions

Our simulations are drawn from a suite of individual MWmass halos that are simulated with the same resolution, cosmology, and physics model. We first run a dark matteronly simulation within a periodic volume of length 85.5 Mpc with Λ CDM cosmology: $\Omega_{\Lambda} = 0.728$, $\Omega_{\text{matter}} = 0.272$, $\Omega_{\rm baryon} = 0.0455, h = 0.702, \sigma_8 = 0.807, \text{ and } n_s = 0.961.$ From this, we select halos at z = 0 based *only* on their mass, $M_{200\mathrm{m}} = 1 - 2 \times 10^{12} \,\mathrm{M_{\odot}}$, and an isolation criterion (no neighboring halos of similar mass within at least $5 R_{200m}$) to limit computational cost. We select a sample of ~ 10 halos for simulation (listed in Garrison-Kimmel et al. 2017b), agnostic to any halo properties beyond mass and isolation, including formation history, concentration, spin, or subhalo population. We then trace particles within $5 R_{200m}$ back to z = 99 and regenerated the encompassing convex hull at high resolution, embedded within the lower-resolution volume, using MUSIC (Hahn & Abel 2011). Rerun to z = 0, all of the zoom-in regions are uncontaminated with low-resolution dark matter out to at least $d_{\rm host} = 600\,{\rm kpc}$. Within the zoomin region, the particle mass resolution is $m_{\rm dm}=35,000\,{\rm M}_{\odot}$ and $m_{\rm gas,initial} = m_{\rm star,initial} = 7070 \, {\rm M}_{\odot}$ (though because of stellar mass loss, at z = 0, a typical star particle has $m_{\rm star} \approx 5000\,{\rm M_{\odot}}$, and individual gas particle masses can be up to $\sim 2-3$ times higher). Dark matter and stars have fixed gravitational softening: $h_{\rm dm}=40~{\rm pc}$ and $h_{\rm star}=4~{\rm pc}$ (Plummer equivalent). The minimum gas resolution (interelement spacing) and softening length reached in each simulation (in the densest regions) is ~ 1 pc.

For our initial synthetic catalogs, we select three galaxies (m12i, m12f, and m12m) which are approximately MW-like

in terms of stellar and gas mass, size, and stellar morphology. We consider these three systems the most immediately useful for generating synthetic surveys, though we plan to release synthetic catalogs from all of our MW-mass simulations in the future. These galaxies first were presented in Wetzel et al. (2016) (m12i), Garrison-Kimmel et al. (2017a) (m12f), and Hopkins et al. (2017) (m12m). Tables 1 and 2 list their halowide and galaxy-wide properties at z=0.6 Table 2 compares some global properties of the three simulated galaxies with MW values from Bland-Hawthorn & Gerhard (2016).

As an example of this suite, Figure 1 shows two images of m12i, demonstrating its ability to self-consistently model the formation of a MW-like stellar disk, a realistic population of satellites, and a realistic stellar halo with streams and shells.

These simulations produce galaxies with many properties that reasonably agree with those of the MW, M31, and similar-mass galaxies at $z \sim 0$, without any "fine-tuning", including: their stellar-to-halo mass relation (Hopkins et al. 2017), stellar thin plus thick disk morphology and metallicity gradients (Ma et al. 2017), HI gas kinematics (El-Badry et al. 2018); giant molecular clouds (Lakhlani et al., in prep.); circum-galactic medium observations of HI and OVI as compared with the COS-Halos survey (Hummels et al., in prep.), realistic populations of satellite dwarf galaxies that do not suffer from the "missing satellites" or "toobig-to-fail" problems (Wetzel et al. 2016; Garrison-Kimmel et al. 2018) and have realistic metallicity distributions (Escala et al. 2018); and stellar halos (Sanderson et al. 2017; Bonaca et al. 2017). Using the FIRE-1 simulations, which implemented the same stellar physics (though with somewhat different numerical implementations) and used a SPH hydrodynamics solver, we showed that energy and momentum injection by stellar feedback on the scale of star-forming regions as modeled in FIRE self-consistently produces a Kennicutt-Schmidt relation (Hopkins et al. 2014; Orr et al. 2018), galactic winds (Muratov et al. 2015, 2017; Anglés-Alcázar et al. 2017), and high-redshift circum-galactic medium properties (Faucher-Giguère et al. 2015, 2016) in broad agreement with observational constraints.

That said, cosmologically selected galaxies cannot provide exact representations of all properties of the MW, and our simulations are no exception. For example, these simulations span a range of two in stellar mass, and m12m, in particular, has stellar mass of $1.0 \times 10^{11} \, \mathrm{M}_{\odot}$, about twice the MW's stellar mass of $5 \times 10^{10} \, \mathrm{M}_{\odot}$ (Bland-Hawthorn & Gerhard 2016), and closer to M31's stellar mass. All three of these galaxies have higher cold gas masses and SFRs at z=0 than the MW, though the MW does have lower SFR than typical disk galaxies of similar stellar mass at $z\approx 0$ (Licquia et al.

⁶ Movies showing the formation histories of these galaxies are at: http://www.tapir.caltech.edu/~sheagk/firemovies.html

2015). While the spatial disk structure of m12i, m12f, m12m are all similar to the MW, the kinematic structure is more analogous to M31 (Dorman et al. 2015), in particular, in the fiducial solar cylinder ($|z| < 0.3 \mathrm{kpc}$, $7.95 < R/\mathrm{kpc} < 8.45$, see section 3.2 for details), the magnitude of the total *stellar* velocity dispersion is larger than the MW (see Nordström et al. 2004) at all ages (see Figure 2). We explore the physical processes that set this velocity dispersion at birth and cause it to increase it with time in Loebman et al., in prep. Finally, because we compute self-consistent dust extinction, based on the gas metallicity distribution in the simulations, the extinction map will differ from that of the MW. Thus, we caution those using these simulations for mock MW catalogs to be aware of these differences.

3. COORDINATE SYSTEMS

Within each simulation snapshot, we establish a galactocentric coordinate system and choose a "solar viewpoint;" specifically, a phase-space position for the local standard of rest (LSR) of each synthetic survey. First we determine the "galactocentric" coordinate frame, centered on and aligned with the stars in the galaxy. We represent galactocentric coordinates using lowercase \vec{x} , \vec{v} . Then we assume a phase-space location for the LSR in the simulation, to establish a system of "LSR" coordinates that we represent with capital \vec{X} , \vec{V} notation in Cartesian or cylindrical coordinates or equivalently using angular coordinates ℓ, b for longitude and latitude respectively and D for LSR-centric distance. In the real Milky Way, the Sun has a small positional offset from the exact midplane of the Galactic disk and a small velocity offset relative to the mean motion of young stars on circular orbits in the vicinity of the Sun (how the LSR is usually defined). The resolution of the simulations is not fine enough to distinguish a difference between the LSR and a solar position/velocity, so heliocentric and LSR coordinates are equivalent for the purposes of these mock catalogs. In this section we describe the details of these transformations.

3.1. Galactocentric coordinates

We first determine the center position of each galaxy, using an iterative "shrinking spheres" method, recursively computing the center of mass of star particles in a sphere, reducing the radius by 50% and re-centering on the new center of mass at each iteration. We then measure the center-of-mass velocity of the galaxy using all star particles within 15 kpc of this center. We define this location as $(\vec{x}, \vec{v}) = (\vec{0}, \vec{0})$.

We then rotate the centered simulation into the principal-axis frame of the galactic disk. First we assume that the sun is located at $R_{\odot}=8.2\,\mathrm{kpc}$ (Bland-Hawthorn & Gerhard 2016) in all three simulations (see discussion in §3.2). Then, to define the principal axes, we compute the moment of inertia tensor using young star particles (age < 1 Gyr) inside of

this radius. This establishes the Z direction perpendicular to the plane of the galactic disk. As is the case for standard Galactocentric coordinates, we choose the orientation of the Z axis such that the total angular momentum of the galactic disk points in the -Z direction, so that the simulated galaxy rotates clockwise. If the LSR position is then located on the -X axis, the rotation of the galaxy carries it in the +Y direction, consistent with the standard assumptions used for Galactic coordinate systems.

We choose to define the orientation of the disk plane using young stars rather than gas for two reasons. First, the gas disks in the simulated galaxies can be more misaligned (or warped) than the young stars with the axis defined by all stars. Specifically, we find that the principal axis defined via all stars versus via gas ($\langle R_{\odot} \rangle$) leads to typical differences of 0.5, 1.1, and 1.3 degrees in the orientations of the disks of m12m, m12f, and m12i. This effect is less pronounced in the MW, and we do not wish this misalignment to complicate interpretations of mock surveys of stars. Second, we anticipate that Gaia itself may permit independent measurements of the disk centerline using stars alone, a case that potentially could be tested using our mock surveys. The principal axis defined using only young stars differs far less relative to the gas than using all stars together, less than 0.5 degrees in all three cases. Thus, we use young stars as a compromise between using all stars and gas.

3.2. Local standard of rest

Once the galaxy is centered and aligned, it remains to establish a coordinate system centered on a solar viewpoint and "local standard of rest" (LSR). We first determine a suitable position for the "solar circle" R_{\odot} . We explored whether to scale R_{\odot} differently for each simulation based on disk scale radii, local density, or the local circular velocity, but none of these possibilities showed a strong (or self-consistent) motivation, so we chose to prioritize simplicity and fix R_{\odot} at the consensus value of 8.2 kpc (Bland-Hawthorn & Gerhard 2016). As a result, the azimuthally averaged local density in the "solar neighborhood" varies among the different simulations by roughly a factor of 3, which should be borne in mind when making comparisons with the MW. Table 3 summarizes relevant characteristics of the three simulations at $R_{\odot}=8.2\,\mathrm{kpc}$.

With R_{\odot} fixed, we choose solar viewpoints at three evenly spaced azimuthal angles ϕ_{\odot} around each simulated galaxy, using a prime number of viewpoints to avoid aliasing with features having azimuthal symmetries like bars (m=2) or spiral arms (usually m=2n). We place each viewpoint directly on the disk centerline $(Z_{\odot}=0)$, because the current consensus value of 10 pc for the Sun's height above the disk plane (Bland-Hawthorn & Gerhard 2016) is comparable to the force-softening length for star and gas particles in the

Table 1. Halo-wide properties of our simulations at z=0

| Name | $N_{ m particle}$ | $M_{200\mathrm{m}}~[M_{\odot}]$ | $R_{200\mathrm{m}} \ [\mathrm{kpc}]$ | R_{-2} [kpc] | $M_{*,\mathrm{total}} [M_{\odot}]$ |
|------|-------------------|---------------------------------|--------------------------------------|----------------|------------------------------------|
| m12i | 50,800,000 | 1.2e12 | 336 | 12.3 | 7.3e10 |
| m12f | 74,400,000 | 1.7e12 | 380 | 14.1 | 9.7e10 |
| m12m | 74,500,000 | 1.6e12 | 371 | 10.7 | 1.3e11 |

NOTE— $N_{\rm particle}$: total number of dark matter, gas, and stars particles within $R_{\rm 200m}$. $M_{\rm 200m}$, $R_{\rm 200m}$: mass and radius that enclose 200 times the mean matter density. $R_{\rm -2}$: radius where log-slope of dark matter density profile is -2. $M_{*,total}$: total stellar mass within $R_{\rm 200m}$.

Table 2. Properties of the MW and Simulated Galaxies in This Paper.

| | N_* | M_* | $R_{*,90}$ | $Z_{*,90}$ | $R_{*,e}{}^{b}$ | $M_{\rm gas}$ | SFR |
|------------------------|------------|---------------|------------|------------|-----------------|---------------|-------------------------------|

f The azimuthally averaged gas vertical density profile in m12i is nearly constant to this height, though individual regions show smaller scale heights and dense clouds.

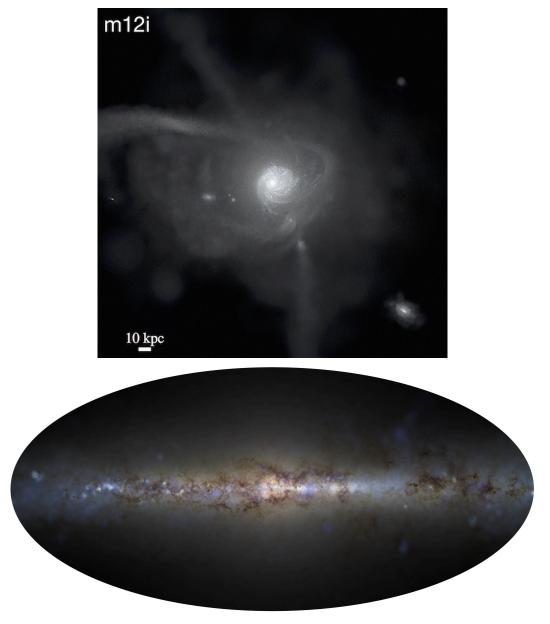

Figure 1. Mock real-color images, computed using stellar SEDs, of m12i at z=0, as an example of our simulation suite. Top: Zoom-out image shows a disk-dominated MW-like galaxy at center, a realistic population of satellite dwarf galaxies, and a diffuse stellar halo, including tidal streams and shells from disrupted satellites. The simulations achieve sufficiently high dynamic range to capture dense star clusters (visible in the central disks and the streams) and satellite dwarf galaxies, all within a live cosmological setting. Bottom: Mock Galactic (Aitoff) projection, including dust extinction, as seen at the solar circle of m12i. Individual, filamentary giant molecular cloud (GMC) complexes and young star clusters are visible, and the galaxy has a thin plus thick disk morphology.

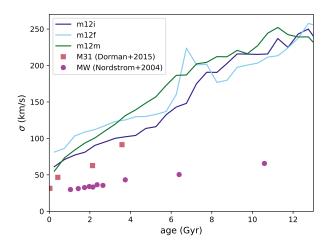

Figure 2. Age-velocity dispersion relation for star particles within |z| < 0.3 kpc, 7.95 < R < 8.45 kpc, $0^{\circ} \le \phi < 360^{\circ}$ for m12i, m12f, m12m (shown in dark blue, light blue, and forest green respectively). Stars in these disks are born hot and are steadily heated with time, similar to M31 (shown in salmon, assuming constant star formation rate, Dorman et al. 2015). The MW relation (shown in magenta, Nordström et al. 2004) is substantially cooler and possibly a kinematic outlier.

simulation. To compute the LSR velocity, we find all star particles within 200 pc of each solar viewpoint. We use 200 pc as a compromise between identifying a sufficiently "local" LSR and having enough star particles to avoid sampling noise. We find that using 200 pc typically leads to ~ 100 star particles. We then compute the median velocity using all star particles within 200 pc of each solar viewpoint, and we use this to define the LSR velocity vector. Ideally we would use only young stars to set the LSR as well as the disk plane; however, we use all star particles to keep the estimate as local as possible given the resolution of the simulation. In practice, the median age of the star particles used to estimate the LSR ranges between 1.7 and 3.6 Gyr, compared to a median age of $\sim\!\!6$ Gyr in the full simulated galaxies, so they are in fact reasonably young.

Table 4 lists the galactocentric phase-space coordinates for each solar viewpoint used to generate a mock catalog. The mock catalogs contain positions in the LSR frame using Cartesian coordinates; to recover the galactocentric Cartesian coordinates use

$$\vec{x} = \vec{X} + \vec{x}_{\odot},\tag{1}$$

$$\vec{v} = \vec{V} + \vec{v}_{\odot}; \tag{2}$$

that is, *add* the appropriate vectors in Table 4 to the positions and velocities in the corresponding mock catalog.

3.3. Elemental abundances

We report the simulation's 11 elemental abundances (H, He, C, N, O, Ne, Mg, Si, S, Ca, Fe) alongside the phase-space data for stars in the mock catalogs. Because the simulations natively track the total mass of each element, which is produced self-consistently during the simulation, we assume Solar values to convert to metallicities of the form $[\Xi/H]$. We use the Solar values from Asplund et al. (2009) to calculate

$$[\Xi/H] \equiv \frac{m_{\Xi}/m_{\Xi,\odot}}{m_H/m_{H,\odot}} \tag{3}$$

for each star particle and each element Ξ , where m_{Ξ} is the mass of a given element associated with the star particle and $m_{\Xi,\odot}$ is its Solar value.

4. MOCK CATALOGS

Cosmological simulations such as ours produce distributions of star *particles*, each of which represents the position, velocity, and properties like age and metallicity for an IMF-averaged ensemble⁷ of stars. On the other hand, observed stellar properties from a survey like *Gaia* are frequently a function of apparent magnitude and stellar type; i.e., the position of a given star on the Hertzsprung-Russell diagram and its LSR-centric distance. In order to create a true synthetic survey, therefore, one must follow an algorithm for creating a so-called "mock catalog" by generating a set of *synthetic stars* from each star particle in the simulation.

In the case of the simulations here, star particles have an initial mass of $7070\,M_\odot$ (and a typical mass of $\approx 5000\,M_\odot$ at z=0). We therefore can treat the properties of each star particle as representing a population of stars, as is done in the simulation itself to follow stellar evolution and calculate feedback and metal enrichment. Specifically, we consider stars in the population represented by one star particle to have a single age and identical abundances, thus described by one model isochrone.

To create a mock catalog, synthetic stars are spawned from each star particle in the simulated galaxy following the resampling algorithm outlined in (Sharma et al. 2011), which we adapt here for our purpose. In brief, we follow these steps:

- 1. Draw stellar masses adding up to the total mass of the star particle by sampling the Kroupa (2001) initial mass function (IMF), consistent with the IMF used in the simulation (§4.1).
- 2. Compute the stellar properties and absolute Gaia G, G_{Bp} , and G_{Rp} magnitudes of each synthetic star by interpolating in initial stellar mass over the isochrone with the closest metallicity and age from a model grid

⁷ Incorporation of stochastic IMF sampling, necessary only at much higher resolution than the simulations here, is ongoing; see Wheeler et al. in prep.

Table 4. Phase-space coordinates of the local standard of rest (LSR), corresponding to each solar viewpoint, for the nine mock catalogs, in the galactocentric reference frame described in $\S 3.1$. Positions are in kpc and velocities in km s⁻¹. We also list velocities in cylindrical coordinates for reference. See $\S 3.2$ for discussion.

($\S4.2$). All stars produced from a given star particle are assigned the same age and elemental abundances as the generating particle, consistent with our interpretation of star particles as tracking single stellar populations. Stars with estimated apparent magnitudes in the *Gaia* range (3 < G < 21, ignoring extinction) are added to the mock catalog.

3. Place each synthetic star in phase space by sampling from a locally varying one-dimensional kernel in each of position and velocity space, centered on the generating star particle. To achieve greater dynamic range in phase-space density, we use a series of different density kernels for stars of different ages (see §4.3).

The resulting mock catalog contains all stars that would fall in the *Gaia* survey if there were no Galactic extinction. Below we describe the specific assumptions used to generate the stellar parameters (using an IMF and model isochrones) and phase-space positions (using a density estimator) of the synthetic stars.

4.1. Initial mass function

We assume that the initial masses m_i of the synthetic stars represented by each star particle are distributed according to the initial mass function (IMF) represented by the continuous PDF

$$p(m_i)dm_i = \mathcal{N} \begin{cases} m_i^{-0.3} & 0.01 < m_i < 0.08 M_{\odot} \\ 0.08 m_i^{-1.3} & 0.08 < m_i < 0.5 M_{\odot} \\ 0.04 m_i^{-2.3} & 0.5 < m_i \end{cases}$$
(4)

as proposed in Kroupa (2001), where ${\cal N}$ is the normalization factor such that

$$\int_{0.01M_{\odot}}^{120M_{\odot}} p(m_i)dm_i = 1.$$
 (5)

In practice, although the IMF is defined over the full range $0.01 < m_i < 120 M_{\odot}$, we draw stars from a subrange of

this IMF. For efficiency, we define the minimum mass m_i^{\min} associated with each star particle individually, by setting the minimum absolute magnitude corresponding to the faint apparent magnitude limit of the survey at the distance of the star particle, allowing for the local size of the kernel used to spread out the synthetic stars.

In the simulation the star particle's mass represents the total mass of stars *currently* part of the associated stellar population, excluding mass lost to winds and stars that have become stellar remnants. This sets an upper limit m_i^{max} on the range of the IMF to be sampled based on the prediction of the isochrone with the appropriate age and metallicity for the most massive star that is still part of the population. In practice we use the closest isochrone in the model grid to set m_i^{max} . This introduces a slight inconsistency in the sense that the isochrones used to create the mock catalogs (from the Padova group, Marigo et al. 2017) are not the same set as were used in the simulation, which uses STARBURST99 v7.0 to track stellar evolution and mass loss via the Geneva evolutionary tracks for high-mass stars (Leitherer et al. 1999, 2014). These two sets of isochrone models take into account different subsets of effects that control the evolution of highmass stars: for example the version of STARBURST99 used in the simulation includes enhanced mass loss from rotation, while the Marigo et al. (2017) isochrones include thermal pulsations from AGB stars. However, the effect of this discrepancy is probably mitigated by our assumption that the mass-loss rate is mass-independent, which we use to compute the total number of stars to sample from each particle. Nevertheless users wishing to do detailed studies of the synthetic evolved stellar populations should keep this limitation

To determine the number of stars to sample from each star particle, we compute the fraction of the IMF within the subrange being sampled,

$$f_{\rm IMF} = \int_{m_i^{\rm min}}^{m_i^{\rm max}} p(m_i) dm_i, \tag{6}$$

and estimate the number of stars associated with the star particle using the median initial stellar mass \mathfrak{m}_i , defined by

$$\frac{1}{2} = \int_{0.01M_{\odot}}^{\mathfrak{m}_i} p(m_i) dm_i. \tag{7}$$

Assuming a mass-loss rate independent of stellar mass, this implies that the *total* number of stars to be sampled over the entire IMF for a star particle with mass m_p is

$$\tilde{N}_{\text{tot}} = \frac{m_p}{\mathbf{m}_i} \tag{8}$$

and the number in the subrange is

$$\tilde{N} = f_{\rm IMF} \frac{m_p}{\mathfrak{m}_i}.$$
 (9)

Because \tilde{N} is not an integer we use stochastic rounding to determine the integer number N of stars to generate by drawing a random number u from a uniform distribution on [0,1) and setting:

$$N = \begin{cases} \lfloor \tilde{N} \rfloor + 1 & \tilde{N} - \lfloor \tilde{N} \rfloor \ge u \\ \lfloor \tilde{N} \rfloor & \text{otherwise} \end{cases}$$
 (10)

Because our particle mass, $m_p \sim 7000 M_{\odot}$, is nearly two orders of magnitude larger than the maximum allowed stellar mass on the IMF (120 M_{\odot}), we consider this approach adequate to represent the high-mass end of the IMF.

The initial mass of each of N synthetic stars belonging to the generating particle is then sampled from the IMF between m_i^{\min} and m_i^{\max} . We use this mass to place the synthetic star on a model isochrone, which determines its magnitude, color, and stellar parameters.

4.2. Isochrones

To describe stellar populations we use the PARSEC model isochrones (release v1.2S and COLIBRI release PR16), as in Marigo et al. (2017) (see also Bressan et al. 2012 and Marigo et al. 2013). We use isochrone tables computed for the *Gaia* DR2 photometric system, including models for O-and C-rich circumstellar dust⁸ from Groenewegen (2006). These were tabulated with CMD 3.0⁹ for a grid of 34 metallicities from Z=0.0001 (1/300th solar) to Z=0.03 (roughly twice solar) and 71 age values evenly spaced from $\log_{10}(\text{age/yr})=6.6$ (3.98 Myr) to $\log_{10}(\text{age/yr})=10.1$ (12.6 Gyr). These isochrone tables extend to a minimum stellar mass of $0.08\,M_{\odot}$; they do not include a model of the instability strip or the white dwarf sequence.

Simulated star particles have abundances that range from the initial floor of [Fe/H] = -4 to a maximum of [Fe/H] =

1.5; only a few percent of these fall outside of the range spanned by the model isochrones (Figure 3, left panel). For these we use the isochrone at the appropriate edge of the model grid. Extremely low [Fe/H] values below the edge of the model grid are likely seriously affected by stochastic noise and the choice of the floor value, so we counsel users to treat synthetic stars at these abundances with caution. High-[Fe/H] outliers mainly occur in the bulge, which is significantly extincted in the synthetic survey; low-[Fe/H] outliers are only a significant contributor in dwarf satellite galaxies, which will have relatively few stars bright enough to enter the survey volume (Figure 3, right panel). Thus we consider this model grid to be sufficiently broad for most users of the synthetic survey.

4.3. Phase-space density

We spread out the synthetic stars in six-dimensional phase space relative to their generating star particle using a kernel $\mathcal{K}(r)$ with the parabolic or Epanechnikov (1969) form

$$\mathcal{K}(r)dr \propto (1-r^2)r^5dr,$$
 (11)

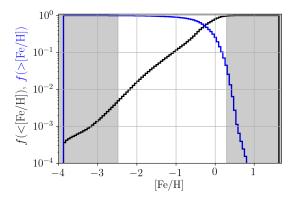

normalized to integrate to 1 over the kernel volume in six dimensions. The kernel radius r is related to the smoothing length in the ith dimension h_i by

$$r = \sqrt{\sum_{i=1}^{6} (\delta y_i / h_i)^2},$$
(12)

where δy is the distance vector in the six dimensional phase space relative to the generating star particle. The phase space is defined in the Cartesian position and velocity dimensions of the LSR frame, (X, Y, Z, V_X, V_Y, V_Z) , and the kernel size is computed in this coordinate system at the point of each star particle using the EnBiD scheme (Steinmetz et al. 2006) such that the local density in position and velocity space varies smoothly from particle to particle (see Sharma et al. 2011, for a full discussion). The scheme computes a locally adaptive metric making use of a binary space partitioning tree scheme, where the partitioning criterion is determined by comparing the Shannon entropy or information along different dimensions. The scheme was further refined in the EnLink code for the purpose of clustering analysis (Sharma & Johnston 2009). We here use the EnLink code (instead of the publicly available EnBiD code) and employ the cubic cell scheme of EnBiD, which means that $h_1 = h_2 = h_3$ and $h_4 = h_5 = h_6$. For the two independent smoothing lengths we use the geometric mean of the smoothing lengths along each of the three dimensions. Relative to a fully multivariate six-dimensional phase-space kernel, this approach allows for faster and less noisy sampling. For this work we use the nearest eight neighboring star particles to compute the kernel size.

 $^{^8}$ Specifically, the ${\tt dpmod60alox40}$ model for O-rich dust and the ${\tt AMCSIC15}$ model for C-rich dust

⁹ stev.oapd.inaf.it/cmd

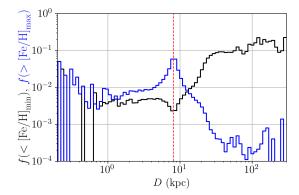

Figure 3. Most star particles in the simulated galaxies have [Fe/H] within the isochrone model grid used to generate the mock catalogs. **Left:** Cumulative (black) and reverse-cumulative (blue) distributions of [Fe/H] for star particles in m12i-0 within 300 kpc of the solar position (established as described in §3). The model isochrone series used to create synthetic stars spans the [Fe/H] range shown in white; simulated star particles in the grey-shaded regions are assigned to the isochrone at the edge of the grid. **Right:** Fraction of star particles falling above (blue) or below (black) the [Fe/H] range of the model isochrones, as a function of distance. The regions containing the most outliers are either in the bulge (red dashed line), which in the final synthetic survey is heavily extincted, or in the distant halo, where few stars will be bright enough to enter the synthetic survey.

In general, an N-body system is composed of various stellar populations each having its own unique phase-space density. If the phase-space density is calculated by treating all the N-body particles as a single population, fine phasespace structures in the distribution that overlap with interlopers from kinematically hotter populations in either position or velocity space will be oversmoothed (for further details see Sharma et al. 2011). To overcome this, in Sharma et al. (2011), while sampling the N-body stellar halo of Bullock & Johnston (2005), each satellite galaxy was treated as a separate population. In our case the phase-space properties change with age. Hence, to mitigate this problem of oversmoothing, we generate separate kernel maps for stars formed in situ (within 30 physical kpc of the main galaxy; see Bonaca et al. 2017 and Sanderson et al. 2017) in the eight age bins corresponding to the populations of the Besançon Milky Way model (Robin et al. 2003), and a separate kernel for all stars formed further than 30 kpc from the main galaxy. Star particles belonging to each of these subsets are resampled to produce synthetic stars using the kernel generated from that subset alone. This strategy allows us to better resolve cold phase-space structures, especially in a few key contexts: young stars in the thin disk, triaxial features like bars in the galactic center, and tidal streams in the halo. Figure 4 illustrates the advantage of this density resampling strategy using m12i. The first three rows show the projected density distribution for each subset of particles used to generate a kernel. The dense, kinematically cold structures in the thin disk and halo are clearly seen, as is a triaxial component in the center of the galaxy. The hotter, older populations, which still change shape slightly with age, can also be faithfully represented. Many of these interesting features would vanish if all particles were considered together (bottom left and cen-

ter panels). Our subdivisions are sufficiently few that each density distribution is well resolved (bottom right panel).

5. SYNTHETIC SURVEY

The mock catalog described in §4 includes perfect information for all the synthetic stars that would be observed by *Gaia* in the absence of galactic extinction. To create a true synthetic survey, we must include models for extinction and observational uncertainties, in order to determine which stars actually fall in the magnitude range accessible to *Gaia*. These stars constitute what we call a "synthetic *Gaia* survey" of one of the simulated galaxies, for a particular solar viewpoint. In this section we summarize the models used to determine extinction and observational error.

5.1. Extinction modeling

The simulated galaxies self-consistently include gas and its metallicity. While the simulations do not include self-consistent dust creation/destruction, we infer the line-of-sight extinction by dust by assuming that dust traces metal-enriched gas.

Previous mock catalogs have imposed the empirical model of the MW itself to provide interpolated extinction and reddening. While this was appropriate for models like Besançon and TRILEGAL, which are intended to reproduce the stellar density and structure of the MW, it is not accurate or self-consistent for simulated galaxies. Indeed, one of the advantages of cosmological simulations featuring detailed models for stellar feedback and ISM physics (as in our FIRE-2 simulations) is the ability to capture features like massive young clusters and spiral arms in the disks of the simulated galaxies; correctly incorporating these features into a synthetic survey requires properly estimating the extinction from the gas

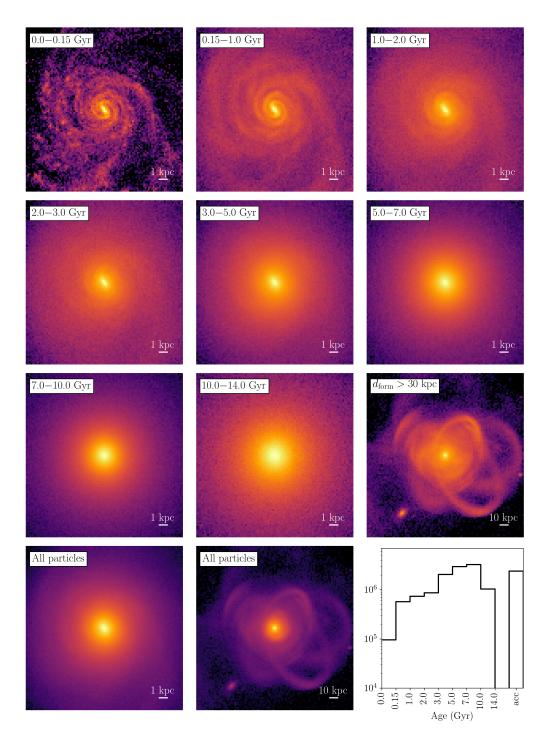

Figure 4. Different star particle subsets used to construct density kernels for resampling the phase-space distribution of m12i. The top three rows show the projected density in the different age bins of in situ stars (those formed within 30 kpc of the main halo) and accreted stars (formed beyond 30 kpc from the main halo). Each panel's color range is independently adjusted to show the full range of projected densities in the subset. Substructure apparent in many of the subsets is mostly washed out if all the particles are considered together (bottom row, left and center panels). Each bin in the top three rows still contains at least 10^5 particles, and usually more than 10^6 , to sample the phase-space density (bottom right panel).

and dust that are (physically) highly correlated with them. Likewise it is well known that dust is specifically correlated with locations of star formation and massive young stars, both locally (in GMC-scale environments) and globally (in the scale-lengths and heights of the cold gas, dust, and star-forming disks). Artificially imposing the MW extinction map on stellar populations and star-forming structures that are not in the same locations as the MW can introduce a large number of un-physical features and potentially serious biases. We therefore base our extinction model on the *same* gas/dust distribution that the simulations calculate and use to determine where stars form.

We compute the integrated column density of hydrogen, weighted by its total metallicity (from all species that we track),

$$N_H^{\text{eff}} = \int_0^{r_*} (n_{\text{H1,gas}} + 2 \, n_{\text{H2,gas}}) \, \left(\frac{Z_{\text{gas}}}{Z_{\odot}}\right) d\ell,$$
 (13)

along the line of sight ℓ from the solar position adopted for the mock catalog (defined as the origin using the transformations discussed in §3) to the location of the star particle, r_* . Here $n_{\rm H1,gas}+2\,n_{\rm H2,gas}$ is the total (atomic+molecular) number density of neutral hydrogen atoms in the gas, calculated self-consistently in-code, weighted by $Z_{\rm gas}/Z_{\odot}$, the ratio of the local total metal mass to solar. We assume a constant dust-to-metals ratio in the neutral gas, rather than a constant dust-to-gas ratio, to account for variations in the gas metallicity along the line of sight. We compute this integration for all star particles within 500 kpc of the galactic center (as defined in §3.1).

Using this densely sampled, three-dimensional map of the column density, we calculate the column density to each synthetic star either by direct assignment (if the synthetic star is located at the exact position of its generating particle) or by linear interpolation with its closest neighbors in a three-dimensional Delaunay triangulation (Barber et al. 1996; Jones et al. 2001). We then calculate the corresponding B-V reddening according to

$$\frac{N_H^{\text{eff}}}{E(B-V)} \equiv Q_{\text{dust}} \sim 2.5 \times 10^{22} \,\text{H cm}^{-2} \,\text{mag}^{-1}. \quad (14)$$

We intentionally choose a conservatively high value of $Q_{\rm dust}$, such that it produces a *smaller* amount of reddening than median observational estimates in the MW (but within the range of systematic uncertainties and line-of-sight variance; see Watson 2011; Gudennavar et al. 2012; Willingale et al. 2013; Nguyen et al. 2018, who find $Q_{\rm dust} \sim 0.3-5\times 10^{22}$ in these units). We err on the side of under-estimating the reddening and extinction for three reasons. First, this includes *more* stars in the synthetic survey, allowing users to increase the extinction or vary the input extinction curve, if desired, while maintaining completeness

of the catalog. Second, some authors have argued this value better represents many nearby MW-mass galaxies, to which our galaxies may be better proxies (see Kahre et al. 2018). Third, this choice produces a distribution of E(B-V) versus latitude in the simulations that better match the MW (Drimmel et al. 2003), likely because our simulated galaxies are more gas-rich (with higher column density) than the MW.

We use the standard law

$$A_0 = 3.1E(B - V) (15)$$

to calculate the extinction. This relation is consistent with the assumption used in Gaia Collaboration et al. (2018b), which gives the formulae for transformations from the global extinction to extinction in the Gaia DR2 passbands that we then use to calculate A_G , $A_{G_{BP}}$, and $A_{G_{RP}}$. We use these extinctions to calculate the observed (extincted) magnitudes and reddened colors of synthetic stars, to determine which stars fall in the Gaia apparent magnitude range.

5.2. Error modeling and selection function

The final step in producing a synthetic survey is to simulate the observational uncertainties using an error model. Gaia errors have spatially complex structure because of the scanning law that determines the number of times each star transits its two telescopes, compounded by further choices in filtering these transits to determine the subset used to produce the final measurements. Additional complexity arises in crowded fields from, for example, deciding which stars participate in the full five-parameter astrometric solution. Therefore, the Gaia error model continues to evolve from its pre-launch characterization, but no updated error model for DR2 is yet available. For our first release, we therefore choose simplicity in representing the observational uncertainties and selection function, while also reporting the underlying or "true" values of the observables for each star, so users can apply more sophisticated models of the *Gaia* errors to the synthetic survey as needed. We hope to do the same in a future mock catalog release.

5.2.1. Selection function

We include stars in the synthetic survey whose error-convolved, extincted apparent $Gaia\ G$ magnitude is in the range 3 < G < 21. The error model thus influences which stars end up in the final catalog in a limited way, especially given that the estimated photometric uncertainty at G=21 for DR2 is approximately 10 mmag. This range is consistent at the faint end with the magnitude at which completeness drops below 90% in DR1, and with the faint limit for stars that are consistently included in the five-parameter astrometric solution in DR2. We strongly discourage any overinterpretation of comparisons at the faint end of the synthetic surveys. At the bright end there are few stars in the synthetic

surveys; we urge users of the mock catalogs in this regime to keep in mind the caution of the *Gaia* team that the completeness is likely quite uneven for bright stars in the real *Gaia* survey.

Gaia measures radial velocities for a subset of bright stars. In DR2, and in our synthetic surveys, RVs are reported for stars with $G_{RVS} < 14$ and estimated effective temperatures in the range $3550 < T_{\rm eff} < 6900~{\rm K}.$

The true *Gaia* selection function is far more complex than this. We chose to use a simple selection (magnitude and, for RV data, temperature cuts alone) to avoid interference with more detailed selection function models, which are currently a work in progress; as they become available, we will apply to our synthetic surveys. We encourage users of the synthetic surveys to consider how their applications may be affected by the Gaia selection function, and to apply the appropriate level of modeling for their science case.

5.2.2. Error model

The true error model for *Gaia* DR2 is a complex function of sky position, magnitude, color, and temperature that involves the spacecraft scanning law and a full characterization of the reduction processes for the different astrometric, photometric, and spectroscopic measurements contributing to the final catalog. Preliminary versions of simplified models for the uncertainties have been provided in the public software package pygaia¹⁰, but as this package has not been updated since DR2, the error prescriptions in this package differ significantly in some cases from the behavior noted in the DR2 release paper (Gaia Collaboration et al. 2018a). We anticipate, moreover, that improved characterizations of the DR2 error model, as well as those for subsequent data releases, will become available in the future, and we wish to encourage the application of these to the mock catalogs.

Instead, we provide with this release a single draw from an error model described by a simple set of functions calibrated to the characterizations in Gaia Collaboration et al. (2018a). In all cases we model the uncertainties as solely dependent on apparent G magnitude using an exponential form,

$$\sigma_i = a_i + b_i \exp(G/c_i), \tag{16}$$

fit to the estimates given in the paper. The coefficients used for the uncertainties on different quantities are listed in Table 5. For the radial velocities we add a systematic noise floor of $0.11~\rm km~s^{-1}$ as described in the documentation for the *Gaia* DR2 data model. ¹¹

For convenience, we provide both the underlying values and one set of "error-convolved" values (random draws from one-dimensional Gaussian distributions centered on the underlying values) for *Gaia* observables as well as error estimates using our simple model. We caution that, given the simplistic nature of our error model, the error-convolved values should not be used for detailed explorations of, for example, the *Gaia* selection function, or analysis near the magnitude limit of the survey. The error-convolved values are intended for convenience, to understand broadly how the magnitude-dependence of the observational errors affects results in an order-of-magnitude sense.

5.3. Changing the synthetic surveys

Users can alter the synthetic surveys as more knowledge about any of its components (the extinction model, the error model, or the selection function) is gained. The most complex task is to alter the extinction model, which implicitly requires reapplication of the other two components. In this section we outline how users can reprocess a synthetic survey under new assumptions.

Changing the extinction model will alter the apparent magnitudes and colors of the stars in the synthetic survey, requiring reapplication of the error model and selection function. To allow for changing the extinction model, we also provide the intermediate quantities $N_H^{\rm eff}$, E(B-V), and A_0 used to compute the extincted magnitudes of each synthetic star, as well as their intrinsic magnitudes $G^{\rm int}$, $G^{\rm Bp}_{\rm int}$, $G^{\rm Rp}_{\rm int}$ and the associated colors $G^{\rm Bp}_{\rm int}-G^{\rm Rp}_{\rm int}$, $G^{\rm Bp}_{\rm int}-G^{\rm int}$, and $G^{\rm int}-G^{\rm Rp}_{\rm int}$. Applying a new extinction model to the survey thus comprises the following four steps:

- 1. Use the new extinction model to recompute E(B-V) and A_0 from $N_H^{\rm eff}$. Refer to Gaia Collaboration et al. (2018b) to convert these to extinctions A_G , $A_{G_{BP}}$, and $A_{G_{RP}}$ in the Gaia passbands.
- 2. Recompute new extincted apparent magnitudes from the intrinsic magnitudes provided by applying the new extinctions in each passband, for example:

$$G^{\text{ext}} = G^{\text{int}} + A_G \tag{17}$$

If desired, also update the reddened colors.

- 3. Apply an error model (either the one in §5.2.2 or whatever is desired) to recompute the new observational uncertainties on all observed quantities, since all depend on apparent magnitude. Re-sample from the unconvolved observed quantities using the new uncertainties for at least the apparent *G* magnitudes, and for any other error-convolved quantities desired.
- 4. Apply a selection function (either the one in §5.2.1 or whatever is desired) to the *error-convolved* apparent G magnitudes to determine which stars now fall in the reprocessed synthetic survey.

Table 5. Coefficients of the simplistic Gaia DR2 error model used for the synthetic surveys.

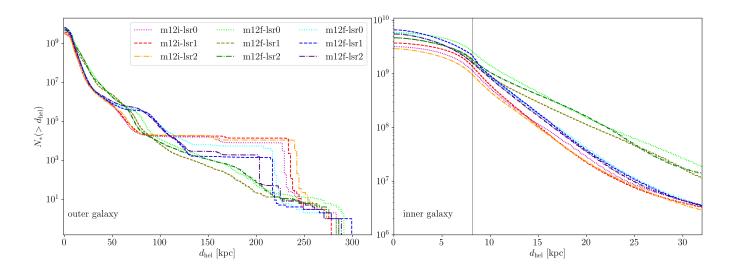

Figure 5. The true distribution of stars in the synthetic surveys shows broad variety in both the inner and outer galaxy. **Left**: a view of the full extent of the synthetic surveys shows that they include at least a handful of stars at the edge of the simulated galaxy, and show significant variation because of accreted substructure. Steep drop-offs in the cumulative histogram correspond to bound satellite galaxies. **Right**: A view of the inner galaxy shows the variation in local solar densities, bulge contribution, and extent of stars beyond the solar neighborhood. m12f has a fairly large tidal stream at 15-25 kpc that contributes to the enhancement at these distances, relative to the other two simulations (see Figure 3 of Sanderson et al. 2017).

The ability to vary the extinction model *post facto* will be limited by the fact that only stars whose extincted magnitudes *in our dust model* are bright enough for *Gaia* are included in the survey. Thus, extinction models that predict significantly *less* extinction than our adopted default will require re-running on the *un-extincted* mock catalogs, rather than on the synthetic surveys. Since the un-extincted mocks contain 2–4 times as many stars as the extincted synthetic surveys, and we anticipate that most users will want to increase the extinction from our baseline and therefore will not need them, we have not made the un-extincted mocks available for public download but are happy to provide them on request.

Changing the error model or selection function requires only a subset of the steps enumerated here. If varying only the error model is desired, start from step 3 in the above list. To change the selection function, simply follow step 4.

To arrive at the nine synthetic *Gaia* surveys in this data release, we generated a total of 125 billion synthetic stars in the mock catalogs, of which around 43 billion made it into the synthetic surveys after applying the extinction model and magnitude selection. Table 6 summarizes the data release, which was split up into ten LSR-centric distance bins per survey for portability. Because we ignore the effect of crowding and use a conservatively low value for the extinction, and because our simulated galaxies range in total stellar mass up to twice that of the MW, the synthetic surveys all have a larger total number of stars than the real *Gaia* DR2.

Figure 5 shows a cumulative histogram of the stars in each synthetic survey as a function of their true LSR-centric distance, to illustrate how both the synthetic and real *Gaia* surveys reach far beyond the local solar neighborhood. The wide variation in the contents of the synthetic surveys, especially in the outer reaches, underlines the importance of the fully cosmological context of our simulations. In this section we give an overview of the contents of the synthetic surveys.

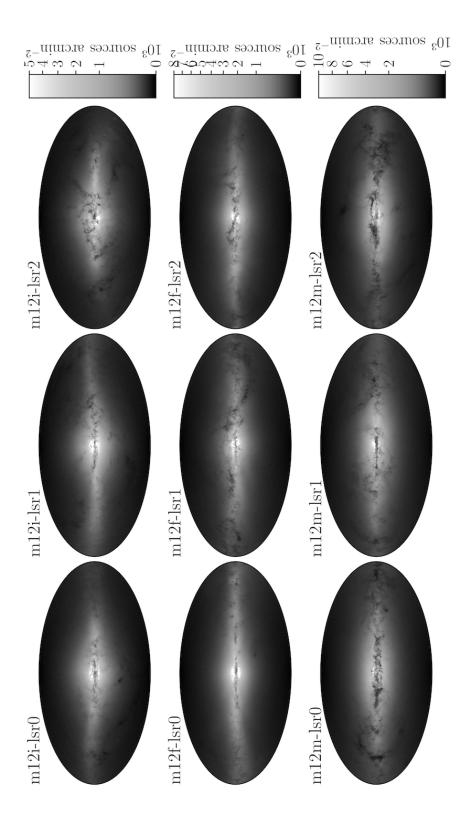

Figure 6. All-sky star count maps of synthetic *Gaia*-like surveys (compare to Figure 3 of Gaia Collaboration et al. 2018a) display a wide variety of features, even for different viewpoints in the same galaxy. The labeling refers to the simulation and the solar viewpoint chosen; see Tables 4 and 6.

6.1. Multidimensional views of simulated galaxies

One can compare our synthetic surveys directly with *Gaia* DR2. Detailed comparisons of specific properties of the simulated versus MW populations are beyond the scope of this work; we discuss some aspects of a few such studies in progress in §8 but defer further comparison to future work. Instead we present a few views, generated from one of our synthetic surveys, that visually can be compared with some of the key first results from *Gaia* DR2.

As for the real data, we generate the star-count maps shown in Figure 6 (comparable to Figure 3 of Gaia Collaboration et al. 2018a). The extinction distribution, which is prominent in our simulated maps as well as in the real *Gaia* data, varies substantially even for different viewpoints within the same simulation. Some (like m12f-lsr0 and m12m-lsr1) show a thin plane of dense extinction like the real MW, while in others (like m12i-lsr2 and m12f-lsr1) the line-of-sight extinction has little or no identifiable thin structure and extends far out of the disk plane. When interpreting these views, it is important to keep in mind our assumption of a constant dust-to-metals ratio in computing the extinction (§5.1), and the generally higher gas masses of the simulated galaxies relative to the MW (Table 2).

Another notable difference between the simulated surveys and the MW is the absence of the Magellanic Clouds; none of the simulated galaxies have companions as large and close by. The galactic disk displays warps or truncations near anticenter in some cases (m12i-1sr1, m12f-1sr0), providing some interesting test cases for those interested in searching for such features in the MW. The bulge is fairly prominent in many cases behind the extinction, which serves as an important reminder that our synthetic surveys do not attempt to model crowding.

The variation in the synthetic surveys is also on display in Figure 7, which shows RGB flux maps for one viewpoint from each of the three simulated galaxies (comparable to Figure 4 of Gaia Collaboration et al. 2018a). Even the dominant colors of the different simulated galaxies vary substantially. Clusters of bright blue young stars are apparent in this view, highlighting the ability of our simulation code to resolve individual regions of star formation as well as the importance of a self-consistent extinction calculation.

To illustrate the multi-dimensionality of the synthetic surveys, we show a set of three Hertzsprung-Russell diagrams (HRDs) of m12m-1sr0 for different ranges of the transverse velocity V_T , expressed in terms of the proper motions $\mu_{\alpha*}$ and μ_{δ} and the parallax ϖ as

$$V_T \equiv \frac{1}{\pi} \sqrt{\mu_{\alpha*} + \mu_{\delta}}.$$
 (18)

This strategy was adopted to create Figure 21 of Gaia Collaboration et al. (2018b) from the *Gaia* DR2 data. As in that

paper, we select for this plot only stars with estimated parallax error better than 10 percent, estimated G magnitude error less than 0.22, estimated G_{BP} and G_{RP} errors less than 0.054, and extinction $A_G < 0.015$. Selecting only stars with these accurate measurements means that some traces of the isochrone grid are still visible in the bright end of the HRDs where the grid is sparsest, but these blur out quickly if the data quality selections are loosened. Figure 8 is qualitatively similar to what is seen in DR2 with the exception of the white dwarf sequence, which we do not simulate. Several separate main sequences can be identified in the stars moving with the LSR (left-hand panel), including one sequence that dominates for stars with larger V_T (center panel). At highest V_T (right-hand panel) the main sequence, the turnoff, and the red clump are significantly broader compared to the other panels, reflecting the heterogeneous mixture of stars at these veloci-

As a second illustration of the power of synthetic phasespace surveys, we also present two views of the Toomre diagram of the LSR volume (stars within 3 kpc) for m12i-lsr0 (Figure 9). In the right-hand panel is the standard view of the density distribution in the plane $(V_{\phi}, \sqrt{V_R^2 + V_z^2})$, where clustering and structure are apparent in both the stars moving with the LSR and in the diffuse, kinematically hot component. This illustrates the ability of our density sampling strategy to reproduce structures in velocity space at different scales and locations. We chose to show this example particularly because it includes examples of streams passing through the local volume on both highly retrograde and highly prograde orbits. The lefthand panel illustrates how adding abundance information gives clues to the identities of some of these features: the clusters near $V_{\phi} \sim 0$ belong to the local high-[Fe/H] disk, while the clumps near (-350, 100) and (+350, 200) km s⁻¹ have a lower [Fe/H] than even the rest of the hot component centered on the galactic center, supporting the idea that they are tidal streams intersecting the local volume.

Figure 10 illustrates the importance of a self-consistent extinction model for synthesizing surveys from cosmological baryonic simulations. Comparing the density distribution for young stars (top) to the extinction computed either self-consistently (middle) or by applying the Drimmel et al. (2003) MW dust map (bottom), it is clear that a self-consistent calculation of the extinction is required to properly represent star-forming regions and young star clusters in the simulated galaxy. When the total survey is depicted (as in Figure 6, lower left-hand panel) the disk extinction appears relatively thin and well organized, similar to the MW's, but it is apparent that the distance distribution in the near field is quite different, further supporting the use of a self-consistent model. The difference in scale heights between the MW's dust distribution and the simulated galaxy's is yet another

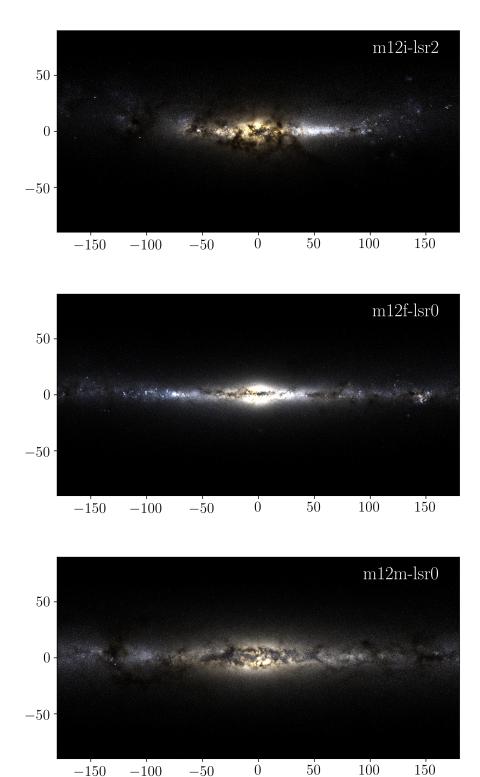

Figure 7. RGB flux maps of three of the synthetic surveys, m12i-lsr2 (top), m12f-lsr0 (middle), and m12m-lsr0 (bottom), highlight the differences in apparent color of different simulated galaxies. Total flux in the G_{Rp} band was assigned to the R channel, in the G band to the G channel, and in the G_{Rp} band to the G channel. The images were median-filtered using the 6 neighboring pixels to diminish the effect of "hot" pixels caused by individual nearby stars. Axes show galactic coordinates in degrees.

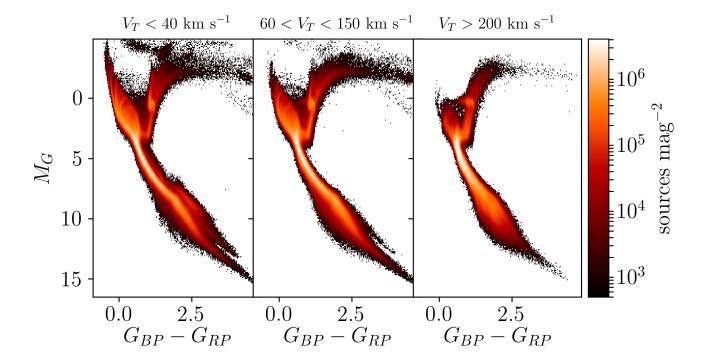

Figure 8. The HertzsprungRussell diagram as a function of tangential velocity for stars in the synthetic survey m12f-lsr0 shown in Figure 6, with quality selections as discussed in the text (compare Figure 21 of Gaia Collaboration et al. 2018b), showcases the variety in stellar populations of the "solar neighborhood" in the synthetic surveys. For this subsample of synthetic stars with negligible extinction and high-quality proper motions and distances, some echoes of the underlying grid of isochrones are still visible at the brightest magnitudes, where the model grid is sparsest. In less pristine subsamples these artifacts will not be apparent.

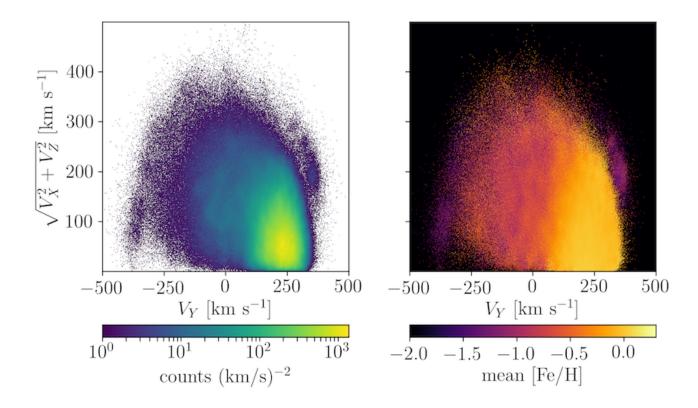

Figure 9. Toomre diagram of m12i-1sr0 in LSR coordinates (see §3.2) show the ability of the synthetic surveys to capture fine structure in a wide range of conditions. **Left**: density of stars within 3 kpc of the LSR position that satisfy the quality cuts used in Figure 8 and have measured radial velocities. **Right**: the same stars colored by mean [Fe/H] per pixel. Our high-fidelity sampling strategy has reproduced the small-scale clumpiness at high density near the LSR around (235,0) km s⁻¹ and also captures stream-like structures at lower densities passing through the local "solar volume" near (-350,100) and (+350, 200) km s⁻¹. Viewed in abundance space (right), [Fe/H] varies with kinematic position as expected: stars moving with the LSR have solar-like [Fe/H] while the stream-like structures have lower [Fe/H] than even the smooth hot component.

reason that a self-consistent extinction model is necessary; as shown in Figure 6, some viewpoints have gas that extends (and extincts) far above and below the galactic plane or has a substantially different scale height (compare for example m12i-lsr2 and m12f-lsr0, or even the different viewpoints of m12m).

6.2. Data access

As of this writing, the nine mock catalogs described in this work are available through the data service ythub, at the website http://ananke.hub.yt. This service includes the ability to remotely analyze the mock catalogs through a browser-based Jupyter notebook interface, eliminating the need to download the data to a local machine. In the near future they will also be available through the NASA/IPAC Infrared Science Archive, at https://irsa.ipac.caltech.edu/Missions/ananke.html, where they can be searched and explored alongside Gaia DR2. We anticipate that this resource will expand to new simulations and new mock catalogs in future and, given the size

of the datasets, may move to a different dedicated site. An up-to-date list of data access points will be maintained at http://fire.northwestern.edu/ananke.

In addition to the nine mock catalogs, we also provide alongside these the corresponding "raw" simulation snapshots of our three MW-mass systems at z=0, including all dark matter, gas, and star particles. As of this writing, we are releasing only each simulation's snapshot at z=0, though in the future we plan to release higher-redshift snapshots as well.

6.3. Contents and data model of the synthetic surveys

In this section we describe in detail each of the fields in the synthetic surveys. We use the same names and units for quantities that are in the real DR2 catalog where this was suitable, and attempt to use a relatively consistent naming convention for other fields where possible. As discussed in §5, we report the intrinsic and error-convolved values for observables delivered by *Gaia*: for a quantity Q, the field Q contains the error-convolved quantity, the field Q-true contains the un-

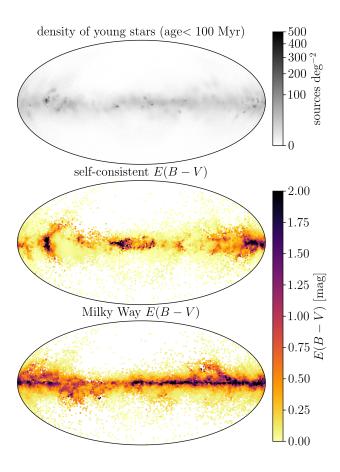

Figure 10. A self-consistent extinction model is crucial to generating a synthetic survey from a cosmological baryonic simulation. This example uses the synthetic survey m12m-0 (see Table 4) within 3 kpc of the LSR ("solar") position. Top: density (in square-root scaling) of synthetic stars with ages younger than 100 Myr. **Middle:** E(B-V) reddening (linear scale from 0 to 2), computed self-consistently from the simulation as described in §5.1, for a subset of the stars depicted in the top panel. **Bottom:** E(B-V)reddening (linear scale from 0 to 2) computed from the Drimmel et al. (2003) three-dimensional extinction map of the Milky Way. In the bottom two panels, stars at *larger* distances, with higher reddening, are plotted on top to emphasize the regions with the most dust. It is apparent from comparing the three panels that both proper correlations between young star clusters and regions of high extinction, and a correct global structure in the disk plane, require a selfconsistent calculation of the extinction.

derlying intrinsic value and Q_error contains the estimated error, such that Q is a single random sample from a Gaussian centered at Q_true with standard deviation Q_error.

The surveys each consist of a set of ten data files containing the synthetic stars for different ranges in distance. The distance ranges and the number of synthetic stars per file for each of the nine synthetic surveys are given in Table 6. The data model is summarized in Table 7, found at the end of this

Table 6. Contents of the ananke synthetic surveys of the Latte MW-mass suite of FIRE simulations.

NOTE—"Index" is the file number containing information for synthetic stars in the distance range $d_{\min}-d_{\max}$. N_* is the number of synthetic stars in each distance range. Table 4 gives the solar viewpoint locations for the different surveys.

paper, in which quantities with names identical to *Gaia* DR2 are listed first, followed by supplemental information.

6.3.1. Indices

We provide a number of different integers for identifying synthetic stars and associating them with their generating star particle in the simulation snapshots.

source_id is a unique integer for each synthetic star in a given synthetic survey (IDs may be reused in different surveys but do not indicate an association).

random_index can be used to select a random subset of synthetic stars within the distance range of one data file. To select a random subset of N stars from one file, sort by random_index and select the first N. To generate a random subset from an entire survey broken up over separate files, one should choose n_i stars from each of the data files comprising the survey, where $\sum n_i = N$ and the individual n_i are chosen by Poisson distribution based on the number of stars per file (given in Table 6).

parentid is the array index of the star particle from which a given synthetic star was spawned. Synthetic stars with the same parentid came from the same star particle, and the index can be used to locate the full properties of the star particle in the z=0 snapshot. It is also useful to get a sense of the local scale of the smoothed kernel used to distribute synthetic stars in phase space, by plotting all synthetic stars with a common parentid in a region of interest. Note that star particles in the FIRE simulations have an ID associated with them; however, our pipeline never uses this ID (because it is not always unique across star particles). Thus, we emphasize that parentid refers to array index of the star particle within the simulation snapshot file(s).

partid indicates whether a synthetic star is located at the exact phase-space coordinates of its generating star particle. The first synthetic star to be spawned (partid=0) is always assigned the coordinates of the generating particle, but this star may or may not fall in the survey volume, even if others drawn from the local phase-space kernel around the same generating particle (partid=1) do. This often provides a quick way to access some information about the generating star particle without loading the complete snapshot.

6.3.2. Phase space

The heart of the real and mock *Gaia* surveys is the position and velocity information for each star in the survey. We start with Cartesian positions and velocities in the LSR frame, and use the transformations provided by the astropy package (The Astropy Collaboration et al. 2018) to calculate positions and proper motions on the celestial sphere (right ascension and declination) and in Galactic latitude and longitude. In order to transform to Galactic coordinates, we rotate each system by the angle

$$\phi = \pi + \arctan\left(\frac{y_{\rm LSR}}{x_{\rm LSR}}\right) \tag{19}$$

about the Z axis, to follow the standard convention that the line from the LSR position to the Galactic center points in

the positive \hat{x} direction (the "sun" is on the -X axis), and that the solar rotation is in the $+\hat{y}$ direction. We use the rotated stellar positions to compute ℓ , b, and their associated proper motions. From these we then make the transformation to celestial-sphere coordinates. Given these assumptions, Table 7 provides the types of phase-space coordinates listed below.

px_true, py_true, pz_true are the intrinsic or "true" Cartesian position of the synthetic star relative to the LSR, placing the Sun at x=-8.2 kpc. To get back to the galactocentric principal-axis frame described in $\S 3$, first rotate the positions and velocities in the x-y plane by the angle ϕ based on the values in Table 4, then use Equations 1-2 to translate back to the galactocentric frame.

vx_true, vy_true, vz_true are the true Cartesian velocity of the synthetic star relative to the LSR, related to the galactocentric principal-axis frame in the same way as the positions.

dhel_true, dmod_true are the LSR-centric distance and distance modulus of the synthetic star, related by

$$d\text{mod}_{\text{true}} = 5\log_{10}(d_{\text{hel,true}}) - 5. \tag{20}$$

parallax_true, parallax are the true and errorconvolved parallaxes of the synthetic star, with the associated estimated error parallax_error from the model described in §5 and Table 5. The parallax is related to the LSR-centric distance via

$$\frac{\text{parallax}_{\text{true}}}{\text{mas}} = \frac{1.0 \text{kpc}}{d_{\text{hel,true}}}.$$
 (21)

ra_true, ra; dec_true, dec are the true and errorconvolved positions of the synthetic star on the celestial sphere, with their associated estimated errors
ra_error and dec_error. The true RA and dec are
calculated from the true Galactic latitude and longitude
(themselves a product of the LSR-centric Cartesian coordinates) before error convolution.

pmra_true, pmra; pmdec_true, pmdec are the true and error-convolved proper motions of the synthetic star in the RA and declination directions, with their associated estimated errors pmra_error and pmdec_error. The RA proper motion includes the standard factor cos(dec).

radial_velocity_true, radial_velocity are
the true and error-convolved radial velocities (with
estimated error radial_velocity_error). Gaia
measures radial velocities for stars down to a brighter

limiting magnitude than the astrometric survey. We report radial_velocity_true for all stars, but proonly for stars satisfying the magnitude and temperature limits cited by Gaia DR2, as discussed in §5.

1_true, 1; b_true, b are the Galactic longitude and latitude of the synthetic star. The "true" values are transformed from the true Cartesian positions while the error-convolved values are transformed from the errorconvolved RA and dec.

6.3.3. Photometry

We provide three types of photometric quantities in the synthetic surveys:

- intrinsic magnitudes and colors (suffix _int), which do not include any extinction or reddening and are not errorconvolved;
- true magnitudes and colors (suffix _true), which have an extinction model applied to each band (hence the magnitudes are extincted and colors are reddened) but have not been error-convolved;
- observed magnitudes and colors (no suffix), which have been extincted and then error-convolved according to the error estimated from the true extincted magnitudes. The _error used to generate each observed magnitude is also provided.

We also provide a series of other quantities related to the extinction calculation, which can be used to change the extinction model if desired.

- lognh is the effective metal-weighted column density of hydrogen along the line of sight between the synthetic star and the solar position, as defined in $\S 5.1$.
- ${ t ebv}$ is the reddening given $N_H^{ t eff}$ above, related by the dust efficiency coefficient as discussed in §5.1.
- A0 is the extinction at 550 nm, related to the reddening above via the standard dust model $A_0 = 3.1E(B - V)$.
- a_g_val, a_bp_val, a_rp_val are the line-of-sight extinctions in the Gaia G, G_{BP} , and G_{RP} bands, calculated from the extinction at 550 nm (A_0) using the polynomial models in , as described in §5.1.
- e_bp_min_rp_val is the reddening between the two Gaia spectrophotometric bands, $E(G_{BP} - G_{RP})$, equivalent to a_bp_val-a_rp_val.

6.3.4. Stellar parameters

We provide unconvolved values of stellar parameters for vide radial_velocity and radial_velocity_error the synthetic stars in our catalog, interpolated from the isochrone models described in 4.2. Gaia DR2 reports values without 1D uncertainties for some of these quantities, because the error model is fairly complex; the derivation of these parameters is expected to improve substantially in subsequent data releases. We therefore do not attempt to simulate any observational errors on these values.

> teff_val is the effective temperature as given by the isochrone model.

lum_val is the stellar total luminosity.

logg is the log surface gravity in cm s^{-2} .

- mact is the present-day stellar mass of the synthetic star, accounting for stellar evolution.
- mini was the mass of the synthetic star on the zero-age main sequence.
- age is the log of the stellar age in Gyr, passed directly from the generating star particle and used to select the stellar isochrone to represent the single stellar population. All stars spawned from the same generating particle have the same age.
- mtip is the mass of a star with the same age and metallicity at the tip of the giant branch. Evolved stars can be simply selected using the criterion mact>mtip. All stars spawned from the same generating particle share this value.

6.3.5. Abundances

FIRE simulations track 11 elemental abundances (H, He, C, N, O, Ne, Mg, Si, S, Ca, Fe) through the stellar yield table network and subgrid turbulent metal diffusion models described in §2.1. We pass these elemental abundances directly to each synthetic star from its generating star particle, consistent with our assumption of single-aged, single-abundance stellar population. Thus all stars sharing the same generating particle will have the same abundances. All abundances are reported compared to hydrogen and relative to the solar abundance (for which we take the values reported in Asplund et al. 2009, self-consistent with the values assumed to map to the model isochrones). We also provide for convenience the quantity alpha, which is the ratio of magnesium to iron abundance relative to solar. The full list of abundances is provided in Table 7.

7. USING THE SYNTHETIC SURVEYS

Below are a few points to keep in mind when starting out using the synthetic surveys.

- Scripts that run on Gaia DR2 data should work without much tweaking on the synthetic surveys, because fields common to the synthetic and real surveys have identical names. There are two main exceptions:
 - In the synthetic surveys ra_error and dec_error are in degrees (consistent with the units of ra and dec), not milliarcsec (as in DR2).
 - Some data quality flags are not present in the mock data, because there was no way to model them; columns in both the mock and real data are listed first in Table 7.
- Depending on the science case, not all ten files associated with each synthetic survey may be needed, so keep the distance bins (Table 6) in mind. For example, all stars with complete 6-D positions and good parallaxes (sufficient for using distance=1/parallax) are in slices 0 and 1 of each synthetic survey.
- As discussed in §5.1, the extinction model for the synthetic surveys is deliberately conservative, using a value for the dust efficiency that is on the low end of the range estimated for the MW. As a result the mocks all contain more stars than the real DR2 even when the local stellar density is comparable. If users want to assume a stronger extinction model, the parameter Q_{dust} in Equation 14 can be increased; a prescription for how to reprocess the survey with a different Q_{dust} is given in §5.3. Likewise if an analysis assumes the MW extinction map, this assumption is inconsistent with the dust extinction in the synthetic surveys, which is computed self-consistently from the simulation.
- If an analysis is particularly sensitive to the details of the DR2 selection function, this should be applied to the mock data before using them. There are several options available publicly depending on the science case.
- There are two ways to access information about the star particle that generated a particular synthetic star in a survey:
 - The column parentid contains the *index* of the generating star particle; to access it in the corresponding simulation snapshot, read in the entire snapshot and then use this value to index into the arrays. For example, if the snapshot is read into the object part, then the star particle's position is part['star']['position'][parentid]. (Note that star particles in the simulation snapshot have an ID parameter, but we do not use this in creating the synthetic catalogs, so users should ignore it.)

- The column partid has the value 0 for synthetic stars that have the exact position and velocity of their generating particle, so this information can be accessed without loading the simulation snapshot by selecting a star with the same parentid as the one of interest and partid equal to 0. Properties like the chemical abundances and ages of synthetic stars are carried over identically from the generating particle as well; these properties are noted in Table 7.
- Finally: remember that our FIRE cosmological simulations are not the Milky Way: if an analysis is tailored to the MWs structure too specifically, it is likely to fail on the synthetic surveys. Either use the snapshots and visualizations bundled with the synthetic surveys to select the ones that best match the assumptions of the analysis method, or relax the assumptions. Conversely, these synthetic surveys provide a framework for testing whether a given inference on the observed MW is robust to effects (and their uncertainties) such as detailed morphology, structure, and dynamical state.

8. FUTURE WORK

We anticipate that we and other members of the community will make detailed comparisons between these simulations and *Gaia* for many different science cases, including the evolutionary structure of the disk and the phase-space structure of accreted stars. We plan to explore further, for example, the reason for the differences in the age-velocity dispersion relation observed in Figure 2. We also plan to validate statistical methods for modeling the Galactic mass distribution (e.g., Sanderson et al. 2015) using these catalogs to realistically represent both the expected observational uncertainties and a fully cosmological galaxy.

Currently, the FIRE project has ~ 15 simulations of MW-mass galaxies at sufficient resolution that could be added to this initial database. As with the real Gaia dataset, we anticipate that periodic future releases will incorporate synthetic surveys of these new simulations. Users should visit http://fire.northwestern.edu/ananke for an up-to-date list. Eventually, we plan to release a public version of ananke along-side a webtool for creating user-described synthetic surveys of simulation snapshots. We hope that the tools provided here and in these subsequent releases will prove a fitting counterpart to a new, data-rich era of Milky Way science.

ACKNOWLEDGMENTS

The authors thank Justin Howell and Vandana Desai of IPAC, Kacper Kowalik and Matt Turk of yt, and Mark Bartelt at Caltech for their crucial assistance with the public data releases. We thank Anthony Brown for discussions on the char-

acteristics of Gaia DR2 and Julianne Dalcanton for advice on models of dust extinction.

This work grew out of two series of *Gaia* preparatory meetings focused on data analysis challenges. First, the *Gaia* Challenge Workshops (held 2011–2015), which were organized through the *Gaia* Research for European Astronomy Training Initial Training Network programme supported by the European Commission through its FP7 Marie Curie programme under grant agreement 264895. Second, the *Gaia* Sprints (held 2016–present). Code for this project was developed in part at the 2017 Heidelberg *Gaia* Sprint, hosted by the Max-Planck-Institut für Astronomie, Heidelberg.

This work has made use of data from the European Space Agency (ESA) mission Gaia (http://www.cosmos.esa.int/gaia), processed by the Gaia Data Processing and Analysis Consortium (DPAC, http://www.cosmos.esa.int/web/gaia/dpac/consortium). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the Gaia Multilateral Agreement.

RES was supported by an NSF Astronomy & Astrophysics Postdoctoral Fellowship under grant AST-1400989, and by NASA through grant JPL 1589742. AW was supported by NASA through ATP grant 80NSSC18K1097 and grants HST-GO-14734 and HST-AR-15057 via STScI. Support for SL was provided by NASA through Hubble Fellowship grant HST-JF2-51395.001-A awarded by the Space Telescope Science Institute, which is operated by the As-

sociation of Universities for Research in Astronomy, Inc., for NASA, under contract NAS5-26555. Support for PFH was provided by an Alfred P. Sloan Research Fellowship, NSF Collaborative Research Grant #1715847 and CAREER grant #1455342, and NASA grants NNX15AT06G, and JPL 1589742. Support for SGK was provided by NASA through Einstein Postdoctoral Fellowship grant number PF5-160136 awarded by the Chandra X-ray Center, which is operated by the Smithsonian Astrophysical Observatory for NASA under contract NAS8-03060. CAFG was supported by NSF through grants AST-1412836, AST-1517491, AST-1715216, and CAREER award AST-1652522, by NASA through grant NNX15AB22G, and by a Cottrell Scholar Award from the Research Corporation for Science Advancement. DK was supported by NSF grant AST-1715101 and the Cottrell Scholar Award from the Research Corporation for Science Advancement. EQ was supported by a Simons Investigator Award from the Simons Foundation and by NSF grant AST-1715070.

Numerical calculations were run on the Caltech compute cluster "Wheeler," allocations from XSEDE TG-AST130039 and PRAC NSF.1713353 supported by the NSF, NASA HEC SMD-16-7592, and the High Performance Computing at Los Alamos National Lab.
