## Preface

This is a series of lecture notes and problems on "Essential Graduate Physics", consisting of the following four parts:

> CM: Classical Mechanics (for a 1 -semester course), EM: Classical Electrodynamics ( 2 semesters), QM: Quantum Mechanics (2 semesters), and SM: Statistical Mechanics (1 semester).

The parts share a teaching style, structure, and (with few exceptions) notation, and are interlinked by extensive cross-referencing. I believe that due to this unity, the notes may be used for teaching these courses not only in the (preferred) sequence shown above, but in almost any order - or in parallel.

Each part is a two-component package consisting of:
(i) Lecture Notes chapter texts, ${ }^{2}$ with a list of exercise problems in the end of each chapter, and
(ii) Exercise and Test Problems with Model Solutions files.

The series also includes two brief reference appendices, MA: Selected Mathematical Formulas (16 pp.) and CA: Selected Physics Constants ( 2 pp ), and a list of references.

The series is a by-product of the so-called core physics courses I taught at Stony Brook University from 1991 to 2013. Reportedly, most physics departments require their graduate students to either take a set of similar courses or pass comprehensive exams based on an approximately similar body of knowledge. This is why I hope that my notes may be useful for both instructors and students of such courses, as well as for individual learners.

The motivation for composing the lecture notes (which had to be typeset because of my horrible handwriting) for Stony Brook students was my desperation to find textbooks I could actually use for teaching. First of all, the textbooks I could find, including the most influential Theoretical Physics series by L. Landau and E. Lifshitz, did not match my classes, which included experiment-oriented students, some PhD candidates from other departments, US college graduates with insufficient undergraduate background, and a few advanced undergraduates. Second, for the rigid time restrictions imposed on the core physics courses, most available textbooks are way too long, and using them would mean hopping from one topic to another, picking up a chapter here and a section there, at a high risk of losing the necessary background material and logical connections between course components - and students’ interest with them. On the other hand, many textbooks lack even brief discussions of several traditional and modern topics that I believe are necessary parts of every professional physicist's education. ${ }^{3,4}$

[^1]The main goal of my courses was to make students familiar with the basic notions and ideas of physics (hence the series' title), and my main effort was to organize the material in a logical sequence the students could readily follow and enjoy, at each new step understanding why exactly they need to swallow the next knowledge pill. As a back side of such a minimalistic goal, I believe that my texts may be used by advanced undergraduate physics students as well. Moreover, I hope that selected parts of the series may be useful for graduate students of other disciplines, including astronomy, chemistry, mechanical engineering, electrical, computer and electronic engineering, and material science.

At least since Confucius and Sophocles, i.e. for the last 2,500 years, teachers have known that students can master a new concept or method only if they have seen its application to at least a few particular problems. This is why in my notes, the range of theoretical physics methods is limited to the approaches that are indeed necessary for solution of the problems I had time to discuss, and the introduction of every new technique is always accompanied by an application example or two. Additional exercise problems are listed in the end of each chapter of the lecture notes, and may be used for homeworks. Individual readers are strongly encouraged to solve as many of these problems as possible. ${ }^{5}$

Detailed model solutions of the exercise problems (some with additional expansion of the lecture material), and several shorter problems suitable for tests (also with model solutions), are gathered in 6 separate files - one per semester. These files are available for both university instructors and individual readers - free of charge, but in return for a signed commitment to avoid unlimited distribution of the solutions - see p. vii below. For instructors, these files are available not only in the Adobe Systems' Portable Document Format (*.pdf), but also in the Microsoft Office 1997-2003 format (*.doc) free of macros, so that the problem assignments and solutions may be readily grouped, edited, etc., before their distribution to students, using either virtually any version of Microsoft Word or independent software tools - e.g., the public-domain OpenOffice.org.

I know that that my texts are far from perfection. In particular, some sacrifices made at the topic selection, always very subjective, were extremely painful. (Most regretfully, I could not find time for even a brief introduction to the general relativity. ${ }^{6}$ ) Moreover, it is very probable that despite all my effort and the great help from SBU students and teaching assistants, not all typos/errors have been weeded out. This is why all remarks (however candid) and suggestions by the readers would be highly appreciated. All significant contributions will be gratefully acknowledged - both online and in possible future editions of the series. ${ }^{7}$

[^2]
## Disclaimer

Since these materials are available free of charge, it is hard to imagine that somebody would blame their author for deceiving "customers" for his commercial gain. Still, I would like to go a little bit beyond the usual litigation-avoiding claims, ${ }^{8}$ and offer a word of caution to the potential reader, in order to preempt his or her possible later disappointment.

## This is NOT a course of theoretical physics - at least in the contemporary sense of the term

Though much of the included material is similar to that in textbooks on "theoretical physics" (most notably in the famous series by L. Landau and E. Lifshitz), this lecture note series is different from them by its emphasis on the basic concepts and ideas of physics, their relation to experimental data, and most important applications - rather than on sophisticated theoretical techniques. Indeed, the set of theoretical methods discussed in the notes is limited to the minimum necessary for quantitative understanding of the key notions of physics and for solving a few (or rather about a thousand :-) core problems. Moreover, because of the notes' shortness, I have not been able to cover some key fields of theoretical physics, most notably the general relativity and quantum field theory - beyond some introductory elements of quantum electrodynamics in QM Chapter 9. If you want to work in modern theoretical physics, you need to know much more than these lectures!

## Moreover, this is NOT a textbook - at least not the usual one

A usual textbook tries (though most commonly fails) to cover virtually all aspects of the addressed field. As a result, it is typically way too long for being fully read and understood by students during the time allocated for the corresponding course, so that the instructors are forced to pick up selected chapters and sections, frequently loosing narrative's logic lines. In contrast, these notes are much shorter (about 200 pages per semester), enabling their thorough reading - perhaps with just a few later sections dropped, depending on reader's interests. I have tried to mitigate the losses due to this minimalistic approach by providing extensive further reading recommendations on the topics I had no time to cover. The reader is highly encouraged to use these sources (and/or the corresponding chapters of more detailed textbooks) on any topic(s) of his or her special interest.

## Then, what these notes ARE and why you may like to use them (I think)

By tradition, graduate physics education consists of two main components: research experience and advanced physics courses. Unfortunately, the latter component is currently under pressure in many physics departments, apparently because of two reasons. On one hand, the average knowledge level of students entering graduate school is not improving, so that bringing them up to the level of contemporary research becomes increasingly difficult. On the other hand, the research itself is becoming more fragmented, so that the students frequently do not feel an immediate need for a broad physics

[^3]knowledge base for their PhD project success. Some thesis advisors, trying to maximize the time they could use students as a cheap laboratory workforce, do not help.

I believe that this trend toward the reduction of a broad physics education in graduate school is irresponsible. Experience shows that during his or her future research career, a typical current student will change research fields several times. Starting from scratch in a new field is hard - terribly hard in an advanced age (believe me :-). However, physics is fortunate to have a hard core of knowledge, that many other sciences lack. With this knowledge, the student will always feel in physics at home, while without it, he or she may not be able even to understand research literature in the new field, and would risk being reduced to auxiliary work roles - if any.

I have seen the main objective of my Stony Brook courses to give an introduction to this hard core of physics knowledge, at the same time trying to convey my own enchantment by the unparalleled beauty of the concepts and ideas of this science, and the remarkable logic of their fusion into a wonderful single construct. Let me hope that these notes relay not only the knowledge as such, but also at least a part of my enchantment.

## Versions and Acknowledgements

This is a preliminary ("Beta") version of the series. My plans are to publish, in a few years, its final version. Until that has happened, I commit to keeping the Beta stable. The only changes still to be made in it will be corrections of the typos noticed by the readers and myself, and minor stylistic edits.

I am extremely grateful to my faculty colleagues and other readers who commented on certain sections of the notes; here is their list (in the alphabetic order) ${ }^{9}$
A. Abanov, P. Allen, D. Averin, S. Berkovich, P.-T. de Boer, M. Fernandez-Serra, R. F. Hernandez, T. Konstantinova, A. Korotkov, V. Semenov, F. Sheldon, E. Tikhonov, X. Wang.
(Evidently, these kind people are not responsible for the remaining deficiencies.)
The Department of Physics and Astronomy of the Stony Brook University was very responsive to my requests of certain time ordering of my teaching assignments, that was beneficial for note writing and editing. The department, and the university as the whole, also provided a very friendly general environment for my work during the past 25 years.

A large part of my scientific background and experience, reflected in these materials, came from my education (and then research work) in the Department of Physics of Moscow State University.

And last but not least, I would like to thank my wife Lioudmila for several good advices on aesthetic aspects of note typesetting, and for all her love, care, and patience - without them, this project would be impossible.

Konstantin.Likharev@StonyBrook.edu

[^4]
## Problem Solution Request Templates

Requests should be sent to konstantin.likharev@stonybrook.edu in either of the following forms:

- an e-mail from a valid university address,
- a scanned copy of a signed letter - as an e-mail attachment.

Approximate contents:

## A. Request from a Prospective Instructor

Dear Dr. Likharev,
My plans are to use your lecture notes and/or problems of the Essential Graduate Physics series, part <select: CM, EM, QM, SM>, in my course <title> during <semester, year> in the <department, university>. I would appreciate sending me file Exercise and Test Problems with Model Solutions of that part of the series in the <select: .pdf, both .doc and .pdf> format(s).

I will avoid unlimited distribution of the solutions, in particular their posting on externally searchable Web sites. If I distribute the solutions among my students, I will ask them to adhere to the same restraint.

I will let you know of any significant typos / deficiencies I may find.
Sincerely, <signature, full name, university position, work phone number>

## B. Request from an Individual Learner

Dear Dr. Likharev,
My plans are to use your lecture notes and problems of the Essential Graduate Physics series, part(s) <select: CM, EM, QM, SM>, for my personal education. I would appreciate sending me file(s) Exercise and Test Problems with Model Solutions of that part(s) of the series.

I will not share the material with anyone, and will not use it for passing courses that are officially based on your series.

I will let you know of any significant typos / deficiencies I may find.
Sincerely, <signature, full name, present home address (in English), acting phone number>

## Notation

## Abbreviations

Eq. any formula (e.g., equation)
Fig. figure
Sec. section
c.c. complex conjugate
h. c. Hermitian conjugate
c.

## Fonts

$F, \not \subset$ scalar variables ${ }^{10}$
F, $\boldsymbol{7}$ vector variables
$\hat{F}, \hat{\not}$ scalar operators
$\hat{\mathbf{F}}, \hat{\boldsymbol{F}}$ vector operators
F matrix
$F_{j j}$, matrix element

## Parts of the series

CM: Classical Mechanics
EM: Classical Electrodynamics
QM: Quantum Mechanics
SM: Statistical Mechanics

## Symbols

- time differentiation operator $(d / d t)$
$\nabla$ spatial differentiation vector (del)
$\approx$ approximately equal to
$\sim$ of the same order as
$\propto$ proportional to
$\equiv$ equal to by definition (or evidently)
- scalar ("dot-") product
$\times$ vector ("cross-") product
- time averaging
$\rangle$ statistical averaging
[, ] commutator
\{, \} anticommutator

## Appendices

MA: Selected Mathematical Formulas
CA: Selected Physical Constants

## Prime signs

The prime signs ( ${ }^{\prime},{ }^{\prime \prime}$, etc) are used to distinguish similar variables or indices (such as $j$ and $j^{\prime}$ in the matrix element above), rather than to denote derivatives.

## Formulas

The most general and/or important formulas are highlighted with blue frames and short titles on the margins.

## Numbering

Chapter numbers are dropped in all references to formulas, figures, footnotes, and problems within the same chapter.

# Part CM: <br> Classical Mechanics 

Last corrections: 2019/07/31

A revised version of this material is now published by the IOP under the title
"Classical Mechanics: Lecture notes"
(Essential Advanced Physics - Volume 1, ISBN 978-0-7503-1398-8), with the model solutions of the exercise problems published under the title
"Classical Mechanics: Problems with solutions"
(Essential Advanced Physics - Volume 2, ISBN 978-0-7503-1401-5)

## Table of Contents

## Chapter 1. Review of Fundamentals (14 pp.)

1.1. Mechanics and dynamics
1.2. Kinematics: Basic notions
1.3. Dynamics: Newton laws
1.4. Conservation laws
1.5. Potential energy and equilibrium
1.6. OK, can we go home now?
1.7. Self-test problems (12)

Chapter 2. Lagrangian Formalism (14 pp.)
2.1. Lagrange equation
2.2. Examples
2.3. Hamiltonian function and energy
2.4. Other conservation laws
2.5. Exercise problems (10)

Chapter 3. A Few Simple Problems ( 20 pp.)
3.1. One-dimensional and 1D-reducible systems
3.2. Equilibrium and stability
3.3. Hamiltonian 1D systems
3.4. Planetary problems
3.5. $2^{\text {nd }}$ Kepler law
3.6. $1^{\text {st }}$ and $3^{\text {rd }}$ Kepler laws
3.7. Elastic scattering
3.8. Exercise problems (16)

Chapter 4. Oscillations (34 pp.)
4.1. Free and forced oscillations
4.2. Weakly nonlinear oscillations
4.3. RWA equations
4.4. Self-oscillations and phase locking
4.5. Parametric excitation
4.6. Fixed point classification
4.7. Numerical approach
4.8. Harmonic and subharmonic oscillations
4.9. Exercise problems (14)

Chapter 5. From Oscillations to Waves (22 pp.)
5.1. Two coupled oscillators
5.2. $N$ coupled oscillators
5.3. 1D Waves in periodic systems
5.4. Interfaces and boundaries
5.5. Dissipative, parametric, and nonlinear phenomena
5.6. Exercise problems (15)

## Chapter 6. Rigid Body Motion (30 pp.)

6.1. Angular velocity vector
6.2. Inertia tensor
6.3. Fixed-axis rotation
6.4. Free rotation
6.5. Torque-induced precession
6.6. Non-inertial reference frames
6.7. Exercise problems (22)

## Chapter 7. Deformations and Elasticity (38 pp.)

7.1. Strain
7.2. Stress
7.3. Hooke's law
7.4. Equilibrium
7.5. Rod bending
7.6. Rod torsion
7.7. 3D acoustic waves
7.8. Elastic waves in restricted geometries
7.9. Exercise problems (15)

Chapter 8. Fluid Mechanics (26 pp.)
8.1. Hydrostatics
8.2. Surface tension effects
8.3. Kinematics
8.4. Dynamics: Ideal fluids
8.5. Dynamics: Viscous fluids
8.6. Turbulence
8.7. Exercise problems (19)

## Chapter 9. Deterministic Chaos (14 pp.)

9.1. Chaos in maps
9.2. Chaos in dynamic systems
9.3. Chaos in Hamiltonian systems
9.4. Chaos and turbulence
9.5. Exercise problems (4)

Chapter 10. A Bit More of Analytical Mechanics (14 pp.)
10.1. Hamiltonian equations
10.2. Adiabatic invariance
10.3. The Hamilton principle
10.4. The Hamilton-Jacobi equation
10.5. Exercise problems (9)

Additional file (available upon request):
Exercise and Test Problems with Model Solutions (136 + 40 = 176 problems; 227 pp.)

## This <br>  <br> $\square$

## Chapter 1. Review of Fundamentals

After elaborating a bit on the title and contents of the course, this short introductory chapter lists the basic notions and facts of the classical mechanics, that are supposed to be known to the reader from undergraduate studies. ${ }^{1}$ Due to this reason, the explanations are very brief.

### 1.1. Mechanics and dynamics

A more fair title of this course would be Classical Mechanics and Dynamics, because the notions of mechanics and dynamics, though much intertwined, are still somewhat different. Term mechanics, in its narrow sense, means deriving the equations of motion of point-like particles and their systems (including solids and fluids), solution of these equations, and interpretation of the results. Dynamics is a more ambiguous term; it may mean, in particular:
(i) the part of mechanics that deals with motion (in contrast to statics);
(ii) the part of mechanics that deals with reasons for motion (in contrast to kinematics);
(iii) the part of mechanics that focuses on its two last tasks, i.e. the solution of the equations of motion and discussion of the results.

The last definition invites a question. It may look that mechanics and dynamics are just two sequential steps of a single process; why should they be considered separate disciplines? The main reason is that the many differential equations of motion, obtained in classical mechanics, also describe processes in different systems, so that their analysis may reveal important features of these systems as well. For example, the famous ordinary differential equation

$$
\begin{equation*}
\ddot{x}+\omega_{0}^{2} x=0 \tag{1.1}
\end{equation*}
$$

describes sinusoidal 1D oscillations not only of a mass on a spring, but also of an electric or magnetic field in a resonator, and many other systems. Similarly, the well-known partial differential equation

$$
\begin{equation*}
\left(\frac{1}{v^{2}} \frac{\partial^{2}}{\partial t^{2}}-\nabla^{2}\right) f(\mathbf{r}, t)=0 \tag{1.2}
\end{equation*}
$$

where $v$ is a constant and $\nabla^{2}$ is the Laplace operator, ${ }^{2}$ describes not only acoustic waves in an elastic mechanical continuum (solid or fluid), but also electromagnetic waves in a non-dispersive media, certain chemical reactions, etc. Thus the results of analysis of the dynamics described by these equations may be reused for applications well beyond mechanics.

[^6]To summarize, term "dynamics" is so ambiguous ${ }^{3}$ that, after some hesitation, I have opted to using for this course the traditional name Classical Mechanics, implying its broader meaning, which includes (similarly to Quantum Mechanics and Statistical Mechanics) studies of dynamics of some nonmechanical systems.

### 1.2. Kinematics: Basic notions

The basic notions of kinematics may be defined in various ways, and some mathematicians pay a lot of attention to analyzing such systems of axioms and relations between them. In physics, we typically stick to less rigorous ways (in order to proceed faster to particular problems), and end debating a definition as soon as everybody in the room agrees that we are all speaking about the same thing. Let me hope that the following notions used in classical mechanics do satisfy this criterion:
(i) All the Euclidean geometry notions, including the geometric point (the mathematical abstraction for the position of a very small object), straight line, etc.
(ii) The orthogonal, linear ("Cartesian") coordinates ${ }^{4} r_{j}$ of a geometric point in a particular reference frame - see Fig. $1 .{ }^{5}$

Fig. 1.1. Cartesian coordinates and radius-vector of a point/particle.

The coordinates may be used to define the point's radius-vector ${ }^{6}$
${ }^{3}$ Another important issue is: Definition (iii) of dynamics is suspiciously close to the part of mathematics devoted to the differential equation analysis; what is the difference? To answer, we have to dip, for just a second, into the philosophy of physics. Physics may be described as an art (and a bit of science :-) of description of Mother Nature by mathematical means; hence in many cases the approaches of a mathematician and a physicist to a problem are very similar. The main difference is that physicists try to express the results of their analysis in terms of system's motion rather than function properties, and as a result develop some sort of intuition ("gut feeling") about how other, apparently similar, systems may behave, even if their exact equations of motion are somewhat different - or not known at all. The intuition so developed has an enormous heuristic power, and most discoveries in physics have been made through gut-feeling-based insights rather than by plugging one formula into another one.
${ }^{4}$ In these notes the Cartesian coordinates are denoted either as either $\left\{r_{1}, r_{2}, r_{3}\right\}$ or $\{x, y, z\}$, depending on convenience in the particular case. Note that axis numbering is important for operations like the vector ("cross") product; the "correct" (meaning generally accepted) numbering order is such that rotation $\mathbf{n}_{1} \rightarrow \mathbf{n}_{2} \rightarrow \mathbf{n}_{3} \rightarrow \mathbf{n}_{1} \ldots$ looks counterclockwise if watched from a point with all $r_{i}>0-$ see Fig. 1.
${ }^{5}$ In references to figures, formulas, problems and sections within the same chapter of these notes, the chapter number is dropped for brevity.
${ }^{6}$ From the point of view of the tensor theory (in which the physical vectors like $\mathbf{r}$ are considered the rank-1 tensors), it would be more natural to use superscripts in the components $r_{j}$ and other "contravariant" vectors. However, the superscripts may be readily confused with the power signs, and I will postpone this notation (as well as the implied summation over the repeated indices) until the discussion of relativity in EM Chapter 9.

Radius -vector

Euclidean metric

Velocity

Acceleration
and its acceleration:

$$
\begin{equation*}
\mathbf{a}(t) \equiv \frac{d \mathbf{v}}{d t} \equiv \dot{\mathbf{v}}=\ddot{\mathbf{r}} . \tag{1.6}
\end{equation*}
$$

Since the above definitions of vectors $\mathbf{r}, \mathbf{v}$, and a depend on the chosen reference frame (are "reference-frame-specific"), there is a need to relate those vectors as observed in different frames. Within the Euclidean geometry, for two reference frames with the corresponding axes parallel in the moment of interest (Fig. 2), the relation between the radius-vectors is very simple:
Radiusvector's transformation

$$
\begin{equation*}
\mathbf{r}=\sum_{j=1}^{3} \mathbf{n}_{j} r_{j} \tag{1.3}
\end{equation*}
$$

where $\mathbf{n}_{1}, \mathbf{n}_{2}, \mathbf{n}_{3}$ are the unit vectors along coordinate axis directions, with the Euclidean metric:
which is independent, in particular, of the distribution of matter in space.
(iii) The time - as described by a continuous scalar variable (say, $t$ ), typically considered an independent argument of various physical observables, in particular the point's radius-vector $\mathbf{r}(t)$. By accepting Eq. (4), and an implicit assumption that time $t$ runs similarly in all reference frames, we subscribe to the notion of the absolute ("Newtonian") space/time, and hence abstain from a discussion of relativistic effects. ${ }^{7}$
(iv) The (instant) velocity of the point,

$$
\begin{equation*}
\mathbf{v}(t) \equiv \frac{d \mathbf{r}}{d t} \equiv \dot{\mathbf{r}}, \tag{1.5}
\end{equation*}
$$

$$
\begin{equation*}
\left.\mathbf{r}\right|_{\text {in } O^{\prime}}=\left.\mathbf{r}\right|_{\text {in } O}+\left.\mathbf{r}_{O}\right|_{\text {in } O^{\prime}} \tag{1.7}
\end{equation*}
$$

Fig. 1.2. Coordinate transfer between two reference frames.

[^7]If the frames move versus each other by translation only (no mutual rotation!), similar relations are valid for velocity and acceleration as well:

$$
\begin{align*}
& \left.\mathbf{v}\right|_{\text {in } O^{\prime}}=\left.\mathbf{v}\right|_{\text {in } O}+\left.\mathbf{v}_{O}\right|_{\text {in } O^{\prime}},  \tag{1.8}\\
& \left.\mathbf{a}\right|_{\text {in } O^{\prime}}=\left.\mathbf{a}\right|_{\text {in } O}+\left.\mathbf{a}_{O}\right|_{\text {in } O^{\prime}} . \tag{1.9}
\end{align*}
$$

In the case of mutual rotation of the reference frames, notions like $\left.\mathbf{v}_{O}\right|_{\text {in } O}$, are not well defined. (Indeed, different points of a rigid body connected to frame $O$ may have different velocities in frame $O^{\prime}$.) As a result, the transfer laws for velocities and accelerations are more complex than those given by Eqs. (8) and (9). It will be more natural for me to discuss them in the end of Chapter 5 that is devoted to rigid body motion.
(v) The particle: a localized physical object whose size is negligible, and shape unimportant for the given problem. Note that the last qualification is extremely important. For example, the size and shape of a Space Shuttle are not too important for the discussion of its orbital motion, but are paramount when its landing procedures are being developed. Since classical mechanics neglects the quantum mechanical uncertainties, ${ }^{8}$ particle's position, at any particular instant $t$, may be identified with a single geometric point, i.e. one radius-vector $\mathbf{r}(t)$. Finding the laws of motion $\mathbf{r}(t)$ of all particles participating in the given problem is frequently considered the final goal of classical mechanics.

### 1.3. Dynamics: Newton laws

Generally, the classical dynamics is fully described (in addition to the kinematic relations given above) by three Newton laws. ${ }^{9}$ In contrast to the impression some textbooks on theoretical physics try to create, these laws are experimental in nature, and cannot be derived from purely theoretical arguments. ${ }^{10}$

I am confident that the reader of these notes is already familiar with the Newton laws, in one or another formulation. Let me note only that in some formulations the $l^{\text {st }}$ Newton law looks just as a particular case of the $2^{\text {nd }}$ law - for the case of zero net force acting on a particle. In order to avoid this duplication, the $1^{\text {st }}$ law may be formulated as the following postulate:

- There exists at least one reference frame, called inertial, in which any free particle (i.e. a $1^{\text {st }}$ Newton particle isolated from the rest of the Universe) moves with $\mathbf{v}=$ const, i.e. with $\mathbf{a}=0$.

According to Eq. (9), this postulate immediately means that there is also an infinite number of inertial frames, because all frames $O^{\prime}$ moving without rotation or acceleration relative to the postulated inertial frame $O$ (i.e. having $\left.\mathbf{a}_{O}\right|_{\text {in }} O^{\prime}=0$ ) are also inertial.

[^8]On the other hand, the $2^{\text {nd }}$ and $3^{\text {rd }}$ Newton laws may be postulated together in the following elegant way. Each particle, say number $k$, may be characterized by a scalar constant (called mass $m_{k}$ ), such that at any interaction of $N$ particles (isolated from the rest of the Universe), in any inertial system,

$$
\begin{equation*}
\mathbf{P} \equiv \sum_{k=1}^{N} m_{k} \mathbf{v}_{k}=\text { const. } \tag{1.10}
\end{equation*}
$$

(Each component of this sum,

$$
\begin{equation*}
\mathbf{p}_{k} \equiv m_{k} \mathbf{v}_{k}, \tag{1.11}
\end{equation*}
$$

is called the mechanical momentum of the corresponding particle, and the whole sum $\mathbf{P}$, the total momentum of the system.)

Let us apply this postulate to just two interacting particles. Differentiating Eq. (10), written for this case, over time, we get

$$
\begin{equation*}
\dot{\mathbf{p}}_{1}=-\dot{\mathbf{p}}_{2} \tag{1.12}
\end{equation*}
$$

Let us give the derivative $\dot{\mathbf{p}}_{1}$ (i.e., a vector) the name of force $\mathbf{F}_{1}$ excerted on particle 1. In our current case, when the only possible source of force is particle 2, the force may be denoted as $\mathbf{F}_{12}$. Similarly, $\mathbf{F}_{21} \equiv \dot{\mathbf{p}}_{2}$, so that we get the $3^{\text {rd }}$ Newton law

3rd Newton law

$$
\begin{equation*}
\mathbf{F}_{12}=-\mathbf{F}_{21} . \tag{1.13}
\end{equation*}
$$

Now, returning to the general case of several interacting particles, we see that an additional (but very natural) assumption that all partial forces $\mathbf{F}_{k k^{\prime}}$ acting on particle $k$ add up as vectors, leads to the general form of the $2^{\text {nd }}$ Newton law ${ }^{11}$

$$
\begin{equation*}
m_{k} \mathbf{a}_{k} \equiv \dot{\mathbf{p}}_{k}=\sum_{k^{\prime} \neq k} \mathbf{F}_{k k^{\prime}} \equiv \mathbf{F}_{k}, \tag{1.14}
\end{equation*}
$$

that allows a clear interpretation of the mass as a measure of particle's inertia.
As a matter of principle, if the dependence of all pair forces $\mathbf{F}_{k k^{\prime}}$ of particle positions (and generally maybe of time as well) is known, Eq. (14) augmented with kinematic relations (4) and (5), allows the calculation of the laws of motion $\mathbf{r}_{k}(t)$ of all particles of the system. For example, for one particle the $2^{\text {nd }}$ law (14) gives the ordinary differential equation of the second order,

$$
\begin{equation*}
m \ddot{\mathbf{r}}=\mathbf{F}(\mathbf{r}, t) \tag{1.15}
\end{equation*}
$$

that may be integrated - either analytically or numerically.
For certain cases, this is very simple. As an elementary example, the Newton's gravity field
Newton's gravity law
(where $\mathbf{R} \equiv \mathbf{r}-\mathbf{r}$ ' is the distance between particles of masses $m$ and $m^{\prime}$ ) ${ }^{12}$, is virtually uniform and may be approximated as

[^9]\[

$$
\begin{equation*}
\mathbf{F}=m \mathbf{g}, \tag{1.16b}
\end{equation*}
$$

\]

Uniform gravity field
with the vector $\mathbf{g} \equiv\left(G m^{\prime} / r^{\prime 3}\right) \mathbf{r}^{\prime}$ being constant, for local, relatively small-scale motions, with $r \ll r^{\prime} .{ }^{13}$ As a result, $m$ in Eq. (15) cancels, it is reduced to just $\ddot{\mathbf{r}}=\mathbf{g}$, and may be easily integrated twice:

$$
\begin{gather*}
\dot{\mathbf{r}}(t) \equiv \mathbf{v}(t)=\int_{0}^{t} \mathbf{g} d t^{\prime}+\mathbf{v}(0)=\mathbf{g} t+\mathbf{v}(0)  \tag{1.17}\\
\mathbf{r}(t)=\int_{0}^{t} \mathbf{v}\left(t^{\prime}\right) d t^{\prime}+\mathbf{r}(0)=\mathbf{g} \frac{t^{2}}{2}+\mathbf{v}(0) t+\mathbf{r}(0) \tag{1.18}
\end{gather*}
$$

thus giving the full solution of all those undergraduate problems on the projectile motion, which should be so familiar to the reader.

All this looks (and indeed is) very simple, but in most other cases leads to more complex calculations. As an example, let us consider another simple problem: a bead of mass $m$ sliding, without friction, along a round ring of radius $R$ in a gravity field obeying Eq. (16b) - see Fig. 3.

Fig. 1.3. Bead moving on a vertical ring.

Suppose we are only interested in bead's velocity $v$ in the lowest point, after it has been dropped from the rest at the rightmost position. If we want to solve this problem using only the Newton laws, we have to do the following steps:
(i) consider the bead in an arbitrary intermediate position on a ring, described, for example by the angle $\theta$ shown in Fig. 3;
(ii) draw all the forces acting on the particle - in our current case, the gravity force $m \mathbf{g}$ and the reaction force $\mathbf{N}$ exerted by the ring;

[^10](iii) write the $2^{\text {nd }}$ Newton law for two nonvanishing components of the bead acceleration, say for its vertical and horizontal components $a_{x}$ and $a_{y}$;
(iv) recognize that in the absence of friction, the force $\mathbf{N}$ should be normal to the ring, so that we can use two additional equations, $N_{x}=-N \sin \theta$ and $N_{y}=N \cos \theta$;
(v) eliminate unknown variables $N, N_{x}$, and $N_{y}$ from the resulting system of four equations, thus getting a single second-order differential equation for one variable, for example $\theta$;
(vi) integrate this equation once to get the expression relating the velocity $\dot{\theta}$ and the angle $\theta$; and, finally,
(vii) using our specific initial condition ( $\dot{\theta}=0$ at $\theta=\pi / 2$ ), find the final velocity as $v=R \dot{\theta}$ at $\theta=0$.

All this is very much doable, but please agree that the procedure it too cumbersome for such a simple problem. Moreover, in many other cases even writing equations of motion along relevant coordinates is very complex, and any help the general theory may provide is highly valuable. In many cases, such help is given by conservation laws; let us review the most general of them.

### 1.4. Conservation laws

(i) Energy conservation is arguably the most general law of physics, but in mechanics it takes a more humble form of mechanical energy conservation that has limited applicability. To derive it, we first have to define the kinetic energy of a particle as

Kinetic energy

$$
\begin{equation*}
T \equiv \frac{m}{2} v^{2} \tag{1.19}
\end{equation*}
$$

and then recast its differential as ${ }^{14}$

$$
\begin{equation*}
d T=d\left(\frac{m}{2} v^{2}\right)=d\left(\frac{m}{2} \mathbf{v} \cdot \mathbf{v}\right)=m \mathbf{v} \cdot d \mathbf{v}=m \frac{d \mathbf{v} \cdot d \mathbf{r}}{d t}=\frac{d \mathbf{p}}{d t} \cdot d \mathbf{r} . \tag{1.20}
\end{equation*}
$$

Now plugging in the momentum's derivative from the $2^{\text {nd }}$ Newton law, $d \mathbf{p} / d t=\mathbf{F}$, where $\mathbf{F}$ is the full force acting on the particle, we get relation $d T=\mathbf{F} \cdot d \mathbf{r}$. Its integration along particle's trajectory between some points $A$ and $B$ gives the relation that is sometimes called the work-energy principle:

Energy-
work
principle

$$
\begin{equation*}
\Delta T \equiv T\left(\mathbf{r}_{B}\right)-T\left(\mathbf{r}_{A}\right)=\int_{A}^{B} \mathbf{F} \cdot d \mathbf{r} \tag{1.21}
\end{equation*}
$$

where the integral in the right-hand part is called the work of the force $\mathbf{F}$ on the path from $A$ to $B$.
The further step may be made only for potential (also called "conservative") forces that may be presented as (minus) gradients of some scalar function $U(\mathbf{r})$, called the potential energy. ${ }^{15}$ The vector operator $\nabla$ (called either del or nabla) of spatial differentiation ${ }^{16}$ allows a very compact expression of this fact:

[^11]\[

$$
\begin{equation*}
\mathbf{F}=-\nabla U \tag{1.22}
\end{equation*}
$$

\]

For example, for the uniform gravity field (16b),

$$
\begin{equation*}
U=m g h+\text { const }, \tag{1.23}
\end{equation*}
$$

where $h$ is the vertical coordinate directed "up" - opposite to the direction of the vector $\mathbf{g}$.
Integrating the tangential component $F_{\tau}$ of the vector $\mathbf{F}$, given by Eq. (22), along an arbitrary path connecting points $A$ and $B$, we get

$$
\begin{equation*}
\int_{A}^{B} F_{\tau} d r \equiv \int_{A}^{B} \mathbf{F} \cdot d \mathbf{r}=U\left(\mathbf{r}_{A}\right)-U\left(\mathbf{r}_{B}\right), \tag{1.24}
\end{equation*}
$$

i.e. work of potential forces may be presented as the difference of values of function $U(\mathbf{r})$ in the initial and final point of the path. (Note that according to Eq. (24), work of a potential force on any closed trajectory, with $\mathbf{r}_{A}=\mathbf{r}_{B}$, is zero.)

Now returning to Eq. (21) and comparing it with Eq. (24), we see that

$$
\begin{equation*}
T\left(\mathbf{r}_{B}\right)-T\left(\mathbf{r}_{A}\right)=U\left(\mathbf{r}_{A}\right)-U\left(\mathbf{r}_{B}\right), \tag{1.25}
\end{equation*}
$$

so that the total mechanical energy $E$, defined as

$$
\begin{equation*}
E \equiv T+U \tag{1.26}
\end{equation*}
$$

is indeed conserved:

$$
\begin{equation*}
E\left(\mathbf{r}_{A}\right) \equiv E\left(\mathbf{r}_{B}\right), \tag{1.27}
\end{equation*}
$$

[^12]If we sum up the resulting Eqs. (14) for all particles of the system then, due to the $3^{\text {rd }}$ Newton law (13), the contributions of all internal forces to this double sum in the right-hand part cancel, and we get the equation

System's momentum evolution

$$
\begin{equation*}
\dot{\mathbf{P}}=\mathbf{F}^{(\mathrm{ext})}, \quad \text { where } \mathbf{F}^{(e x t)} \equiv \sum_{k=1}^{N} \mathbf{F}_{k}^{(\mathrm{ext})} \tag{1.30}
\end{equation*}
$$

which tells us that the translational motion of the system as the whole is similar to that of a single particle, under the effect of the net external force $\mathbf{F}^{(\text {ext })}$. As a simple sanity check, if the external forces have a zero sum, we return to postulate (10). Just one reminder: Eq. (30), just as its precursor Eq. (14), is only valid in an inertial reference frame.
(iii) Angular momentum of a particle ${ }^{18}$ is defined as the following vector:

Angular momentum: definition

$$
\begin{equation*}
\mathbf{L} \equiv \mathbf{r} \times \mathbf{p} \tag{1.31}
\end{equation*}
$$

where $\mathbf{a} \times \mathbf{b}$ means the vector (or "cross-") product of the vector operands. ${ }^{19}$ Now, differentiating Eq. (31) over time, we get

$$
\begin{equation*}
\dot{\mathbf{L}}=\dot{\mathbf{r}} \times \mathbf{p}+\mathbf{r} \times \dot{\mathbf{p}} \tag{1.32}
\end{equation*}
$$

In the first product, $\dot{\mathbf{r}}$ is just the velocity vector $\mathbf{v}$ which is parallel to the particle momentum $\mathbf{p}=\mathrm{mv}$, so that this product vanishes, since the vector product of any two parallel vectors is zero. In the second product, $\dot{\mathbf{p}}$ equals the full force $\mathbf{F}$ acting on the particle, so that Eq. (32) is reduced to

Angular
momentum: evolution

Torque
where vector

$$
\begin{equation*}
\dot{\mathbf{L}}=\boldsymbol{\tau} \tag{1.33}
\end{equation*}
$$

is called the torque of force $\mathbf{F}$. (Note that the torque is evidently reference-frame specific - and again, the frame has to be inertial for Eq. (33) to be valid.) For an important particular case of a central force $\mathbf{F}$ that is parallel to the radius vector $\mathbf{r}$ of a particle (as measured from the force source point), the torque vanishes, so that (in that particular reference frame only!) the angular momentum is conserved:

$$
\begin{equation*}
\mathbf{L}=\text { const. } \tag{1.35}
\end{equation*}
$$

For a system of $N$ particles, the total angular momentum is naturally defined as

$$
\begin{equation*}
\mathbf{L} \equiv \sum_{k=1}^{N} \mathbf{L}_{k} . \tag{1.36}
\end{equation*}
$$

Differentiating this equation over time, using Eq. (33) for each $\dot{\mathbf{L}}_{k}$, and again partitioning each force in a accordance with Eq. (29), we get

[^13]\[

$$
\begin{equation*}
\dot{\mathbf{L}}=\sum_{\substack{k, k^{\prime}=1 \\ k \neq k}}^{N} \mathbf{r}_{k} \times \mathbf{F}_{k k^{\prime}}+\boldsymbol{\tau}^{(e x t)}, \quad \text { where } \boldsymbol{\tau}^{(e x t)} \equiv \sum_{k=1}^{N} \mathbf{r}_{k} \times \mathbf{F}_{k}^{(e x t)} \tag{1.37}
\end{equation*}
$$

\]

The first (double) sum may be always divided into pairs of the type $\left(\mathbf{r}_{k} \times \mathbf{F}_{k k^{\prime}}+\mathbf{r}_{k^{\prime}} \times \mathbf{F}_{k^{\prime} k}\right)$. With a natural assumption of the central forces $\left(\mathbf{F}_{k k^{\prime}} \| \mathbf{r}_{k}-\mathbf{r}_{k^{\prime}}\right.$ ), each of these pairs equals zero. Indeed, in this case both components of the pair are vectors perpendicular to the plane passed through positions of both particles and the reference frame origin, i.e. to the plane of drawing of Fig. 4. Also, due to the $3^{\text {rd }}$ Newton law (13) the two forces are equal and opposite, and the magnitude of each term in the sum may be presented as $\left|F_{k k^{\prime}}\right| h_{k k^{\prime}}$, with equal "lever arms" $h_{k k^{\prime}}=h_{k^{\prime} k}$. As a result, each sum $\left(\mathbf{r}_{k} \times \mathbf{F}_{k k^{\prime}}+\mathbf{r}_{k^{\prime}} \times \mathbf{F}_{k^{\prime} k}\right)$, and hence the whole double sum in Eq. (37) vanish, and it is reduced to a very simple result,

$$
\begin{equation*}
\dot{\mathbf{L}}=\boldsymbol{\tau}^{(\mathrm{ext})} \tag{1.38}
\end{equation*}
$$

that is similar to Eq. (33) for a single particle, and is the angular analog of Eq. (30). In particular, Eq. (38) shows that if the full external torque $\tau^{(\text {ext })}$ vanishes by some reason (e.g., if the system of particles is isolated from the rest of the Universe), the conservation law (35) is valid for the full angular momentum $\mathbf{L}$, even if its individual components $\mathbf{L}_{k}$ are not conserved due to inter-particle interactions.

Fig. 1.4. Internal and external forces, and the internal torque cancellation in a system of two particles.

From the mathematical point of view, most conservation laws present the first integrals of motion which sometimes liberate us from the necessity to integrate the second-order differential equations of motion, following from the Newton laws, twice.

### 1.5. Potential energy and equilibrium

Another important role of the potential energy $U$, especially for dissipative systems whose total mechanical energy $E$ is not conserved because it may be drained to the environment, is finding the positions of equilibrium (sometimes called the fixed points of the system under analysis) and analyzing their stability with respect to small perturbations. For a single particle, this is very simple: force (22) vanishes at each extremum (minimum or maximum) of the potential energy. ${ }^{20}$ Of those fixed points, only the minimums of $U(\mathbf{r})$ are stable - see Sec. 3.2 below for a discussion of this point.

[^14]A slightly more subtle case is a particle with potential energy $U(\mathbf{r})$, subjected to an additional external force $\mathbf{F}^{(\text {ext })}(\mathbf{r})$. In this case, the stable equilibrium is reached at the minimum of not function $U(\mathbf{r})$, but of what is sometimes called the Gibbs potential energy

$$
\begin{equation*}
U_{\mathrm{G}}(\mathbf{r}) \equiv U(\mathbf{r})-\int^{\mathbf{r}} \mathbf{F}^{(\mathrm{ext})}\left(\mathbf{r}^{\prime}\right) \cdot d \mathbf{r}^{\prime} \tag{1.39}
\end{equation*}
$$

which is defined, just as $U(\mathbf{r})$ is, to an arbitrary constant. The proof of Eq. (39) is very simple: in an extremum of this function, the total force acting on the particle,

$$
\begin{equation*}
\mathbf{F}^{(\mathrm{tot})}=\mathbf{F}+\mathbf{F}^{(\mathrm{ext})} \equiv-\nabla U+\nabla \int^{\mathbf{r}} \mathbf{F}^{(\mathrm{ext})}\left(\mathbf{r}^{\prime}\right) \cdot d \mathbf{r}^{\prime}=-\nabla U_{\mathrm{G}} \tag{1.40}
\end{equation*}
$$

vanishes, as it should. ${ }^{21}$ For the simplest (and very frequent) case of the applied force independent on particle's position, the Gibbs potential energy is just

$$
\begin{equation*}
U_{\mathrm{G}}(\mathbf{r}) \equiv U(\mathbf{r})-\mathbf{F}^{(\mathrm{ext})} \cdot \mathbf{r}+\text { const } . \tag{1.41}
\end{equation*}
$$

This is all very straightforward, but since the notion of $U_{\mathrm{G}}$ is not well known to some students, ${ }^{22}$ let me offer a very simple example. Consider a 1D deformation of the usual elastic spring providing the returning force $(-\kappa x)$, where $x$ is the deviation from spring's equilibrium. In order for the force to comply with Eq. (22), its potential energy should equal to $U=\kappa x^{2} / 2+$ const, so that its minimum corresponds to $x=0$. This works fine until the spring comes under effect of a nonvanishing external force $F$, say independent of $x$. Then the equilibrium deformation of the spring, $x_{0}=F / \kappa$, evidently corresponds not to the minimum of $U$ but rather to that of the Gibbs potential energy (41): $U_{\mathrm{G}}=U-F x=\kappa x^{2} / 2-F x+$ const.

### 1.6. OK, we've got it - can we go home now?

Not yet. In many cases the conservation laws discussed above provide little help, even in systems without dissipation. Consider for example a generalization of the bead-on-the-ring problem shown in Fig. 3, in which the ring is rotated by external forces, with a constant angular velocity $\omega$, about its vertical diameter (Fig. 5). ${ }^{23}$ In this problem (to which I will repeatedly return below, using it as

[^15]an analytical mechanics "testbed"), none of the three conservation laws listed in the last section, holds. In particular, bead's energy,
\[

$$
\begin{equation*}
E=\frac{m}{2} v^{2}+m g h, \tag{1.42}
\end{equation*}
$$

\]

is not constant, because the external forces rotating the ring may change it. Of course, we still can solve the problem using the Newton laws, but this is even more complex than for the above case of the ring at rest, in particular because the force $\mathbf{N}$ exerted on the bead by the ring now may have three rather than two Cartesian components, which are not simply related. One can readily see that if we could exclude the so-called reaction forces such as $\mathbf{N}$, that ensure external constraints of the particle motion, in advance, that would help a lot. Such an exclusion may be provided by analytical mechanics, in particular its Lagrangian formulation, which will be discussed in the next chapter.

Fig. 1.5. Bead sliding along a rotating ring.

An even more important motivation for analytical mechanics is given by dynamics of "nonmechanical" systems, for example, of the electromagnetic field - possibly interacting with charged particles, conducting bodies, etc. In many such systems, the easiest (and sometimes the only practicable) way to find the equations of motion is to derive then from the Lagrangian or Hamiltonian function of the system. In particular, the Hamiltonian formulation of the analytical mechanics (to be discussed in Chapter 10) offers a direct pathway to deriving Hamiltonian operators of systems, which is the standard entry point for analysis of their quantum-mechanical properties.

### 1.7. Self-test problems

1.1. A bicycle, ridden with velocity $v$ on a wet pavement, has no mudguards on its wheels. How far behind should the following biker ride to avoid being splashed over? Neglect the air resistance effects.
1.2. Two round disks of radius $R$ are firmly connected with a coaxial cylinder of a smaller radius $r$, and a thread is wound on the resulting spool. The spool is placed on a horizontal surface, and thread's end is being pooled out at angle $\varphi$-see Fig. on the right. Assuming that the spool does not slip on the surface, what direction would it roll?

(Sometimes the device is called the "Watt's governor", after the famous engineer J. Watts who used it in 1788 in one of his first steam engines, though it had been used in European windmills at least since the 1600s.)
1.3. Calculate the equilibrium shape of a flexible, heavy rope of length $l$, with a constant mass $\mu$ per unit length, if it is hung in a uniform gravity field between two points separated by a horizontal distance $d$ - see Fig. on the right.

1.4. A uniform, long, thin bar is placed horizontally on two similar round cylinders rotating toward each other with the same angular velocity $\omega$ and displaced by distance $d$ - see Fig. on the right. Calculate the laws of relatively slow horizontal motions of the bar within the plane of drawing for both possible directions of cylinder rotation, assuming that the friction force between the slipping surfaces of the bar and each cylinder obeys the usual simple law $|F|=\mu N$, where $N$ is the normal
 pressure force between them, and $\mu$ is a constant (velocityindependent) coefficient. Formulate the condition of validity of your result.
1.5. A small block slides, without friction, down a smooth slide that ends with a round loop of radius $R$ - see Fig. on the right. What smallest initial height $h$ allows the block to make its way around the loop without dropping from the slide, if it is launched with negligible initial velocity?

1.6. A satellite of mass $m$ is being launched from height $H$ over the surface of a spherical planet with radius $R$ and mass $M \gg m$ - see Fig. on the right. Find the range of initial velocities $\mathbf{v}_{0}$ (normal to the radius) providing closed orbits above the planet's surface.

1.7. Prove that the thin-uniform-disk model of a galaxy describes small harmonic oscillations of stars inside it along the direction normal to the disk, and calculate the frequency of these oscillations in terms of the Newton's gravitational constant $G$ and the average density $\rho$ of the star/dust matter of the galaxy.
1.8. Derive the differential equations of motion for small oscillations of two similar pendula coupled with a spring (see Fig. on the right), within the vertical plane. Assume that at the vertical position of both pendula, the spring is not stretched $(\Delta L=0)$.

1.9. One of popular futuristic concepts of travel is digging a straight railway tunnel through the Earth and letting a train go through it, without initial velocity - driven only by gravity. Calculate train's travel time through such a tunnel, assuming that the Earth's density $\rho$ is constant, and neglecting the friction and planet rotation effects.
1.10. A small bead of mass $m$ may slide, without friction, along a light string, stretched with a force $\mathscr{T} \gg m g$ between two points separated by a horizontal distance $2 d-$ see Fig. on the right. Calculate the frequency of horizontal oscillations of the bead about its equilibrium position.

1.11. Find the acceleration of a rocket due to the working jet motor, and explore the resulting equation of rocket's motion.

Hint: For the sake of simplicity, you may consider a 1D motion.
1.12. Prove the following virial theorem: ${ }^{24}$ for a set of $N$ particles performing a periodic motion,

$$
\bar{T}=-\frac{1}{2} \sum_{k=1}^{N} \overline{\mathbf{F}_{k} \cdot \mathbf{r}_{k}},
$$

where (as everywhere in these notes), the top bar means time averaging - in this case over the motion period. What does the virial theorem say about:
(i) the 1 D motion of a particle in a confining potential $U(x)=a x^{2 s}$, with $a>0$ and $s>0$, and
(ii) the orbital motion of a particle moving in a central potential $U(r)=-C / r$ ?

Hint: Explore the time derivative of the following scalar function of time: $G(t) \equiv \sum_{k=1}^{N} \mathbf{p}_{k} \cdot \mathbf{r}_{k}$.

[^16]
## Chapter 2. Lagrangian Formalism

The goal of this chapter is to describe the Lagrangian formulation of analytical mechanics, which is extremely useful for obtaining the differential equations of motion (and sometimes their first integrals) not only for mechanical systems with holonomic constraints, but also other dynamic systems.

### 2.1. Lagrange equations

In many cases, the constraints imposed on 3D motion of a system of $N$ particles may be described by $N$ vector (i.e. $3 N$ scalar) algebraic equations

$$
\begin{equation*}
\mathbf{r}_{k}=\mathbf{r}_{k}\left(q_{1}, q_{2}, \ldots, q_{j}, \ldots, q_{J}, t\right), \quad 1 \leq k \leq N \tag{2.1}
\end{equation*}
$$

where $q_{j}$ are certain generalized coordinates which (together with constraints) completely define the system position, and $J \leq 3 N$ is the number of the actual degrees of freedom. The constraints that allow such description are called holonomic. ${ }^{1}$

For example, for our testbed, bead-on-rotating-ring problem (see Fig. 1.5 and Fig. 1 below) $J=$ 1, because taking into account the constraints imposed by the ring, bead's position may be uniquely determined by just one generalized coordinate - for example, its polar angle $\theta$. Indeed, selecting the reference frame as shown in Fig. 1 and using the well-known formulas for the spherical coordinates, ${ }^{2}$ we see that in this case Eq. (1) in Cartesian coordinates has the form

$$
\begin{equation*}
\mathbf{r} \equiv\{x, y, z\}=\{R \sin \theta \cos \varphi, R \sin \theta \sin \varphi, R \cos \theta\}, \quad \text { where } \varphi=\omega t+\text { const } \tag{2.2}
\end{equation*}
$$

where the constant depends on the exact selection of axes $x$ and $y$ and the time origin. Since $\varphi(t)$ is a fixed function of time, and $R$ is a fixed constant, the position of particle in space at any instant $t$ is indeed completely determined by the value of its only generalized coordinate $\theta$. Note that the dimensionality of the generalized coordinate may be different from that of Cartesian coordinates (meters)!

Fig. 2.1. Bead on a rotating ring as a example of the system with just one degree of freedom: $J=1$.

[^17]Now returning to the general case of $J$ degrees of freedom, let us consider a set of small variations (alternatively called "virtual displacements") $\delta q_{j}$ allowed by the constraints. Virtual displacements differ from the actual small displacements (described by differentials $d q_{j}$ proportional to time variation $d t$ ) in that $\delta q_{j}$ describes not the system's motion as such, but rather its possible variation see Fig. 1.

Fig. 2.2. Actual displacement $d q_{j}$ vs. the virtual one (i.e. variation) $\delta q_{j}$.

Generally, operations with variations are the subject of a special field of mathematics, the calculus of variations. ${ }^{3}$ However, the only math background necessary for our current purposes is the understanding that operations with variations are similar to those with the usual differentials, though we need to watch carefully what each variable is a function of. For example, if we consider the variation of the radius-vectors (1), at a fixed time $t$, as a function of independent variations $\delta q_{j}$, we may use the usual formula for the differentiation of a function of several arguments: ${ }^{4}$

$$
\begin{equation*}
\delta \mathbf{r}_{k}=\sum_{j} \frac{\partial \mathbf{r}_{k}}{\partial q_{j}} \delta q_{j} \tag{2.3}
\end{equation*}
$$

Now let us break the force acting upon the $k$-th particle into two parts: the frictionless, constraining part $\mathbf{N}_{k}$ of the reaction force and the remaining part $\mathbf{F}_{k}$ - including the force components from other sources and possibly the friction part of the reaction force. Then the $2^{\text {nd }}$ Newton law for $k$-th particle of the system may be presented as

$$
\begin{equation*}
m_{k} \dot{\mathbf{v}}_{k}-\mathbf{F}_{k}=\mathbf{N}_{k} \tag{2.4}
\end{equation*}
$$

Since any variation of the motion has to be allowed by the constraints, its 3 N -dimensional vector with $N$ 3D-vector components $\delta \mathbf{r}_{k}$ has to be perpendicular to the 3 N -dimensional vector of the constraining forces, also with $N$ 3D-vector components $\mathbf{N}_{k}$. (For example, for the problem shown in Fig. 2.1, the virtual displacement vector $\delta \mathbf{r}_{k}$ may be directed only along the ring, while the constraining force $\mathbf{N}$, exerted by the ring, has to be perpendicular to that direction.) This condition may be expressed as

$$
\begin{equation*}
\sum_{k} \mathbf{N}_{k} \cdot \delta \mathbf{r}_{k}=0, \tag{2.5}
\end{equation*}
$$

[^18]where the scalar product of 3 N -dimensional vectors is defined exactly as that of 3 D vectors, i.e. as the sum of the products of the corresponding components of the operands. The substitution of Eq. (4) into Eq. (5) results in the so-called D'Alembert principle: ${ }^{5}$

D'Alembert principle

$$
\begin{equation*}
\sum_{k}\left(m_{k} \dot{\mathbf{v}}_{k}-\mathbf{F}_{k}\right) \cdot \delta \mathbf{r}_{k}=0 \tag{2.6}
\end{equation*}
$$

Now we may plug Eq. (3) into Eq. (6) to get

$$
\begin{equation*}
\sum_{j}\left\{\sum_{k} m_{k} \dot{\mathbf{v}}_{k} \cdot \frac{\partial \mathbf{r}_{k}}{\partial q_{j}}-\boldsymbol{7}_{j}\right\} \delta q_{j}=0 \tag{2.7}
\end{equation*}
$$

where scalars $\mathcal{7}_{j}$, called generalized forces, are defined as follows: ${ }^{6}$

$$
\begin{equation*}
\boldsymbol{7}_{j} \equiv \sum_{k} \mathbf{F}_{k} \cdot \frac{\partial \mathbf{r}_{k}}{\partial q_{j}} . \tag{2.8}
\end{equation*}
$$

Now we may use the standard argument of the calculus of variations: in order for the left-hand part of Eq. (7) to be zero for an arbitrary selection of independent variations $\delta q_{j}$, the expressions in the curly brackets, for every $j$, should equal zero. This gives us a set of $J$ equations

$$
\begin{equation*}
\sum_{k} m_{k} \dot{\mathbf{v}}_{k} \cdot \frac{\partial \mathbf{r}_{k}}{\partial q_{j}}-\boldsymbol{\gamma}_{j}=0 \tag{2.9}
\end{equation*}
$$

let us present them in a more convenient form. First, using the differentiation by parts to calculate the following time derivative:

$$
\begin{equation*}
\frac{d}{d t}\left(\mathbf{v}_{k} \cdot \frac{\partial \mathbf{r}_{k}}{\partial q_{j}}\right)=\dot{\mathbf{v}}_{k} \cdot \frac{\partial \mathbf{r}_{k}}{\partial q_{j}}+\mathbf{v}_{k} \frac{d}{d t}\left(\frac{\partial \mathbf{r}_{k}}{\partial q_{j}}\right) \tag{2.10}
\end{equation*}
$$

we may notice that the first term in the right-hand part is exactly the scalar product in the first term of Eq. (9).

Second, let us use another key fact of the calculus of variations (which is, essentially, evident from Fig. 3): the differentiation of a variable over time and over the generalized coordinate variation (at fixed time) are interchangeable operations.

Fig. 2.3. Variation of the differential (of any function $f$ ) equals the differential of its variation.

[^19]As a result, in the second term on the right-hand part of Eq. (10) we may write

$$
\begin{equation*}
\frac{d}{d t}\left(\frac{\partial \mathbf{r}_{k}}{\partial q_{j}}\right)=\frac{\partial}{\partial q_{j}}\left(\frac{d \mathbf{r}_{k}}{d t}\right) \equiv \frac{\partial \mathbf{v}_{k}}{\partial q_{j}} \tag{2.11}
\end{equation*}
$$

Finally, let us differentiate of Eq. (1) over time:

$$
\begin{equation*}
\mathbf{v}_{k} \equiv \frac{d \mathbf{r}_{k}}{d t}=\sum_{j} \frac{\partial \mathbf{r}_{k}}{\partial q_{j}} \dot{q}_{j}+\frac{\partial \mathbf{r}_{k}}{\partial t} \tag{2.12}
\end{equation*}
$$

This equation shows that particle velocities $\mathbf{v}_{k}$ may be considered as linear functions of the generalized velocities $\dot{q}_{j}$ considered as independent variables, with proportionality coefficients

$$
\begin{equation*}
\frac{\partial \mathbf{v}_{k}}{\partial \dot{q}_{j}}=\frac{\partial \mathbf{r}_{k}}{\partial q_{j}} \tag{2.13}
\end{equation*}
$$

With the account of Eqs. (10), (11), and (13), Eq. (9) turns into

$$
\begin{equation*}
\frac{d}{d t} \sum_{k} m_{k} \mathbf{v}_{k} \cdot \frac{\partial \mathbf{v}_{k}}{\partial \dot{q}_{j}}-\sum_{k} m_{k} \mathbf{v}_{k} \frac{\partial \mathbf{v}_{k}}{\partial q_{j}}-\mathcal{Z}_{j}=0 \tag{2.14}
\end{equation*}
$$

This result may be further simplified by making, for the total kinetic energy of the system,

$$
\begin{equation*}
T \equiv \sum_{k} \frac{m_{k}}{2} v_{k}^{2}=\frac{1}{2} \sum_{k} m_{k} \mathbf{v}_{k} \cdot \mathbf{v}_{k} \tag{2.15}
\end{equation*}
$$

the same commitment as for $\mathbf{v}_{k}$, i.e. considering $T$ a function of not only the generalized coordinates $q_{j}$ and time $t$, but also of the generalized velocities $\dot{q}_{i}$ - as variables independent of $q_{j}$ and $t$. Then we may calculate the partial derivatives of $T$ as

$$
\begin{equation*}
\frac{\partial T}{\partial q_{j}}=\sum_{k} m_{k} \mathbf{v}_{k} \cdot \frac{\partial \mathbf{v}_{k}}{\partial q_{j}}, \quad \frac{\partial T}{\partial \dot{q}_{j}}=\sum_{k} m_{k} \mathbf{v}_{k} \cdot \frac{\partial \mathbf{v}_{k}}{\partial \dot{q}_{j}} \tag{2.16}
\end{equation*}
$$

and notice that they are exactly the two sums participating in Eq. (14). As a result, we get a system of $J$ Lagrange equations, ${ }^{7}$

$$
\begin{equation*}
\frac{d}{d t} \frac{\partial T}{\partial \dot{q}_{j}}-\frac{\partial T}{\partial q_{j}}-7_{j}=0, \quad \text { for } j=1,2, \ldots, J \tag{2.17}
\end{equation*}
$$

Their big advantage over the initial Newton law equations (4) is that the Lagrange equations do not include the constraining forces $\mathbf{N}_{\mathrm{k}}$.

This is as far as we can go for arbitrary forces. However, if all the forces may be expressed in the form similar but somewhat more general than Eq. (1.31), $\mathbf{F}_{k}=-\nabla_{k} U\left(\mathbf{r}_{1}, \mathbf{r}_{2}, \ldots, \mathbf{r}_{N}, t\right.$, where $U$ is the

[^20]effective potential energy of the system, ${ }^{8}$ and $\operatorname{sign} \nabla_{k}$ denotes differentiation over coordinates of $k$-th particle, we may recast Eq. (8) into a simpler form:
\[

$$
\begin{equation*}
\boldsymbol{Z}_{j} \equiv \sum_{k} \mathbf{F}_{k} \cdot \frac{\partial \mathbf{r}_{k}}{\partial q_{j}}=-\sum_{k}\left(\frac{\partial U}{\partial x_{k}} \cdot \frac{\partial x_{k}}{\partial q_{j}}+\frac{\partial U}{\partial y_{k}} \cdot \frac{\partial y_{k}}{\partial q_{j}}+\frac{\partial U}{\partial z_{i}} \cdot \frac{\partial z_{i}}{\partial q_{j}}\right) \equiv-\frac{\partial U}{\partial q_{j}} . \tag{2.18}
\end{equation*}
$$

\]

Since we assume that $U$ depends only on particle coordinates (and possibly time), but not velocities, $\partial U / \partial \dot{q}_{j}=0$, with the substitution of Eq. (18), the Lagrange equation (17) may be presented in its canonical form

Canonical Lagrange equations

$$
\begin{equation*}
\frac{d}{d t} \frac{\partial L}{\partial \dot{q}_{j}}-\frac{\partial L}{\partial q_{j}}=0, \quad \text { where } L \equiv T-U \tag{2.19a}
\end{equation*}
$$

where $L$ is called the Lagrangian function (or just the "Lagrangian"), defined as

$$
\begin{equation*}
L \equiv T-U . \tag{2.19b}
\end{equation*}
$$

It is crucial to distinguish this function from the mechanical energy (1.26), $E=T+U$.
Using the Lagrangian formalism in practice, the reader should always remember that:
(i) Each system has only one Lagrange function $L$, but is described by $J \geq 1$ Lagrange equations of motion (for $j=1,2, \ldots, J$ ).
(ii) Differentiating $T$, we have to consider the generalized velocities $\dot{q}_{j}$ as independent variables, ignoring the fact they are actually the time derivatives of $q_{j}$.

### 2.2. Examples

As the first, simplest example, consider a particle constrained to move along one axis (say, $x$ ):

$$
\begin{equation*}
T=\frac{m}{2} \dot{x}^{2}, \quad U=U(x, t) \tag{2.20}
\end{equation*}
$$

In this case, it is natural to consider $x$ as the (only) generalized coordinate, and $\dot{x}$ as the generalized velocity, so that

$$
\begin{equation*}
L \equiv T-U=\frac{m}{2} \dot{x}^{2}-U(x, t) . \tag{2.21}
\end{equation*}
$$

Considering $\dot{x}$ an independent variable, we get $\partial L / \partial \dot{x}=m \dot{x}$, and $\partial L / \partial x=-\partial U / \partial x$, so that the Lagrange equation of motion (only one equation in this case of the single degree of freedom!) yields

$$
\begin{equation*}
\frac{d}{d t}(m \dot{x})-\left(-\frac{\partial U}{\partial x}\right)=0, \tag{2.22}
\end{equation*}
$$

[^21]evidently the same result as the $x$-component of the $2^{\text {nd }}$ Newton law with $F_{x}=-\partial U / \partial x$. This is a good sanity check, but we see that the Lagrange formalism does not provide too much advantage in this particular case.

This advantage is, however, evident for our testbed problem - see Fig. 1. Indeed, taking the polar angle $\theta$ for the (only) generalized coordinate, we see that in this case the kinetic energy depends not only on the generalized velocity, but also on the generalized coordinate: ${ }^{9}$

$$
\begin{align*}
& T=\frac{m}{2} R^{2}\left(\dot{\theta}^{2}+\omega^{2} \sin ^{2} \theta\right), \quad U=-m g z+\text { const }=-m g R \cos \theta+\text { const },  \tag{2.23}\\
& L \equiv T-U=\frac{m}{2} R^{2}\left(\dot{\theta}^{2}+\omega^{2} \sin ^{2} \theta\right)+m g R \cos \theta+\text { const. }
\end{align*}
$$

Here it is especially important to remember that at substantiating the Lagrange equation, $\theta$ and $\dot{\theta}$ have to be treated as independent arguments of $L$, so that

$$
\begin{equation*}
\frac{\partial L}{\partial \dot{\theta}}=m R^{2} \dot{\theta}, \quad \frac{\partial L}{\partial \theta}=m R^{2} \omega^{2} \sin \theta \cos \theta-m g R \sin \theta \tag{2.24}
\end{equation*}
$$

giving us the following equation of motion:

$$
\begin{equation*}
\frac{d}{d t}\left(m R^{2} \dot{\theta}\right)-\left(m R^{2} \omega^{2} \sin \theta \cos \theta-m g R \sin \theta\right)=0 \tag{2.25}
\end{equation*}
$$

As a sanity check, at $\omega=0$, Eq. (25) is reduced to the correct equation of the usual pendulum:

$$
\begin{equation*}
\ddot{\theta}+\Omega^{2} \sin \theta=0, \quad \text { where } \Omega \equiv\left(\frac{g}{R}\right)^{1 / 2} . \tag{2.26}
\end{equation*}
$$

We will explore the full dynamic equation (25) in more detail later, but please note how simple its derivation was - in comparison with writing the Newton laws and then excluding the reaction force.

Next, though the Lagrangian formalism was derived from the Newton law for mechanical systems, the resulting equations (19) are applicable to other dynamic systems, especially those for which the kinetic and potential energies may be readily expressed via some generalized coordinates. As the simplest example, consider the well-known connection (Fig. 4) of a capacitor with capacitance $C$ to an inductive coil with self-inductance $L .{ }^{10}$ (Electrical engineers frequently call it the $L C$ tank circuit.)

Fig. 2.4. $L C$ tank circuit.

[^22]As the reader certainly knows, at relatively low frequencies we may use the so-called lumpedcircuit approximation, in which the total energy of the system as the sum of two components, the electric energy $E_{C}$ localized inside the capacitor, and the magnetic energy $E_{L}$ localized inside the inductance coil

$$
\begin{equation*}
E_{C}=\frac{Q^{2}}{2 C}, \quad E_{L}=\frac{L I^{2}}{2} \tag{2.27}
\end{equation*}
$$

Since the electric current $I$ through the coil and the electric charge $Q$ on the capacitor are connected by the charge continuity equation $d Q / d t=I$ (evident from Fig. 4), it is natural to declare the charge a generalized coordinate, and the current, the generalized velocity. With this choice, the electrostatic energy $E_{C}(Q)$ may be treated as the potential energy $U$ of the system, and the magnetic energy $E_{L}(I)$, as its kinetic energy $T$. With this attribution, we get

$$
\begin{equation*}
\frac{\partial T}{\partial \dot{q}} \equiv \frac{\partial E_{L}}{\partial I}=L I \equiv L \dot{Q}, \quad \frac{\partial T}{\partial q} \equiv \frac{\partial E_{L}}{\partial Q}=0, \quad \frac{\partial U}{\partial q} \equiv \frac{\partial E_{C}}{\partial Q}=\frac{Q}{C} \tag{2.28}
\end{equation*}
$$

so that the Lagrange equation of motion is

$$
\begin{equation*}
\frac{d}{d t}(L \dot{Q})-\left(-\frac{Q}{C}\right)=0 \tag{2.29}
\end{equation*}
$$

Note, however, that the above choice of the generalized coordinate and velocity is not unique. Instead, one can use as the generalized coordinate the magnetic flux $\Phi$ through the inductive coil, related to the common voltage $V$ across the circuit (Fig. 4) by Faraday's induction law $V=-d \Phi / d t$. With this choice, $(-V)$ becomes the generalized velocity, $E_{L}=\Phi^{2} / 2 L$ should be understood as the potential energy, and $E_{C}=C V^{2} / 2$ treated as the kinetic energy. It is straightforward to verify that for this choice, the resulting Lagrange equation of motion is equivalent to Eq. (29). If both parameters of the circuit, $L$ and $C$, are constant in time, Eq. (29) is just the harmonic oscillator equation similar to Eq. (1.1), and describes sinusoidal oscillations with frequency

$$
\begin{equation*}
\omega_{0}=\frac{1}{(L C)^{1 / 2}} . \tag{2.30}
\end{equation*}
$$

This is of course a very well known result that may be derived in the more standard way by equating the voltage drops across the capacitor $(V=Q / C)$ and the inductor $\left(V=-L d I / d t=-L d^{2} Q / d t^{2}\right)$. However, the Lagrangian approach is much more convenient for more complex systems, for example, for the description of electromagnetic field and its interaction with charged relativistic particles. ${ }^{11}$

### 2.3. Hamiltonian function and energy

The canonical form (19) of the Lagrange equation has been derived using Eq. (18), which is formally similar to Eq. (1.22) for a potential force. Does this mean that the system described by Eq. (19) always conserves energy? Not necessarily, because the "potential energy" $U$, that participates in Eq. (18), may depend not only on the generalized coordinates, but on time as well. Let us start the analysis of this issue with the introduction of two new (and very important!) notions: the generalized momenta corresponding to each generalized coordinate $q_{j}$,

[^23]\[

$$
\begin{equation*}
p_{j} \equiv \frac{\partial L}{\partial \dot{q}_{j}} \tag{2.31}
\end{equation*}
$$

\]

and the Hamiltonian function ${ }^{12}$

$$
\begin{equation*}
H \equiv \sum_{j} \frac{\partial L}{\partial \dot{q}_{j}} \dot{q}_{j}-L \equiv \sum_{j} p_{j} \dot{q}_{j}-L \tag{2.32}
\end{equation*}
$$

In order to see whether the Hamiltonian function is conserved, let us differentiate its definition (32) over time:

$$
\begin{equation*}
\frac{d H}{d t}=\sum_{j}\left[\frac{d}{d t}\left(\frac{\partial L}{\partial \dot{q}_{j}}\right) \dot{q}_{j}+\frac{\partial L}{\partial \dot{q}_{j}} \ddot{q}_{j}\right]-\frac{d L}{d t} . \tag{2.33}
\end{equation*}
$$

If we want to make use of the Lagrange equation (19), the last derivative has to be calculated considering $L$ as a function of independent arguments $q_{j}, \dot{q}_{j}$, and $t$ :

$$
\begin{equation*}
\frac{d L}{d t}=\sum_{j}\left(\frac{\partial L}{\partial q_{j}} \dot{q}_{j}+\frac{\partial L}{\partial \dot{q}_{j}} \ddot{q}_{j}\right)+\frac{\partial L}{\partial t}, \tag{2.34}
\end{equation*}
$$

where the last term is the derivative of $L$ as an explicit function of time. We see that the last term in the square brackets of Eq. (33) immediately cancels with the last term in the parentheses of Eq. (34). Moreover, using the Lagrange equation (19) for the first term in the square brackets of Eq. (33), we see that it cancels with the first term in the parentheses of Eq. (34). Thus we arrive at a very simple and important result:

$$
\begin{equation*}
\frac{d H}{d t}=-\frac{\partial L}{\partial t} \tag{2.35}
\end{equation*}
$$

Hamiltonian function
and coincides with particle's mechanical energy $E=T+U$. Since the Lagrangian does not depend on time explicitly, both $H$ and $E$ are conserved.

However, it is not always that simple! Indeed, let us return again to our testbed problem (Fig. 1). In this case, the generalized momentum corresponding to the generalized coordinate $\theta$ is

$$
\begin{equation*}
p_{\theta} \equiv \frac{\partial L}{\partial \dot{\theta}}=m R^{2} \dot{\theta} \tag{2.39}
\end{equation*}
$$

and Eq. (32) yields:

$$
\begin{align*}
H & \equiv p_{\theta} \dot{\theta}-L=m R^{2} \dot{\theta}^{2}-\left[\frac{m}{2} R^{2}\left(\dot{\theta}^{2}+\omega^{2} \sin ^{2} \theta\right)+m g R \cos \theta\right]+\mathrm{const}  \tag{2.40}\\
& =\frac{m}{2} R^{2}\left(\dot{\theta}^{2}-\omega^{2} \sin ^{2} \theta\right)-m g R \cos \theta+\text { const. }
\end{align*}
$$

This means that (as soon as $\omega \neq 0$ ), the Hamiltonian function differs from the mechanical energy

$$
\begin{equation*}
E \equiv T+U=\frac{m}{2} R^{2}\left(\dot{\theta}^{2}+\omega^{2} \sin ^{2} \theta\right)-m g R \cos \theta+\text { const } . \tag{2.41}
\end{equation*}
$$

The difference, $E-H=m R^{2} \omega^{2} \sin ^{2} \theta$ (besides an inconsequential constant), may change at bead's motion along the ring, so that although $H$ is an integral of motion (since $\partial L / \partial t=0$ ), energy $E$ is not conserved.

Let us find out when do these two functions, $E$ and $H$, coincide. In mathematics, there is a notion of a homogeneous function $f\left(x_{1}, x_{2}, \ldots\right)$ of degree $\lambda$, defined in the following way: for an arbitrary constant $a$,

$$
\begin{equation*}
f\left(a x_{1}, a x_{2}, \ldots\right)=a^{\lambda} f\left(x_{1}, x_{2}, \ldots\right) \tag{2.42}
\end{equation*}
$$

Such functions obey the following Euler theorem: ${ }^{13}$

$$
\begin{equation*}
\sum_{j} \frac{\partial f}{\partial x_{j}} x_{j}=\lambda f \tag{2.43}
\end{equation*}
$$

that may be readily proven by differentiating both parts of Eq. (42) over $a$ and then setting this parameter to the particular value $a=1$. Now, consider the case when the kinetic energy is a quadratic form of all generalized velocities $\dot{q}_{j}$ :

$$
\begin{equation*}
T=\sum_{j, j^{\prime}} t_{j j^{\prime}}\left(q_{1}, q_{2}, \ldots, t\right) \dot{q}_{j} \dot{q}_{j^{\prime}}, \tag{2.44}
\end{equation*}
$$

with no other terms. It is evident that such $T$ satisfies the definition of a homogeneous function of the velocities with $\lambda=2,{ }^{14}$ so that the Euler theorem (43) gives

$$
\begin{equation*}
\sum_{j} \frac{\partial T}{\partial \dot{q}_{j}} \dot{q}_{j}=2 T . \tag{2.45}
\end{equation*}
$$

[^24]But since $U$ is independent of the generalized velocities, $\partial L / \partial \dot{q}_{j}=\partial T / \partial \dot{q}_{j}$, and the left-hand part of Eq. (45) is exactly the first term in the definition (32) of the Hamiltonian function, so that in this case

$$
\begin{equation*}
H=2 T-L=2 T-(T-U)=T+U=E . \tag{2.46}
\end{equation*}
$$

So, for the kinetic energy of the type (44), for example a free particle with the kinetic energy considered as a function of its Cartesian velocities,

$$
\begin{equation*}
T=\frac{m}{2}\left(v_{x}^{2}+v_{y}^{2}+v_{z}^{2}\right), \tag{2.47}
\end{equation*}
$$

the notions of the Hamiltonian function and mechanical energy are identical. (Indeed, some textbooks, very regretfully, do not distinguish these notions at all!) However, as we have seen from our bead-on-the-rotating-ring example, this is not always true. For that problem, the kinetic energy, in addition to the term proportional to $\dot{\theta}^{2}$, has another, velocity-independent term - see the first of Eqs. (23) - and hence is not a quadratic-homogeneous function of the angular velocity.

Thus, Eq. (36) expresses a new conservation law, generally different from that of the mechanical energy conservation.

### 2.4. Other conservation laws

Looking at the Lagrange equation (19), we immediately see that if $L \equiv T-U$ as a whole is independent of some generalized coordinate $q_{j}, \partial L / \partial q_{j}=0,{ }^{15}$ then the corresponding generalized momentum is an integral of motion: ${ }^{16}$

$$
\begin{equation*}
p_{j} \equiv \frac{\partial L}{\partial \dot{q}_{j}}=\text { const. } \tag{2.48}
\end{equation*}
$$

For example, for a 1D particle with Lagrangian (21), momentum $p_{x}$ is conserved if the potential energy is constant (the $x$-component of force is zero) - of course. As a less obvious example, let us consider a 2D motion of a particle in the field of central forces. If we use polar coordinates $r$ and $\varphi$ in the role of the generalized coordinates, the Lagrangian function, ${ }^{17}$

$$
\begin{equation*}
L \equiv T-U=\frac{m}{2}\left(\dot{r}^{2}+r^{2} \dot{\varphi}^{2}\right)-U(r) \tag{2.49}
\end{equation*}
$$

is independent of $\varphi$ and hence the corresponding generalized momentum,

$$
\begin{equation*}
p_{\varphi} \equiv \frac{\partial L}{\partial \dot{\varphi}}=m r^{2} \dot{\varphi} \tag{2.50}
\end{equation*}
$$

[^25]is conserved. This is just a particular (2D) case of the angular momentum conservation - see Eq. (1.24). Indeed, for the 2D motion within the $[x, y]$ plane, the angular momentum vector,
\[

\mathbf{L} \equiv \mathbf{r} \times \mathbf{p}=\left|$$
\begin{array}{ccc}
\mathbf{n}_{x} & \mathbf{n}_{y} & \mathbf{n}_{z}  \tag{2.51}\\
x & y & z \\
m \dot{x} & m \dot{y} & m \dot{z}
\end{array}
$$\right|,
\]

has only one nonvanishing component, perpendicular to the motion plane:

$$
\begin{equation*}
L_{z}=x(m \dot{y})-y(m \dot{x}) . \tag{2.52}
\end{equation*}
$$

Differentiating the well-known relations between the polar and Cartesian coordinates,

$$
\begin{equation*}
x=r \cos \varphi, \quad y=r \sin \varphi, \tag{2.53}
\end{equation*}
$$

over time, and plugging the result into Eq. (52), we see that $L_{z}=m r^{2} \dot{\varphi}=p_{\varphi}$.
Thus the Lagrangian formalism provides a powerful way of searching for non-evident integrals of motion. On the other hand, if such conserved quantity is evident or known a priori, it is helpful for the selection of the most appropriate generalized coordinates, giving the simplest Lagrange equations. For example, in the last problem, if we have known in advance that $p_{\varphi}$ had to be conserved, this could provide a motivation for using angle $\varphi$ as one of generalized coordinates.

### 2.5. Exercise problems

In each of Problems 2.1-2.10:
(i) introduce a set of convenient generalized coordinate(s) $q_{j}$ of the system,
(ii) write down Lagrangian $L$ as a function of $q_{j}, \dot{q}_{j}$, and (if appropriate) time,
(iii) write down the Lagrangian equation(s) of motion,
(iv) calculate the Hamiltonian function $H$; find out whether it is conserved,
(v) calculate energy $E$; is $E=H$ ?; is energy conserved?
(vi) any other evident integrals of motion?
2.1. Double pendulum - see Fig. on the right. Consider only the motion confined to a vertical plane containing the suspension point.

2.2. Stretchable pendulum (i.e. a mass hung on an elastic cord that exerts force $F$ $=-\kappa\left(l-l_{0}\right)$, where $\kappa$ and $l_{0}$ are positive constants), confined to a vertical plane:

2.3. Fixed-length pendulum hanging from a horizontal support whose motion law $x_{0}(t)$ is fixed. (No vertical plane constraint here.)

2.4. A pendulum of mass $m$ hung on another point mass $m$ ' that may slide, without friction, along a straight horizontal rail (see Fig. on the right). Its motion is confined to the vertical plane that contains the rail.
2.5. A bead of mass $m$, sliding without friction along a light string stretched by fixed force $T$, between two horizontally displaced points - see Fig. on the right. Here, in contrast to the similar Problem 1.10, string tension $T$ may be comparable with bead's weight mg , and
 the motion is not restricted to the vertical plane.
2.6. A bead of mass $m$, sliding without friction along a light string of fixed length $2 l$, which is hung between two points, horizontally displaced by distance $2 d<2 l-$ see Fig. on the right. As in the previous problem, the motion is not restricted to the vertical plane.

2.7. A block of mass $m$ that can slide, without friction, along the inclined plane surface of a heavy wedge with mass $m^{\prime}$. The wedge is free to move, also without friction, along a horizontal surface - see Fig. on the right. (Both motions are within the vertical plane containing the steepest slope line.)
2.8. The two-pendula system that was the subject of Problem $1.8-$ see Fig. on the right.

2.9. A system of two similar, inductively-coupled LC circuits - see Fig. on the right.

2.10.* A small Josephson junction, i.e. a system of two superconductors coupled by Cooper-pair tunneling through a thin insulating layer that separates them (see Fig. on the right).

Hints:
(i) At not very high frequencies (whose quantum $\hbar \omega$ is lower than the binding energy $2 \Delta$ of the Cooper pairs), the Josephson effect may be described by coupling energy

$$
U(\varphi)=-E_{\mathrm{J}} \cos \varphi+\text { const },
$$

where constant $E_{\mathrm{J}}$ describes the coupling strength, and variable $\varphi$ (called the Josephson phase difference) is related to voltage $V$ across the junction via the famous frequency-to-voltage relation

$$
\frac{d \varphi}{d t}=\frac{2 e}{\hbar} V,
$$

where $e \approx 1.6 \times 10^{-19} \mathrm{C}$ is the fundamental electric charge and $\hbar \approx 1.054 \times 10^{-34} \mathrm{~J} \cdot \mathrm{~s}$ is the Planck constant. ${ }^{18}$ (ii) The junction (as any system of two close conductors) has a substantial electric capacitance $C$.

[^26]

## Chapter 3. A Few Simple Problems

In this chapter, I will review the solutions of a few simple but very important problems of particle motion, that may be reduced to one dimension, including the famous "planetary" problem of two particles interacting via a spherically-symmetric potential. In the process, we will discuss several methods that will be useful for the analysis of more complex systems.

### 3.1. One-dimensional and 1D-reducuble systems

If a particle is confined to motion along a straight line (say, axis $x$ ), its position, of course, is completely defined by this coordinate. In this case, as we already know, particle's Lagrangian is given by Eq. (2.21):

$$
\begin{equation*}
L=T(\dot{x})-U(x, t), \quad T(\dot{x})=\frac{m}{2} \dot{x}^{2} \tag{3.1}
\end{equation*}
$$

so that the Lagrange equation of motion (2.22)

$$
\begin{equation*}
m \ddot{x}=-\frac{\partial U(x, t)}{\partial x} \tag{3.2}
\end{equation*}
$$

is just the $x$-component of the $2^{\text {nd }}$ Newton law.
It is convenient to discuss the dynamics of such really $1 D$ systems in the same breath with that of effectively $1 D$ systems whose position, due to holonomic constraints and/or conservation laws, is also fully determined by one generalized coordinate $q$, and whose Lagrangians may be presented in a form similar to Eq. (1):

$$
\begin{equation*}
L=T_{\mathrm{ef}}(\dot{q})-U_{\mathrm{ef}}(q, t), \quad T_{\mathrm{ef}}=\frac{m_{\mathrm{ef}}}{2} \dot{q}^{2} \tag{3.3}
\end{equation*}
$$

where $m_{\mathrm{ef}}$ is some constant which may be considered as the effective mass of the system, and the function $U_{\text {ef }}$ its effective potential energy. In this case the Lagrange equation (2.19) describing the system dynamics has a form similar to Eq. (2):

$$
\begin{equation*}
m_{\mathrm{ef}} \ddot{q}=-\frac{\partial U_{\mathrm{ef}}(q, t)}{\partial q} . \tag{3.4}
\end{equation*}
$$

As an example, let us return again to our testbed system shown in Fig. 1.5. We have already seen that for that system, having one degree of freedom, the genuine kinetic energy $T$, expressed by the first of Eqs. (2.23), is not a quadratically-homogeneous function of the generalized velocity. However, the system's Lagrangian (2.23) still may be presented in form (3),

$$
\begin{equation*}
L=\frac{m}{2} R^{2} \dot{\theta}^{2}+\frac{m}{2} R^{2} \omega^{2} \sin ^{2} \theta+m g R \cos \theta+\mathrm{const}=T_{\mathrm{ef}}-U_{\mathrm{ef}}, \tag{3.5}
\end{equation*}
$$

if we take

$$
\begin{equation*}
T_{\mathrm{ef}} \equiv \frac{m}{2} R^{2} \dot{\theta}^{2}, \quad U_{\mathrm{ef}} \equiv-\frac{m}{2} R^{2} \omega^{2} \sin ^{2} \theta-m g R \cos \theta+\text { const. } \tag{3.6}
\end{equation*}
$$

In this new partitioning of function $L$, which is legitimate because $U_{\text {ef }}$ depends only on the generalized coordinate $\theta$, but not on the corresponding generalized velocity, $T_{\text {ef }}$ includes only a part of the full kinetic energy $T$ of the bead, while $U_{\text {ef }}$ includes not only the real potential energy $U$ of the bead in the gravity field, but also an additional term related to ring rotation. (As we will see in Sec. 6.6, this term may be interpreted as the effective potential energy due to the inertial centrifugal "force".)

Returning to the general case of effectively 1D systems with Lagrangian (3), let us calculate their Hamiltonian function, using its definition (2.32):

$$
\begin{equation*}
H=\frac{\partial L}{\partial \dot{q}} \dot{q}-L=m_{\mathrm{ef}} \dot{q}^{2}-\left(T_{\mathrm{ef}}-U_{\mathrm{ef}}\right)=T_{\mathrm{ef}}+U_{\mathrm{ef}} \tag{3.7}
\end{equation*}
$$

So, $H$ is expressed via $T_{\text {ef }}$ and $U_{\text {ef }}$ exactly as the mechanical energy $E$ is expressed via genuine $T$ and $U$.

### 3.2. Equilibrium and stability

Autonomous systems are defined as the dynamic systems whose equations of motion do not depend on time. For 1D (and effectively 1D) systems obeying Eq. (4), this means that their function $U_{\text {ef }}$, and hence the Lagrangian function (5) should not depend on time explicitly. According to Eqs. (2.35), in such systems the Hamiltonian function (7), i.e. the sum $T_{\text {ef }}+U_{\text {ef }}$, is an integral of motion. However, be careful! This may not be true for system's mechanical energy $E$; for example, as we already know from Sec. 2.2, for our testbed problem, with the generalized coordinate $q=\theta$ (Fig. 2.1), $H \neq E$.

According to Eq. (4), an autonomous system, at appropriate initial conditions, may stay in equilibrium at one or several stationary (alternatively called fixed) points $q_{n}$, corresponding to either the minimum or a maximum of the effective potential energy (see Fig. 1):

$$
\begin{equation*}
\frac{d U_{\mathrm{ef}}}{d q}\left(q_{n}\right)=0 \tag{3.8}
\end{equation*}
$$

In order to explore the stability of such fixed points, let us analyze the dynamics of small deviations

$$
\begin{equation*}
\widetilde{q}(t) \equiv q(t)-q_{n} \tag{3.9}
\end{equation*}
$$

from the equilibrium. For that, let us expand function $U_{\text {ef }}(\mathrm{q})$ in the Taylor series at a fixed point,

$$
\begin{equation*}
U_{\mathrm{ef}}(q)=U_{\mathrm{ef}}\left(q_{n}\right)+\frac{d U_{\mathrm{ef}}}{d q}\left(q_{n}\right) \widetilde{q}+\frac{1}{2} \frac{d^{2} U_{\mathrm{ef}}}{d q^{2}}\left(q_{n}\right) \widetilde{q}^{2}+\ldots \tag{3.10}
\end{equation*}
$$

The first term in the right-hand part, $U_{\text {ef }}\left(q_{n}\right)$, is arbitrary and does not affect motion. The next term, linear in deviation $\widetilde{q}$, is equal zero - see the fixed point definition (8). Hence the fixed point stability is determined by the next term, quadratic in $\widetilde{q}$, more exactly by its coefficient,

$$
\begin{equation*}
\kappa_{\mathrm{ef}} \equiv \frac{d^{2} U_{\mathrm{ef}}}{d q^{2}}\left(q_{n}\right) \tag{3.11}
\end{equation*}
$$

which plays the role of the effective spring constant. Indeed, neglecting the higher terms of the Taylor expansion (10), ${ }^{1}$ we see that Eq. (4) takes the familiar form - cf. Eq. (1.1):

$$
\begin{equation*}
m_{\mathrm{ef}} \ddot{\tilde{q}}+\kappa_{\mathrm{ef}} \widetilde{q}=0 . \tag{3.12}
\end{equation*}
$$

I am confident that the reader of these notes knows everything about this equation, but since we will soon run into similar but more complex equations, let us review the formal procedure of its solution. From the mathematical standpoint, Eq. (12) is an ordinary, linear differential equation of the second order, with constant coefficients. The theory of such equations tells us that its general solution (for any initial conditions) may be presented as

$$
\begin{equation*}
\widetilde{q}(t)=c_{+} e^{\lambda_{+} t}+c_{-} e^{\lambda_{-} t} \tag{3.13}
\end{equation*}
$$

where constants $c_{ \pm}$are determined by initial conditions, while the so-called characteristic exponents $\lambda_{ \pm}$ are completely defined by the equation itself. In order to find the exponents, it is sufficient to plug just one partial solution, $\exp \{\lambda t\}$, into the equation. In our simple case (12), this yields the following characteristic equation:

$$
\begin{equation*}
m_{\mathrm{ef}} \lambda^{2}+\kappa_{\mathrm{ef}}=0 \tag{3.14}
\end{equation*}
$$

If the ratio $k_{\mathrm{ef}} / m_{\mathrm{ef}}$ is positive, ${ }^{2}$ i.e. the fixed point corresponds to the minimum of potential energy (e.g., points $q_{0}$ and $q_{2}$ in Fig. 1), the characteristic equation yields

$$
\begin{equation*}
\lambda_{ \pm}= \pm i \omega_{0}, \quad \omega_{0} \equiv\left(\frac{\kappa_{\mathrm{ef}}}{m_{\mathrm{ef}}}\right)^{1 / 2} \tag{3.15}
\end{equation*}
$$

(where $i$ is the imaginary unit, $i^{2}=-1$ ), so that Eq. (13) describes sinusoidal oscillations of the system,

$$
\begin{equation*}
\widetilde{q}(t)=c_{+} e^{+i \omega_{0} t}+c_{-} e^{-i \omega_{0} t}=c_{c} \cos \omega_{0} t+c_{s} \sin \omega_{0} t \tag{3.16}
\end{equation*}
$$

with eigenfrequency (or "own frequency") $\omega_{0}$, about the fixed point which is thereby stable. On the other hand, at the potential energy maximum ( $k_{\mathrm{ef}}<0$, e.g., at point $q_{1}$ in Fig. 1), we get

$$
\begin{equation*}
\lambda_{ \pm}= \pm \lambda, \quad \lambda \equiv\left(\frac{\left|\kappa_{\mathrm{ef}}\right|}{m_{\mathrm{ef}}}\right)^{1 / 2}, \quad \widetilde{q}(t)=c_{+} e^{+\lambda t}+c_{-} e^{-\lambda t} . \tag{3.17}
\end{equation*}
$$

Since the solution has an exponentially growing part, ${ }^{3}$ the fixed point is unstable.

[^27]Note that the quadratic expansion of function $U_{\text {ef }}(q)$, given by Eq. (10), is equivalent to a linear expansion of the effective force:

$$
\begin{equation*}
F_{\mathrm{ef}} \equiv-\left.\frac{d U_{\mathrm{ef}}}{d q}\right|_{q=q_{n}} \approx-\kappa_{\mathrm{ef}} \widetilde{q}, \tag{3.18}
\end{equation*}
$$

immediately resulting in the linear equation (12). Hence, in order to analyze the stability of a fixed point $q_{n}$, it is sufficient to linearize the equation of motion in small deviations from that point, and study possible solutions of the resulting linear equation.

As an example, let us return to our testbed problem (Fig. 2.1) whose function $U_{\text {ef }}$ we already know - see the second of Eqs. (6). With it, the equation of motion (4) becomes

$$
\begin{equation*}
m R^{2} \ddot{\theta}=-\frac{d U_{\mathrm{ef}}}{d \theta}=m R^{2}\left[\omega^{2} \cos \theta-\Omega^{2}\right] \sin \theta, \text { i.e. } \ddot{\theta}=\left[\omega^{2} \cos \theta-\Omega^{2}\right] \sin \theta \tag{3.19}
\end{equation*}
$$

where $\Omega \equiv(g / R)^{1 / 2}$ is the frequency of small oscillations of the system at $\omega=0$ - see Eq. (2.26). ${ }^{4}$ From requirement (8), we see that on any $2 \pi$-long segment of angle $\theta,{ }^{5}$ the system may have four fixed points:

$$
\begin{equation*}
\theta_{0}=0, \quad \theta_{1}=\pi, \quad \theta_{2,3}= \pm \cos ^{-1} \frac{\Omega^{2}}{\omega^{2}} \tag{3.20}
\end{equation*}
$$

The last two fixed points, corresponding to the bead rotating on either side of the ring, exist only if the angular velocity $\omega$ of ring rotation exceeds $\Omega$. (In the limit of very fast rotation, $\omega \gg \Omega$, Eq. (20) yields $\theta_{2,3} \rightarrow \pm \pi / 2$, i.e. the stationary positions approach the horizontal diameter of the ring - in accordance with physical intuition.)

In order to analyze the fixed point stability, similarly to Eq. (9), we plug $\theta=\theta_{n}+\widetilde{\theta}$ into Eq. (19) and Taylor-expand the trigonometric functions of $\theta$ up to the first term in $\widetilde{\theta}$ :

$$
\begin{equation*}
\ddot{\tilde{\theta}}=\left[\omega^{2}\left(\cos \theta_{n}-\sin \theta_{n} \widetilde{\theta}\right)-\Omega^{2}\right]\left(\sin \theta_{n}+\cos \theta_{n} \widetilde{\theta}\right) \tag{3.21}
\end{equation*}
$$

Generally, this equation may be linearized further by purging its right-hand part of the term proportional to $\widetilde{\theta}^{2}$; however in this simple case, Eq. (21) is already convenient for analysis. In particular, for the fixed point $\theta_{0}=0$ (corresponding to the bead position at the bottom of the ring), we have $\cos \theta_{0}=1$ and $\sin \theta_{0}=0$, so that Eq. (21) is reduced to a linear differential equation

$$
\begin{equation*}
\ddot{\tilde{\theta}}=\left(\omega^{2}-\Omega^{2}\right) \tilde{\theta} \tag{3.22}
\end{equation*}
$$

whose characteristic equation is similar to Eq. (14) and yields

$$
\begin{equation*}
\lambda^{2}=\omega^{2}-\Omega^{2}, \quad \text { for } \theta \approx \theta_{0} \tag{3.23a}
\end{equation*}
$$

[^28]This result shows that if $\omega<\Omega$, when both roots $\lambda$ are imaginary, this fixed point is stable. However, as the rotation speed $\omega$ is increased beyond $\Omega$, the roots become real, $\lambda_{ \pm}=\left(\omega^{2}-\Omega^{2}\right)^{1 / 2}$, with one of them positive, so that the fixed point becomes unstable beyond this threshold, i.e. as soon as fixed points $\theta_{2,3}$ exist. An absolutely similar calculations for other fixed points yield

$$
\begin{align*}
& \lambda^{2}=\Omega^{2}+\omega^{2}>0, \quad \text { for } \theta \approx \theta_{1}  \tag{3.23b}\\
& \lambda^{2}=\Omega^{2}-\omega^{2}, \quad \text { for } \theta \approx \theta_{2,3} \tag{3.23c}
\end{align*}
$$

These results show that fixed point $\theta_{1}$ (bead on the top of the ring) is always unstable - just as we could foresee, while the side fixed points $\theta_{2,3}$ are stable as soon as they exist (at $\omega>\Omega$ ).

Thus, our fixed-point analysis may be summarized in a simple way: an increase of the ring rotation speed $\omega$ beyond a certain threshold value, equal to $\Omega$ (2.26), causes the bead to move on one of the ring sides, oscillating about one of the fixed points $\theta_{2,3}$. Together with the rotation about the vertical axis, this motion yields quite a complex spatial trajectory as observed from a lab frame, so it is fascinating that we could analyze it qualitatively in such a simple way.

Later in this course we will repeatedly use the linearization of the equations of motion for the analysis of stability of more complex systems, including those with energy dissipation.

### 3.3. Hamiltonian 1D systems

The autonomous systems that are described by time-independent Lagrangians, are frequently called Hamiltonian, because their Hamiltonian function $H$ (again, not necessarily equal to the genuine mechanical energy $E!$ ) is conserved. In our current 1D case, described by Eq. (3),

$$
\begin{equation*}
H=\frac{m_{\mathrm{ef}}}{2} \dot{q}^{2}+U_{\mathrm{ef}}(q)=\text { const } \tag{3.24}
\end{equation*}
$$

This is the first integral of motion. Solving Eq. (24) for $\dot{q}$, we get the first-order differential equation,

$$
\begin{equation*}
\frac{d q}{d t}= \pm\left\{\frac{2}{m_{\mathrm{ef}}}\left[H-U_{\mathrm{ef}}(q)\right]\right\}^{1 / 2}, \tag{3.25}
\end{equation*}
$$

which may be readily integrated:

$$
\begin{equation*}
\pm\left(\frac{m_{\mathrm{ef}}}{2}\right)^{1 / 2} \int_{q\left(t_{0}\right)}^{q(t)} \frac{d q^{\prime}}{\left[H-U_{\mathrm{ef}}\left(q^{\prime}\right)\right]^{1 / 2}}=t-t_{0} \tag{3.26}
\end{equation*}
$$

Since constant $H$ (as well as the proper sign before the integral - see below) is fixed by initial conditions, Eq. (26) gives the reciprocal form, $t=t(q)$, of the desired law of system motion, $q(t)$. Of course, for any particular problem the integral in Eq. (26) still has to be worked out, either analytically or numerically, but even the latter procedure is typically much easier than the numerical integration of the initial, second-order differential equation of motion, because at addition of many values (to which the numerical integration is reduced ${ }^{6}$ ) the rounding errors are effectively averaged out.

[^29]Moreover, Eqs. (24)-(25) also allow a general classification of 1D system motion. Indeed:
(i) If $H>U_{\text {ef }}(q)$ in the whole range of interest, the effective kinetic energy $T_{\text {ef }}$ (3) is always positive. Hence derivative $d q / d t$ cannot change sign, so that the effective velocity retains the sign it had initially. This is the unbound motion in one direction (Fig. 2a).
(ii) Now let the particle approach a classical turning point $A$ where $H=U_{\text {ef }}(x)$ - see Fig. 2b. ${ }^{7}$ According to Eqs. (25), (26), at that point the particle velocity vanishes, while its acceleration, according to Eq. (4), is still finite. Evidently, this corresponds to the particle reflection from the "potential wall", with the change of velocity sign.
(iii) If, after the reflection from point $A$, the particle runs into another classical turning point $B$ (Fig. 2c), the reflection process is repeated again and again, so that the particle is bound to a periodic motion between two turning points.

(c)

Fig. 3.2. Graphical representation of Eq. (25) for three different cases: (a) unbound motion, with the velocity sign conserved, (b) reflection from the "classical turning point", accompanied with the velocity sign change, and (c) bound, periodic motion between two turning points - schematically. (d) Effective potential energy (6) of the bead on the rotating ring (Fig. 1.5) for $\omega>\Omega$, in units of $2 m g R$.

The last case of periodic oscillations presents large practical interest, and the whole next chapter will be devoted to a detailed analysis of this phenomenon and numerous associated effects. Here I will only note that Eq. (26) immediately enables us to calculate the oscillation period:

$$
\begin{equation*}
\tau=2\left(\frac{m_{\mathrm{ef}}}{2}\right)^{1 / 2} \int_{B}^{A} \frac{d q}{\left[H-U_{\mathrm{ef}}(q)\right]^{1 / 2}} \tag{3.27}
\end{equation*}
$$

[^30]where the additional upfront factor 2 accounts for two time intervals: for the motion from $B$ to A and back (Fig. 2c). Indeed, according to Eq. (25), in each classically allowed point $q$ the velocity magnitude is the same, so that these time intervals are equal to each other. ${ }^{8}$

Now let us link Eq. (27) to the fixed point analysis carried out in the previous section. As Fig. 2c shows, if $H$ is reduced to approach $U_{\min }$, the oscillations described by Eq. (27) take place at the very bottom of "potential well", about a stable fixed point $q_{0}$. Hence, if the potential energy profile is smooth enough, we may limit the Taylor expansion (10) by the quadratic term. Plugging it into Eq. (27), and using the mirror symmetry of this particular problem about the fixed point $q_{0}$, we get

$$
\begin{equation*}
\tau=4\left(\frac{m_{\mathrm{ef}}}{2}\right)^{1 / 2} \int_{0}^{A} \frac{d \widetilde{q}}{\left[H-\left(U_{\min }+\kappa_{\mathrm{ef}} \widetilde{q}^{2} / 2\right)\right]^{1 / 2}}=\frac{4}{\omega_{0}} I, \quad \text { with } I \equiv \int_{0}^{1} \frac{d \xi}{\left(1-\xi^{2}\right)^{1 / 2}}, \tag{3.28}
\end{equation*}
$$

where $\xi \equiv \widetilde{q} / A$, with $A \equiv\left(2 / \kappa_{\mathrm{ef}}\right)^{1 / 2}\left[H-U_{\mathrm{min}}\right]^{1 / 2}$ being the classical turning point, i.e. the oscillation amplitude, and $\omega_{0}$ is the eigenfrequency given by Eq. (15). Taking into account that the elementary integral $I$ in that equation equals $\pi / 2,{ }^{9}$ we finally get

$$
\begin{equation*}
\tau=\frac{2 \pi}{\omega_{0}} \tag{3.29}
\end{equation*}
$$

as it should be for harmonic oscillations (16). Note that the oscillation period does not depend on the oscillation amplitude $A$, i.e. on the difference $\left(H-U_{\min }\right)$ - while it is small.

### 3.4. Planetary problems

Leaving a more detailed study of oscillations for the next chapter, let us now discuss the socalled planetary systems ${ }^{10}$ whose description, somewhat surprisingly, may be also reduced to an effectively 1D problem. Consider two particles that interact via a conservative, central force $\mathbf{F}_{21}=-\mathbf{F}_{12}$ $=\mathbf{n}_{r} F(r)$, where $r$ and $\mathbf{n}_{r}$ are, respectively, the magnitude and direction of the distance vector $\mathbf{r} \equiv \mathbf{r}_{1}-\mathbf{r}_{2}$ connecting the two particles (Fig. 3).

Fig. 3.3. Vectors in the "planetary" problem.
${ }^{8}$ Note that the dependence of points $A$ and $B$ on the "energy" $H$ is not necessarily continuous. For example, for our testbed problem, whose effective potential energy is plotted in Fig. 2d (for a particular value of $\omega>\Omega$ ), a gradual increase of $H$ leads to a sudden jump, at $H=H_{1}$, of point $B$ to position $B^{\prime}$, corresponding to a sudden switch from oscillations about one fixed point $\theta_{2,3}$ to oscillations about two adjacent fixed points (before the beginning of a persistent rotation along the ring at $H>H_{2}$ ).
${ }^{9}$ Introducing a new variable $\zeta$ by relation $\xi \equiv \sin \zeta$, we get $d \xi=\cos \zeta d \zeta=\left(1-\xi^{2}\right)^{1 / 2} d \zeta$, so that the function under the integral is just $d \zeta$.
${ }^{10}$ This name is very conditional, because this group of problems includes, for example, charged particle scattering (see Sec. 3.7 below).

Generally, two particles moving without constrains in 3D space, have $3+3=6$ degrees of freedom that may be described, e.g., by their Cartesian coordinates $\left\{x_{1}, y_{1}, z_{1}, x_{2}, y_{2}, z_{2}\right\}$ However, for this particular form of interaction, the following series of tricks allows the number of essential degrees of freedom to be reduced to just one.

First, the central, conservative force of particle interaction may be described by timeindependent potential energy $U(r)$. Hence the Lagrangian of the system is

$$
\begin{equation*}
L \equiv T-U(r)=\frac{m_{1}}{2} \dot{\mathbf{r}}_{1}^{2}+\frac{m_{2}}{2} \dot{\mathbf{r}}_{2}^{2}-U(r) . \tag{3.30}
\end{equation*}
$$

Let us perform the transfer from the initial six scalar coordinates of the particles to six generalized coordinates: three Cartesian components of the distance vector

$$
\begin{equation*}
\mathbf{r} \equiv \mathbf{r}_{1}-\mathbf{r}_{2} \tag{3.31}
\end{equation*}
$$

and three components of vector

$$
\begin{equation*}
\mathbf{R} \equiv \frac{m_{1} \mathbf{r}_{1}+m_{2} \mathbf{r}_{2}}{M}, \quad M \equiv m_{1}+m_{2} \tag{3.32}
\end{equation*}
$$

which defines the position of the center of mass of the system. Solving the system of two linear equations (31) and (32) for the $\mathbf{r}_{1}$ and $\mathbf{r}_{2}$, we get

$$
\begin{equation*}
\mathbf{r}_{1}=\mathbf{R}+\frac{m_{2}}{M} \mathbf{r}, \quad \mathbf{r}_{2}=\mathbf{R}-\frac{m_{1}}{M} \mathbf{r} \tag{3.33}
\end{equation*}
$$

Plugging these relations into Eq. (30), we may reduce it to

$$
\begin{equation*}
L=\frac{M}{2} \dot{\mathbf{R}}^{2}+\frac{m}{2} \dot{\mathbf{r}}^{2}-U(r) \tag{3.34}
\end{equation*}
$$

where $m$ is the so-called reduced mass:

$$
\begin{equation*}
m \equiv \frac{m_{1} m_{2}}{M}, \quad \text { so that } \frac{1}{m} \equiv \frac{1}{m_{1}}+\frac{1}{m_{2}} \tag{3.35}
\end{equation*}
$$

Reduced mass

Note that according to Eq. (35), the reduced mass is lower than that of the lightest component of the two-body system. If one of $m_{1,2}$ is much less that is counterpart (like it is in most star-planet or planetsatellite systems), then with a good precision $m \cong \min \left[m_{1}, m_{2}\right]$.

Since the Lagrangian function (34) depends only on $\dot{\mathbf{R}}$ rather than $\mathbf{R}$ itself, according to our discussion in Sec. 2.4, the Cartesian components of $R$ are cyclic coordinates, and the corresponding generalized momenta are conserved:

$$
\begin{equation*}
P_{j} \equiv \frac{\partial L}{\partial \dot{R}_{j}}=M \dot{R}_{j}=\text { const }, \quad j=1,2,3 . \tag{3.36}
\end{equation*}
$$

Physically, this is just the conservation law for the full momentum $\mathbf{P} \equiv M \mathbf{R}$ of our system, due to absence of external forces. Actually, in the axiomatics used in Sec. 1.3 this law is postulated - see Eq. (1.10) - but now we may attribute momentum $\mathbf{P}$ to a certain geometric point, the center of mass $\mathbf{R}$. In particular, since according to Eq. (36) the center moves with constant velocity in the inertial reference
frame used to write Eq. (30), we may create a new inertial frame with the origin at point $\mathbf{R}$. In this new frame, $\mathbf{R} \equiv 0$, so that vector $\mathbf{r}$ (and hence scalar $r$ ) remain the same as in the old frame (because the frame transfer vector adds equally to $\mathbf{r}_{1}$ and $\mathbf{r}_{2}$, and cancels in $\mathbf{r}=\mathbf{r}_{1}-\mathbf{r}_{2}$ ), and the Lagrangian (34) is now reduced to

$$
\begin{equation*}
L=\frac{m}{2} \dot{\mathbf{r}}^{2}-U(r) . \tag{3.37}
\end{equation*}
$$

Thus our initial problem has been reduced to just three degrees of freedom - three scalar components of vector $\mathbf{r}$. Moreover, Eq. (37) shows that dynamics of vector $\mathbf{r}$ of our initial, two-particle system is identical to that of the radius-vector of a single particle with the effective mass $m$, moving in the central potential field $U(r)$.

## 3.5. $2^{\text {nd }}$ Kepler law

Two more degrees of freedom may be excluded from the planetary problem by noticing that according to Eq. (1.35), the angular momentum $\mathbf{L}=\mathbf{r} \times \mathbf{p}$ of our effective particle is also conserved, both in magnitude and direction. Since the direction of $\mathbf{L}$ is, by its definition, perpendicular to both of $\mathbf{r}$ and $\mathbf{v}$ $=\mathbf{p} / m$, this means that particle's motion is confined to a plane (whose orientation in space is determined by the initial directions of vectors $\mathbf{r}$ and $\mathbf{v}$ ). Hence we can completely describe particle's position by just two coordinates in that plane, for example by distance $r$ to the center, and the polar angle $\varphi$. In these coordinates, Eq. (37) takes the form identical to Eq. (2.49):

$$
\begin{equation*}
L=\frac{m}{2}\left(\dot{r}^{2}+r^{2} \dot{\varphi}^{2}\right)-U(r) . \tag{3.38}
\end{equation*}
$$

Moreover, the latter coordinate, polar angle $\varphi$, may be also eliminated by using the conservation of angular momentum's magnitude, in the form of Eq. (2.50): ${ }^{11}$

$$
\begin{equation*}
L_{z}=m r^{2} \dot{\varphi}=\text { const. } \tag{3.39}
\end{equation*}
$$

A direct corollary of this conservation is the so-called $2^{\text {nd }}$ Kepler law: ${ }^{12}$ the radius-vector $\mathbf{r}$ sweeps equal areas $A$ in equal times. Indeed, in the linear approximation in $d A \ll A$, the area differential $d A$ equals to the area of a narrow right triangle with the base being the arc differential $r d \varphi$, and the height equal to $r$-see Fig. 4. As a result, according to Eq. (39), the time derivative of the area,

$$
\begin{equation*}
\frac{d A}{d t}=\frac{r(r d \varphi) / 2}{d t}=\frac{1}{2} r^{2} \dot{\varphi}=\frac{L_{z}}{2 m}, \tag{3.40}
\end{equation*}
$$

remains constant. Integration of this equation over an arbitrary (not necessarily small!) time interval proves the $2^{\text {nd }}$ Kepler law.

[^31]

Fig. 3.4. Area differential in the polar coordinates.

Now note that since $\partial L / \partial t=0$, the Hamiltonian function $H$ is also conserved, and since, according to Eq. (38), the kinetic energy of the system is a quadratic-homogeneous function of the generalized velocities $\dot{r}$ and $\dot{\varphi}, H=E$, so that the system energy $E$,

$$
\begin{equation*}
E=\frac{m}{2} \dot{r}^{2}+\frac{m}{2} r^{2} \dot{\varphi}^{2}+U(r), \tag{3.41}
\end{equation*}
$$

is also a first integral of motion. ${ }^{13}$ But according to Eq. (39), the second term of Eq. (41) may be presented as

$$
\begin{equation*}
\frac{m}{2} r^{2} \dot{\varphi}^{2}=\frac{L_{z}^{2}}{2 m r^{2}} \tag{3.42}
\end{equation*}
$$

so that energy (41) may be expressed as that of a 1D particle moving along axis $r$,

$$
\begin{equation*}
E=\frac{m}{2} \dot{r}^{2}+U_{\mathrm{ef}}(r) \tag{3.43}
\end{equation*}
$$

in the following effective potential:

$$
\begin{equation*}
U_{\mathrm{ef}}(r) \equiv U(r)+\frac{L_{z}^{2}}{2 m r^{2}} \tag{3.44}
\end{equation*}
$$

Effective
potential energy

So the planetary motion problem has been reduced to the dynamics of an effectively 1 D system. ${ }^{14}$
Now we may proceed just like we did in Sec. 3, with due respect for the very specific effective potential (44) which, in particular, diverges at $r \rightarrow 0$ - possibly besides the very special case of an exactly radial motion, $L_{z}=0$. In particular, we may solve Eq. (43) for $d r / d t$ to get

$$
\begin{equation*}
d t=\left(\frac{m}{2}\right)^{1 / 2} \frac{d r}{\left[E-U_{\mathrm{ef}}(r)\right]^{1 / 2}} \tag{3.45}
\end{equation*}
$$

The integration of this relation allows us not only to get a direct relation between time $t$ and distance $r$, similar to Eq. (26),

[^32]\[

$$
\begin{equation*}
t= \pm\left(\frac{m}{2}\right)^{1 / 2} \int \frac{d r}{\left[E-U_{\mathrm{ef}}(r)\right]^{1 / 2}}= \pm\left(\frac{m}{2}\right)^{1 / 2} \int \frac{d r}{\left[E-U(r)-L_{z}^{2} / 2 m r^{2}\right]^{1 / 2}}, \tag{3.46}
\end{equation*}
$$

\]

but also do a similar calculation of angle $\varphi$. Indeed, integrating Eq. (39),

$$
\begin{equation*}
\varphi \equiv \int \dot{\varphi} d t=\frac{L_{z}}{m} \int \frac{d t}{r^{2}} . \tag{3.47}
\end{equation*}
$$

and plugging $d t$ from Eq. (45), we get an explicit expression for particle's trajectory $\varphi(r)$ :

$$
\begin{equation*}
\varphi= \pm \frac{L_{z}}{(2 m)^{1 / 2}} \int \frac{d r}{r^{2}\left[E-U_{\text {ef }}(r)\right]^{1 / 2}}= \pm \frac{L_{z}}{(2 m)^{1 / 2}} \int \frac{d r}{r^{2}\left[E-U(r)-L_{z}^{2} / 2 m r^{2}\right]^{1 / 2}} \tag{3.48}
\end{equation*}
$$

Note that according to Eq. (39), derivative $d \varphi / d t$ does not change sign at the reflection from any classical turning point $r \neq 0$, so that, in contrast to Eq. (46), the sign in the right-hand part of Eq. (48) is uniquely determined by the initial conditions and cannot change during the motion.

Let us use these results, valid for any interaction law $U(r)$, for the planetary motion's classification. The following cases should be distinguished. (Following a good tradition, in what follows I will select the arbitrary constant in the potential energy in the way to provide $U_{\text {ef }} \rightarrow 0$ at $r \rightarrow \infty$.)

If the particle interaction is attractive, and the divergence of the attractive potential at $r \rightarrow 0$ is faster than $1 / r^{2}$, then $U_{\text {ef }}(r) \rightarrow-\infty$ at $r \rightarrow 0$, so that at appropriate initial conditions $(E<0)$ the particle may drop on the center even if $L_{z} \neq 0$ - the event called the capture. On the other hand, with $U(r)$ either converging or diverging slower than $1 / r^{2}$ at $r \rightarrow 0$, the effective energy profile $U_{\text {eff }}(r)$ has the shape shown schematically in Fig. 5. This is true, in particular, for the very important case

Attractive Coulomb potential

$$
\begin{equation*}
U(r)=-\frac{\alpha}{r}, \quad \alpha>0 \tag{3.49}
\end{equation*}
$$

which describes, in particular, the Coulomb (electrostatic) interaction of two particles with electric charges of the opposite sign, and Newton's gravity law (1.16a). This particular case will be analyzed in the following section, but now let us return to the analysis of an arbitrary attractive potential $U(r)<0$ leading to the effective potential shown in Fig. 5, when the angular-momentum term dominates at small distances $r$.

Fig. 3.5. Effective potential profile of, and two types of motion in an attractive central field.

According to the analysis of Sec. 3, such potential profile, with a minimum at some distance $r_{0}$, may sustain two types of motion, depending on the energy $E$ (which is of course determined by the initial conditions):
(i) If $E>0$, there is only one classical turning point where $E=U_{\mathrm{ef}}$, so that distance $r$ either grows with time from the very beginning, or (if the initial value of $\dot{r}$ was negative) first decreases and then, after the reflection from the increasing potential $U_{\text {ef }}$, starts to grow indefinitely. The latter case, of course, describes scattering.
(ii) On the opposite, if the energy is within the range

$$
\begin{equation*}
U_{\text {ef }}\left(r_{0}\right) \leq E<0, \tag{3.50}
\end{equation*}
$$

the system moves periodically between two classical turning points $r_{\text {min }}$ and $r_{\text {max }}$. These oscillations of distance $r$ correspond to the bound orbital motion of our effective particle about the attracting center. ${ }^{15}$

Let us start with the discussion of the bound motion, with energy within the range (50). If energy has its minimal possible value,

$$
\begin{equation*}
E=U_{\mathrm{ef}}\left(r_{0}\right)=\min \left[U_{\mathrm{ef}}(r)\right], \tag{3.51}
\end{equation*}
$$

the distance cannot change, $r=r_{0}=$ const, so that the orbit is circular, with the radius $r_{0}$ satisfying the condition $d U_{\mathrm{ef}} / d r=0$. Let us see whether this result allows for an elementary explanation. Using Eq. (44) we see that the condition for $r_{0}$ may be written as

$$
\begin{equation*}
\frac{L_{z}^{2}}{m r_{0}^{3}}=\left.\frac{d U}{d r}\right|_{r=r_{0}} . \tag{3.52}
\end{equation*}
$$

Since in a circular motion, velocity $\mathbf{v}$ is perpendicular to the radius vector $\mathbf{r}, L_{z}$ is just $m r_{0} v$, the left-hand part of Eq. (52) equals $m v^{2} / r_{0}$, while its right-hand part is just the magnitude of the attractive force, so that this equation expresses the well-known $2^{\text {nd }}$ Newton law for the circular motion. Plugging this result into Eq. (47), we get a linear law of angle change, $\varphi=\omega t+$ const, with angular velocity

$$
\begin{equation*}
\omega=\frac{L_{z}}{m r_{0}^{2}}=\frac{v}{r_{0}}, \tag{3.53}
\end{equation*}
$$

and hence the rotation period $\tau_{\varphi} \equiv 2 \pi / \omega$ obeys the elementary relation

$$
\begin{equation*}
\tau_{\varphi}=\frac{2 \pi r_{0}}{v} \tag{3.54}
\end{equation*}
$$

Now, let the energy be above its minimum value. Using Eq. (46) just as in Sec. 3, we see that distance $r$ now oscillates with period

$$
\begin{equation*}
\tau_{r}=(2 m)^{1 / 2} \int_{r_{\min }}^{r_{\max }} \frac{d r}{\left[E-U(r)-L_{z}^{2} / 2 m r^{2}\right]^{1 / 2}} \tag{3.55}
\end{equation*}
$$

[^33]This period is, in general, different from $\tau_{\varphi}$. Indeed, the change of angle $\varphi$ between two sequential points of the nearest approach, that follows from Eq. (48),

$$
\begin{equation*}
|\Delta \varphi|=2 \frac{L_{z}}{(2 m)^{1 / 2}} \int_{\mathrm{r}_{\min }}^{r_{\max }} \frac{d r}{r^{2}\left[E-U(r)-L_{z}^{2} / 2 m r^{2}\right]^{1 / 2}}, \tag{3.56}
\end{equation*}
$$

is generally different from $2 \pi$. Hence, the general trajectory of the bound motion has a spiral shape see, e.g., an illustration in Fig. 6.

Fig. 3.6. Typical open orbit of a particle moving in a non-Coulomb central field.

## 3.6. $1^{\text {st }}$ and $3^{\text {rd }}$ Kepler laws

The situation is special, however, for a very important particular case, namely that of the Coulomb potential described by Eq. (49). Indeed, plugging this potential into Eq. (48), we get

$$
\begin{equation*}
\varphi= \pm \frac{L_{z}}{(2 m)^{1 / 2}} \int \frac{d r}{r^{2}\left(E+\alpha / r-L_{z}^{2} / 2 m r^{2}\right)^{1 / 2}} . \tag{3.57}
\end{equation*}
$$

This is a table integral, ${ }^{16}$ equal to

$$
\begin{equation*}
\varphi= \pm \cos ^{-1} \frac{L_{z}^{2} / m \alpha r-1}{\left(1+2 E L_{z}^{2} / m \alpha^{2}\right)^{1 / 2}}+\text { const } \tag{3.58}
\end{equation*}
$$

The reciprocal function, $r(\varphi)$, is $2 \pi$-periodic:

$$
\begin{equation*}
r=\frac{p}{1+e \cos (\varphi+\text { const })}, \tag{3.59}
\end{equation*}
$$

Elliptic orbit
nd its parameters
so that at $E<0$, the orbit a closed line, ${ }^{17}$ characterized with the following parameters:

$$
\begin{equation*}
p \equiv \frac{L_{z}^{2}}{m \alpha}, \quad e \equiv\left[1+\frac{2 E L_{z}^{2}}{m \alpha^{2}}\right]^{1 / 2} \tag{3.60}
\end{equation*}
$$

[^34]The physical meaning of these parameters is very simple. Indeed, according to the general Eq. (52), in the Coulomb potential, for which $d U / d r=\alpha / r^{2}$, we see that $p$ is just the circular orbit radius ${ }^{18}$ for given $L_{z}: r_{0}=L_{z}{ }^{2} / m \alpha \equiv p$, and

$$
\begin{equation*}
\min \left[U_{\mathrm{ef}}(r)\right] \equiv U_{\mathrm{ef}}\left(r_{0}\right)=-\frac{\alpha^{2} m}{2 L_{z}^{2}}, \tag{3.61}
\end{equation*}
$$

Using this equality, parameter $e$ (called eccentricity) may be presented just as

$$
\begin{equation*}
e=\left\{1-\frac{E}{\min \left[U_{\mathrm{ef}}(r)\right]}\right\}^{1 / 2} . \tag{3.62}
\end{equation*}
$$

Analytical geometry tells us that Eq. (59), with $e<1$, is one of canonical forms for presentation of an ellipse, with one of its two focuses located at the origin. This fact is known as the $1^{\text {st }}$ Kepler law. Figure 7 shows the relation between the main dimensions of the ellipse and parameters $p$ and $e .{ }^{19}$

Fig. 3.7. Ellipse, and its special points and dimensions.

In particular, the major axis $a$ and minor axis $b$ are simply related to $p$ and $e$ and hence, via Eqs. (60), to the motion integrals $E$ and $L_{z}$ :

$$
\begin{equation*}
a=\frac{p}{1-e^{2}}=\frac{\alpha}{2|E|}, \quad b=\frac{p}{\left(1-e^{2}\right)^{1 / 2}}=\frac{L_{z}}{(2 m|E|)^{1 / 2}} . \tag{3.63}
\end{equation*}
$$

As was mentioned above, at $E \rightarrow \min \left[U_{\text {ef }}(r)\right]$ the orbit is almost circular, with $r(\varphi) \cong r_{0}=p$. On the contrary, as $E$ is increased to approach zero (its maximum value for the closed orbit), then $e \rightarrow 1$, so that the aphelion point $r_{\max }=p /(1-e)$ tends to infinity, i.e. the orbit becomes extremely extended. If the energy is exactly zero, Eq. (59) (with $e=1$ ) is still valid for all values of $\varphi$ (except for one special point $\varphi=\pi$ where $r$ becomes infinite) and describes a parabolic (i.e. open) trajectory. At $E>0$, Eq. (59) is still valid within a certain sector of angles $\varphi$ (in that it yields positive results for $r$ ), and describes an open, hyperbolic trajectory - see the next section.

For $E<0$, the above relations also allow a ready calculation of the rotation period $\tau_{\equiv} \tau_{r}=\tau_{\varphi}$. (In the case of a closed trajectory, $\tau_{r}$ and $\bar{T}_{\varphi}$ have to coincide.) Indeed, it is well known that the ellipse area $A=\pi a b$. But according to the $2^{\text {nd }}$ Kepler law (40), $d A / d t=L_{z} / 2 m=$ const. Hence

[^35]\[

$$
\begin{equation*}
\tau=\frac{A}{d A / d t}=\frac{\pi a b}{L_{z} / 2 m} . \tag{3.64a}
\end{equation*}
$$

\]

Using Eqs. (60) and (63), this result may be presented in several other forms:

$$
\begin{equation*}
\tau=\frac{\pi p^{2}}{\left(1-e^{2}\right)^{3 / 2}\left(L_{z} / 2 m\right)}=\pi \alpha\left(\frac{m}{2|E|^{3}}\right)^{1 / 2}=2 \pi a^{3 / 2}\left(\frac{m}{\alpha}\right)^{1 / 2} \tag{3.64b}
\end{equation*}
$$

Since for the Newtonian gravity (1.16a), $\alpha=G m_{1} m_{2}=G m M$, at $m_{1} \ll m_{2}$ (i.e. $m \ll M$ ) this constant is proportional to $m$, and the last form of Eq. (64b) yields the $3^{\text {rd }}$ Kepler law: periods of motion of different planets in the same central field, say that of our Sun, scale as $T \propto a^{3 / 2}$. Note that in contrast to the $2^{\text {nd }}$ Kepler law (that is valid for any central field), the $1^{\text {st }}$ and $3^{\text {rd }}$ Kepler laws are potentialspecific.

### 3.7. Classical theory of elastic scattering

If $E>0$, the motion is unbound for any interaction potential. In this case, the two most important parameters of the particle trajectory are the scattering angle $\theta$ and impact parameter $b$ (Fig. 8), and the main task for theory is to find the relation between them in the given potential $U(r)$. For that, it is convenient to note that $b$ is related to two conserved quantities, particle's energy ${ }^{20} E$ and its angular momentum $L_{z}$, in a simple way: ${ }^{21}$

$$
\begin{equation*}
L_{z}=b(2 m E)^{1 / 2} \tag{3.65}
\end{equation*}
$$

Hence the angular contribution to the effective potential (44) may be presented as

$$
\begin{equation*}
\frac{L_{z}^{2}}{2 m r^{2}}=E \frac{b^{2}}{r^{2}} \tag{3.66}
\end{equation*}
$$

Second, according to Eq. (48), the trajectory sections from infinity to the nearest approach point ( $r=$ $r_{\text {min }}$ ), and from that point to infinity, have to be similar, and hence correspond to equal angle changes $\varphi_{0}$ - see Fig. 8.

Fig. 3.8. Main geometric parameters of the scattering problem.

[^36]Hence we may apply the general Eq. (48) to just one of the sections, say $\left[r_{\min }, \infty\right.$ ], to find the scattering angle:

$$
\begin{equation*}
\theta=\pi-2 \varphi_{0}=\pi-2 \frac{L_{z}}{(2 m)^{1 / 2}} \int_{r_{\min }}^{\infty} \frac{d r}{r^{2}\left[E-U(r)-L_{z}^{2} / 2 m r^{2}\right]^{1 / 2}}=\pi-2 \int_{r_{\min }}^{\infty} \frac{b d r}{r^{2}\left[1-U(r) / E-b^{2} / r^{2}\right]^{1 / 2}} \cdot( \tag{3.67}
\end{equation*}
$$

In particular, for the Coulomb potential (49), now with an arbitrary sign of $\alpha$, we can apply the same table integral as in the previous section to get ${ }^{22}$

$$
\begin{equation*}
\theta=\left|\pi-2 \cos ^{-1} \frac{\alpha / 2 E b}{\left[1+(\alpha / 2 E b)^{2}\right]^{1 / 2}}\right| \tag{3.68a}
\end{equation*}
$$

This result may be more conveniently rewritten as

$$
\begin{equation*}
\tan \frac{|\theta|}{2}=\frac{|\alpha|}{2 E b} \tag{3.68b}
\end{equation*}
$$

Very clearly, the scattering angle's magnitude increases with the potential strength $\alpha$, and decreases as either the particle energy or the impact parameter (or both) are increased.

The general equation (67) and the Coulomb-specific relations (68) present a formally complete solution of the scattering problem. However, in a typical experiment on elementary particle scattering the impact parameter $b$ of a single particle is random and unknown. In this case, our results may be used to obtain statistics of the scattering angle $\theta$, in particular the so-called differential cross-section ${ }^{23}$

$$
\begin{equation*}
\frac{d \sigma}{d \Omega} \equiv \frac{1}{n} \frac{d N}{d \Omega}, \tag{3.69}
\end{equation*}
$$

where $n$ is the average number of the incident particles per unit area, and $d N$ is the average number of particles scattered into a small solid angle range $d \Omega$. For a spherically-symmetric scattering center, which provides an axially-symmetric scattering pattern, $d \sigma / d \Omega$ may be calculated by counting the number of incident particles within a small range $d b$ of the impact parameter:

$$
\begin{equation*}
d N=n 2 \pi b d b \tag{3.70}
\end{equation*}
$$

and hence scattered into the corresponding small solid angle range $d \Omega=2 \pi \sin \theta d \theta$. Plugging these relations into Eq. (69), we get the following general geometric relation:

$$
\begin{equation*}
\frac{d \sigma}{d \Omega}=\frac{b}{\sin \theta}\left|\frac{d b}{d \theta}\right| \tag{3.71}
\end{equation*}
$$

In particular, for the Coulomb potential (49), a straightforward differentiation of Eq. (68) yields the so-called Rutherford scattering formula

[^37]Rutherford scattering formula

$$
\begin{equation*}
\frac{d \sigma}{d \Omega}=\left(\frac{\alpha}{4 E}\right)^{2} \frac{1}{\sin ^{4}(\theta / 2)} \tag{3.72}
\end{equation*}
$$

This result, which shows very strong scattering to small angles (so strong that the integral that expresses the full cross-section $\sigma$ is formally diverging at $\theta \rightarrow 0$ ), ${ }^{24}$ and weak backscattering (scattering to angles $\theta \approx \pi$ ) was historically extremely significant: in the early 1910s its good agreement with $\alpha$ particle scattering experiments carried out by E. Rutherford's group gave a strong justification for "planetary" models of atoms, with electrons moving about very small nuclei.

Note that elementary particle scattering is frequently accompanied with electromagnetic radiation and/or other processes leading to the loss of the initial mechanical energy of the system, leading to inelastic scattering, that may give significantly different results. (In particular, a capture of an incoming particle becomes possible even for a Coulomb attracting center.) Also, quantum-mechanical effects may be important at scattering, so that the above results should be used with caution.

### 3.8. Exercise problems

3.1. For the system considered in Problem 2.5 (a bead sliding along a string with fixed tension $T$, see Fig. on the right), analyze small oscillations of the bead near the equilibrium.

3.2. Calculate the functional dependence of period $\tau$ of oscillations of a 1D particle of mass $m$ in potential $U(q)=\alpha q^{2 n}$ (where $\alpha>0$, and $n$ is a positive integer) on energy $E$. Explore the limit $n \rightarrow \infty$.
3.3. Explain why the term $m r^{2} \dot{\varphi}^{2} / 2$, recast in accordance with Eq. (42), cannot be merged with $U(r)$ in Eq. (38), to form an effective 1D potential energy $U(r)-L_{z}{ }^{2} / 2 m r^{2}$, with the second term's sign opposite to that given by Eq. (44). We have done an apparently similar thing for our testbed, bead-on-rotating-ring problem in the very end of Sec. 1 - see Eq. (3.6); why cannot the same trick work for the planetary problem? Besides a formal explanation, discuss the physics behind this difference.
3.4. A dumbbell, consisting of two equal masses $m$ on a light rod of length $l$, can slide without friction along a vertical ring of radius $R$, rotated about its vertical diameter with constant angular velocity $\omega$ - see Fig. on the right. Derive the condition of stability of the lower horizontal position of the dumbbell.

[^38]3.5. ${ }^{25}$ Analyze the dynamics of the so-called spherical pendulum - a point mass hung, in a uniform gravity field $\mathbf{g}$, on a light cord of length $l$, with no motion's confinement to a vertical plane. In particular:
(i) find the integrals of motion and reduce the problem to a 1 D one,
(ii) calculate the time period of the possible circular motion around the vertical axis,
(iii) explore small deviations from the circular motion. (Are the pendulum orbits closed?)
3.6. The orbits of Mars and Earth around the Sun may be well approximated as circles, with a radii ratio of $3 / 2$. Use this fact, and the Earth year duration (which you should know :-), to calculate the time of travel to Mars spending least energy, neglecting the planets' size and the effects of their gravitational fields on the spacecraft.
3.7. Derive first-order and second-order differential equations for $u \equiv 1 / r$ as a function of $\varphi$, describing the trajectory of particle's motion in a central potential $U(r)$. Spell out the latter equation for the particular case of the Coulomb potential (3.49) and discuss the result.
3.8. For motion in the central potential
$$
U(r)=-\frac{\alpha}{r}+\frac{\beta}{r^{2}},
$$
(i) find the orbit $r(\varphi)$, for positive $\alpha$ and $\beta$, and all possible ranges of energy $E$;
(ii) prove that in the limit $\beta \rightarrow 0$, and for energy $E<0$, the orbit may be represented as a slowly rotating ellipse;
(iii) express the angular velocity of this slow orbit rotation via parameters $\alpha$ and $\beta$ of the potential, particle's mass $m$, its energy $E$, and the angular momentum $L_{z}$.
3.9. A particle is moving in the field of an attractive central force, with potential
$$
U(r)=-\frac{\alpha}{r^{n}}, \quad \text { where } \alpha n>0
$$

For what values of $n$ is a circular orbit stable?
3.10. Determine the condition for a particle of mass $m$, moving under the effect of a central attractive force

$$
\mathbf{F}=-\alpha \frac{\mathbf{r}}{r^{3}} \exp \left\{-\frac{r}{R}\right\}
$$

where $\alpha$ and $R$ are positive constants, to have a stable circular orbit.
3.11. A particle of mass $m$, with angular momentum $L_{z}$, moves in the field of an attractive central force with a distance-independent magnitude $F$. If particle's energy $E$ is slightly higher than the value $E_{\min }$ corresponding to the circular orbit of the particle, what is the time period of its radial oscillations? Compare the period with that of the circular orbit at $E=E_{\min }$.

[^39]3.12. For particle scattering in a repulsive Coulomb field, calculate the minimum approach distance $r_{\text {min }}$ and velocity $v_{\text {min }}$ at that point, and analyze their dependence on the impact parameter $b$ (see Fig. 3.8 of the lecture notes) and the initial velocity $v_{\infty}$ of the particle.
3.13. A particle is launched from afar, with impact parameter $b$, toward an attracting center with central potential
$$
U(r)=-\frac{\alpha}{r^{n}}, \quad \text { with } n>2, \alpha>0
$$
(i) Express the minimum distance between the particle and the center via $b$, if the initial kinetic energy $E$ of the particle is barely sufficient for escaping the capture by the attracting center.
(ii) Calculate capture's full cross-section; explore the limit $n \rightarrow 2$.
3.14. A meteorite with initial velocity $v_{\infty}$ approaches an atmosphere-free planet of mass $M$ and radius $R$.
(i) Find the condition on the impact parameter $b$ for the meteorite to hit planet's surface.
(ii) If the meteorite barely avoids the collision, what is its scattering angle?
3.15. Calculate the differential and full cross-sections of the classical, elastic scattering of small particles by a hard sphere of radius $R$.
3.16. The most famous ${ }^{26}$ confirmation of Einstein's general relativity theory has come from the observation, by A. Eddington and his associates, of light's deflection by the Sun, during the May 1919 solar eclipse. Considering light photons as classical particles propagating with the light speed $v_{0} \rightarrow c \approx$ $2.998 \times 10^{8} \mathrm{~m} / \mathrm{s}$, and the astronomic data for Sun's mass, $M_{S} \approx 1.99 \times 10^{30} \mathrm{~kg}$, and radius, $R_{S} \approx$ $0.6957 \times 10^{9} \mathrm{~m}$, calculate the nonrelativistic mechanics' prediction for the angular deflection of the light rays grazing the Sun's surface.

[^40]

## Chapter 4. Oscillations

In this course, oscillations in $1 D$ (and effectively 1D) systems are discussed in detail, because of their key importance for physics and engineering. We will start with the so-called "linear" oscillator whose differential equation of motion is linear and hence allows the full analytical solutions, and then proceed to "nonlinear" and parametric systems whose dynamics may be only explored by either approximate analytical or numerical methods.

### 4.1. Free and forced oscillations

In Sec. 3.2 we briefly discussed oscillations in a very important Hamiltonian system - a 1D harmonic oscillator described by a simple 1D Lagrangian ${ }^{1}$

$$
\begin{equation*}
L \equiv T(\dot{q})-U(q)=\frac{m}{2} \dot{q}^{2}-\frac{\kappa}{2} q^{2}, \tag{4.1}
\end{equation*}
$$

whose Lagrangian equation of motion,

$$
\begin{equation*}
m \ddot{q}+\kappa q=0, \quad \text { i.e. } \ddot{q}+\omega_{0}^{2} q=0, \quad \text { with } \omega_{0}^{2} \equiv \frac{\kappa}{m} \geq 0, \tag{4.2}
\end{equation*}
$$

is a linear homogeneous differential equation. Its general solution is presented by Eq. (3.16), but it is frequently useful to recast it into another, amplitude-phase form:

$$
\begin{equation*}
q(t)=u \cos \omega_{0} t+v \sin \omega_{0} t=A \cos \left(\omega_{0} t-\varphi\right) \tag{4.3a}
\end{equation*}
$$

where $A$ is the amplitude and $\varphi$ the phase of the oscillations, which are determined by the initial conditions. Mathematically, it is frequently easier to work with sinusoidal functions as complex exponents, by rewriting Eq. (3a) in one more form: ${ }^{2}$

$$
\begin{equation*}
q(t)=\operatorname{Re}\left[A e^{-i\left(\omega_{0} t-\varphi\right)}\right]=\operatorname{Re}\left[a e^{-i \omega_{0} t}\right] \tag{4.3b}
\end{equation*}
$$

where $a$ is the complex amplitude of the oscillations:

$$
\begin{equation*}
a \equiv A e^{i \varphi}, \quad|a|=A, \quad \operatorname{Re} a=A \cos \varphi=u, \quad \operatorname{Im} a=A \sin \varphi=v . \tag{4.4}
\end{equation*}
$$

Equations (3) represent the so-called free oscillations of the system, that are physically due to the initial energy of the system. At an account for dissipation, i.e. energy leakage out of the system, such oscillations decay with time. The simplest model of this effect is represented by an additional linear friction ("drag") force that is proportional to the generalized velocity and directed opposite to it:
${ }^{1}$ For the notation simplicity, in this chapter I will drop indices "ef" in the energy components $T$ and $U$, and parameters like $m, \kappa$, etc. However, the reader should still remember that $T$ and $U$ do not necessarily coincide with the real kinetic and potential energies (even if those energies may be uniquely identified) - see Sec. 3.1.
${ }^{2}$ Note that this is the so-called physics convention. Most engineering texts use the opposite sign in the imaginary exponent, $\exp \{-i \omega t\} \rightarrow \exp \{i \omega t\}$, with the corresponding sign implications for intermediate formulas, but (of course) similar final results for real variables.

$$
\begin{equation*}
F_{v}=-\eta \dot{q}, \tag{4.5}
\end{equation*}
$$

where constant $\eta$ is called the drag coefficient. ${ }^{3}$ The inclusion of this force modifies the equation of motion (2) to become

$$
\begin{equation*}
m \ddot{q}+\eta \dot{q}+\kappa q=0 \tag{4.6a}
\end{equation*}
$$

This equation is frequently presented in the form

$$
\begin{equation*}
\ddot{q}+2 \delta \ddot{q}+\omega_{0}^{2} q=0, \quad \text { with } \delta \equiv \frac{\eta}{2 m} \tag{4.6b}
\end{equation*}
$$

Free
oscillator
with
damping
where parameter $\delta$ is called the damping coefficient. Note that Eq. (6) is still a linear homogeneous second-order differential equation, and its general solution still has the form of the sum (3.13) of two exponents of the type $\exp \{\lambda t\}$, with arbitrary pre-exponential coefficients. Plugging such an exponent into Eq. (4), we get the following algebraic characteristic equation for $\lambda$ :

$$
\begin{equation*}
\lambda^{2}+2 \delta \lambda+\omega_{0}^{2}=0 \tag{4.7}
\end{equation*}
$$

Solving this quadratic equation, we get

$$
\begin{equation*}
\lambda_{ \pm}=-\delta \pm i \omega_{0}^{\prime}, \quad \text { where } \omega_{0}^{\prime} \equiv\left(\omega_{0}^{2}-\delta^{2}\right)^{1 / 2} \tag{4.8}
\end{equation*}
$$

so that for not very high damping $\left(\delta<\omega_{0}\right)^{4}$ we get the following generalization of Eq. (3):

$$
\begin{equation*}
q_{\text {free }}(t)=c_{+} e^{\lambda_{+} t}+c_{-} e^{\lambda_{-} t}=\left(u_{0} \cos \omega_{0}^{\prime} t+v_{0} \sin \omega_{0}{ }^{\prime} t\right) e^{-\delta t}=A_{0} e^{-\delta t} \cos \left(\omega_{0}{ }^{\prime} t-\varphi_{0}\right) . \tag{4.9}
\end{equation*}
$$

The result shows that, besides a certain correction to the free oscillation frequency (which is very small in the most interesting case of low damping, $\delta \ll \omega_{0}$ ), the energy dissipation leads to an exponential decay of oscillation amplitude with time constant $\tau=1 / \delta$ :

$$
\begin{equation*}
A=A_{0} e^{-t / \tau}, \quad \text { where } \tau \equiv \frac{1}{\delta}=\frac{2 m}{\eta} . \tag{4.10}
\end{equation*}
$$

A convenient, dimensionless measure of damping is the so-called quality factor $Q$ (or just $Q$ factor ) which is defined as $\omega_{0} / 2 \delta$, and may be rewritten in several other useful forms:

[^41]\[

$$
\begin{equation*}
Q \equiv \frac{\omega_{0}}{2 \delta}=\frac{m \omega_{0}}{\eta}=\frac{(m \kappa)^{1 / 2}}{\eta}=\pi \frac{\tau}{\tau}=\frac{\omega_{0} \tau}{2}, \tag{4.11}
\end{equation*}
$$

\]

where $T=2 \pi / \omega_{0}$ is the oscillation period in the absence of damping - see Eq. (3.29). Since the oscillation energy $E$ is proportional to their amplitude squared, i.e. decays as $\exp \{-2 t / \tau\}$, with time constant $\tau / 2$, the last form of Eq. (11) may be used to rewrite the $Q$-factor in one more form:

$$
\begin{equation*}
Q=\omega_{0} \frac{E}{(-\dot{E})} \equiv \omega_{0} \frac{E}{\mathcal{P}}, \tag{4.12}
\end{equation*}
$$

where $\mathcal{P}$ is the dissipation power. (Two other useful ways to measure $Q$ will be discussed in a minute.) The range of $Q$-factors of important oscillators is very broad, all the way from $Q \sim 10$ for a human leg (with relaxed muscles), to $Q \sim 10^{4}$ of the quartz crystals used in "electronic" clocks and watches, all the way up to $Q \sim 10^{12}$ for microwave cavities with superconducting walls.

In contrast to the decaying free oscillations, the forced oscillations, induced by an external force $F(t)$, may maintain their amplitude infinitely, even at nonvanishing damping. This process may be described by a still linear but now inhomogeneous differential equation

$$
\begin{equation*}
m \ddot{q}+\eta \dot{q}+\kappa q=F(t) \tag{4.13a}
\end{equation*}
$$

or, more conveniently, by the following generalization of Eq. (6b):

$$
\begin{equation*}
\ddot{q}+2 \delta \dot{q}+\omega_{0}^{2} q=f(t), \quad \text { where } f(t) \equiv F(t) / m \tag{4.13b}
\end{equation*}
$$

For a particle of mass $m$, confined to a straight line, Eq. (12a) is just an expression of the $2^{\text {nd }}$ Newton law (or rather one of its Cartesian component). More generally, according to Eq. (1.41), Eq. (13) is valid for any dissipative 1D system whose Gibbs potential energy (1.39) has the form $U_{\mathrm{G}}(q, t)=\kappa q^{2} / 2-F(t) q$.

The forced-oscillation solutions may be analyzed by two mathematically equivalent methods whose relative convenience depends on the character of function $f(t)$.
(i) Frequency domain. Let us present function $f(t)$ as a Fourier sum of sinusoidal harmonics: ${ }^{5}$

$$
\begin{equation*}
f(t)=\sum_{\omega} f_{\omega} e^{-i \omega t} \tag{4.14}
\end{equation*}
$$

Then, due to linearity of Eq. (13), its general solution may be presented as a sum of the decaying free oscillations (9) with frequency $\omega_{0}$ ', independent of function $F(t)$, and forced oscillations due to each of the Fourier components of the force: ${ }^{6}$

General solution of Eq. (13)

$$
\begin{equation*}
q(t)=q_{\text {free }}(t)+q_{\text {forced }}(t), \quad q_{\text {forced }}(t)=\sum_{\omega} a_{\omega} e^{-i \omega t} \tag{4.15}
\end{equation*}
$$

Plugging Eq. (15) into Eq. (13), and requiring the factors before each $e^{-i \omega t}$ in both parts to be equal, we get

[^42]\[

$$
\begin{equation*}
a_{\omega}=f_{\omega} \chi(\omega), \tag{4.16}
\end{equation*}
$$

\]

where complex function $\chi(\omega)$, in our particular case equal to

$$
\begin{equation*}
\chi(\omega)=\frac{1}{\left(\omega_{0}^{2}-\omega^{2}\right)-2 i \omega \delta} \tag{4.17}
\end{equation*}
$$

is called either the response function or (especially for non-mechanical oscillators) the generalized susceptibility. From here, the real amplitude of oscillations under the effect of a sinusoidal force that may be represented by just one Fourier harmonic of the sum (15), is

$$
\begin{equation*}
A_{\omega} \equiv\left|a_{\omega}\right|=\left|f_{\omega} \| \chi(\omega)\right|, \quad \text { with }|\chi(\omega)|=\frac{1}{\left[\left(\omega_{0}^{2}-\omega^{2}\right)^{2}+(2 \omega \delta)^{2}\right]^{1 / 2}} \tag{4.18}
\end{equation*}
$$

Forced oscillation's amplitude

This formula describes, in particular, an increase of the oscillation amplitude $A_{\omega}$ at $\omega \rightarrow \omega_{0}$ - see Fig. 1. At the exact resonance,

$$
\begin{equation*}
|\chi(\omega)|_{\omega=\omega_{0}}=\frac{1}{2 \omega_{0} \delta}, \tag{4.19}
\end{equation*}
$$

so that, according to Eq. (11), the ratio of the oscillator response magnitudes at $\omega=\omega_{0}$ and at $\omega=0$ $\left(|\chi(\omega)|_{\omega=0}=1 / \omega_{0}^{2}\right)$ is exactly equal to the $Q$-factor. Thus, the response increase is especially strong in the low damping limit ( $\delta \ll \omega_{0}$, i.e. $Q \gg 1$ ); moreover at $Q \rightarrow \infty$ and $\omega \rightarrow \omega_{0}$ the response diverges. (This fact is very useful for the approximate methods to be discussed later in this chapter.) This is of course the classical description of the famous phenomenon of resonance, so ubiquitous in physics.

Fig. 4.1. Resonance in a harmonic oscillator (13), for several values of the $Q$-factor.

Due to the increase of the resonance peak height, its width is inversely proportional to $Q$. Quantitatively, in the most interesting low-damping limit, $Q \gg 1$, the reciprocal $Q$-factor gives the normalized value of the so-called FWHM ("full-width at half-maximum") of the resonance curve:

$$
\begin{equation*}
\frac{\Delta \omega}{\omega_{0}}=\frac{1}{Q} \tag{4.20}
\end{equation*}
$$

Indeed, $\Delta \omega$ is defined as the difference ( $\omega_{+}-\omega_{\text {. }}$ ) between the two values of $\omega$ at that the square of oscillator response function, $|\chi(\omega)|^{2}$ (proportional to the oscillation energy), equals a half of its
resonance value (19). In the low damping limit, both these points are very close to $\omega_{0}$, so that in the first (linear) approximation in $\left(\omega-\omega_{0}\right) \ll \omega_{0}, \omega$ we can take $\left(\omega_{0}{ }^{2}-\omega^{2}\right) \equiv-\left(\omega+\omega_{0}\right)\left(\omega-\omega_{0}\right) \approx(-2 \omega \xi) \approx\left(-2 \omega_{0} \xi\right)$, where

$$
\begin{equation*}
\xi \equiv \omega-\omega_{0} \tag{4.21}
\end{equation*}
$$

is a convenient parameter called detuning. (We will repeatedly use it later in this chapter.) In this approximation, the second of Eqs. (18) is reduced to

$$
\begin{equation*}
|\chi(\omega)|^{2}=\frac{1}{4 \omega^{2}\left(\delta^{2}+\xi^{2}\right)} \tag{4.22}
\end{equation*}
$$

As a result, points $\omega_{ \pm}$correspond to $\xi^{2}=\delta^{2}$, i.e. $\omega_{ \pm}=\omega_{0} \pm \delta=\omega_{0}(1 \pm 1 / 2 Q)$, so that $\Delta \omega \equiv \omega_{+}-\omega_{-}=$ $\omega_{0} / Q$, thus proving Eq. (20).
(ii) Time domain. Returning to the general problem of linear oscillations, one may argue that Eqs. (9), (15)-(17) provide a full solution of the forced oscillation problem. This is formally correct, but this solution may be very inconvenient if the external force is far from sinusoidal function of time. In this case, we should first calculate the complex amplitudes $f_{\omega}$ participating in the Fourier sum (14). In the general case of non-periodic $f(t)$, this is actually the Fourier integral,

$$
\begin{equation*}
f(t)=\int_{-\infty}^{+\infty} f_{\omega} e^{-i \omega t} d t \tag{4.23}
\end{equation*}
$$

so that $f_{\omega}$ should be calculated using the reciprocal Fourier transform,

$$
\begin{equation*}
f_{\omega}=\frac{1}{2 \pi} \int_{-\infty}^{+\infty} f\left(t^{\prime}\right) e^{i \omega t^{\prime}} d t^{\prime} \tag{4.24}
\end{equation*}
$$

Now we can use Eq. (16) for each Fourier component of the resulting forced oscillations, and rewrite the last of Eqs. (15) as

$$
\begin{align*}
q_{\text {forced }}(t) & =\int_{-\infty}^{+\infty} a_{\omega} e^{-i \omega t} d \omega=\int_{-\infty}^{+\infty} \chi(\omega) f_{\omega} e^{-i \omega t} d \omega=\int_{-\infty}^{+\infty} d \omega \chi(\omega) \frac{1}{2 \pi} \int_{-\infty}^{+\infty} d t^{\prime} f\left(t^{\prime}\right) e^{i \omega\left(t^{\prime}-t\right)} \\
& =\int_{-\infty}^{+\infty} d t^{\prime} f\left(t^{\prime}\right)\left[\frac{1}{2 \pi} \int_{-\infty}^{+\infty} d \omega \chi(\omega) e^{i \omega\left(t^{\prime}-t\right)}\right], \tag{4.25}
\end{align*}
$$

with the response function $\chi(\omega)$ given, in our case, by Eq. (17). Besides requiring two integrations, Eq. (25) is conceptually uncomforting: it seems to indicate that the oscillator's coordinate at time $t$ depends not only on the external force exerted at earlier times $t^{\prime}<t$, but also in future times. This would contradict one of the most fundamental principles of physics (and indeed, science as a whole), the causality: no effect may precede its cause.

Fortunately, a straightforward calculation (left for reader's exercise) shows that the response function (17) satisfies the following rule: ${ }^{7}$

[^43]\[

$$
\begin{equation*}
\int_{-\infty}^{+\infty} \chi(\omega) e^{-i \omega \tau} d \omega=0, \quad \text { for } \tau<0 \tag{4.26}
\end{equation*}
$$

\]

This fact allows the last form of Eq. (25) to be rewritten in either of the following equivalent forms:

$$
\begin{equation*}
q_{\text {forced }}(t)=\int_{-\infty}^{t} f\left(t^{\prime}\right) G\left(t-t^{\prime}\right) d t^{\prime}=\int_{0}^{\infty} f(t-\tau) G(\tau) d \tau \tag{4.27}
\end{equation*}
$$

Linear system's response

Temporal
Green's function
is called the (temporal) Green's function of the system. According to Eq. (26), $G(\tau)=0$ for all $\tau<0$.
While the second form of Eq. (27) is more convenient for calculations, its first form is more clear conceptually. Namely, it expresses the linear superposition principle in time domain, and may be interpreted as follows: the full effect of force $f(t)$ on an oscillator (actually, any linear system ${ }^{8}$ ) may be described as a sum of effects of short pulses of duration $d t^{\prime}$ and magnitude $f\left(t^{\prime}\right)$ :

$$
\begin{equation*}
q_{\text {forced }}(t)=\lim _{\Delta t^{\prime} \rightarrow 0} \sum_{t^{\prime}=-\infty}^{t} G\left(t-t^{\prime}\right) f\left(t^{\prime}\right) \Delta t^{\prime} . \tag{4.29}
\end{equation*}
$$

- see Fig. 2. The Green's function $G(\tau)$ thus describes the oscillator response to a unit pulse of force, measured at time $\tau=t-t^{\prime}$ after the pulse.

Fig. 4.2. Presentation of the force as a function of time as a sum of short pulses.

Mathematically, it is more convenient to go to the limit $d t t^{\prime} \rightarrow 0$ and describe the elementary, unit-area pulse by Dirac's $\delta$-function, ${ }^{9}$ thus returning to Eq. (27). This line of reasoning also gives a convenient way to calculate the Green's function. Indeed, for the particular case,

$$
\begin{equation*}
f(t)=\delta\left(t-t_{0}\right), \quad \text { with } t_{0}<t \tag{4.30}
\end{equation*}
$$

Eq. (27) yields $q(t)=G\left(t-t_{0}\right)$. In particular, if $t>0$, we may take $t_{0}=0$; then $q(t)=G(t)$. Hence the Green's function may be calculated as a solution of the differential equation of motion of the system, in our case, Eq. (13), with the $\delta$-functional right-hand part:

$$
\begin{equation*}
\frac{d^{2} G(\tau)}{d \tau^{2}}+2 \delta \frac{d G(\tau)}{d \tau}+\omega_{0}^{2} G(\tau)=\delta(\tau) \tag{4.31}
\end{equation*}
$$

[^44]and zero initial conditions:
\[

$$
\begin{equation*}
G(-0)=\frac{d G}{d \tau}(-0)=0 \tag{4.32}
\end{equation*}
$$

\]

where $t=-0$ means the instant immediately preceding $t=0$.
This calculation may be simplified even further. Let us integrate both sides of Eq. (31) over a infinitesimal interval including the origin, e.g. $[-d \tau / 2,+d \tau / 2]$, and then follow the limit $d \tau \rightarrow 0$. Since Green's function has to be continuous because of its physical sense as the (generalized) coordinate, all terms in the left hand part but the first one vanish, while the first term yields $d G /\left.d \tau\right|_{+0}-d G /\left.d \tau\right|_{-0}$. Due to the second of Eqs. (32), the last of these two terms equals zero, while the right-hand part yields 1. Thus, $G(\tau)$ may be calculated for $\tau>0$ (i.e. for all times when $G(\tau) \neq 0$ ) by solving the homogeneous version of system's equation of motion for $\tau>0$, with the following special initial conditions:

$$
\begin{equation*}
G(0)=0, \quad \frac{d G}{d \tau}(0)=1 \tag{4.33}
\end{equation*}
$$

This approach gives us a convenient way for calculation of Green's functions of linear systems. In particular for the oscillator with not very low damping ( $\delta>\omega_{0}$, i.e. $Q>1 / 2$ ), imposing boundary conditions (33) on the general free-oscillation solution (9), we immediately get ${ }^{10}$ function

$$
\begin{equation*}
G(\tau)=\frac{1}{\omega_{0}{ }^{\prime}} e^{-\delta \tau} \sin \omega_{0}{ }^{\prime} \tau \tag{4.34}
\end{equation*}
$$

Equations (27) and (34) provide a very convenient recipe for solving most forced oscillations problems. As a very simple example, let us calculate the transient process in an oscillator under the effect of a constant force being turned on at $t=0$ :

$$
f(t)=\left\{\begin{array}{cc}
0, & t<0  \tag{4.35}\\
f_{0}, & t>0
\end{array}\right.
$$

provided that at $t<0$ the oscillator was at rest, so that $q_{\text {free }}(t) \equiv 0$. Then the second form of Eq. (27) yields

$$
\begin{equation*}
q(t)=\int_{0}^{\infty} f(t-\tau) G(\tau) d \tau=f_{0} \int_{0}^{t} \frac{1}{\omega_{0}{ }^{\prime}} e^{-\delta \tau} \sin \omega_{0}{ }^{\prime} \tau d \tau \tag{4.36}
\end{equation*}
$$

The simplest way to work out such integrals is to present the sine function as the imaginary part of $\exp \left\{i \omega_{0}{ }^{\prime} t\right\}$, and merge the two exponents, getting

$$
\begin{equation*}
q(t)=f_{0} \frac{1}{\omega_{0}{ }^{\prime}} \operatorname{Im}\left[\frac{1}{\delta+i \omega_{0}{ }^{\prime}} e^{-\delta \tau-i \omega_{0}{ }^{\prime} \tau}\right]_{0}^{t}=\frac{F_{0}}{k}\left[1-e^{-\delta t}\left(\cos \omega_{0}{ }^{\prime} t+\frac{\delta}{\omega_{0}{ }^{\prime}} \sin \omega_{0}{ }^{\prime} t\right)\right] . \tag{4.37}
\end{equation*}
$$

This result, plotted in Fig. 3, is rather natural: it describes nothing more than the transient from the initial equilibrium position $q=0$ to the new equilibrium position $q_{0}=f_{0} / \omega_{0}{ }^{2}=F_{0} / \kappa$, accompanied by

[^45]decaying oscillations. For this particular simple function $f(t)$, the same result might be also obtained by introducing a new variable $\widetilde{q}(t) \equiv q(t)-q_{0}$ and solving the resulting homogeneous equation for $\widetilde{q}$ (with appropriate initial condition $\left.\widetilde{q}(0)=-q_{0}\right)$, but for more complicated functions $f(t)$ the Green's function approach is irreplaceable.

Fig. 4.3. Transient process in a linear oscillator, induced by a step-like force $f(t)$, for the particular case $\delta / \omega_{0}=0.1$ (i.e., $Q=5$ ).

Note that for any particular linear system, its Green's function should be calculated only once, and then may be repeatedly used in Eq. (27) to calculate the system response to various external forces either analytically or numerically. This property makes the Green's function approach very popular in many other fields of physics - with the corresponding generalization or re-definition of the function. ${ }^{11}$

### 4.2. Weakly nonlinear oscillations

In comparison with systems discussed in the last section, which are described by linear differential equations with constant coefficients and thus allow a complete and exact analytical solution, oscillations in nonlinear systems generally present a complex and, generally, analytically intractable problem. Let us start a discussion of such nonlinear oscillations ${ }^{12}$ from an important case that may be explored analytically. In many important 1D oscillators, higher terms in the potential expansion (3.10) cannot be neglected, but are small and may be accounted for approximately. If, in addition, damping is low (or negligible), the equation of motion may be presented as a slightly modified Eq. (13):

$$
\begin{equation*}
\ddot{q}+\omega^{2} q=f(t, q, \dot{q}, \ldots) \tag{4.38}
\end{equation*}
$$

Weakly nonlinear oscillator
where $\omega \approx \omega_{0}$ is the anticipated frequency of oscillations (whose choice is to a certain extent arbitrary see below), and the right-hand part $f$ is small (say, scales as some small dimensionless parameter $\varepsilon \ll$ $1)$, and may be considered as a perturbation.

Since at $\varepsilon=0$ this equation has the sinusoidal solution given by Eq. (3), one might naïvely think that at nonvanishing but small $\varepsilon$, the approximate solution to Eq. (38) should be sought in the form

$$
\begin{equation*}
q(t)=q^{(0)}+q^{(1)}+q^{(2)}+\ldots, \quad \text { where } q^{(n)} \propto \varepsilon^{n} \tag{4.39}
\end{equation*}
$$

with $q^{(0)}=A \cos \left(\omega_{0} t-\varphi\right) \propto \varepsilon^{0}$. This is a good example of an apparently impeccable mathematical reasoning that would lead to a very inefficient procedure. Indeed, let us apply it to the problem we

[^46]already know the exact solution for, namely the free oscillations in a linear but damped oscillator, for this occasion assuming the damping to be very low, $\delta / \omega_{0} \sim \varepsilon \ll 1$. The corresponding equation of motion, Eq. (6), may be presented in form (38) if we take $\omega=\omega_{0}$ and
\[

$$
\begin{equation*}
f=-2 \delta \dot{q}, \quad \delta \propto \varepsilon . \tag{4.40}
\end{equation*}
$$

\]

The naïve approach described above would allow us to find small corrections, of the order of $\delta$, to the free, non-decaying oscillations $A \cos \left(\omega_{0} t-\varphi\right.$ ). However, we already know from Eq. (9) that the main effect of damping is a gradual decrease of the free oscillation amplitude to zero, i.e. a very large change of the amplitude, though at low damping, $\delta \ll \omega_{0}$, this decay takes large time $t \sim \tau \gg 1 / \omega_{0}$. Hence, if we want our approximate method to be productive (i.e. to work at all time scales, in particular for forced oscillations with established, constant amplitude and phase), we need to account for the fact that the small right-hand part of Eq. (38) may eventually lead to essential changes of oscillation amplitude $A$ (and sometimes, as we will see below, also of oscillation phase $\varphi$ ) at large times, because of the slowly accumulating effects of the small perturbation. ${ }^{13}$

This goal may be achieved by the account of these slow changes already in the " 0 th approximation", i.e. the basic part of the solution in expansion (39):
$0^{\text {th }}$ order
RWA solution

$$
\begin{equation*}
q^{(0)}=A(t) \cos [\omega t-\varphi(t)], \quad \text { with } \dot{A}, \dot{\varphi} \rightarrow 0 \quad \text { at } \varepsilon \rightarrow 0 . \tag{4.41}
\end{equation*}
$$

The approximate methods based on Eqs. (39) and (41) have several varieties and several names, ${ }^{14}$ but their basic idea and the results in the most important approximation (41) are the same. Let me illustrate this approach on a particular, simple but representative example of a dissipative (but high- $Q$ ) pendulum driven by a weak sinusoidal external force with a nearly-resonant frequency:

$$
\begin{equation*}
\ddot{q}+2 \delta \dot{q}+\omega_{0}^{2} \sin q=f_{0} \cos \omega t \tag{4.42}
\end{equation*}
$$

with $\left|\omega-\omega_{0}\right|, \delta \ll \omega_{0}$, and the force amplitude $f_{0}$ so small that $|q| \ll 1$ at all times. From what we know about the forced oscillations from Sec. 1, it is natural to identify $\omega$ in the left-hand part of Eq. (38) with the force frequency. Expanding $\sin q$ into the Taylor series in small $q$, keeping only the first two terms of this expansion, and moving all the small terms to the right-hand part, we can bring Eq. (42) to the canonical form (38): ${ }^{15}$

$$
\begin{equation*}
\ddot{q}+\omega^{2} q=-2 \delta \dot{q}+2 \xi \omega q+\alpha q^{3}+f_{0} \cos \omega t \equiv f(t, q, \dot{q}) \tag{4.43}
\end{equation*}
$$

Here $\alpha=\omega_{0}{ }^{2} / 6$ in the case of the pendulum (though the calculations below will be valid for any $\alpha$ ), and the second term in the right-hand part was obtained using the approximation already employed in Sec. 1:

[^47]$\left(\omega^{2}-\omega_{0}^{2}\right) q \approx 2 \omega\left(\omega-\omega_{0}\right) q=2 \omega \xi q$, where $\xi \equiv \omega-\omega_{0}$ is the detuning parameter that was already used earlier - see Eq. (21).

Now, following the general recipe expressed by Eqs. (39) and (41), in the $1^{\text {st }}$ approximation in $f$ $\propto \varepsilon,{ }^{16}$ we may look for the solution to Eq. (43) in the form

$$
\begin{equation*}
q(t)=A \cos \Psi+q^{(1)}(t), \quad \text { where } \Psi \equiv \omega t-\varphi, \quad q^{(1)} \sim \varepsilon \tag{4.44}
\end{equation*}
$$

Let us plug this assumed solution into both parts of Eq. (43), leaving only the terms of the first order in $\varepsilon$. Thanks to our (smart :-) choice of $\omega$ in the left-hand part of that equation, the two zero-order terms in that part cancel each other. Moreover, since each term in the right-hand part of Eq. (43) is already of the order of $\varepsilon$, we may drop $q^{(1)} \propto \varepsilon$ from the substitution into that part at all, because this would give us only terms $O\left(\varepsilon^{2}\right)$ or higher. As a result, we get the following approximate equation:

$$
\begin{equation*}
\ddot{q}^{(1)}+\omega^{2} q^{(1)}=f^{(0)} \equiv-2 \delta \frac{d}{d t}(A \cos \Psi)+2 \xi \omega A \cos \Psi+\alpha(A \cos \Psi)^{3}+f_{0} \cos \omega t . \tag{4.45}
\end{equation*}
$$

According to Eq. (41), generally $A$ and $\varphi$ should be considered as (slow) functions of time. However, let us leave the analyses of transient process and system stability until the next section, and use Eq. (45) to find stationary oscillations in the system, that are established after the initial transient. For that limited task, we may take $A=$ const, $\varphi=$ const, so that $q^{(0)}$ presents sinusoidal oscillations of frequency $\omega$. Sorting the terms in the right-hand part according to their time dependence, ${ }^{17}$ we see that it has terms with frequencies $\omega$ and $3 \omega$.

$$
\begin{equation*}
f^{(0)}=\left(2 \xi \omega A+\frac{3}{4} \alpha A^{3}+f_{0} \cos \varphi\right) \cos \Psi+\left(2 \delta \omega A-f_{0} \sin \varphi\right) \sin \Psi+\frac{1}{4} \alpha A^{3} \cos 3 \Psi \tag{4.46}
\end{equation*}
$$

Now comes the main trick of the rotating-wave approximation: mathematically, Eq. (45) may be viewed as the equation of oscillations in a linear, dissipation-free harmonic oscillator of frequency $\omega$ (not $\omega_{0}!$ ) under the action of an external force represented by the right-hand part of the equation. In our particular case, it has three terms: two quadrature components at that very frequency $\omega$, and the third one at frequency $3 \omega$. As we know from our analysis of this problem in Sec. 1, if any of the first two components is nonvanishing, $q^{(1)}$ grows to infinity - see Eq. (19) with $\delta=0$. At the same time, by the very structure of the rotating-wave approximation, $q^{(1)}$ has to be finite - moreover, small! The only way out of this contradiction is to require that amplitudes of both quadrature components of $f^{(0)}$ with frequency $\omega$ are equal to zero:

$$
\begin{equation*}
2 \xi \omega A+\frac{3}{4} \alpha A^{3}+f_{0} \cos \varphi=0, \quad 2 \delta \omega A-f_{0} \sin \varphi=0 \tag{4.47}
\end{equation*}
$$

These two harmonic balance equations enable us to find both parameters of the forced oscillations: their amplitude $A$ and phase $\varphi$. In particular, the phase may be readily eliminated from this

[^48]system (most easily, by expressing $\sin \varphi$ and $\cos \varphi$ from the corresponding equations, and then requiring the sum $\sin ^{2} \varphi+\cos ^{2} \varphi$ to equal 1), and the solution for amplitude $A$ presented in the following implicit but convenient form:
\[

$$
\begin{equation*}
A^{2}=\frac{f_{0}^{2}}{4 \omega^{2}} \frac{1}{\xi^{2}(A)+\delta^{2}}, \quad \text { where } \quad \xi(A) \equiv \xi+\frac{3}{8} \frac{\alpha A^{2}}{\omega}=\omega-\left(\omega_{0}-\frac{3}{8} \frac{\alpha A^{2}}{\omega}\right) \tag{4.48}
\end{equation*}
$$

\]

This expression differs from Eq. (22) for the linear resonance in the low-damping limit only by the replacement of the detuning $\xi$ with its effective amplitude-dependent value $\xi(A)$ or, equivalently, of the eigenfrequency $\omega_{0}$ of the resonator with its effective, amplitude-dependent value

$$
\begin{equation*}
\omega_{0}(A)=\omega_{0}-\frac{3}{8} \frac{\alpha A^{2}}{\omega} . \tag{4.49}
\end{equation*}
$$

The physical meaning of $\omega_{0}(A)$ is simple: this is just the frequency of free oscillations of amplitude $A$ in a similar nonlinear system, but with zero damping. Indeed, for $\delta=0$ and $f_{0}=0$ we could repeat our calculations, assuming that $\omega$ is an amplitude-dependent eigenfrequency $\omega_{0}(A)$, to be found. Then the second of Eqs. (47) is trivially satisfied, while the second of them gives Eq. (49).

Expression (48) allows one to draw the curves of this nonlinear resonance just by bending the linear resonance plots (Fig. 1) according to the so-called skeleton curve expressed by Eq. (49). Figure 4 shows the result of this procedure. Note that at small amplitude, $\omega(A) \rightarrow \omega_{0}$, and we return to the usual, "linear" resonance (22).

Fig. 4.4. Nonlinear resonance in the Duffing oscillator, as described by the rotating-wave approximation result (48), for the particular case $\alpha=\omega_{0}^{2} / 6, \delta / \omega=0.01$ (i.e. $Q=50$ ), and seven values of parameter $f_{0} / \omega_{0}^{2}$, increased bv eaual stens from 0 to 0.035 .

To bring our solution to its logical completion, we should still find the first perturbation $q^{(1)}(t)$ from what is left of Eq. (45). Since the structure of this equation is similar to Eq. (13) with the force of frequency $3 \omega$ and zero damping, we may use Eqs. (16)-(17) to obtain

$$
\begin{equation*}
q^{(1)}(t)=-\frac{1}{32 \omega^{2}} \alpha A^{3} \cos 3(\omega t-\varphi) . \tag{4.50}
\end{equation*}
$$

Adding this perturbation (note the negative sign!) to the sinusoidal oscillation (41), we see that as the amplitude $A$ of oscillations in a system with $\alpha>0$ (e.g., a pendulum) grows, their waveform become a bit more "blunt" near the maximum deviations from the equilibrium.

Expression (50) also allows an estimate of the range of validity of the rotating-wave approximation: since it has been based on the assumption $\left|q^{(1)}\right| \ll\left|q^{(0)}\right| \leq A$, for this particular problem we have to require $\alpha A^{2} / 32 \omega^{2} \ll 1$. For a pendulum (with $\alpha=\omega_{0}^{2} / 6$ ), this condition becomes $A^{2} \ll 192$. Though numerical coefficients in such strong inequalities should be taken with a grain of salt, the large magnitude of this particular coefficient gives a good hint that the method should give very good results even for relatively large oscillations with $A \sim 1$. In Sec. 7 below, we will see that this is indeed the case.

From the mathematical viewpoint, the next step would be to calculate the next approximation

$$
\begin{equation*}
q(t)=A \cos \Psi+q^{(1)}(t)+q^{(2)}(t), \quad q^{(2)} \sim \varepsilon^{2}, \tag{4.51}
\end{equation*}
$$

and plug it into the Duffing equation (43), which (thanks to our special choice of $q^{(0)}$ and $q^{(1)}$ ) would retain only $\ddot{q}^{(2)}+\omega^{2} q^{(2)}$ in its left-hand part. Again, requiring that amplitudes of two quadrature components of frequency $\omega$ in the right-hand part to be zero, we may get the second-order corrections to $A$ and $\varphi$. Then we may use the remaining part of the equation to calculate $q^{(2)}$, and then go after the third-order terms, etc. However, for most purposes the sum $q^{(0)}+q^{(1)}$, and sometimes even just the crudest approximation $q^{(0)}$ alone, are completely sufficient. For example, according to Eq. (50), for a simple pendulum ( $\alpha=\omega_{0}{ }^{2} / 6$ ) swinging as much as between the opposite horizontal positions ( $A=\pi / 2$ ), the $1^{\text {st }}$ order correction $q^{(1)}$ is of the order of $0.5 \%$. (Soon beyond this value, completely new dynamic phenomena start - see Sec. 7 below, but these phenomena cannot be covered by the rotating-wave approximation, at least in our current form.) Due to this reason, higher approximations are rarely pursued either in physics or engineering.

### 4.3. RWA equations

A much more important issue is the stability of solutions described by Eq. (48). Indeed, Fig. 4 shows that within a certain range of parameters, these equations give three different values for the oscillation amplitude (and phase), and it is important to understand which of these solutions are stable. Since these solutions are not the fixed points in the sense discussed in the Sec. 3.2 (each point in Fig. 4 represents a nearly-sinusoidal oscillation), their stability analysis needs a more general approach that would be valid for oscillations with amplitude and phase slowly evolving in time. This approach will also enable the analysis of non-stationary (especially the initial transient) processes that are of key importance for some dynamic systems.

First of all, let us formalize the way the harmonic balance equations, such as Eqs. (47), are obtained for the general case (38) - rather than for the particular Eq. (43) considered in the last section. After plugging in the $0^{\text {th }}$ approximation (41) into the right-hand part of equation (38) we have to require the amplitudes of its both quadrature components of frequency $\omega$ to be zero. From the standard Fourier analysis we know that these requirements may be presented as

$$
\begin{equation*}
\overline{f^{(0)} \sin \Psi}=0, \quad \overline{f^{(0)} \cos \Psi}=0 \tag{4.52}
\end{equation*}
$$

where symbol $\ldots$ means time averaging - in our current case, over the period $2 \pi / \omega$ of the right-hand part of Eq. (52), with the arguments calculated in the $0^{\text {th }}$ approximation:

$$
\begin{equation*}
f^{(0)} \equiv f\left(t, q^{(0)}, \dot{q}^{(0)}, \ldots\right) \equiv f(t, A \cos \Psi,-A \omega \sin \Psi, \ldots), \quad \text { with } \Psi=\omega t-\varphi \tag{4.53}
\end{equation*}
$$

Now, for a transient process the contribution of $q^{(0)}$ to left-hand part of Eq. (38) is not zero any longer, because both amplitude and phase may be slow functions of time - see Eq. (41). Let us calculate this contribution. The exact result would be

$$
\begin{align*}
\ddot{q}^{(0)}+\omega^{2} q^{(0)} & \equiv\left(\frac{d^{2}}{d t^{2}}+\omega^{2}\right) A \cos (\omega t-\varphi)  \tag{4.54}\\
& =\left(\ddot{A}+2 \dot{\varphi} \omega A-\dot{\varphi}^{2} A\right) \cos (\omega t-\varphi)-2 \dot{A}(\omega-\dot{\varphi}) \sin (\omega t-\varphi)
\end{align*}
$$

However, in the first approximation in $\varepsilon$, we may neglect the second derivative of $A$, and also the squares and products of the first derivatives of $A$ and $\varphi$ (that are all of the second order in $\varepsilon$ ), so that Eq. (54) is reduced to

$$
\begin{equation*}
\ddot{q}^{(0)}+\omega^{2} q^{(0)} \approx 2 A \dot{\varphi} \omega \cos (\omega t-\varphi)-2 \dot{A} \omega \sin (\omega t-\varphi) \tag{4.55}
\end{equation*}
$$

In the right-hand part of Eq. (52), we can neglect the time derivatives of the amplitude and phase at all, because this part is already proportional to the small parameter. Hence, in the first order in $\varepsilon$, Eq. (38) becomes

$$
\begin{equation*}
\ddot{q}^{(1)}+\omega^{2} q^{(1)}=f_{\mathrm{ef}}^{(0)} \equiv f^{(0)}-(2 A \dot{\varphi} \omega \cos \Psi-2 \dot{A} \omega \sin \Psi) \tag{4.56}
\end{equation*}
$$

Now, applying Eqs. (52) to function $f_{\text {ef }}{ }^{(0)}$, and taking into account that the time averages of $\sin ^{2} \Psi$ and $\cos ^{2} \Psi$ are both equal to $1 / 2$, while the time average of the product $\sin \Psi \cos \Psi$ vanishes, we get a pair of so-called RWA equations (alternatively called "the reduced equations" or sometimes "the van der Pol equations") for the time evolution of the amplitude and phase:

$$
\begin{equation*}
\dot{A}=-\frac{1}{\omega} \overline{f^{(0)} \sin \Psi}, \quad \dot{\varphi}=\frac{1}{\omega A} \overline{f^{(0)} \cos \Psi} \tag{4.57a}
\end{equation*}
$$

Extending the definition (4) of the complex amplitude of oscillations to their slow evolution in time, $a(t)$ $\equiv A(t) \exp \{i \varphi(t)\}$, and differentiating this relation, we see that two equations (57a) may be also re-written in the form of either one equation for $a$ :

Alternative forms of RWA equations

$$
\begin{equation*}
\dot{a}=\frac{i}{\omega} \overline{f^{(0)} e^{i(\Psi+\varphi)}} \equiv \frac{i}{\omega} \overline{f^{(0)} e^{i \omega t}} \tag{4.57b}
\end{equation*}
$$

or two equations for the real and imaginary parts of $a(t)=u(t)+i v(t)$ :

$$
\begin{equation*}
\dot{u}=-\frac{1}{\omega} \overline{f^{(0)} \sin \omega t}, \quad \dot{v}=\frac{1}{\omega} \overline{f^{(0)} \cos \omega t} . \tag{4.57c}
\end{equation*}
$$

The first-order harmonic balance equations (52) are evidently just the particular case of the RWA equations (57) for stationary oscillations ( $\dot{A}=\dot{\varphi}=0$ ). ${ }^{18}$

Superficially, the system (57a) of two coupled, first-order differential equations may look more complex than the initial, second-order differential equation (38), but actually it is usually much simpler.

[^49]For example, let us spell them out for the easy case of free oscillations a linear oscillator with damping. For that, we may reuse the ready Eq. (46) with $\alpha=f_{0}=0$, turning Eqs. (4.57a) into

$$
\begin{align*}
& \dot{A}=-\frac{1}{\omega} \overline{f^{(0)} \sin \Psi}=-\frac{1}{\omega} \overline{(2 \xi \omega A \cos \Psi+2 \delta \omega A \sin \Psi) \sin \Psi}=-\delta A,  \tag{4.58a}\\
& \dot{\varphi}=\frac{1}{\omega A} \overline{f^{(0)} \cos \Psi}=\frac{1}{\omega A} \overline{(2 \xi \omega A \cos \Psi+2 \delta \omega A \sin \Psi) \cos \Psi}=\xi \tag{4.58b}
\end{align*}
$$

The solution of Eq. (58a) gives us the same "envelope" law $A(t)=A(0) e^{-\delta t}$ as the exact solution (10) of the initial differential equation, while the elementary integration of Eq. (58b) yields $\varphi(t)=\xi t+$ $\varphi(0)=\omega t-\omega_{0} t+\varphi(0)$. This means that our approximate solution,

$$
\begin{equation*}
q^{(0)}(t)=A(t) \cos [\omega t-\varphi(t)]=A(0) e^{-\delta t} \cos \left[\omega_{0} t-\varphi(0)\right] \tag{4.59}
\end{equation*}
$$

agrees with the exact Eq. (9), and misses only correction (8) to the oscillation frequency, that is of the second order in $\delta$, i.e. of the order of $\varepsilon^{2}$ - beyond the accuracy of our first approximation. It is remarkable how nicely do the RWA equations recover the proper frequency of free oscillations in this autonomous system - in which the very notion of $\omega$ is ambiguous.

The situation is different at forced oscillations. For example, for the (generally, nonlinear) Duffing oscillator described by Eq. (43) with $f_{0} \neq 0$, Eqs. (57a) yield the RWA equations,

$$
\begin{equation*}
\dot{A}=-\delta A+\frac{f_{0}}{2 \omega} \sin \varphi, \quad A \dot{\varphi}=\xi(A) A+\frac{f_{0}}{2 \omega} \cos \varphi \tag{4.60}
\end{equation*}
$$

which are valid for an arbitrary function $\xi(A)$, provided that the nonlinear detuning remains much smaller than the oscillation frequency. Here (after a transient), the amplitude and phase tend to the stationary states described by Eqs. (47). This means that $\varphi$ becomes a constant, so that $q^{(0)} \rightarrow A \cos (\omega t-$ const), i.e. the RWA equations again automatically recover the correct frequency of the solution, in this case equal to that of the external force.

Note that each stationary oscillation regime, with certain amplitude and phase, corresponds to a fixed point of the RWA equations, so that the stability of those fixed points determine that of the oscillations. In what follows, we will carry out such an analysis for several simple systems of key importance for physics and engineering.

### 4.4. Self-oscillations and phase locking

The rotating-wave approximation was pioneered by B. van der Pol in the late 1920s for analysis of one more type of oscillatory motion: self-oscillations. Several systems, e.g., electronic rf amplifiers with positive feedback, and optical media with quantum level population inversion, provide convenient means for the compensation, and even over-compensation of the intrinsic energy losses in oscillators. Phenomenologically, this effect may be described as the change of sign of the damping coefficient $\delta$ from positive to negative. Since for small oscillations the equation of motion is still linear, we may use Eq. (9) to describe its general solution. This equation shows that at $\delta<0$, even infinitesimal deviations from equilibrium (say, due to unavoidable fluctuations) lead to oscillations with exponentially growing amplitude. Of course, in any real system such growth cannot persist infinitely, and shall be limited by
this or that effect - e.g., in the above examples, respectively, by amplifier saturation or electron population exhaustion.

In many cases, the amplitude limitation may be described reasonably well by nonlinear damping:

$$
\begin{equation*}
2 \delta \dot{q} \rightarrow 2 \dot{q} \dot{q}+\beta \dot{q}^{3} \tag{4.61}
\end{equation*}
$$

with $\beta>0$. Let us analyze this phenomenon, applying the rotating-wave approximation to the corresponding homogeneous differential equation:

$$
\begin{equation*}
\ddot{q}+2 \delta \dot{q}+\beta \dot{q}^{3}+\omega_{0}^{2} q=0 \tag{4.62}
\end{equation*}
$$

Carrying out the dissipative and detuning terms to the right hand part as $f$, we can readily calculate the right-hand parts of the RWA equations (57a), getting ${ }^{19}$

$$
\begin{gather*}
\dot{A}=-\delta(A) A, \quad \text { where } \delta(A) \equiv \delta+\frac{3}{8} \beta \omega^{2} A^{2}  \tag{4.63a}\\
A \dot{\varphi}=\xi A \tag{4.63b}
\end{gather*}
$$

The second of these equations has exactly the same form as Eq. (58b) for the case of decaying oscillations and hence shows that the self-oscillations (if they happen, i.e. if $A \neq 0$ ) have frequency $\omega_{0}$ of the oscillator itself - see Eq. (59). Equation (63a) is more interesting. If the initial damping $\delta$ is positive, it has only the trivial fixed point, $A_{0}=0$ (that describes the oscillator at rest), but if $\delta$ is negative, there is also another fixed point,

$$
\begin{equation*}
A_{1}=\left(\frac{8|\delta|}{3 \beta \omega^{2}}\right)^{1 / 2} \tag{4.64}
\end{equation*}
$$

which describes steady self-oscillations with a non-zero amplitude.
Let us apply the general approach discussed in Sec. 3.2, the linearization of equations of motion, to this RWA equation. For the trivial fixed point $A_{0}=0$, the linearization of Eq. (63a) is reduced to discarding the nonlinear term in the definition of the amplitude-dependent damping $\delta(A)$. The resulting linear equation evidently shows that the system's equilibrium point, $A=A_{0}=0$, is stable at $\delta>0$ and unstable at $\delta<0$. (We have already discussed this self-excitation condition above.) The linearization of Eq. (63a) near the non-trivial fixed point $A_{1}$ requires a bit more math: in the first order in $\widetilde{A} \equiv A-A_{1} \rightarrow 0$, we get

$$
\begin{equation*}
\dot{\tilde{A}} \equiv \dot{A}=-\delta\left(A_{1}+\widetilde{A}\right)-\frac{3}{8} \beta \omega^{2}\left(A_{1}+\widetilde{A}\right)^{3} \approx-\delta \widetilde{A}-\frac{3}{8} \beta \omega^{2} 3 A_{1}^{2} \widetilde{A}=(-\delta+3 \delta) \widetilde{A}=2 \widetilde{\delta A} \tag{4.65}
\end{equation*}
$$

where Eq. (64) has been used to eliminate $A_{1}$. We see that fixed point $A_{1}$ (and hence the whole process) is stable as soon as it exists $(\delta<0)$ - similar to the situation in our "testbed problem" (Fig. 2.1).

Now let us consider another important problem: the effect of a external sinusoidal force on a self-excited oscillator. If the force is sufficiently small, its effects on the self-excitation condition and the oscillation amplitude are negligible. However, if frequency $\omega$ of such weak force is close to the

[^50]eigenfrequency $\omega_{0}$ of the oscillator, it may lead to a very important effect of phase-locking (also called "synchronization"). At this effect, oscillator's frequency deviates from $\omega_{0}$, and becomes exactly equal to the external force's frequency $\omega$, within a certain range
\[

$$
\begin{equation*}
-\Delta \leq \omega-\omega_{0}<+\Delta . \tag{4.66}
\end{equation*}
$$

\]

In order to prove this fact, and also to calculate the phase locking range width $2 \Delta$, we may repeat the calculation of the right-hand parts of the RWA equations (57a), adding term $f_{0} \cos \omega t$ to the righthand part of Eq. (62) - cf. Eqs. (42)-(43). This addition modifies Eqs. (63) as follows: ${ }^{20}$

$$
\begin{gather*}
\dot{A}=-\delta(A) A+\frac{f_{0}}{2 \omega} \sin \varphi,  \tag{4.67a}\\
A \dot{\varphi}=\xi A+\frac{f_{0}}{2 \omega} \cos \varphi . \tag{4.67b}
\end{gather*}
$$

If the system is self-excited, and the external force is weak, its effect on the oscillation amplitude is small, and in the first approximation in $f_{0}$ we can take $A$ to be constant and equal to the value $A_{1}$ given by Eq. (64). Plugging this approximation into Eq. (67b), we get a very simple equation ${ }^{21}$

$$
\begin{equation*}
\dot{\varphi}=\xi+\Delta \cos \varphi \tag{4.68}
\end{equation*}
$$

where in our current case

$$
\begin{equation*}
\Delta \equiv \frac{f_{0}}{2 \omega A_{1}} \tag{4.69}
\end{equation*}
$$

Within the range $-|\Delta|<\xi<+|\Delta|$, Eq. (68) has two fixed points on each $2 \pi$-segment of variable $\varphi$ :

$$
\begin{equation*}
\varphi_{ \pm}= \pm \cos ^{-1}\left(-\frac{\xi}{\Delta}\right)+2 \pi n . \tag{4.70}
\end{equation*}
$$

It is easy to linearize Eq. (68) near each point to analyze their stability in our usual way; however, let me this case to demonstrate another convenient way to do this in 1D systems, using the socalled phase plane - the plot of the right-hand part of Eq. (68) as a function of $\varphi$ - see Fig. 5.

Fig. 4.5. Phase plane of a phaselocked oscillator, for the particular case $\xi=\Delta / 2, f_{0}>0$.

[^51]Since the positive values of this function correspond to the growth of $\varphi$ in time, and vice versa, we may draw the arrows showing the direction of phase evolution. From this graphics, it is clear that one of these fixed points (for $f_{0}>0, \varphi_{+}$) is stable, while its counterpart is unstable. Hence the magnitude of $\Delta$ given by Eq. (69) is indeed the phase locking range (or rather it half) that we wanted to find. Note that the range is proportional to the amplitude of the phase locking signal - perhaps the most important feature of phase locking.

In order to complete our simple analysis, based on the assumption of fixed oscillation amplitude, we need to find the condition of validity of this assumption. For that, we may linearize Eq. (67a), for the stationary case, near value $A_{1}$, just as we have done in Eq. (65) for the transient process. The stationary result,

$$
\begin{equation*}
\widetilde{A} \equiv A-A_{1}=\frac{1}{2 \mid \delta} \frac{f_{0}}{2 \omega} \sin \varphi_{ \pm} \approx A_{1}\left|\frac{\Delta}{2 \delta}\right| \sin \varphi_{ \pm} \tag{4.71}
\end{equation*}
$$

shows that our assumption, $|\tilde{A}| \ll A_{1}$. and hence the final result (69), are valid if the phase locking range, $2 \Delta$, is much smaller than $4|\delta|$.

### 4.5. Parametric excitation

In both problems solved in the last section, the stability analysis was easy because it could be carried out for just one slow variable, either amplitude or phase. Generally, such analysis of the RWA equations involves both these variables. The classical example of such situation is provided by one important physical phenomenon - the parametric excitation of oscillations. An elementary example of such oscillations is given by a pendulum with an externally-changed parameter, for example length $l(t)$ see Fig. 6. Experiments (including those with playground swings :-) and numerical simulations show that if the length is changed (modulated) periodically, with frequency $2 \omega$ that is close to $2 \omega_{0}$ and a sufficiently large swing $\Delta l$, the equilibrium position of the pendulum becomes unstable, and it starts swinging with frequency $\omega$ equal exactly to the half of the length modulation frequency (and hence only approximately equal to the average eigenfrequency $\omega_{0}$ of the oscillator).

Fig. 4.6. Parametric excitation of pendulum oscillations.

For an elementary analysis of this effect we may consider the simplest case when the oscillations are small. At the lowest point $(\theta=0)$, where the pendulum moves with the highest velocity $v_{\max }$, string's tension $\tau$ is higher than $m g$ by the centripetal force: $\tau_{\max }=m g+m v_{\max }{ }^{2} / l$. On the contrary, at the maximum deviation of the pendulum from the equilibrium, the force is weakened by string's tilt: $\tau_{\min }$ $=m g \cos \theta_{\max }$. Using the energy conservation, $E=m v_{\max }^{2} / 2=m g l\left(1-\cos \theta_{\max }\right)$, we may express these values as $T_{\max }=m g+2 E / l$ and $T_{\min }=m g-E / l$. Now, if during each oscillation period the string is pulled
up sharply and slightly by $\Delta l(|\Delta l| \ll l)$ at each of its two passages through the lowest point, and is let to go down by the same amount at each of two points of the maximum deviation, the net work of the external force per period is positive:

$$
\begin{equation*}
W \approx 2\left(\tau_{\max }-\tau_{\min }\right) \Delta l \approx 6 \frac{\Delta l}{l} E, \tag{4.72}
\end{equation*}
$$

and hence results in an increase of the oscillator's energy. If the so-called modulation depth $\Delta l / 2 l$ is sufficient, this increase may be sufficient to overcompensate the energy drained out by damping. Quantitatively, Eq. (10) shows that low damping ( $\delta \ll \omega_{0}$ ) leads to the following energy decrease,

$$
\begin{equation*}
\Delta E \approx-4 \pi \frac{\delta}{\omega_{0}} E \tag{4.73}
\end{equation*}
$$

per oscillation period. Comparing Eqs. (72) and (73), we see that the net energy flow into the oscillations is positive, $W+\Delta E>0$, i.e. oscillation amplitude has to grow if ${ }^{22}$

$$
\begin{equation*}
\frac{\Delta l}{l}>\frac{2 \pi \delta}{3 \omega_{0}} \equiv \frac{\pi}{3 Q} . \tag{4.74}
\end{equation*}
$$

Since this result is independent on $E$, the growth of energy and amplitude is exponential (for sufficiently low $E$ ), so that Eq. (74) is the condition of parametric excitation - in this simple model.

However, this result does not account for the possible difference between the oscillation frequency $\omega$ and the eigenfrequency $\omega_{0}$, and also does not clarify whether the best phase shift between the parametric oscillations and parameter modulation, assumed in the above calculation, may be sustained automatically. In order to address these issues, we may apply the rotating-wave approximation to a simple but reasonable linear equation

$$
\begin{equation*}
\ddot{q}+2 \delta \dot{q}+\omega_{0}^{2}(1+\mu \cos 2 \omega t) q=0, \tag{4.75}
\end{equation*}
$$

describing the parametric excitation for a particular case of sinusoidal modulation of $\omega_{0}{ }^{2}(t)$. Rewriting this equation in the canonical form (38),

$$
\begin{equation*}
\ddot{q}+\omega^{2} q=f(t, q, \dot{q})=-2 \delta \dot{q}+2 \xi \omega q-\mu \omega_{0}^{2} q \cos 2 \omega t, \tag{4.76}
\end{equation*}
$$

and assuming that the dimensionless ratios $\delta / \omega$ and $\mid \xi / \omega$, and the modulation depth $\mu$ are all much less than 1, we may use general Eqs. (57a) to get the following RWA equations:

$$
\begin{align*}
& \dot{A}=-\delta A-\frac{\mu \omega}{4} A \sin 2 \varphi,  \tag{4.77}\\
& A \dot{\varphi}=A \xi-\frac{\mu \omega}{4} A \cos 2 \varphi .
\end{align*}
$$

These equations evidently have a fixed point $A_{0}=0$, but its stability analysis (though possible) is not absolutely straightforward, because phase $\varphi$ of oscillations is undetermined at that point. In order to

[^52]avoid this (technical rather than conceptual) difficulty, we may use, instead of the real amplitude and phase of oscillations, either their complex amplitude $a=A \exp \{i \varphi\}$, or its Cartesian components $u$ and $v$ - see Eqs. (4). Indeed, for our function $f$, Eq. (57b) gives
\[

$$
\begin{equation*}
\dot{a}=(-\delta+i \xi) a-i \frac{\mu \omega}{4} a^{*}, \tag{4.78}
\end{equation*}
$$

\]

while Eqs. (57c) yield

$$
\begin{align*}
\dot{u} & =-\delta u-\xi v-\frac{\mu \omega}{4} v  \tag{4.79}\\
\dot{v} & =-\delta v+\xi u-\frac{\mu \omega}{4} u
\end{align*}
$$

We see that in contrast to Eqs. (77), in Cartesian coordinates $\{u, v\}$ the trivial fixed point $a_{0}=0$ (i.e. $u_{0}=v_{0}=0$ ) is absolutely regular. Moreover, equations (78)-(79) are already linear, so they do not require any additional linearization. Thus we may use the same approach as was already used in Secs. 3.2 and 4.1, i.e. look for the solution of Eqs. (79) in the exponential form $\exp \{\lambda t\}$. However, now we are dealing with two variables, and should allow them to have, for each value of $\lambda$, a certain ratio $u / v$. For that, we should take the partial solution in the form

$$
\begin{equation*}
u=c_{u} e^{\lambda t}, \quad v=c_{v} e^{\lambda t} \tag{4.80}
\end{equation*}
$$

where constants $c_{u}$ and $c_{v}$ are frequently called the distribution coefficients. Plugging this solution into Eqs. (79), we get for them the following system of two linear algebraic equations:

$$
\begin{align*}
& (-\delta-\lambda) c_{u}+\left(-\xi-\frac{\mu \omega}{4}\right) c_{v}=0  \tag{4.81}\\
& \left(\xi-\frac{\mu \omega}{4}\right) c_{u}+(-\delta-\lambda) c_{v}=0
\end{align*}
$$

The characteristic equation of this system,

$$
\left|\begin{array}{cc}
-\delta-\lambda & -\xi-\frac{\mu \omega}{4}  \tag{4.82}\\
\xi-\frac{\mu \omega}{4} & -\delta-\lambda
\end{array}\right| \equiv \lambda^{2}+2 \delta \lambda+\delta^{2}+\xi^{2}-\left(\frac{\mu \omega}{4}\right)^{2}=0
$$

has two roots:

$$
\begin{equation*}
\lambda_{ \pm}=-\delta \pm\left[\left(\frac{\mu \omega}{4}\right)^{2}-\xi^{2}\right]^{1 / 2} \tag{4.83}
\end{equation*}
$$

Requiring the fixed point to be unstable, $\operatorname{Re} \lambda_{+}>0$, we get the parametric excitation condition

$$
\begin{equation*}
\frac{\mu \omega}{4}>\left(\delta^{2}+\xi^{2}\right)^{1 / 2} . \tag{4.84}
\end{equation*}
$$

Thus the parametric excitation may indeed happen without any artificial phase adjustment: the arising oscillations self-adjust their phase to pick up energy from the external source responsible for the parameter variation.

Our key result (84) may be compared with two other calculations. First, in the case of negligible damping ( $\delta=0$ ), Eq. (84) turns into condition $\mu \omega / 4>|\xi|$. This result may be compared with the welldeveloped theory of the so-called Mathieu equation whose canonical form is

$$
\begin{equation*}
\frac{d^{2} y}{d v^{2}}+(a-2 b \cos 2 v) y=0 . \tag{4.85}
\end{equation*}
$$

It is evident that with the substitutions $y \rightarrow q, v \rightarrow \omega t, a \rightarrow\left(\omega_{0} / \omega\right)^{2}, b \rightarrow-\mu / 2$, this equation is just a particular case of Eq. (75) for $\delta=0$. In terms of Eq. (85), the result of our approximate analysis may be re-written just as $b>|a-1|$, and is supposed to be valid for $b \ll 1$. This condition is shown in Fig. 7 together with the numerically calculated ${ }^{23}$ stability boundaries of the Mathieu equation.

Fig. 4.7. Stability boundaries of the Mathieu equation (85), as calculated: numerically (curves) and using the rotating-wave approximation (dashed straight lines). In the regions numbered by various $n$ the trivial solution $y=0$ of the equation is unstable, i.e. its general solution $y(v)$ includes an exponentially growing term.

One can see that the rotating-wave approximation works just fine within its applicability limit (and beyond :-), though it fails to predict some other important features of the Mathieu equation, such as the existence of higher, more narrow regions of parametric excitation (at $a \approx n^{2}$, i.e. $\omega_{0} \approx \omega / n$, for all integer $n$ ), and some spill-over of the stability region into the lower half-plane $a<0 .{ }^{24}$ The reason of these failures is the fact that, as can be seen in Fig. 7, these phenomena do not appear in the first approximation in the parameter modulation amplitude $\mu \propto q$, that is the RWA applicability realm.

In the opposite case of finite damping but exact tuning ( $\xi=0, \omega \approx \omega_{0}$ ), Eq. (84) gives

$$
\begin{equation*}
\mu>\frac{4 \delta}{\omega_{0}} \equiv \frac{2}{Q} . \tag{4.86}
\end{equation*}
$$

[^53]This condition may be compared with Eq. (74), taking $\Delta l / l=2 \mu$.. The comparison shows that though the structure of these conditions is similar, the numerical coefficients are different by a factor close to 2 . The first reason of this difference is that the instant parameter change at optimal moments of time is more efficient then the smooth, sinusoidal variation described by (75). Even more significantly, the change of pendulum's length modulates not only its eigenfrequency $\omega_{0}$, as Eq. (75) implies, but also its mechanical impedance $Z \equiv(g l)^{1 / 2}$ - the notion to be discussed in detail in the next chapter. (Due to the time restrictions, I have to leave the analysis of the general case of the simultaneous modulation of $\omega_{0}$ and $Z$ for reader's exercise.)

Before moving on, let me summarize the most important differences between the parametric and forced oscillations:
(i) Parametric oscillations completely disappear outside of their excitation range, while the forced oscillations have a non-zero amplitude for any frequency and amplitude of the external force see Eq. (18).
(ii) Parametric excitation may be described by a linear homogeneous equation - e.g., Eq. (75) which cannot predict any finite oscillation amplitude within the excitation range, even at finite damping. In order to describe stationary parametric oscillations, some nonlinear effect has to be taken into account. (Again, I am leaving analyses of such effects for reader's exercises.)

One more important feature of the parametric oscillations will be discussed in the end of the next section.

### 4.6. Fixed point classification

RWA equations (79) give us a good pretext for a brief discussion of fixed points of a dynamic system described by two time-independent, first-order differential equations. ${ }^{25}$ After their linearization near a fixed point, the equations for deviations can always be presented in the form similar to Eq. (79):

$$
\begin{align*}
& \dot{\tilde{q}}_{1}=M_{11} \widetilde{q}_{1}+M_{12} \widetilde{q}_{2},  \tag{4.87}\\
& \dot{\tilde{q}}_{2}=M_{21} \widetilde{q}_{1}+M_{22} \widetilde{q}_{2},
\end{align*}
$$

where $M_{j j}$ ' $($ with $j, j '=1,2)$ are some real scalars that may be understood as elements of a $2 \times 2$ matrix M . Looking for an exponential solution of the type (80),

$$
\begin{equation*}
\widetilde{q}_{1}=c_{1} e^{\lambda t}, \quad \widetilde{q}_{2}=c_{2} e^{\lambda t} \tag{4.88}
\end{equation*}
$$

we get a more general system of two linear equations for the distribution coefficients $c_{1,2}$ :

$$
\begin{align*}
& \left(M_{11}-\lambda\right) c_{1}+M_{12} c_{2}=0 \\
& M_{21} c_{1}+\left(M_{22}-\lambda\right) c_{2}=0 . \tag{4.89}
\end{align*}
$$

These equations are consistent if

[^54]\[

\left|$$
\begin{array}{cc}
M_{11}-\lambda & M_{12} \\
M_{21} & M_{22}-\lambda
\end{array}
$$\right|=0
\]

Characteristic equation of system (87)
giving us a quadratic characteristic equation

$$
\begin{equation*}
\lambda^{2}-\lambda\left(M_{11}+M_{22}\right)+\left(M_{11} M_{22}-M_{12} M_{21}\right)=0 \tag{4.91}
\end{equation*}
$$

Its solution, ${ }^{26}$

$$
\begin{equation*}
\lambda_{ \pm}=\frac{1}{2}\left(M_{11}+M_{22}\right) \pm \frac{1}{2}\left[\left(M_{11}-M_{22}\right)^{2}+4 M_{12} M_{21}\right]^{1 / 2} \tag{4.92}
\end{equation*}
$$

shows that the following situations are possible:
A. The expression under the square root, $\left(M_{11}-M_{22}\right)^{2}+4 M_{12} M_{21}$, is positive. In this case, both characteristic exponents $\lambda_{ \pm}$are real, and we can distinguish three sub-cases:
(i) Both $\lambda_{+}$and $\lambda_{\text {- }}$ are negative. In this case, the fixed point is evidently stable. Because of generally different magnitudes of exponents $\lambda_{ \pm}$, the process presented on the phase plane [ $\widetilde{q}_{1}, \widetilde{q}_{2}$ ] (Fig. 8a) may be seen as consisting of two stages: first, a faster (with rate $\left|\lambda_{-}\right|$) relaxation to a linear asymptote, ${ }^{27}$ and then a slower decline, with rate $\left|\lambda_{+}\right|$, along this line, i.e. at the virtually fixed ratio of the variables. Such fixed point is called the stable node.
(ii) Both $\lambda_{+}$and $\lambda_{\text {- }}$ are positive. This case (rarely met in actual physical systems) of the unstable node differs from the previous one only by the direction of motion along the phase plane trajectories (see dashed arrows in Fig. 8a). Here the variable ratio is also approaching a constant soon, but now the one corresponding to $\lambda_{+}>\lambda_{\text {. }}$
(iii) Finally, in the case of a saddle $\left(\lambda_{+}>0, \lambda_{-}<0\right)$ the system dynamics is different (Fig. $8 b)$ : after the rate- $\lambda_{-} \mid$relaxation to the $\lambda_{+}$-asymptote, the perturbation starts to grow, with the rate $\lambda_{+}$, along one of two opposite directions. (The direction is determined on which side of another straight line, called separatrix, the system has been initially.) It is evident that the saddle ${ }^{28}$ is an unstable fixed point.
B. The expression under the square root, $\left(M_{11}-M_{22}\right)^{2}+4 M_{12} M_{21}$, is negative. In this case the square root in Eq. (92) is imaginary, making the real parts of both roots equal, $\operatorname{Re} \lambda_{ \pm}=\left(M_{11}+M_{22}\right) / 2$, and their imaginary parts equal but sign-opposite. As a result, here there can be just two types of fixed points:
(i) Stable focus, at $\left(M_{11}+M_{22}\right)<0$. The phase plane trajectories are spirals going to the center (i.e. toward the fixed point) - see Fig. 8c with solid arrow.
(ii) Unstable focus, taking place at $\left(M_{11}+M_{22}\right)>0$, differs from the stable one only by the direction of motion along the phase trajectories - see the dashed arrow in Fig. 8c.

[^55]

Fig. 4.8. Typical trajectories on the phase plane $\left[\widetilde{q}_{1}, \widetilde{q}_{2}\right]$ near fixed points of various types: (a) node, (b) saddle, (c) focus, and (d) center. The particular values of the matrix M used in the first three panels correspond to the RWA equations (81) for parametric oscillators with $\xi=\delta$, and three different values of parameter $\mu \omega / 4 \delta$ : (a) 1.25 , (b) 1.6 and (c) 0.
C. Sometimes the border case, $M_{11}+M_{22}=0$, is also distinguished, and the corresponding fixed point is refereed to as the center (Fig. 8d). Considering centers a special category makes sense because such fixed points are typical for Hamiltonian systems whose first integral of motion may be frequently presented as the distance of the from a fixed point. For example, a harmonic oscillator without dissipation may be described by the system

$$
\begin{equation*}
\dot{q}=\frac{p}{m}, \quad \dot{p}=-m \omega_{0}^{2} q, \tag{4.94}
\end{equation*}
$$

that is evidently a particular case of Eq. (87) with $M_{11}=M_{22}=0, M_{12} M_{21}=-\omega_{0}{ }^{2}<0$, and hence ( $M_{11}$ $\left.M_{22}\right)^{2}+4 M_{12} M_{21}=-4 \omega_{0}^{2}<0$, and $M_{11}+M_{22}=0$. The phase plane of the system may be symmetrized by plotting $q$ vs. the properly normalized momentum $p / m \omega_{0}$. On the symmetrized plane, sinusoidal oscillations of amplitude $A$ are represented by a circle of radius $A$ about the center-type fixed point $A=$ 0 . Such a circular trajectory correspond to the conservation of the oscillator's energy

$$
\begin{equation*}
E=\frac{m \dot{q}^{2}}{2}+\frac{m \omega_{0}^{2} q^{2}}{2}=\frac{m \omega_{0}^{2}}{2}\left[\left(\frac{p}{m \omega_{0}}\right)^{2}+q^{2}\right] \tag{4.95}
\end{equation*}
$$

This is a convenient moment for a brief discussion of the so-called Poincaré (or "slow-variable", or "stroboscopic") plane. ${ }^{29}$ From the point of view of the rotating-wave approximation, sinusoidal oscillations $q(t)=A \cos (\omega t-\varphi)$, in particular those described by a circular trajectory on the real (or "fast") phase plane (Fig. 8c) correspond to a fixed point $\{A, \varphi\}$, which may conveniently presented by a steady geometrical point on a plane with these polar coordinates (Fig. 9a). (As follows from Eq. (4), the Cartesian coordinates on that plane are $u$ and $v$.) The quasi-sinusoidal process (41), with slowly changing $A$ and $\varphi$, may be represented by a slow motion of that point on this Poincaré plane.

Fig. 4.9. (a) Presentation of a sinusoidal oscillation (point) and a slow transient (line) on the Poincaré plane, and (b) transfer from the "fast" phase plane to the "slow" (Poincaré) plane.

Figure 9 b shows one possible way to visualize the relation between the "real" phase plane of an oscillator, with symmetrized Cartesian coordinates $q$ and $p / m \omega_{0}$, and the Poincaré plane with Cartesian coordinates $u$ and $v$ : the latter reference frame rotates relative to the former one about the origin clockwise, with angular velocity $\omega .{ }^{30}$ Another, "stroboscopic" way to generate the Poincaré plane pattern is to have a fast glance at the "real" phase plane just once during the oscillation period $T=2 \pi / \omega$.

In many cases, such presentation is more convenient than that on the "real" phase plane. In particular, we have already seen that the RWA equations for such important phenomena as phase locking and parametric oscillations, whose original differential equations include time explicitly, are time-independent - cf., e.g., (75) and (79) describing the latter effect. This simplification brings the

[^56]equations into the category considered in this section, and enables the classification of their fixed points, which may shed additional light on their dynamic properties.

In particular, Fig. 10 shows the classification of the trivial fixed point of a parametric oscillator, which follows from Eq. (83). As the parameter modulation depth $\mu$ is increased, the type of the trivial fixed point $A_{1}=0$ on the Poincaré plane changes from a stable focus (typical for a simple oscillator with damping) to a stable node and then to a saddle describing the parametric excitation. In the last case, the two directions of the perturbation growth, so prominently featured in Fig. 8b, correspond to the two possible values of the oscillation phase $\varphi$, with the phase choice determined by initial conditions.

Fig. 4.10. Types of the trivial fixed point of a parametric oscillator.

This double degeneracy of the parametric oscillation's phase could already be noticed from Eqs. (77), because they are evidently invariant with respect to replacement $\varphi \rightarrow \varphi+\pi$. Moreover, the degeneracy is not an artifact of the rotating-wave approximation, because the initial Eq. (75) is already invariant with respect to the corresponding replacement $q(t) \rightarrow q(t-\pi / \omega)$. This invariance means that all other characteristics (e.g., the amplitude) of the parametric oscillations excited with either of two phases are absolutely similar. At the dawn of the computer age (in the late 1950s and early 1960s), there were substantial attempts, especially in Japan, to use this property for storage and processing digital information coded in the phase-binary form.

### 4.7. Numerical approach

If the amplitude of oscillations, by whatever reason, becomes so large that the nonlinear terms in the equation describing a system are comparable to its linear terms, numerical methods are virtually the only avenue available for their study. In Hamiltonian 1D systems, such methods may be applied directly to integral (3.26), but dissipative and/or parametric systems typically lack first integrals of motion similar to Eq. (3.24), so that the initial differential equation has to be solved.

Let us discuss the general idea of such methods on the example of what mathematicians call the Cauchy problem (finding the solution for all moments of time, starting from known initial conditions) for first-order differential equation

$$
\begin{equation*}
\dot{q}=f(t, q) . \tag{4.96}
\end{equation*}
$$

(The generalization to a set of several such equations is straightforward.) Breaking the time axis into small, equal steps $h$ (Fig. 11) we can reduce the equation integration problem to finding the function value in the next time point, $q_{n+1} \equiv q\left(t_{n+1}\right)=q\left(t_{n}+h\right)$ from the previously found value $q_{n}=q\left(t_{n}\right)$ - and, if
necessary, the values of $q$ at other previous time steps. In the generic approach (called the Euler method), $q_{n+1}$ is found using the following formula:

$$
\begin{align*}
& q_{n+1}=q_{n}+k  \tag{4.97}\\
& k \equiv h f\left(t_{n}, q_{n}\right) .
\end{align*}
$$

It is evident that this approximation is equivalent to the replacement of the genuine function $q(t)$, on the segment $\left[t_{n}, t_{n+1}\right]$, with the two first terms of its Taylor expansion in point $t_{n}$ :

$$
\begin{equation*}
q\left(t_{n}+h\right) \approx q\left(t_{n}\right)+\dot{q}\left(t_{n}\right) h \equiv q\left(t_{n}\right)+h f\left(t_{n}, q_{n}\right) . \tag{4.98}
\end{equation*}
$$

Fig. 4.11. The basic notions used at numerical integration of ordinary differential equations.

Such approximation has an error proportional to $h^{2}$. One could argue that making the step $h$ sufficiently small the Euler's method error might be done arbitrary small, but even with the numbercrunching power of modern computers, the computation time necessary to reach sufficient accuracy may be too high for large problems. ${ }^{31}$ Besides that, the increase of the number of time steps, which is necessary at $h \rightarrow 0$, increases the total rounding errors, and eventually may cause an increase, rather than the reduction of the overall error of the computed result.

A more efficient way is to modify Eq. (97) to include the terms of the second order in $h$. There are several ways to do this, for example using the $2^{\text {nd }}$-order Runge-Kutta method:

$$
\begin{align*}
& q_{n+1}=q_{n}+k_{2} \\
& k_{2} \equiv h f\left(t_{n}+\frac{h}{2}, q_{n}+\frac{k_{1}}{2}\right), \quad k_{1} \equiv h f\left(t_{n}, q_{n}\right) . \tag{4.99}
\end{align*}
$$

One can readily check that this method gives the exact result if function $q(t)$ is a quadratic polynomial, and hence in the general case its errors are of the order of $h^{3}$. We see that the main idea here is to first break the segment $\left[t_{n}, t_{n+1}\right]$ in half (Fig. 11), then evaluate the right-hand part of the differential equation (96) at the point intermediate (in both $t$ and $q$ ) between points $n$ and $(n+1)$, and then use this information to predict $q_{n+1}$.

The advantage of the Runge-Kutta approach is that it can be readily extended to the $4^{\text {th }}$ order, without an additional breaking of the interval $\left[t_{n}, t_{n+1}\right]$.:

[^57]\[

$$
\begin{align*}
& q_{n+1}=q_{n}+\frac{1}{6}\left(k_{1}+2 k_{2}+2 k_{3}+k_{4}\right)  \tag{4.100}\\
& k_{4} \equiv h f\left(t_{n}+h, q_{n}+k_{3}\right), k_{3} \equiv h f\left(t_{n}+\frac{h}{2}, q_{n}+\frac{k_{2}}{2}\right), k_{2} \equiv h f\left(t_{n}+\frac{h}{2}, q_{n}+\frac{k_{1}}{2}\right), k_{1} \equiv h f\left(t_{n}, q_{n}\right)
\end{align*}
$$
\]

This method reaches much lower error, $O\left(h^{5}\right)$, without being not too cumbersome. These features have made the $4^{\text {th }}$-order Runge-Kutta the default method in most numerical libraries. Its extension to higher orders is possible but requires more complex formulas and is justified only for some special cases, e.g., very abrupt functions $q(t) .{ }^{32}$ The most frequent enhancement of the method is the automatic adjustment of step $h$ to reach the specified accuracy.

Figure 12 shows a typical example of application of that method to the very simple problem of a damped linear oscillator, for two values of fixed time step $h$ (expressed in terms of the number $N$ of such steps per oscillation period). Black lines connect the points obtained by the $4^{\text {th }}$-order Runge-Kutta method, while the points connected by green straight lines present the exact analytical solution (22). A few-percent errors start to appear only at as few as $\sim 10$ time steps per period, so that the method is indeed very efficient. I will illustrate the convenience and handicaps of the numerical approach to the solution of dynamics problems on the discussion of the following topic.

Fig. 4.12. Results of the fixed-point Runge-Kutta solution to the equation of linear oscillator with damping (with $\delta / \omega_{0}=0.03$ ) for: (a) 30 and (b) 6 points per oscillation period. The results are shown by points; lines are only the guide for the eye.

### 4.8. Higher harmonic and subharmonic oscillations

Figure 13 shows the numerically calculated ${ }^{33}$ transient process and stationary oscillations in a linear oscillator and a very representative nonlinear system, the pendulum described by Eq. (42), both with the same resonance frequency $\omega_{0}$ for small oscillations. Both systems are driven by a sinusoidal

[^58]external force of the same amplitude and frequency - in this illustration, equal to the small-oscillation eigenfrequency $\omega_{0}$ of both systems. The plots show that despite a very substantial amplitude of the pendulum oscillations (an angle amplitude of about one radian) their waveform remains almost exactly sinusoidal. ${ }^{34}$ On the other hand, the nonlinearity affects the oscillation amplitude very substantially. These results illustrate that the validity of the small-parameter method and its RWA extension far exceeds what might be expected from the formal requirement $|q| \ll 1$.

Fig. 4.13. Oscillations induced by a similar sinusoidal external force (turned on at $t=0$ ) in two systems with the same small-oscillation frequency $\omega_{0}$ and low damping - a linear oscillator (two top panels) and a pendulum (two bottom panels). $\delta / \omega_{0}=0.03, f_{0}=0.1$, and $\omega=\omega_{0}$.

The higher harmonic contents in the oscillation waveform may be sharply increased ${ }^{35}$ by reducing the external force frequency to $\sim \omega_{0} / n$, where integer $n$ is the number of the desirable harmonic. For example, Fig. 14a shows oscillations in a pendulum described by the same Eq. (42), but driven at frequency $\omega_{0} / 3$. One can see that the $3^{\text {rd }}$ harmonic amplitude may be comparable with that of the basic harmonic, especially if the external frequency is additionally lowered (Fig. 14b) to accommodate for the deviation of the effective frequency $\omega_{0}(a)$ of own oscillations from its small-oscillation value $\omega_{0}$ - see Eq. (49), Fig. 4 and their discussion in Sec. 2 above.

Generally, the higher harmonic generation by nonlinear systems might be readily anticipated. Indeed, the Fourier theorem tells us that any non-sinusoidal periodic function of time, e.g., an initially sinusoidal waveform of frequency $\omega$, distorted by nonlinearity, may be presented as a sum of its basic harmonic and higher harmonics with frequencies $n \omega$. Note that an effective generation of higher

[^59]harmonics is only possible with adequate nonlinearity of the system. For example, consider the nonlinear term $\alpha q^{3}$ used in equations explored in Secs. 2 and 3. If the waveform $q(t)$ is approximately sinusoidal, such term can create only the basic and $3^{\text {rd }}$ harmonics. The "pendulum nonlinearity" $\sin q$ cannot produce, without a constant component is process $q(t)$, any even (e.g., the $2^{\text {nd }}$ ) harmonic. The most efficient generation of harmonics may be achieved using systems with the sharpest nonlinearities e.g., semiconductor diodes whose current may follow an exponential dependence on the applied voltage through several orders of magnitude.

Fig. 4.14. Oscillations induced in a pendulum with damping $\delta / \omega_{0}=0.03$, driven by a sinusoidal external force of amplitude $f_{0}=0.75$, and frequency $\omega_{0} / 3$ (top panel) and $0.8 \omega_{0} / 3$ (bottom panel).

However, numerical modeling of nonlinear oscillators, as well as experiments with their physical implementations, bring more surprises. For example, the bottom panel of Fig. 15 shows oscillations in a pendulum under effect of a strong sinusoidal force with a frequency close to $3 \omega_{0}$. One can see that at some parameter values and initial conditions the system's oscillation spectrum is heavily contributed (almost dominated) by the $3^{\text {rd }}$ subharmonic, i.e. a component that is synchronous with the driving force of frequency $3 \omega$, but has the frequency $\omega$ that is close to the eigenfrequency $\omega_{0}$ of the system.

This counter-intuitive phenomenon may be explained as follows. Let us assume that the subharmonic oscillations of frequency $\omega \approx \omega_{0}$ have somehow appeared, and coexist with the forced oscillations of frequency $3 \omega$ :

$$
\begin{equation*}
q(t) \approx A \cos \Psi+A_{\mathrm{sub}} \cos \Psi_{\mathrm{sub}}, \quad \text { where } \Psi \equiv 3 \omega t-\varphi, \quad \Psi_{\mathrm{sub}} \equiv \omega t-\varphi_{\mathrm{sub}} . \tag{4.101}
\end{equation*}
$$

Then, the first nonlinear term $\alpha q^{3}$ of the Taylor expansion of pendulum's nonlinearity $\sin q$ yields

$$
\begin{align*}
q^{3} & =\left(A \cos \Psi+A_{\text {sub }} \cos \Psi_{\text {sub }}\right)^{3}  \tag{4.102}\\
& =A^{3} \cos ^{3} \Psi+3 A^{2} A_{\text {sub }} \cos ^{2} \Psi \cos \Psi_{\text {sub }}+3 A A_{\text {sub }}^{2} \cos \Psi \cos ^{2} \Psi_{\text {sub }}+A_{\text {sub }}^{3} \cos ^{3} \Psi_{\text {sub }}
\end{align*}
$$

While the first and the last terms of this expression depend only of amplitudes of the individual components of oscillations, the two middle terms are more interesting because they produce so-called combinational frequencies of the two components. For our case, the third term,

$$
\begin{equation*}
3 A A_{\text {sub }}^{2} \cos \Psi \cos ^{2} \Psi_{\text {sub }}=\frac{3}{4} A A_{\text {sub }}^{2} \cos \left(\Psi-2 \Psi_{\text {sub }}\right)+\ldots \tag{4.103}
\end{equation*}
$$

of a special importance, because it produces, besides other combinational frequencies, the subharmonic component with the total phase

$$
\begin{equation*}
\Psi-2 \Psi_{\text {sub }}=\omega t-\varphi+2 \varphi_{\mathrm{sub}} . \tag{4.104}
\end{equation*}
$$

Thus, within a certain range of the mutual phase shift between the Fourier components, this nonlinear contribution is synchronous with the subharmonic oscillations, and describes the interaction that can deliver to it the energy from the external force, so that the oscillations may be self-sustained. Note, however, that the amplitude of the term (103) describing this energy exchange is proportional to the square of $A_{\text {sub }}$, and vanishes at the linearization of the equations of motion near the trivial fixed point. This means that the point is always stable, i.e., the $3^{\text {rd }}$ subharmonic cannot be self-excited and always need an initial "kick-off" - compare the two panels of Fig. 15. The same is evidently true for higher subharmonics.

Fig. 4.15. Oscillations induced in a pendulum with $\delta / \omega_{0}=0.03$ by a sinusoidal external force of amplitude $f_{0}=3$ and frequency $3 \omega_{0} \times 0.8$, with initial conditions $q(0)=0$ (the top row) and $q(0)=1$ (the bottom row).

Only the second subharmonic presents a special case. Indeed, let us make a calculation similar to Eq. (102), by replacing Eq. (101) with

$$
\begin{equation*}
q(t) \approx A \cos \Psi+A_{\mathrm{sub}} \cos \Psi_{\mathrm{sub}}, \quad \text { where } \Psi \equiv 2 \omega t-\varphi, \quad \Psi_{\mathrm{sub}} \equiv \omega t-\varphi_{\mathrm{sub}} \tag{4.105}
\end{equation*}
$$

for a nonlinear term proportional to $q^{2}$ :

$$
\begin{equation*}
q^{2}=\left(A \cos \Psi+A_{\mathrm{sub}} \cos \Psi_{\mathrm{sub}}\right)^{2}=A^{2} \cos ^{2} \Psi+2 A A_{\mathrm{sub}} \cos \Psi \cos \Psi_{\mathrm{sub}}+A_{\mathrm{sub}}^{2} \cos ^{2} \Psi_{\mathrm{sub}} \tag{4.106}
\end{equation*}
$$

Here the combinational-frequency term capable of supporting the $2^{\text {nd }}$ subharmonic,

$$
\begin{equation*}
2 A A_{\text {sub }} \cos \Psi \cos \Psi_{\text {sub }}=A A_{\text {sub }} \cos \left(\Psi-\Psi_{\text {sub }}\right)=A A_{\text {sub }} \cos \left(\omega t-\varphi+\varphi_{\text {sub }}\right)+\ldots \tag{4.107}
\end{equation*}
$$

is linear in the subharmonic amplitude, i.e. survives the equation linearization near the trivial fixed point. This mean that the second subharmonic may arise spontaneously, from infinitesimal fluctuations.

Moreover, such excitation of the second subharmonic is very similar to the parametric excitation that was discussed in detail in Sec. 5, and this similarity is not coincidental. Indeed, let us redo expansion (4.106) at a somewhat different assumption that the oscillations are a sum of the forced oscillations at the external force frequency $2 \omega$, and an arbitrary but weak perturbation:

$$
\begin{equation*}
q(t)=A \cos (2 \omega t-\varphi)+\widetilde{q}(t), \quad|\widetilde{q}| \ll A . \tag{4.108}
\end{equation*}
$$

Then, neglecting the small term proportional to $\widetilde{q}^{2}$, we get

$$
\begin{equation*}
q^{2} \approx A^{2} \cos ^{2}(2 \omega t-\varphi)+2 \widetilde{q}(t) A \cos (2 \omega t-\varphi) . \tag{4.109}
\end{equation*}
$$

Besides the inconsequential phase $\varphi$, the second term in the last formula is exactly similar to the term describing the parametric effects in Eq. (75). This fact means that for a weak perturbation, a system with a quadratic nonlinearity in the presence of a strong "pumping" signal of frequency $2 \omega$ is equivalent to a system with parameters changing in time with frequency $2 \omega$. This fact is broadly used for the parametric excitation at high (e.g., optical) frequencies where the mechanical means of parameter modulation (see, e.g., Fig. 5) are not practicable. The necessary quadratic nonlinearity at optical frequencies may be provided by a noncentrosymmetric nonlinear crystal, e.g., the $\beta$-phase barium borate $\left(\mathrm{BaB}_{2} \mathrm{O}_{4}\right)$.

Before finishing this chapter, let me elaborate a bit on a general topic: the relation between the numerical and analytical approaches to problems of dynamics (and physics as a whole). We have just seen that sometimes numerical solutions, like those shown in Fig. 15b, may give vital clues for previously unanticipated phenomena such as the excitation of subharmonics. (The phenomenon of deterministic chaos, which will be discussed in Chapter 9 below, presents another example of such "numerical discoveries".) One might also argue that in the absence of exact analytical solutions, numerical simulations may be the main theoretical tool for the study of such phenomena. These hopes are, however, muted by the problem that is frequently called the curse of dimensionality, ${ }^{36}$ in which the last word refers to the number of input parameters of the problem to be solved. ${ }^{37}$

Indeed, let us have another look at Fig. 15. OK, we have been lucky to find a new phenomenon, the $3^{\text {rd }}$ subharmonic generation, for a particular set of parameters - in that case, five of them: $\delta / \omega_{0}=$ $0.03,3 \omega / \omega_{0}=2.4, f_{0}=3, q(0)=1$, and $d q / d t(0)=0$. Could we tell anything about how common this effect is? Are subharmonics with different $n$ possible in the system? The only way to address these

[^60]questions computationally is to carry out similar numerical simulations in many points of the $d$ dimensional (in this case, $d=5$ ) space of parameters. Say, we have decided that breaking the reasonable range of each parameter to $N=100$ points is sufficient. (For many problems, even more points are necessary - see, e.g., Sec. 9.1.) Then the total number of numerical experiments to carry out is $N^{d}=$ $\left(10^{2}\right)^{5}=10^{10}-$ not a simple task even for the powerful modern computing facilities. (Besides the pure number of required CPU cycles, consider storage and analysis of the results.) For many important problems of nonlinear dynamics, e.g., turbulence, the parameter dimensionality $d$ is substantially larger, and the computer resources necessary for one numerical experiment, are much greater.

In the view of the curse of dimensionality concerns, approximate analytical considerations, like those outlined above for the subharmonic excitation, are invaluable. More generally, physics used to stand on two legs, experiment and (analytical) theory. The enormous progress of computer performance during a few last decades has provided it with one more point of support (a tail? :-) - numerical simulation. This does not mean we can afford to cut and throw away any of the legs we are standing on.

### 4.9. Exercise problems

4.1.* Prove Eq. (26) for the response function given by Eq. (17).

Hint: You may like to use the Cauchy integral theorem for analytical functions of complex variable. ${ }^{38}$
4.2. A square-wave pulse of force (see Fig. on the right) is exerted on a linear oscillator with eigenfrequency $\omega_{0}$ (no damping), initially at rest. Calculate the law of motion $q(t)$, sketch it, and interpret the result.
4.3. At $t=0$, a sinusoidal external force $F(t)=F_{0} \cos \omega t$, with constant $A$
 and $\omega$, is applied to a linear oscillator with eigenfrequency $\omega_{0}$ and damping $\delta$, which was at rest at $t \leq 0$.
(i) Calculate the general expression for the time evolution of the oscillator's coordinate, and interpret the result.
(ii) Spell out your result for the case of the resonance $\left(\omega=\omega_{0}\right)$ in a system with low damping ( $\delta$ $\ll \omega_{0}$ ), and, in particular, explore the limit $\delta \rightarrow 0$.
4.4. A pulse of external force $F(t)$, with a finite duration $T$, is exerted on a harmonic oscillator, initially at rest in the equilibrium position. Neglecting dissipation, calculate the change of oscillator's energy, using two different methods, and compare the results.
4.5.* For a system with the following Lagrangian function:

$$
L=\frac{m}{2} \dot{q}^{2}-\frac{\kappa}{2} q^{2}+\frac{\varepsilon}{2} \dot{q}^{2} q^{2},
$$

calculate the frequency of free oscillations as a function of their amplitude $A$, at $A \rightarrow 0$, using two different approaches.

[^61]4.6. For a system with the Lagrangian function
$$
L=\frac{m}{2} \dot{q}^{2}-\frac{\kappa}{2} q^{2}+\varepsilon \dot{q}^{4},
$$
with small parameter $\varepsilon$, use the rotating-wave approximation to find the frequency of free oscillations as a function of their amplitude.
4.7. Find the regions of real, time-independent parameters $a_{1}$ and $a_{2}$, in which the fixed point of the following system of equations,
\[

$$
\begin{aligned}
& \dot{q}_{1}=a_{1}\left(q_{2}-q_{1}\right), \\
& \dot{q}_{2}=a_{2} q_{1}-q_{2},
\end{aligned}
$$
\]

is unstable. On the $\left[a_{1}, a_{2}\right]$ plane, sketch the regions of each fixed point type - stable and unstable nodes, focuses, etc.
4.8. Solve Problem 4.3(ii) using the rotating-wave approximation, and compare the result with the exact solution.
4.9. Use the rotating-wave approximation to analyze forced oscillations in an oscillator with weak nonlinear damping, described by equation

$$
\ddot{q}+2 \delta \dot{q}+\omega_{0}^{2} q+\beta \dot{q}^{3}=f_{0} \cos \omega t,
$$

with $\omega \approx \omega_{0} ; \beta, \delta>0$; and $\beta \omega A^{2} \ll 1$. In particular, find the stationary amplitude of forced oscillations and analyze their stability. Discuss the effect(s) of the nonlinear term on the resonance.
4.10.* Analyze stability of the forced nonlinear oscillations described by Eq. (43). Relate the result to the slope of resonance curves (Fig. 4).
4.11. Use the rotating-wave approximation to analyze parametric excitation of an oscillator with weak nonlinear damping, described by equation

$$
\ddot{q}+2 \delta \dot{q}+\beta \dot{q}^{3}+\omega_{0}^{2}(1+\mu \cos 2 \omega t) q=0
$$

with $\omega \approx \omega_{0} ; \beta, \delta>0$; and $\mu, \beta \omega A^{2} \ll 1$. In particular, find the amplitude of stationary oscillations and analyze their stability.
4.12. Adding nonlinear term $\alpha q^{3}$ to the left-hand part of Eq. (76),
(i) find the corresponding addition to the RWA equations,
(ii) find the stationary amplitude $A$ of parametric oscillations,
(iii) sketch and discuss the $A(\xi)$ dependence,
(iv) find the type and stability of each fixed point of the RWA equations,
(v) sketch the Poincaré phase plane of the system in main parameter regions.
4.13. Use the rotating-wave approximation to find the conditions of parametric excitation in an oscillator with weak modulation of both the effective mass $m(t)=m_{0}\left(1+\mu_{m} \cos 2 \omega t\right)$ and spring constant $\kappa(t)=\kappa_{0}\left[1+\mu_{k} \cos (2 \omega t-\psi)\right]$, with the same frequency $2 \omega \approx 2 \omega_{0}$, but arbitrary modulation depths ratio
$\mu_{m} / \mu_{k}$ and phase shift $\psi$. Interpret the result in terms of modulation of the instantaneous frequency $\omega(t) \equiv$ $[\kappa(t) / m(t)]^{1 / 2}$ and mechanical impedance $Z(t) \equiv[\kappa(t) m(t)]^{1 / 2}$ of the oscillator.
4.14.* Find the condition of parametric excitation of a nonlinear oscillator described by equation

$$
\ddot{q}+2 \delta \dot{q}+\omega_{0}^{2} q+\gamma q^{2}=f_{0} \cos 2 \omega t
$$

with sufficiently small $\delta, \gamma, f_{0}$, and $\xi \equiv \omega-\omega_{0}$.

## Chapter 5. From Oscillations to Waves

In this chapter, the discussion of oscillations is extended to systems with two and more degrees of freedom. This extension naturally leads to another key notion - waves. The discussion of waves (at this stage, in $1 D$ systems) is focused at such key phenomena as their dispersion and reflection from interfaces/boundaries.

### 5.1. Two coupled oscillators

Let us move on to discuss oscillations in systems with more than one degree of freedom, starting from the simplest case of two linear, dissipation-free oscillators. If the Lagrangian of the system may be presented as a sum of those for two harmonic oscillators,

$$
\begin{equation*}
L=L_{1}+L_{2}, \quad L_{1,2}=T_{1,2}-U_{1,2}=\frac{m_{1,2}}{2} \dot{q}_{1,2}^{2}-\frac{\kappa_{1,2}}{2} q_{1,2}^{2}, \tag{5.1}
\end{equation*}
$$

(plus arbitrary, inconsequential constants if you like), then according to Eq. (2.19), the equations of motion of the oscillators are independent of each other, and each one is similar to Eq. (1.1), with its partial frequency $\Omega_{1,2}$ equal to

$$
\begin{equation*}
\Omega_{1,2}^{2}=\frac{\kappa_{1,2}}{m_{1,2}} . \tag{5.2}
\end{equation*}
$$

This means that in this simplest case, the arbitrary motion of the system is just a sum of independent sinusoidal oscillations at two frequencies equal to the partial frequencies (2).

Hence, in order to describe the oscillator coupling (i.e. interaction), the full Lagrangian $L$ should contain an additional mixed term $L_{\text {int }}$ depending on both generalized coordinates $q_{1}$ and $q_{2}$ and/or generalized velocities. The simplest, and most frequently met type of such interaction term is the following bilinear form $U_{\mathrm{int}}=-\kappa q_{1} q_{2}$, where $\kappa$ is a constant, giving $L_{\mathrm{int}}=-U_{\mathrm{int}}=\kappa q_{1} q_{2}$. Figure 1 shows the simplest example of system with such interaction. ${ }^{1}$ In it, three springs, keeping two massive particles between two stiff walls, have generally different spring constants.

Fig. 5.1. Simple system of two coupled harmonic oscillators.

Indeed, in this case the kinetic energy is still separable, $T=T_{1}+T_{2}$, but the total potential energy, consisting of elastic energies of three springs, is not:

$$
\begin{equation*}
U=\frac{\kappa_{L}}{2} q_{1}^{2}+\frac{\kappa_{M}}{2}\left(q_{1}-q_{2}\right)^{2}+\frac{\kappa_{R}}{2} q_{2}^{2}, \tag{5.3a}
\end{equation*}
$$

[^62]where $q_{1.2}$ are the horizontal displacements of particles from their equilibrium positions. It is convenient to rewrite this expression as
\[

$$
\begin{equation*}
U=\frac{\kappa_{1}}{2} q_{1}^{2}+\frac{\kappa_{2}}{2} q_{2}^{2}-\kappa q_{1} q_{2}, \quad \text { where } \kappa_{1} \equiv \kappa_{L}+\kappa_{M}, \quad \kappa_{2} \equiv \kappa_{R}+\kappa_{M}, \quad \kappa \equiv \kappa_{M} \tag{5.3b}
\end{equation*}
$$

\]

showing that the Lagrangian $L=T-U$ of this system indeed contains a bilinear interaction term:

$$
\begin{equation*}
L=L_{1}+L_{2}+L_{\mathrm{int}}, \quad L_{\mathrm{int}}=\kappa q_{1} q_{2} \tag{5.4}
\end{equation*}
$$

The resulting Lagrange equations of motion are

$$
\begin{align*}
& m_{1} \ddot{q}_{1}+m_{1} \Omega_{1}^{2} q_{1}=\kappa q_{2},  \tag{5.5}\\
& m_{2} \ddot{q}_{2}+m_{2} \Omega_{2}^{2} q_{2}=\kappa q_{1} .
\end{align*}
$$

Linearly coupled oscillators

Thus the interaction energy describes effective generalized force $\kappa q_{2}$ exerted on subsystem 1 by subsystem 2, and the reciprocal effective force $\kappa q_{1}$. Note that in contrast to real physical forces (such as $F_{12}=-F_{21}=\kappa_{M}\left(q_{2}-q_{1}\right)$ for the system shown in Fig. 1) the effective forces in the right-hand part of Eqs. (5) do not obey the $3^{\text {rd }}$ Newton law. Note also that they are proportional to the same coefficient $\kappa$, this feature is a result of the general bilinear structure (4) of the interaction energy rather than of any special symmetry.

We already know how to solve Eqs. (5), because it is still a system of linear and homogeneous differential equations, so that its general solution is a sum of particular solutions of the form similar to Eqs. (4.88),

$$
\begin{equation*}
q_{1}=c_{1} e^{\lambda t}, \quad q_{2}=c_{2} e^{\lambda t} \tag{5.6}
\end{equation*}
$$

for all possible values of $\lambda$. These values may be found by plugging Eq. (6) into Eqs. (5), and requiring the resulting system of two linear algebraic equations for the distribution coefficients $c_{1,2}$,

$$
\begin{align*}
& m_{1} \lambda^{2} c_{1}+m_{1} \Omega_{1}^{2} c_{1}=\kappa c_{2}  \tag{5.7}\\
& m_{2} \lambda^{2} c_{2}+m_{2} \Omega_{2}^{2} c_{2}=\kappa c_{1}
\end{align*}
$$

to be self-consistent. In our particular case, we get a characteristic equation,

$$
\left|\begin{array}{cc}
m_{1}\left(\lambda^{2}+\Omega_{1}^{2}\right) & -\kappa  \tag{5.8}\\
-\kappa & m_{2}\left(\lambda^{2}+\Omega_{2}^{2}\right)
\end{array}\right|=0
$$

that is quadratic in $\lambda^{2}$, and thus allows a simple solution:

$$
\begin{align*}
\left(\lambda^{2}\right)_{ \pm} & =-\frac{1}{2}\left(\Omega_{1}^{2}+\Omega_{2}^{2}\right) \mp\left[\frac{1}{4}\left(\Omega_{1}^{2}+\Omega_{2}^{2}\right)^{2}-\Omega_{1}^{2} \Omega_{2}^{2}+\frac{\kappa^{2}}{m_{1} m_{2}}\right]^{1 / 2}  \tag{5.9}\\
& =-\frac{1}{2}\left(\Omega_{1}^{2}+\Omega_{2}^{2}\right) \mp\left[\frac{1}{4}\left(\Omega_{1}^{2}-\Omega_{2}^{2}\right)^{2}+\frac{\kappa^{2}}{m_{1} m_{2}}\right]^{1 / 2} .
\end{align*}
$$

According to Eqs. (2) and (3b), for any positive values of spring constants, product $\Omega_{1} \Omega_{2}=\left(\kappa_{L}+\kappa_{M}\right)\left(\kappa_{R}\right.$ $\left.+\kappa_{M}\right) /\left(m_{1} m_{2}\right)^{1 / 2}$ is always larger than $\kappa /\left(m_{1} m_{2}\right)^{1 / 2}=\kappa_{M} /\left(m_{1} m_{2}\right)^{1 / 2}$, so that the square root in Eq. (9) is always less than $\left(\Omega_{1}{ }^{2}+\Omega_{2}{ }^{2}\right) / 2$. As a result, both values of $\lambda^{2}$ are negative, i.e. the general solution to Eq.
(5) is a sum of four terms, each proportional to $\exp \left\{ \pm i \omega_{ \pm} t\right\}$, where both eigenfrequencies $\omega_{ \pm} \equiv i \lambda_{ \pm}$are real:

$$
\begin{equation*}
\omega_{ \pm}^{2} \equiv-\lambda_{ \pm}^{2}=\frac{1}{2}\left(\Omega_{1}^{2}+\Omega_{2}^{2}\right) \pm\left[\frac{1}{4}\left(\Omega_{1}^{2}-\Omega_{2}^{2}\right)^{2}+\frac{\kappa^{2}}{m_{1} m_{2}}\right]^{1 / 2} \tag{5.10}
\end{equation*}
$$

A plot of these eigenfrequencies as a function of one of the partial frequencies $\Omega$ (say, $\Omega_{1}$ ), with the other partial frequency fixed, gives the famous anticrossing (also called "avoided crossing" or noncrossing") diagram (Fig. 2). One can see that at weak coupling, frequencies $\omega_{ \pm}$are close to the partial frequencies everywhere besides a narrow range near the anticrossing point $\Omega_{1}=\Omega_{2}$. Most remarkably, at passing through this region, $\omega_{+}$smoothly "switches" from following $\Omega_{2}$ to following $\Omega_{1}$ and vice versa.

Fig. 5.2. Anticrossing diagram for two values of the oscillator coupling strength $K /\left(m_{1} m_{2}\right)^{1 / 2} \Omega_{2}{ }^{2}$ : 0.3 (red lines) and 0.1 (blue lines). In this plot, $\Omega_{1}$ is assumed to be changed by varying $\kappa_{1}$ rather than $m_{1}$, but in the opposite case the diagram is qualitatively similar.

The reason for this counterintuitive behavior may be found by examining the distribution coefficients $c_{1,2}$ corresponding to each branch of the diagram, which may be obtained by plugging the corresponding value of $\lambda_{ \pm}=-i \omega_{ \pm}$back into Eqs. (7). For example, at the anticrossing point $\Omega_{1}=\Omega_{2} \equiv \Omega$, Eq. (10) is reduced to

$$
\begin{equation*}
\omega_{ \pm}^{2}=\Omega^{2} \pm \frac{\kappa}{\left(m_{1} m_{2}\right)^{1 / 2}}=\Omega^{2}\left(1 \pm \frac{\kappa}{\left(\kappa_{1} \kappa_{2}\right)^{1 / 2}}\right) . \tag{5.11}
\end{equation*}
$$

Plugging this expression back into any of Eqs. (7), we see that for the two branches of the anticrossing diagram, the distribution coefficient ratio is the same by magnitude but opposite by sign: ${ }^{2}$

$$
\begin{equation*}
\left(\frac{c_{1}}{c_{2}}\right)_{ \pm}=\mp\left(\frac{m_{2}}{m_{1}}\right)^{1 / 2}, \quad \text { at } \Omega_{1}=\Omega_{2} \tag{5.12}
\end{equation*}
$$

In particular, if the system is symmetric ( $m_{1}=m_{2}, \kappa_{L}=\kappa_{R}$ ), then at the upper branch, corresponding to $\omega_{+}>\omega_{-}, c_{1}=-c_{2}$. This means that in this hard mode, ${ }^{3}$ masses oscillate in anti-phase: $q_{1}(t) \equiv-q_{2}(t)$. The

[^63]resulting substantial extension/compression of the middle spring yields additional returning force which increases the oscillation frequency. On the contrary, on the lower branch, corresponding to $\omega$, the particle oscillations are in phase: $c_{1}=c_{2}, q_{1}(t) \equiv q_{2}(t)$, so that the middle spring is never stretched at all. As a result, the soft mode oscillation frequency $\omega_{\text {- }}$ is lower than $\omega_{+}$and does not depend on $\kappa$.
\[

$$
\begin{equation*}
\omega_{-}^{2}=\Omega^{2}-\frac{\kappa}{m}=\frac{\kappa_{L}}{m}=\frac{\kappa_{R}}{m} . \tag{5.13}
\end{equation*}
$$

\]

Note that for both modes, the oscillations equally engage both particles.
Far from the anticrossing point, the situation is completely different. Indeed, an absolutely similar calculation of $c_{1,2}$ shows that on each branch of the diagram, one of the distribution coefficients is much larger (by magnitude) than its counterpart. Hence, in this limit any particular mode of oscillations involves virtually only one particle. A slow change of system parameters, bringing it through the anticrossing, results, first, in a maximal delocalization of each mode, and then in the restoration of the localization, but in a different partial degree of freedom.

We could readily carry out similar calculations for the case when the systems are coupled via their velocities, $L_{\text {int }}=m \dot{q}_{1} \dot{q}_{2}$, where $m$ is a coupling coefficient - not necessarily a certain physical mass. (In mechanics, with $q_{1,2}$ standing for actual particle displacements, such coupling is hard to implement, but there are many dynamic systems of non-mechanical nature in which such coupling is the most natural one.) The results are generally similar to those discussed above, again with the maximum level splitting at $\Omega_{1}=\Omega_{2} \equiv \Omega$ :

$$
\begin{equation*}
\omega_{ \pm}^{2}=\frac{\Omega^{2}}{1 \mp|m| /\left(m_{1} m_{2}\right)^{1 / 2}} \approx \Omega^{2}\left(1 \pm \frac{|m|}{\left(m_{1} m_{2}\right)^{1 / 2}}\right), \tag{5.14}
\end{equation*}
$$

the last relation being valid for weak coupling. The generalization to the case of both coordinate and velocity coupling is also straightforward - see the next section.

The anticrossing diagram shown in Fig. 2 may be met not only in classical mechanics. It is even more ubiquitous quantum mechanics, because, due to the time-oscillatory character of the Schrödinger equation solutions, weak coupling of any two quantum states leads to a qualitatively similar behavior of eigenfrequencies $\omega_{ \pm}$and hence of the eigenenergies ("energy levels") $E_{ \pm}=\hbar \omega_{ \pm} .{ }^{4}$

## 5.2. $N$ coupled oscillators

The calculations of the previous section may be readily generalized to the case of arbitrary number (say, $N$ ) coupled harmonic oscillators, with arbitrary type of coupling. It is evident that in this case Eq. (4) should be replaced with

[^64]\[

$$
\begin{equation*}
L=\sum_{j=1}^{N} L_{j}+\sum_{j, j^{\prime}=1}^{N} L_{i j^{\prime}} \tag{5.15}
\end{equation*}
$$

\]

Moreover, we can generalize the above relations for the mixed terms $L_{i j}$, taking into account their possible dependence not only on the generalized coordinates, but on the generalized velocities, in a bilinear form similar to Eq. (4). The resulting Lagrangian may be presented in a compact form,

$$
\begin{equation*}
L=\sum_{j, j^{\prime}=1}^{N}\left(\frac{m_{i j^{\prime}}}{2} \dot{q}_{j} \dot{q}_{j^{\prime}}-\frac{\kappa_{i j^{\prime}}}{2} q_{j} q_{j^{\prime}}\right) \tag{5.16}
\end{equation*}
$$

where the off-diagonal terms are index-symmetric: $m_{j j^{\prime}}=m_{j^{\prime} j^{\prime}}, \kappa_{j j^{\prime}}=\kappa_{j^{\prime} j}$, and the factors $1 / 2$ compensate the double counting of each term with $j \neq j^{\prime}$, taking place at the summation over two independently running indices. One may argue that Eq. (16) is quite general if we still want the equations of motion to be linear - as they have to be if the oscillations are small enough.

Plugging Eq. (16) into the general form (2.19) of the Lagrange equation, we get $N$ equations of motion of the system, one for each value of index $j^{\prime}=1,2, \ldots, N$ :

$$
\begin{equation*}
\sum_{j=1}^{N}\left(m_{i j} \ddot{q}_{j}+\kappa_{j j} q_{j}\right)=0 \tag{5.17}
\end{equation*}
$$

Just as in the previous section, let us look for a particular solution to this system in the form

$$
\begin{equation*}
q_{j}=c_{j} e^{\lambda t} \tag{5.18}
\end{equation*}
$$

As a result, we are getting a system of $N$ linear, homogeneous algebraic equations,

$$
\begin{equation*}
\sum_{j=1}^{N}\left(m_{i j j^{\prime}} \lambda^{2}+\kappa_{i j^{\prime}}\right) c_{j}=0 \tag{5.19}
\end{equation*}
$$

for the set of $N$ distribution coefficients $c_{j}$. The condition that this system is self-consistent is that the determinant of its matrix equals zero:

$$
\begin{equation*}
\operatorname{Det}\left(m_{j j} \cdot \lambda^{2}+\kappa_{j j^{\prime}}\right)=0 \tag{5.20}
\end{equation*}
$$

This characteristic equation is an algebraic equation of degree $N$ for $\lambda^{2}$, and so has $N$ roots $\left(\lambda^{2}\right)_{n}$. For any Hamiltonian system with stable equilibrium, matrices $m_{j j}$, and $\kappa_{j j}$, ensure that all these roots are real and negative. As a result, the general solution to Eq. (17) is the sum of $2 N$ terms proportional to $\exp \left\{ \pm i \omega_{n} t\right\}$, $n=1,2, \ldots, N$, where all $N$ eigenfrequencies $\omega_{n}$ are real.

Plugging each of these $2 N$ values of $\lambda= \pm i \omega_{n}$ back into the set of linear equations (17), one can find the corresponding set of distribution coefficients $c_{j \pm}$. Generally, the coefficients are complex, but in order to keep $q_{\mathrm{j}}(t)$ real, the coefficients $c_{j+}$ corresponding to $\lambda=+i \omega_{n}$ and $c_{j \text { - }}$ corresponding to $\lambda=-i \omega_{n}$ have to be complex conjugate of each other. Since the sets of the distribution coefficients may be different for each $\lambda_{n}$, they should be marked with two indices, $j$ and $n$. Thus, at general initial conditions, the time evolution of $j$-th coordinate may be presented as

$$
\begin{equation*}
q_{j}=\frac{1}{2} \sum_{n=1}^{N}\left(c_{j n} \exp \left\{+i \omega_{n} t\right\}+c_{j n}^{*} \exp \left\{-i \omega_{n} t\right\}\right)=\operatorname{Re} \sum_{n=1}^{N} c_{j n} \exp \left\{i \omega_{n} t\right\} . \tag{5.21}
\end{equation*}
$$

This formula shows very clearly again the physical sense of the distribution coefficients $c_{j n}$ : a set of these coefficients, with different values of index $j$ but the same $n$, gives the complex amplitudes of oscillations of the coordinates for the special choice of initial conditions, that ensures purely sinusoidal motion of the system, with frequency $\omega_{n}$. Moreover, these coefficients show how exactly such special initial conditions should be selected - within a common constant factor.

Calculation of the eigenfrequencies and distribution coefficients of a coupled system with many degrees of freedom from Eq. (20) is a task that frequently may be only done numerically. ${ }^{5}$ Let us discuss just two particular but very important cases. First, let all the coupling coefficients be small $\left(\left|m_{j j}\right| \ll m_{j}\right.$ $\equiv m_{j j}$ and $\left|\kappa_{j j^{\prime}}\right| \ll \kappa_{j} \equiv \kappa_{j j}$, for all $j \neq j$ ), and all partial frequencies $\Omega_{j} \equiv\left(\kappa_{j} / m_{j}\right)^{1 / 2}$ be not too close to each other:

$$
\begin{equation*}
\frac{\left|\Omega_{j}^{2}-\Omega_{j^{\prime}}^{2}\right|}{\Omega_{j}^{2}} \gg \frac{\left|\kappa_{i j^{\prime}}\right|}{\kappa_{j}}, \frac{\left|m_{j j^{\prime}}\right|}{m_{j}}, \quad \text { for all } j \neq j^{\prime} \tag{5.22}
\end{equation*}
$$

(Such situation frequently happens if parameters of the system are "random" in the sense that they do not follow any special, simple rule.) Results of the previous section imply that in this case the coupling does not produce a noticeable change of oscillation frequencies: $\left\{\omega_{n}\right\} \approx\left\{\Omega_{j}\right\}$. In this situation, oscillations at each eigenfrequency are heavily concentrated in one degree of freedom, i.e. in each set of the distribution coefficients $c_{j n}$ (for a given $n$ ), one coefficient's magnitude is much larger than all others.

Now let the conditions (22) be valid for all but one pair of partial frequencies, say $\Omega_{1}$ and $\Omega_{2}$, while these two frequencies are so close that coupling of the corresponding partial oscillators becomes essential. In this case the approximation $\left\{\omega_{n}\right\} \approx\left\{\Omega_{j}\right\}$ is still valid for all other degrees of freedom, and the corresponding terms may be neglected in Eqs. (19) for $j=1$ and 2. As a result, we return to Eqs. (7) (perhaps generalized for velocity coupling) and hence to the anticrossing diagram (Fig. 2) discussed in the previous section. As a result, an extended change of only one partial frequency (say, $\Omega_{1}$ ) of a weakly coupled system produces a series of eigenfrequency anticrossings - see Fig. 3.

Fig. 5.3. Level anticrossing in a system of $N$ weakly coupled oscillators - schematically.

[^65]
### 5.3. 1D waves in periodic systems

For coupled systems with considerable degree of symmetry, the general results of the last section may be simplified, some with very profound implications. Perhaps the most important of them are waves. Figure 4 shows a classical example of a wave-supporting system - a long 1D chain of massive particles, with the elastic next-neighbor coupling.

Fig. 5.4. Uniform 1D chain of elastically coupled particles.

Let us start from the case when the system is so long (formally, infinite) that the boundary effects may be neglected; then its Lagrangian may be represented by an infinite sum of similar terms, each including the kinetic energy of $j$-th particle, and the potential energy of the spring on one (say, right) side of it:

$$
\begin{equation*}
L=\sum_{j}\left[\frac{m}{2} \dot{q}_{j}^{2}-\frac{\kappa}{2}\left(q_{j+1}-q_{j}\right)^{2}\right] . \tag{5.23}
\end{equation*}
$$

From here, the Lagrange equations of motion (2.19) have the same form for each particle:

$$
\begin{equation*}
m \ddot{q}_{j}-\kappa\left(q_{j+1}-q_{j}\right)+\kappa\left(q_{j}-q_{j-1}\right)=0 . \tag{5.24}
\end{equation*}
$$

Apart from the (formally) infinite size of the system, this is evidently just a particular case of Eq. (17), and thus its particular solution may be looked in the form (18), with $\lambda^{2} \rightarrow-\omega^{2}<0$. With this substitution, Eq. (24) gives the following simple form of the general system (17) for the distribution coefficients $c_{j}$ :

$$
\begin{equation*}
\left(-m \omega^{2}+2 \kappa\right) c_{j}-\kappa c_{j+1}-\kappa c_{j-1}=0 \tag{5.25}
\end{equation*}
$$

Now comes the most important conceptual step toward the wave theory: the translational symmetry of Eq. (23), i.e. its invariance to the replacement $j \rightarrow j+1$, allows it to have a particular solution of the following form:

$$
\begin{equation*}
c_{j}=a e^{i \alpha j} \tag{5.26}
\end{equation*}
$$

where coefficient $\alpha$ may depend on $\omega$ (and system's parameters), but not on the particle number $j$. Indeed, plugging Eq. (26) into Eq. (25) and cancelling the common factor $e^{i \alpha j}$, we see that it is identically satisfied, if $\alpha$ obeys the following algebraic equation:

$$
\begin{equation*}
\left(-m \omega^{2}+2 \kappa\right)-\kappa e^{+i \alpha}-\kappa e^{-i \alpha}=0 . \tag{5.27}
\end{equation*}
$$

The physical sense of solution (26) becomes clear if we use it and Eq. (18) with $\lambda=\mp i \omega$ to write

$$
\begin{equation*}
q_{j}(t)=\operatorname{Re}\left[a e^{i\left(k z_{j} \mp \omega t\right)}\right]=\operatorname{Re}\left[a e^{i k\left(z_{j} \mp v_{\mathrm{ph}} t\right)}\right], \tag{5.28}
\end{equation*}
$$

where wave number $k$ is defined as $k \equiv \alpha / d$, and $z_{j}=j d$ is the equilibrium position of $j$-th particle - the notion that should not be confused with particle's displacement $q_{j}$ from that equilibrium position - see Fig. 4. Relation (28) describes nothing else than a sinusoidal traveling wave of particle displacements (and hence of spring extensions/constrictions), that propagates, depending on the sign before $v_{\mathrm{ph}}$, to the right or to the left along the particle chain with phase velocity

$$
\begin{equation*}
v_{\mathrm{ph}} \equiv \frac{\omega}{k} . \tag{5.29}
\end{equation*}
$$

Perhaps the most important characteristic of a wave is the so-called dispersion relation, i.e. the relation between its frequency $\omega$ and wave number $k$ - essentially between the temporal and spatial frequencies of the wave. For our current system, this relation is given by Eq. (27) with $\alpha \equiv k d$. Taking into account that $\left(2-e^{+i \alpha}-e^{-i \alpha}\right)=2(1-\cos \alpha)=4 \sin ^{2}(\alpha / 2)$, it may be rewritten in a simpler form:

$$
\begin{equation*}
\omega= \pm \omega_{0} \sin \frac{\alpha}{2}= \pm \omega_{0} \sin \frac{k d}{2}, \quad \text { where } \omega_{0} \equiv 2\left(\frac{\kappa}{m}\right)^{1 / 2} \tag{5.30}
\end{equation*}
$$

This result, frequently called the Debye dispersion relation, ${ }^{6}$ is sketched in Fig. 5, and is rather remarkable in several aspects.

Fig. 5.5. The Debye dispersion relation.

First, if the wavelength $\lambda \equiv 2 \pi||k|$ is much larger than the spatial period a of the structure, i.e. if $|k d| \ll 1$ (so that $|\omega| \ll \omega_{0}$ ), the dispersion relation is approximately linear:

$$
\begin{equation*}
\omega= \pm \omega_{0} \frac{k d}{2}= \pm v k \tag{5.31}
\end{equation*}
$$

where parameter $v$ is frequency-independent:

$$
\begin{equation*}
v \equiv \frac{\omega_{0} d}{2}=\left(\frac{\kappa}{m}\right)^{1 / 2} d \tag{5.32}
\end{equation*}
$$

Comparison of Eq. (31) with Eq. (28) shows that this constant plays, in the low-frequency region, the role of phase velocity for any frequency component of a waveform created in the system - say, by initial conditions. As a result, low-frequency waves of arbitrary form can propagate in the system without

[^66]deformation (called dispersion). Such waves are called acoustic, ${ }^{7}$ and are the general property of any elastic continuous medium.

Indeed, the limit $|k d| \ll 1$ means that distance $d$ between adjacent particles is much smaller than wavelength $\lambda=2 \pi /|k|$, i.e. that the differences $q_{j+1}(t)-q_{j}(t)$ and $q_{j}(t)-q_{j-1}(t)$, participating in Eq. (24), are relatively small and may be approximated with $\partial q / \partial j=\partial q / \partial(z / d)=d(\partial q / \partial z)$, with the derivatives taken at middle points between the particles: respectively, $z_{+} \equiv\left(z_{j+1}-z_{j}\right) / 2$ and $z_{-} \equiv\left(z_{j}-z_{j-1}\right) / 2$. Here $z$ in now considered as a continuous argument (and hence the system, as a 1 D continuum), and $q(z, t)$, as a continuous function of space and time. In this approximation, the sum of the last two terms of Eq. (24) is equal to $-\kappa d\left[\partial q / \partial z\left(z_{+}\right)-\partial q / \partial z\left(z_{-}\right)\right]$, and may be similarly approximated by $-\kappa d^{2}\left(\partial^{2} q / \partial z^{2}\right)$, with the second derivative taken at point $\left(z_{+}-z_{-}\right) / 2=z_{j}$, i.e. exactly at the same point as the time derivative. As the result, the ordinary differential equation (24) is reduced to a partial differential equation

$$
\begin{equation*}
m \frac{\partial^{2} q}{\partial t^{2}}-\kappa d^{2} \frac{\partial^{2} q}{\partial z^{2}}=0 \tag{5.33a}
\end{equation*}
$$

Using Eqs. (30) and (32), we may present this equation in a more general form

1D wave equation

$$
\begin{equation*}
\left(\frac{1}{v^{2}} \frac{\partial^{2}}{\partial t^{2}}-\frac{\partial^{2}}{\partial z^{2}}\right) q(z, t)=0 \tag{5.33b}
\end{equation*}
$$

which describes a scalar acoustic wave (of any physical nature) in a 1D linear, dispersion-free continuum - cf. Eq. (1.2). In our current simple model (Fig. 4), direction $z$ of the wave propagation coincides with the direction of particle displacements $q$; such acoustic waves are called longitudinal. However, in Chapter 7 we will see that 3D elastic media may also support different, transverse waves that also obey Eq. (33b), but with a different acoustic velocity $v$.

Second, when the wavelength is comparable with the structure period $d$ (i.e. the product $k d$ is not small), the dispersion relation is not linear, and the system is dispersive. This means that as a wave, whose Fourier spectrum has several essential components with frequencies of the order of $\omega_{0}$, travels along the structure, its waveform (which may be defined as the shape of a snapshot of all $q_{j}$, at the same time) changes. ${ }^{8}$ This effect may be analyzed by presenting the general solution of Eq. (24) as the sum (more generally, an integral) of components (28) with different complex amplitudes $a$ :

$$
\begin{equation*}
q_{j}(t)=\operatorname{Re} \int_{-\infty}^{+\infty} a_{k} e^{i\left[k z_{j}-\omega(k) t\right]} d k \tag{5.34}
\end{equation*}
$$

This notation emphasizes the dependence of the partial wave amplitudes $a_{k}$ and frequencies on the wave number $k$. While the latter dependence is given by the dispersion relation, in our current case by Eq. (30), function $a_{k}$ is determined by the initial conditions. For applications, the case when $a_{k}$ is substantially different from zero only is a narrow interval, of width $\Delta k \ll k_{0}$ around some central value $k_{0}$, is of special importance. (The Fourier transform reciprocal to Eq. (34) shows that this is true, in particular for a so-called wave packet - a sinusoidal wave modulated by an envelope with a large width

[^67]$\Delta z \sim 1 / \Delta k \gg 1 / k_{0}-$ see Fig. 6.) Using that strong inequality, the wave packet propagation may be analyzed by expending the dispersion relation $\omega(k)$ into the Taylor series at point $k_{0}$, and, in the first approximation in $\Delta k / k_{0}$, restricting the expansion by its first two terms:
\[

$$
\begin{equation*}
\omega(k) \approx \omega_{0}+\left.\frac{d \omega}{d k}\right|_{k=k_{0}} \widetilde{k}, \quad \text { where } \omega_{0} \equiv \omega\left(k_{0}\right), \text { and } \tilde{k} \equiv k-k_{0} . \tag{5.35}
\end{equation*}
$$

\]

In this approximation, Eq. (34) yields

$$
\begin{align*}
q_{j}(t) & \approx \operatorname{Re} \int_{-\infty}^{+\infty} a_{k} \exp \left\{i\left[\left(k_{0}+\widetilde{k}\right) z_{j}-\left(\left.\omega_{0}+\frac{d \omega}{d k} \right\rvert\, k=k_{0} \tilde{k}\right) t\right]\right\} d k \\
& =\operatorname{Re}\left[\exp \left\{i\left(k_{0} z_{j}-\omega_{0} t\right)\right\} \int_{-\infty}^{+\infty} a_{k} \exp \left\{i \tilde{k}\left(\left.z_{j}-\frac{d \omega}{d k} \right\rvert\, k=k_{0} t\right)\right\} d k\right] . \tag{5.36}
\end{align*}
$$

Comparing this expression with the initial form of the wave packet,

$$
\begin{equation*}
q_{j}(0)=\operatorname{Re} \int_{-\infty}^{+\infty} a_{k} e^{i k z_{j}} d k=\operatorname{Re}\left[\exp \left\{i k_{0} z_{j} \int_{-\infty}^{+\infty} \int_{k} \exp \left\{i \widetilde{k} z_{j}\right\} d k\right]\right. \tag{5.37}
\end{equation*}
$$

and taking into account that the phase factors before the integrals in the last forms of Eqs. (36) and (37) do not affect its envelope, we see that in this approximation ${ }^{9}$ the envelope sustains its initial form and propagates along the system with the so-called group velocity

$$
\begin{equation*}
\left.v_{\mathrm{gr}} \equiv \frac{d \omega}{d k}\right|_{k=k_{0}} \tag{5.38}
\end{equation*}
$$

Note that, with the exception of the acoustic wave limit (31), this velocity (that characterizes the propagation of waveform's envelope), is different from the phase velocity (28) that describes the propagation of the "carrier" sine wave - for example, one of its zeros - see Fig. 6.

Fig. 5.6. Phase and group velocities of a wave packet.

Next, at the Debye dispersion law (30), the difference between $v_{\mathrm{ph}}$ and $v_{\mathrm{gr}}$ increases as the average frequency $\omega$ approaches $\omega_{0}$, with the group velocity tending to zero, while the phase velocity staying virtually constant. The existence of such a maximum for the wave propagation frequency

[^68]presents one more remarkable feature of this system. It physics may be readily understood by noticing that according to Eq. (30), at $\omega=\omega_{0}$, the wave number $k$ equals $n \pi / d$, where $n$ is an odd integer, and hence the phase shift $\alpha \equiv k d$ is an odd multiple of $\pi$. Plugging this value into Eq. (28), we see that at the Debye frequency, oscillations of two adjacent particles are in anti-phase, for example:
\[

$$
\begin{equation*}
q_{0}(t)=a \exp \{-i \omega t\}, \quad q_{1}(t)=a \exp \{i(\pi-\omega t)\}=-a \exp \{-i \omega t\}=-q_{0}(t) \tag{5.39}
\end{equation*}
$$

\]

It is clear from Fig. 4 that at such phase shift, all the springs are maximally stretched/compressed (just as in the hard mode of the two coupled oscillators analyzed in Sec. 1), so that it is natural that this mode has the highest frequency.

This invites a natural question what happens with the system if it is excited at a frequency $\omega>$ $\omega_{0}$, say by an external force applied at the system's boundary. While the boundary phenomena will be considered in the next section, the most essential part of the answer may be obtained immediately from Eqs. (26) and (30). Indeed, reviewing the calculations that have led to these results, we see that they are valid not only for real but also any complex values of $\alpha$. In particular, at $\omega>\omega_{0}$ the dispersion relation (30) gives

$$
\begin{equation*}
\alpha=n \pi \pm i \frac{d}{\Lambda}, \quad \text { where } \Lambda \equiv \frac{d}{2 \cosh ^{-1}\left(\omega / \omega_{0}\right)} \tag{5.40}
\end{equation*}
$$

Plugging this relation into Eq. (26), we see that the wave's amplitude becomes an exponential function of position:

$$
\begin{equation*}
\left|q_{j}\right|=|a| e^{ \pm j \operatorname{Im} \alpha} \propto e^{ \pm z_{j} / \Lambda} . \tag{5.41}
\end{equation*}
$$

Physically this means that the wave decays penetrating into the structure (from the excitation point), dropping by a factor of $e \approx 3$ on the so-called penetration depth $\Lambda$. (According to Eq. (40), this depth decreases with frequency, but rather slowly, always remaining of the order of the distance between the adjacent particles.) Such a limited penetration is a very common property of various waves, including the electromagnetic waves in plasmas and superconductors, and quantum-mechanical "de Broglie waves" (wavefunctions) in the classically-forbidden regions. Note that this effect of "wave expulsion" from the media they cannot propagate in does not require any energy dissipation.

Finally, one more fascinating feature of the dispersion relation (30) is that if it is satisfied by some wave number $k_{0}(\omega)$, it is also satisfied at any $k_{n}(\omega)=k_{0}(\omega)+2 \pi n / d$, where $n$ is any integer. This property is independent of the particular dynamics of the system: it follows already from Eq. (27), before its substitution into Eq. (25), because such a wave number translation by $2 \pi / d$, i.e. the addition of $2 \pi$ to phase shift $\alpha$, is equivalent to the multiplication of $q_{j}(t)$ by $\exp \{i 2 \pi\}=1$. Thus, such $(2 \pi / d)$ periodicity in the wave number space is a common property of all systems that are $d$-periodic in the usual ("direct") space. ${ }^{10}$

Besides dispersion, one more key characteristic of any wave-supporting system is its wave impedance - the notion strangely missing from many physics (but not engineering) textbooks. It may be

[^69]revealed by calculating the forces in the sinusoidal wave (28). For example, the force exerted by $j$-th particle on its right neighbor, given by the second term in Eq. (24), equals
\[

$$
\begin{equation*}
F_{j+}(t)=\kappa\left[q_{j}(t)-q_{j+1}(t)\right]=\operatorname{Re}\left[\kappa\left(1-e^{i k d}\right) a e^{i\left(k z_{j} \mp \omega t\right)}\right] \rightarrow \operatorname{Re}\left[-i k d \kappa a e^{i\left(k z_{j} \mp \omega t\right)}\right], \tag{5.42}
\end{equation*}
$$

\]

where the last form is valid in the most important acoustic wave limit, $k d \rightarrow 0$. Let us compare this expression for the wave of forces with that for the corresponding wave of particle velocities:

$$
\begin{equation*}
\dot{q}_{j}(t)=\operatorname{Re}\left[\mp i \omega a e^{i\left(k z_{j} \mp \omega t\right)}\right] . \tag{5.43}
\end{equation*}
$$

We see that these two waves have the same phase, and hence their ratio does not depend on either time or the particle number. Moreover, this ratio,

$$
\begin{equation*}
\frac{F_{+}}{\dot{q}}= \pm \frac{k d \kappa}{\omega}= \pm \frac{d \kappa}{v}= \pm Z \tag{5.44}
\end{equation*}
$$

is a real constant independent even on wave's frequency. Its magnitude is called the wave impedance:

$$
\begin{equation*}
Z \equiv \frac{d \kappa}{v}=(\kappa m)^{1 / 2} \tag{5.45}
\end{equation*}
$$

and characterizes the dynamic "stiffness" of the system for the propagating waves.
In particular, the impedance scales the power carried by the wave. Indeed, the direct time averaging of the instantaneous power $\mathcal{P}_{j}(t) \equiv F_{j}(t) d q_{j} / d t$ transferred through particle $j$ to the subsystem on the right of it, using Eqs. (42)-(43), yields a position-independent result

$$
\begin{equation*}
\overline{P_{j}} \equiv \overline{\left[F_{j}(t) \dot{q}_{j}(t)\right]_{ \pm}}= \pm \frac{\omega^{2} Z}{2} a a^{*} \equiv \pm \frac{\omega^{2} Z}{2} A^{2} \tag{5.46}
\end{equation*}
$$

where $A \equiv|a|$ is the real amplitude of the wave, and, as before, the positive sign corresponds to the wave propagating to the right (and vice versa). Note that $\mathcal{P}$ is the power flow in the acoustic wave, and its spatial and temporal independence means that wave's energy is conserved - as could be expected from our Hamiltonian system we are considering. ${ }^{11}$ Hence, the wave impedance $Z$ characterizes the energy transfer along the system rather than its dissipation.

### 5.4. Interfaces and boundaries

The importance of the wave impedance notion becomes even more evident when we consider waves in non-uniform and finite-size systems. Indeed, our previous analysis assumed that the 1D system supporting the waves (Fig. 4) is exactly periodic, i.e. macroscopically uniform, and extends all the way from $-\infty$ to $+\infty$. Now let us examine what happens when this is not true. The simplest (and very important) example of such nonuniform systems is an interface, i.e. a point at which system parameters experience a change. Figure 7 shows a simple and representative example of such a sharp interface, for the same 1D wave system that was analyzed in the last section.

[^70]

Fig. 5.7. 1D system with a sharp interface at $z=0$, and the wave components at the partial reflection of a wave incident from the left.

Since the parameters $\kappa$ and $m$ are still constant on each side of the interface (put, for convenience, at $z_{j}=0$ ), equations of motion (24) are is still valid for $j<0$ and $j>0$ (in the latter case, with the primed parameters), and show that at a fixed frequency $\omega$, they can sustain sinusoidal waves of the type (28). However, the final jump of parameters at the interface ( $m^{\prime} \neq m, \kappa^{\prime} \neq \kappa$ ) leads to a partial reflection of the incident wave from the interface, so that at least on the side of incidence (say, $z_{j} \leq 0$ ), we need to assume two such waves, one describing the incident wave and another, the reflected wave:

$$
q_{j}(t)=\operatorname{Re} \begin{cases}a_{\rightarrow} e^{i\left(k z_{j}-\omega t\right)}+a_{\leftarrow} e^{i\left(-k z_{j}-\omega t\right)}, & \text { for } j \leq 0,  \tag{5.47}\\ a_{\rightarrow}^{\prime} e^{i\left(k^{\prime} z_{j}-\omega t\right)}, & \text { for } j \geq 0 .\end{cases}
$$

In order to obtain boundary conditions for "stitching" these waves (i.e. getting relations between their complex amplitudes) at $j=0$, i.e. $z_{j}=0$, we need to take into account, first, that displacement $q_{0}(t)$ of the interface particle has to be the same whether it is considered a part of the left or right sub-system, and hence participates in Eqs. (24) for both $j \leq 0$ and $j \geq 0$. This gives us the first boundary condition,

$$
\begin{equation*}
a_{\rightarrow}+a_{\leftarrow}=a_{\rightarrow}^{\prime} . \tag{5.48}
\end{equation*}
$$

Second, writing the equation of motion for the special particle with $j=0$,

$$
\begin{equation*}
m_{0} \ddot{q}_{0}-\kappa^{\prime}\left(q_{1}-q_{0}\right)+\kappa\left(q_{0}-q_{-1}\right)=0 . \tag{5.49}
\end{equation*}
$$

and plugging into it the solution (47), we get the second boundary condition

$$
\begin{equation*}
-\omega^{2} m_{0} a_{\rightarrow}^{\prime}-\kappa^{\prime} a_{\rightarrow}^{\prime}\left(e^{i k^{\prime} d}-1\right)+\kappa\left[a_{\rightarrow}\left(1-e^{-i k d}\right)+a_{\leftarrow}\left(1-e^{i k d}\right)\right]=0 . \tag{5.50}
\end{equation*}
$$

The system of two linear equations (48) and (50) allows one to express both $a_{\leftarrow}$ and $a^{\prime}{ }_{\rightarrow}$ via amplitude $a_{\rightarrow}$ of the incident wave, and hence find the reflection $(R)$ and transmission $(T)$ coefficients of the interface: ${ }^{12}$

$$
\begin{equation*}
R \equiv \frac{a_{\leftarrow}}{a_{\rightarrow}}, \quad T \equiv \frac{a_{\rightarrow}^{\prime}}{a_{\rightarrow}} . \tag{5.51}
\end{equation*}
$$

The general result for $R$ and $T$ is a bit bulky, but may be simplified in the most important acoustic wave limit: $k^{\prime} d, k d \rightarrow 0$. Indeed, in this limit all three parentheses participating in Eq. (50) may be approximated by the first terms of their Taylor expansions, e.g., $\exp \{i k ' d\}-1 \approx i k ' d$, etc. Moreover, in this limit, the first term of Eq. (50) is of the second order in small parameter $\omega / \omega_{0} \sim k a \ll 1$ (unless the

[^71]interface particle mass $m_{0}$ is much larger than both $m$ and $m$ '), and hence may be neglected. As a result, Eq. (50) takes a very simple form ${ }^{13}$
\[

$$
\begin{equation*}
\kappa k\left(a_{\rightarrow}-a_{\leftarrow}\right)=\kappa^{\prime} k^{\prime} a_{\rightarrow}^{\prime} . \tag{5.52a}
\end{equation*}
$$

\]

According to Eqs. (31), (32) and (45), in the acoustic limit the ratio of factors $\kappa k$ of the waves (with the same frequency $\omega$ !) propagating at $z<0$ and $z>0$ is equal to that of the wave impedances $Z$ of the corresponding parts of the system, so that Eq. (52a) may be rewritten as

$$
\begin{equation*}
Z\left(a_{\rightarrow}-a_{\leftarrow}\right)=Z^{\prime} a_{\rightarrow}^{\prime} . \tag{5.52b}
\end{equation*}
$$

Now, solving the simple system of linear equations (48) and (52a), we get very important formulas,

$$
\begin{equation*}
R=\frac{Z-Z^{\prime}}{Z+Z^{\prime}}, \quad T=\frac{2 Z}{Z+Z^{\prime}}, \tag{5.53}
\end{equation*}
$$

which are valid for any waves in 1D continua - with the corresponding re-definition of impedance. ${ }^{14}$ Note that coefficients $R$ and $T$ characterize the ratios of wave amplitudes rather than their power. Using Eq. (46), for the time-averaged power flows we get relations

$$
\begin{equation*}
\frac{\mathcal{P}_{\leftarrow}}{\mathcal{P}_{\rightarrow}}=\left(\frac{Z-Z^{\prime}}{Z+Z^{\prime}}\right)^{2}, \quad \frac{P_{\rightarrow}^{\prime}}{\mathcal{P}_{\rightarrow}}=\frac{4 Z Z^{\prime}}{\left(Z+Z^{\prime}\right)^{2}} . \tag{5.54}
\end{equation*}
$$

(Note that $\mathcal{P}_{\leftarrow}+\mathcal{P}_{\rightarrow}^{\prime}{ }_{\rightarrow}=\mathcal{P}_{\rightarrow}$, again reflecting the energy conservation.)
The first important result of this calculation that wave is fully transmitted through the interface if the so-called impedance matching condition $Z^{\prime}=Z$ is satisfied, even if the wave velocities $v(32)$ are different on the left and the right sides of the interface. On the contrary, the equality of the acoustic velocities in two media does not guarantee the full transmission of their interface. Again, this is a very general result.

Now let us consider the two limits in which Eq. (53) predicts a total wave reflection, $\mathcal{P}_{\leftarrow} / \mathcal{P}_{\rightarrow} \rightarrow$ $0: Z^{\prime} / Z \rightarrow \infty$ (when $R=-1$ ) and $Z^{\prime} / Z \rightarrow 0$ (when $R=1$ ). According to Eq. (45), the former limit corresponds to the infinite product $\kappa^{\prime} m^{\prime}$, so that particles on the right side of the interface cannot move at all. This means that this particular case also describes a perfectly rigid boundary (Fig. 8a) for arbitrary $\omega$, i.e. not necessarily in the acoustic wave limit. The negative sign of $R$ in the relation $R=-1$ means that in the reflected wave, the phase of particle oscillations is shifted by $\pi$ relative to the initial wave, $a=a_{\leftarrow}$ $=-a_{\rightarrow}$, so that the sum of these two traveling waves may be also viewed as a single standing wave

$$
\begin{equation*}
q_{j \leq 0}(t)=\operatorname{Re}\left[a e^{i\left(k z_{j}-\omega t\right)}-a e^{i\left(-k z_{j}-\omega t\right)}\right]=\operatorname{Re}\left[2 i a e^{-i \omega t} \sin k z_{j}\right]=2 A \sin (\omega t-\varphi) \sin k z_{j} \tag{5.55}
\end{equation*}
$$

where $a \equiv a_{\rightarrow}=A e^{i \varphi}$. At the boundary $\left(z_{j}=0\right)$ this expression yields $q_{0}(t) \equiv 0$, i.e., a node of particle displacements. On the contrary, the corresponding standing wave of spring forces, described by Eq. (42), has a maximum at $z=0$.

[^72]A similar standing wave forms in the opposite limit $Z^{\prime} / Z \rightarrow 0$, that describes an "open" boundary shown in Fig. 8b. However, in this limit (with $R=+1$ ), the standing wave of displacements has a maximum at $z_{j}=0$,

$$
\begin{equation*}
q_{j \leq 0}(t)=\operatorname{Re}\left[a e^{i\left(k z_{j}-\omega t\right)}+a e^{i\left(-k z_{j}-\omega t\right)}\right]=\operatorname{Re}\left[2 a e^{-i \omega t} \cos k z_{j}\right]=2 A \cos (\omega t-\varphi) \cos k z_{j} \tag{5.56}
\end{equation*}
$$

while the corresponding wave of forces has a node at that point. Most importantly, for both boundaries shown in Fig. 8, the standing waves are formed at any ratio $\omega / \omega_{0}$.

(a)

Fig. 5.8. (a) Rigid and (b) open
(b) boundaries of a 1D chain.

If the opposite boundary of a finite-length chain also provides a total wave reflection, the system may only support standing waves with certain wave numbers $k_{n}$, and hence certain eigenfrequencies $\omega_{n}$ that may be found from the set of $k_{n}$ and the dispersion relation $\omega_{n} \equiv \omega\left(k_{n}\right)$, in our case given by Eq. (30). For example, if both boundaries of a chain with length $L$ are rigid (Fig. 8a), then the standing wave (54) should have nodes at them both, giving the wave number quantization condition ${ }^{15}$

$$
\begin{equation*}
\sin k_{n} L=0, \quad \text { i.e. } k_{n}=\frac{\pi n}{L}, \tag{5.57a}
\end{equation*}
$$

where $n$ is an integer. In order to count the number of different modes in a chain with a finite number $N$ of oscillating particles, let us take into account, first, that adding one period $\Delta k=2 \pi / d$ of the dispersion relation to any $k_{n}$ leads to the same mode. Moreover, changing the sign of $k_{n}$ in standing wave (55) is equivalent to changing the sign of its amplitude. Hence, there are only $N$ different modes, for example with

$$
\begin{equation*}
n=1,2, \ldots, N, \quad \text { i.e. } k_{n}=\frac{\pi}{L}, 2 \frac{\pi}{L}, \ldots, N \frac{\pi}{L} . \tag{5.57b}
\end{equation*}
$$

This fact is of course just a particular case of the general result obtained in Sec. 2.
According to Eq. (56), if both boundaries are open (Fig. 8b), the oscillation modes are different, but their wave numbers form the same set (57). Finally, if the types of boundary conditions on the chain's ends are opposite, the wave number set is somewhat different,

$$
\begin{equation*}
k_{n}=\frac{\pi}{L}\left(n-\frac{1}{2}\right) \tag{5.58}
\end{equation*}
$$

15 This result should be very familiar to the reader from freshmen-level "guitar string"-type problems. Note, however, that Eqs. (54)-(56) are valid not only for continuous 1D systems like a string, but also for (uniform) chains with a finite and arbitrary number $N$ of particles - the fact we will use below.
but since the distance between the adjacent values of $k_{n}$ is still the same $(\pi / N d)$, the system still has exactly $N$ such values within each period $2 \pi / d$ of the dispersion law, and hence, again, exactly $N$ different oscillation modes.

This insensitivity of the number of modes and their equal spacing (called equidistance) on the $k$ axis, enables the following useful (and very popular) trick. In many applications, it is preferable to speak about the number of different traveling, rather than standing waves in a system of a large but finite size, with coordinates $z_{0}$ and $z_{N}$ describing the same particle. One can plausibly argue that the local dynamics of the chain of $N \gg 1$ particles should not be affected if it is gradually bent into a large closed loop of length $L=N d \gg d$. Such a loop may sustain traveling waves, if they satisfy the following periodic Born-Karman condition: $q_{0}(t) \equiv q_{N}(t)$. (A popular vivid image is that the wave "catches its own tail with its teeth".) According to Eq. (27), this condition is equivalent to

$$
\begin{equation*}
e^{i k_{n} L}=1, \quad \text { i.e. } k_{n}=\frac{2 \pi}{L} n \tag{5.59}
\end{equation*}
$$

This equation gives a set of wave numbers twice more sparse than that described by Eqs. (57). However, now we can use $N$ values of $n$, giving $k_{n}$, for example, from $-N$ to $+N$ (strictly speaking, excluding one of the boundary values to avoid double counting of the identical modes with $n= \pm N$ ), because traveling waves (28) with equal but opposite values of $k_{n}$ propagate in opposite directions and hence present different modes. As a result, the total number of different traveling-wave modes is the same $(N)$ as that of different standing-wave modes, and they are similarly (uniformly) distributed along the wave number axis. Since for $N \gg 1$ the exact values of $k_{n}$ are not important, the Born-Carman boundary conditions and the resulting set (59) of wave numbers are frequently used even for multidimensional systems whose bending into a ring along each axis is hardly physically plausible.

### 5.5. Dissipative, parametric, and nonlinear phenomena

In conclusion, let us discuss more complex effects in oscillatory systems with more than one degree of freedom. Starting from linear systems, energy dissipation may be readily introduced, just as for a single oscillator, by adding terms proportional to $\eta_{j} \dot{q}_{j}$, to the equations of motion such as Eqs. (5), (17), or (24). In arbitrary case, viscosity coefficients $\eta_{j}$ are different for different particles; however, in many uniform systems like that shown in Fig. 4, the coefficients are naturally equal, turning Eq. (24) into

$$
\begin{equation*}
m \ddot{q}_{j}+\eta \dot{q}_{j}-\kappa\left(q_{j+1}-q_{j}\right)+\kappa\left(q_{j}-q_{j-1}\right)=0 . \tag{5.60}
\end{equation*}
$$

In the most important limit of acoustic waves, we may now repeat the arguments that have led to the wave equation (33) to get its generalization

$$
\begin{equation*}
\left(\frac{1}{v^{2}} \frac{\partial^{2}}{\partial t^{2}}+\frac{2 \delta}{v^{2}} \frac{\partial}{\partial t}-\frac{\partial^{2}}{\partial z^{2}}\right) q(z, t)=0, \quad \text { with } \delta \equiv \frac{\eta}{2 m} . \tag{5.61}
\end{equation*}
$$

Such dissipative equation may describe two major particular effects. First, it describes the decay in time of the standing waves in an autonomous wave system (say, of a finite length $L$ ) that have been caused by some initial push, described by non-trivial initial conditions, say, $q(z, 0) \neq 0$. In order to analyze these decaying oscillations, one may look for the solution of Eq. (61) in the form of a sum of standing wave modes (that satisfy the given boundary conditions), each with its own, time-dependent

amplitude $A_{n}(t)$. For example, for rigid boundary conditions $(q=0)$ at $z=0$ and $z=L$, we can use Eq. (55) as a hint to write

$$
\begin{equation*}
q(z, t)=\sum_{n=1}^{N} A_{n}(t) \sin k_{n} z, \tag{5.62}
\end{equation*}
$$

where the set of $q_{n}$ is given by Eq. (57). Plugging this solution into Eq. (61), ${ }^{16}$ we get

$$
\begin{equation*}
\frac{1}{v^{2}} \sum_{n=1}^{N}\left(\ddot{A}_{n}+2 \delta \dot{A}_{n}+\omega_{n}^{2} A_{n}\right) \sin k_{n} z=0, \quad \text { with } k_{n}=\frac{\pi}{L} n . \tag{5.63}
\end{equation*}
$$

Since functions $\sin k_{n} z$ are mutually orthogonal, Eq. (63) may be only satisfied if all $N$ expressions in parentheses are equal to zero. As the result, the amplitude of each mode satisfies an ordinary differential equation absolutely similar to that studied in Sec. 4.1, with a similar solution describing the free oscillation decay with the relaxation constant (4.23). Here the wave character of the system gives nothing new, besides that different modes have different $Q$-factors: $Q_{n}=\omega_{n} / 2 \delta$.

More wave-specific is a different situation when the waves are due to their persisting excitation by some actuator at one of the ends (say, $z=0$ ) of a very long structure. In this case, an initial transient process settles to a wave with a time-independent waveform limited by certain envelope $A(z)$ that decays at $z \rightarrow \infty$. In order to find the envelope, for the simplest case of sinusoidal excitation of frequency $\omega$, one may look for a particular solution to Eq. (61) in a form very different from Eq. (60):

$$
\begin{equation*}
q(z, t)=\operatorname{Re}\left[a(z) e^{-i \omega t}\right] \tag{5.64}
\end{equation*}
$$

generally with complex $a(z)$. Plugging this solution into Eq. (61), we see that this is indeed a valid solution, provided that $q(0, t)=a(0) \exp \{-i \omega t\}$ satisfies the boundary condition (now describing the wave excitation), and $a(z)$ obeys an following ordinary differential equation that describes wave's evolution in space rather than in time: ${ }^{17}$

$$
\begin{equation*}
\left(\frac{d^{2}}{d z^{2}}+k^{2}\right) a=0, \quad \text { with } k^{2} \equiv\left(\frac{\omega}{v}\right)^{2}+2 i \frac{\delta \omega}{v^{2}} . \tag{5.65}
\end{equation*}
$$

The general solution to such differential equation is

$$
\begin{equation*}
a(x)=a_{+} e^{i k z}+a_{-} e^{-i k z} \tag{5.66}
\end{equation*}
$$

with $k$ now having both real and imaginary parts, $k=k^{\prime}+i k^{\prime \prime}$, so that the wave (64) is

$$
\begin{equation*}
q(z, t)=a_{+} e^{i\left(k^{\prime} z-\omega t\right)} e^{-k^{\prime \prime} z}+a_{-} e^{i\left(-k^{\prime} z-\omega t\right)} e^{k^{\prime \prime} z} . \tag{5.67}
\end{equation*}
$$

If our boundary conditions correspond to the wave propagating to the right, we have to keep only the first term of this expression, with positive $k$ ". The first exponent of that term describes the wave propagating from the boundary into the system (at low damping, with velocity virtually equal to $v$ ), while the second exponent describes an exponential decay of the wave's amplitude in space:

[^73]\[

$$
\begin{equation*}
A(z) \equiv|a(z)|=A(0) e^{-\alpha z / 2}, \quad \frac{\alpha}{2} \equiv-k^{\prime \prime} \approx \frac{\delta}{v} \tag{5.68}
\end{equation*}
$$

\]

where the last, approximate relation is valid in the weak damping limit ( $\delta \ll \omega$, i.e. $\delta / v \ll k^{\prime}$ ). Constant $\alpha$ is called the attenuation coefficient, and in more general wave systems may depend on frequency $\omega$. Physically, $2 / \alpha$ is the scale of wave penetration into a dissipative system. ${ }^{18}$ Note that our simple solution (68) is only valid if the system length $L$ is much larger than $2 / \alpha$; otherwise we would need to use the second term in Eq. (67) to describe wave reflection from the second end.

Now let me discuss (because of the lack of time, on a semi-quantitative level only), nonlinear and parametric phenomena in oscillatory systems with more than one degree of freedom. One important new effect here is the mutual phase locking of (two or more) weakly coupled self-excited oscillators with close frequencies: if the eigenfrequencies of the oscillators are sufficiently close, their oscillation frequencies "stick together" to become exactly equal. Though its dynamics of this process is very close to that of the phase locking of a single oscillator by external signal, that was discussed in Sec. 4.4, it is rather counter-intuitive in the view of the results of Sec. 1, and in particular the anticrossing diagram shown in Fig. 2. The analysis of the effect using the rotating-wave approximation (that is highly recommend to the reader) shows that the origin of the difference is oscillator's nonlinearity, which makes oscillation amplitude virtually independent of phase evolution - see Eq. (4.68) and its discussion.

One more new effect is the so-called non-degenerate parametric excitation. It may be illustrated of the example of just two coupled oscillators - see Sec. 1 above. Let us assume that the coupling constant $\kappa$, participating in Eqs. (5), is not constant, but oscillates in time - say with frequency $\omega_{p}$. In this case the forces acting on each oscillator from its counterpart, described by the right-hand parts of Eqs. (5), will be proportional to $\kappa q_{2,1}\left(1+\mu \cos \omega_{p} t\right)$. Assuming that oscillations of $q_{1}$ and $q_{2}$ are close to sinusoidal, with frequencies $\omega_{1,2}$, we see that the force acting on each oscillator will contain the socalled combinational frequencies

$$
\begin{equation*}
\omega_{p} \pm \omega_{2,1} \cdot \tag{5.69}
\end{equation*}
$$

If one of these frequencies in the right-hand part of each equation coincides with its own oscillation frequency, we can expect a substantial parametric interaction between the oscillators (on the top of the constant coupling effects discussed in Sec. 1). According to Eq. (69), this may happen in two cases:

$$
\begin{equation*}
\omega_{p}=\omega_{1} \pm \omega_{2} \tag{5.70}
\end{equation*}
$$

The quantitative analysis (also highly recommended for reader's exercise) shows that in the positive sign case, the parameter modulation indeed leads to energy "pumping" into oscillations. As a result, sufficiently large $\mu$, at sufficiently low damping coefficients $\delta_{1,2}$ and effective detuning

$$
\begin{equation*}
\xi \equiv \omega_{p}-\left(\Omega_{1}+\Omega_{2}\right), \tag{5.71}
\end{equation*}
$$

may lead to the simultaneous excitation of two frequency components $\omega_{1,2}$. These frequencies, while being close to corresponding eigenfrequencies of the system, are related to the pumping frequency $\omega_{p}$ by exact relation (70), but otherwise are arbitrary, e.g., incommensurate (Fig. 9a), thus justifying the term

[^74]non-degenerate parametric excitation. (The parametric excitation of a single oscillator, that was analyzed in Sec. 4.5, is a particular, degenerate case of such excitation, with $\omega_{1}=\omega_{2}=\omega_{p} / 2$.) On the other hand, for the case described by Eq. (70) with the negative sign, parameter modulation always pumps energy from the oscillations, effectively increasing system's damping.

Somewhat counter-intuitively, this difference between two cases (70) may be simpler interpreted using the notions of quantum mechanics. Namely, equality $\omega_{p}=\omega_{1}+\omega_{2}$ enables a decay of an external photon of energy $\hbar \omega_{p}$ into two photons of energies $\hbar \omega_{1}$ and $\hbar \omega_{2}$ going into the oscillatory system. (The complementary relation, $\omega_{1}=\omega_{p}+\omega_{2}$, results in the oscillation photon decay.)
(a)

Fig. 5.9. Spectra of oscillations at (a) the non-degenerate parametric excitation, and (b) fourwave mixing. The arrow directions symbolize the power flows into and out of the system.

Proceeding to nonlinear phenomena, let us note, first of all, that the simple reasoning, that accompanied Eq. (4.109), is also valid in the case when oscillations consist of two (or more) sinusoidal components with incommensurate frequencies. Replacing notation $2 \omega$ for $\omega_{p}$, we see that nondegenerate parametric excitation of the type (70a) is possible to implement in a system of two coupled oscillators with a quadratic nonlinearity (of the type $\gamma q^{2}$ ), "pumped" by an intensive external signal at frequency $\omega_{p} \approx \Omega_{1}+\Omega_{2}$. In optics, it is often more convenient to have all signals within the same, relatively narrow frequency range. A simple calculation, similar to the one made in Eqs. (4.108)-(4.109), shows that this may be done using the cubic nonlinearity ${ }^{19}$ of the type $\alpha q^{3}$, which allows the similar parametric energy exchange at frequency relation (Fig. 9b)

Four-
wave mixing

$$
\begin{equation*}
2 \omega=\omega_{1}+\omega_{2}, \quad \text { with } \omega \approx \omega_{1} \approx \omega_{2} \tag{5.72a}
\end{equation*}
$$

This process is often called the four-wave mixing (FWM), because it may be interpreted quantum-mechanically as the transformation of two externally-delivered photons, each with energy $\hbar \omega_{p}$, into two other photons of energies $\hbar \omega_{1}$ and $\hbar \omega_{2}$. Word "wave" in this term stems from the fact that at optical frequencies, it is hard to couple a sufficient volume of a nonlinear medium with lumped-type resonators. It is easier to implement the parametric excitation of light (as well as other nonlinear phenomena like the higher harmonic generation) in distributed systems of a linear size much larger than the involved wavelengths. In such systems, the energy transfer from the incoming wave of frequency $\omega$ to generated waves of frequencies $\omega_{1}$ and $\omega_{2}$ is gradually accumulated at their joint propagation along the system. From the analogy between Eq. (65) (describing the evolution of wave's amplitude in space), and the usual equation of the harmonic oscillator (describing its evolution in time), it is clear that this

[^75]energy transfer accumulation requires not only the frequencies $\omega$, but also wave numbers $k$ be in similar relations. For example, the four-wave mixing requires that not only the frequency balance (72a), but also a similar relation
\[

$$
\begin{equation*}
2 k=k_{1}+k_{2}, \tag{5.72b}
\end{equation*}
$$

\]

to be exactly fulfilled. Since all three frequencies are close, this is easy to arrange if the dispersion relation $\omega(k)$ of the media is not too steep. Unfortunately, due to the lack of time/space, for more discussion of this interesting subject, nonlinear optics, I have to refer the reader to special literature. ${ }^{20}$

Note that even if the frequencies $\omega_{1}$ and $\omega_{2}$ of the parametrically excited oscillations are incommensurate, the oscillations are highly correlated. Indeed, the quantum mechanical theory of this effect ${ }^{21}$ shows that the generated photons are entangled. This fact makes the parametric excitation very popular for a broad class of experiments in several currently active fields including quantum computation and encryption, and Bell inequality / local reality studies. ${ }^{22}$

It may look like a dispersion-free media, with $\omega / k=v=$ const, is the perfect solution for arranging the parametric interaction of waves, because in such media, for example, Eq. (72b) automatically follows from Eq. (72a). However, in such media not only the desirable three parametrically interacting waves, but also all their harmonics, have the same velocity. At these conditions, energy transfer rates between all harmonics are of the same order. Perhaps the most important result of such multi-harmonic interaction is that intensive waves, interacting with nonlinear media, may develop sharply non-sinusoidal waveforms, in particular those with an almost instant change of the field at a certain moment. Such shock waves, especially those of mechanical nature, present large interest for certain applications - some not quite innocent, e.g., the explosion of usual and nuclear bombs. I will only briefly return to shock waves in Sec. 8.5. ${ }^{23}$

### 5.6. Exercise problems

5.1. For the system of two elastically coupled pendula, confined to a vertical plane, with the parameters shown in Fig. on the right (cf. Problem 1.3), find possible frequencies of small sinusoidal oscillations and the corresponding distribution coefficients. Sketch the oscillation modes.

5.2. The same task as in Problem 1, for the double pendulum, confined to the vertical plane containing the support point (considered in Problem 2.1), with $m^{\prime}=m$ and $l=l^{\prime}$ - see Fig. on the right.

[^76]5.3.* The same tasks as in Problem 5.1, for the triple pendulum shown in Fig. on the right, with the motion confined to a vertical plane containing the support point.

Hint: You may use any (e.g., numerical) method to calculate the characteristic equation roots.
5.4. ${ }^{*}$

(i) Explore an approximate way to analyze waves in a continuous 1D system with parameters slowly varying along its length. ${ }^{24}$
(ii) Apply this method to calculate eigenfrequencies of transverse standing waves on a freely hanging heavy rope of length $L$, with constant mass per unit length - see Fig. on the right.
(iii) For three lowest standing wave modes, compare the results with those obtained in the solution of Problem 5.3 for the triple pendulum.

5.5. The same tasks as in Problem 1, for a linear, symmetric system of 3 particles, shown in Fig. on the right. Assume that the connections between the particles not only act as usual elastic springs (as described by their potential energies $U=\kappa \widetilde{l}^{2} / 2$ ), but also resist system's bending, giving an additional potential energy $U^{\prime}=\kappa^{\prime} l^{2} \theta^{2} / 2$, where $\theta$ is the (small) bending angle. ${ }^{25}$
5.6. Three similar beads, which may slide along a circle of radius $R$ without friction, are connected with similar springs with elastic constants $\kappa$ and equilibrium lengths $l_{0}$ - see Fig. on the right. Analyze stability of the symmetric stationary state of the system, and calculate the frequencies and modes of its small oscillations about this state.

5.7. An external force $F(t)$ is applied to the right particle of system of shown in Fig. 5.1 of the lecture notes, with $\kappa_{L}=\kappa_{R}=\kappa^{\prime}$ and $m_{1}=m_{2} \equiv m$ (see Fig. on the right), and the response $q_{1}(t)$ of the left particle to this force is being measured.

5.8. Calculate the spatial distributions of the kinetic and potential energies in a standing, sinusoidal, 1D acoustic wave, and analyze its evolution in time.

[^77]5.9. Calculate the dispersion law $\omega(k)$ and the maximum frequency of small longitudinal waves in an infinite line of similar, spring-coupled pendula - see Fig. on the right.

5.10. Calculate and analyze the dispersion relation $\omega(k)$ for longitudinal waves in an infinite 1D chain of coupled oscillators with alternating masses - see Fig. on the right. In particular, find and discuss dispersion relation's period $\Delta k$.

5.11. Calculate the longitudinal wave reflection from a "point inhomogeneity": a single particle with a different mass $m_{0} \neq m$, in an otherwise uniform 1D chain see Fig. on the right. Analyze the result.

5.12.* Use the rotating-wave approximation to analyze the mutual phase locking of two weakly coupled self-oscillators with the dissipative nonlinearity, for the cases of:
(i) direct coordinate coupling, described by Eq. (5.5) of the lecture notes, and
(ii) linear but otherwise arbitrary coupling of two similar oscillators.
5.13.* Extend the second task of the previous problem to the mutual phase locking of $N$ similar oscillators. In particular, explore the in-phase mode's stability for the case of the so-called global coupling via a single force $F$ contributed equally by all oscillators.
5.14.* Find the condition of non-degenerate parametric excitation in a system of two coupled oscillators, described by Eqs. (5) with time-dependent coupling: $\kappa \rightarrow \kappa\left(1+\mu \cos \omega_{p} t\right)$, with $\omega_{p} \approx \Omega_{1}+$ $\Omega_{2}$, and $\Omega_{2}-\Omega_{1} \gg k / m$.

Hint: Assuming the modulation depth $\mu$, static coupling $\kappa$, and detuning $\xi \equiv \omega_{p}-\left(\Omega_{1}+\Omega_{2}\right)$ sufficiently small, use the rotating-wave approximation for each of the coupled oscillators.
5.15. Show that the cubic nonlinearity of the type $\alpha q^{3}$ indeed enables the parametric interaction ("four-wave mixing") of oscillations with incommensurate frequencies related by Eq. (72a).

## Chapter 6. Rigid Body Motion

This chapter discusses the motion of rigid bodies, with a focus on their rotation. Some byproduct results of this analysis will enable us to discuss, in the end of the chapter, the description of motion of point particles in non-inertial reference frames.

### 6.1. Angular velocity vector

Our study of 1D waves in the past chapter has prepared us to for a discussion of 3D systems of particles. We will start it with a (relatively :-) simple limit when the changes of distances $r_{k k^{\prime}} \equiv\left|\mathbf{r}_{\mathrm{k}}-\mathbf{r}_{\mathrm{k}^{\prime}}\right|$ between particles of the system are negligibly small. Such an abstraction is called the (absolutely) rigid body, and is a reasonable approximation in many practical problems, including the motion of solids. In this model we neglect deformations - that will be the subject of the next two chapters.

The rigid body approximation reduces the number of degrees of freedom of the system from 3 N to just 6 - for example, 3 Cartesian coordinates of one point (say, $O$ ), and 3 angles of the system rotation about 3 mutually perpendicular axes passing through this point. (An alternative way to arrive at the same number 6 is to consider 3 points of the body, which uniquely define its position. If movable independently, the points would have 9 degrees of freedom, but since 3 distances $r_{k k}$, between them are now fixed, the resulting 3 constraints reduce the number of degrees of freedom to 6 .)

Let us show that an arbitrary elementary displacement of such a rigid body may be always considered as a sum of a translational motion and a rotation. Consider a "moving" reference frame, firmly bound to the body, and an arbitrary vector $\mathbf{A}$ - see Fig. 1.

Fig. 6.1. Deriving Eq. (8).

The vector may be represented by its Cartesian components $A_{j}$ in that reference frame:

$$
\begin{equation*}
\mathbf{A}=\sum_{j=1}^{3} A_{j} \mathbf{n}_{j} \tag{6.1}
\end{equation*}
$$

Let us calculate its time derivative in an arbitrary, possibly different ("lab") frame, taking into account that if the body rotates relative to this frame, then the directions of the unit vectors $\mathbf{n}_{j}$ change in time. Hence, we have to differentiate both operands in each product contributing to sum (1):

$$
\begin{equation*}
\left.\frac{d \mathbf{A}}{d t}\right|_{\text {in lab }}=\sum_{j=1}^{3} \frac{d A_{j}}{d t} \mathbf{n}_{j}+\sum_{j=1}^{3} A_{j} \frac{d \mathbf{n}_{j}}{d t} . \tag{6.2}
\end{equation*}
$$

In this expression, the first sum evidently describes the change of vector $\mathbf{A}$ as observed from the moving frame. Each of the infinitesimal vectors $d \mathbf{n}_{j}$ participating in the second sum may be presented by its Cartesian components in the moving frame:

$$
\begin{equation*}
d \mathbf{n}_{j}=\sum_{j^{\prime}=1}^{3} d \varphi_{i j} \mathbf{n}_{j^{\prime}} . \tag{6.3}
\end{equation*}
$$

In order to find more about the set of scalar coefficients $d \varphi_{j j}$, let us scalar-multiply each part of this relation by an arbitrary unit vector $\mathbf{n}_{j}$ ", and take into account the evident orthogonality condition:

$$
\begin{equation*}
\mathbf{n}_{j^{\prime}} \cdot \mathbf{n}_{j^{\prime \prime}}=\delta_{j j^{\prime \prime}} \tag{6.4}
\end{equation*}
$$

As a result, we get

$$
\begin{equation*}
d \varphi_{j j^{\prime \prime}}=d \mathbf{n}_{j} \cdot \mathbf{n}_{j^{\prime \prime}} \tag{6.5}
\end{equation*}
$$

Now let us use Eq. (5) to calculate the first differential of Eq. (4):

$$
\begin{equation*}
d \mathbf{n}_{j^{\prime}} \cdot \mathbf{n}_{j^{\prime \prime}}+\mathbf{n}_{j^{\prime}} \cdot d \mathbf{n}_{j^{\prime \prime}}=d \varphi_{j^{\prime \prime}}+d \varphi_{j^{\prime \prime} j^{\prime}}=0 ; \quad \text { in particular, } 2 d \mathbf{n}_{j} \cdot \mathbf{n}_{j}=2 d \varphi_{j j}=0 \tag{6.6}
\end{equation*}
$$

These relations, valid for any choice of indices $j, j$, and $j$ " of the set $\{1,2,3\}$, mean that the matrix of elements $d \varphi_{i j}$ is antisymmetric; in other words, there are not 9 , but just 3 independent coefficients $d \varphi_{j j}$, all with $j \neq j^{\prime}$. Hence it is natural to renumber them in a simpler way: $d \varphi_{j j}{ }^{\prime}=-d \varphi_{j}{ }^{\prime} \equiv d \varphi_{j^{\prime \prime}}$, where indices $j, j$ ', and $j$ " follow in a "correct" order - either $\{1,2,3\}$, or $\{2,3,1\}$, or $\{3,1,2\}$. Now it is easy to check (say, just by a component-by-component comparison) that in this new notation, Eq. (3) may be presented just as a vector product:

$$
\begin{equation*}
d \mathbf{n}_{j}=d \boldsymbol{\varphi} \times \mathbf{n}_{j}, \tag{6.7}
\end{equation*}
$$

Elementary rotation
where $d \varphi$ is the infinitesimal vector defined by its Cartesian components $d \varphi_{j}$ (in the moving frame).
Relation (7) is the basis of all rotation kinematics. Using it, Eq. (2) may be rewritten as

$$
\begin{equation*}
\left.\frac{d \mathbf{A}}{d t}\right|_{\text {in lab }}=\left.\frac{d \mathbf{A}}{d t}\right|_{\text {in mov }}+\sum_{j=1}^{3} A_{j} \frac{d \boldsymbol{\varphi}}{d t} \times \mathbf{n}_{j}=\left.\frac{d \mathbf{A}}{d t}\right|_{\text {in mov }}+\boldsymbol{\omega} \times \mathbf{A}, \quad \text { where } \boldsymbol{\omega} \equiv \frac{d \boldsymbol{\varphi}}{d t} . \tag{6.8}
\end{equation*}
$$

In order to interpret the physical sense of vector $\omega$, let us apply Eq. (8) to the particular case when $\mathbf{A}$ is the radius-vector $\mathbf{r}$ of a point of the body, and the lab frame is selected in a special way: its origin moves with the same velocity as that of the moving frame in the particular instant under consideration. In this case the first term in the right-hand part of Eq. (8) is zero, and we get

$$
\begin{equation*}
\left.\frac{d \mathbf{r}}{d t}\right|_{\text {in special lab frame }}=\boldsymbol{\omega} \times \mathbf{r}, \tag{6.9}
\end{equation*}
$$

were vector $\mathbf{r}$ is the same in both frames. According to the vector product definition, the particle velocity described by this formula has a direction perpendicular to vectors $\omega$ and $\mathbf{r}$ (Fig. 2), and magnitude $\omega r \sin \theta$. As Fig. 2 shows, this expression may be rewritten as $\omega \rho$, where $\rho=r \sin \theta$ is the distance from the line that is parallel to vector $\omega$ and passes through point $O$. This is of course just the pure rotation about that line (called the instantaneous axis of rotation), with angular velocity $\omega$. Since, according to Eqs. (3) and (8), the angular velocity vector $\omega$ is defined by the time evolution of the moving frame alone, it is the same for all points $\mathbf{r}$, i.e. for the rigid body as a whole. Note that nothing in
our calculations forbids not only the magnitude but also the direction of vector $\omega$, and thus of the instantaneous axis of rotation, to change in time (and in many cases it does); hence the name.

Fig. 6.2. Instantaneous axis of rotation.

Now let us generalize our result a step further, considering two laboratory reference frames that do not rotate versus each other: one arbitrary, and another one selected in the special way described above, so that for it Eq. (9) is valid in it. Since their relative motion of these two reference frames is purely translational, we can use the simple velocity addition rule given by Eq. (1.8) to write

$$
\begin{equation*}
\left.\mathbf{v}\right|_{\left.\right|_{\text {in lab }}}=\left.\mathbf{v}_{o}\right|_{\text {in lab }}+\left.\mathbf{v}\right|_{\text {in special lab frame }}=\left.\mathbf{v}_{o}\right|_{\text {in lab }}+\boldsymbol{\omega} \times \mathbf{r}, \tag{6.10}
\end{equation*}
$$

where $\mathbf{r}$ is the radius-vector of a point is measured in the body-bound ("moving") frame $O$.

### 6.2. Inertia tensor

Since the dynamics of each point of a rigid body is strongly constrained by conditions $r_{k k}=$ const, this is one of the most important fields of application of the Lagrangian formalism that was discussed in Chapter 2. The first thing we need to know for using this approach is the kinetic energy of the body in an inertial reference frame. It is just the sum of kinetic energies of all its points, so that we can use Eq. (10) to write: ${ }^{1}$

$$
\begin{equation*}
T=\sum \frac{m}{2} \mathbf{v}^{2}=\sum \frac{m}{2}\left(\mathbf{v}_{O}+\boldsymbol{\omega} \times \mathbf{r}\right)^{2}=\sum \frac{m}{2} v_{O}^{2}+\sum m \mathbf{v}_{O} \cdot(\boldsymbol{\omega} \times \mathbf{r})+\sum \frac{m}{2}(\boldsymbol{\omega} \times \mathbf{r})^{2} . \tag{6.11}
\end{equation*}
$$

Let us apply to the right-hand part of Eq. (11) two general vector analysis formulas, listed in the Math Appendix: the operand rotation rule MA Eq. (7.6) to the second term, and MA Eq. (7.7b) to the third term. The result is

$$
\begin{equation*}
T=\sum \frac{m}{2} v_{O}^{2}+\sum m \mathbf{r} \cdot\left(\mathbf{v}_{O} \times \boldsymbol{\omega}\right)+\sum \frac{m}{2}\left[\omega^{2} r^{2}-(\boldsymbol{\omega} \cdot \mathbf{r})^{2}\right] . \tag{6.12}
\end{equation*}
$$

This expression may be further simplified by making a specific choice of point $O$ (from the radiusvectors $\mathbf{r}$ of all particles are measured), namely if we use for this point the center of mass of the body. As was already mentioned in Sec. 3.4, radius-vector $\mathbf{R}$ of this point is defined as

$$
\begin{equation*}
M \mathbf{R} \equiv \sum m \mathbf{r}, \quad M \equiv \sum m, \tag{6.13}
\end{equation*}
$$

[^78]where $M$ is just the total mass of the body. In the reference frame centered as that point, $\mathbf{R}=0$, so that in that frame the second sum in Eq. (12) vanishes, so that the kinetic energy is a sum of two terms:
\[

$$
\begin{equation*}
T=T_{\text {tran }}+T_{\mathrm{rot}}, \quad T_{\text {tran }} \equiv \frac{M}{2} V^{2}, \quad T_{\mathrm{rot}} \equiv \sum \frac{m}{2}\left[\omega^{2} r^{2}-(\boldsymbol{\omega} \cdot \mathbf{r})^{2}\right], \tag{6.14}
\end{equation*}
$$

\]

where $\mathbf{V} \equiv d \mathbf{R} / d t$ is the center-of-mass velocity in our inertial reference frame, and all particle positions $\mathbf{r}$ have to be measured in the center-of-mass frame. Since the angular velocity vector $\omega$ is common for all points of a rigid body, it is more convenient to rewrite the rotational energy in a form in which the summation over the components of this vector is clearly separated from the summation over the points of the body:

$$
\begin{equation*}
T_{\mathrm{rot}}=\frac{1}{2} \sum_{j, j^{\prime}=1}^{3} I_{i j} \omega_{j} \omega_{j^{\prime}}, \tag{6.15}
\end{equation*}
$$

where the $3 \times 3$ matrix with elements

$$
\begin{equation*}
I_{i j j^{\prime}} \equiv \sum m\left(r^{2} \delta_{j j^{\prime}}-r_{j} r_{j^{\prime}}\right) \tag{6.16}
\end{equation*}
$$

## Inertia

 tensoris called the inertia tensor of the body.
Actually, the term "tensor" for the matrix has to be justified, because in physics this name implies a certain reference-frame-independent notion, so that its elements have to obey certain rules at the transfer between reference frames. In order to show that the inertia tensor deserves its title, let us calculate another key quantity, the total angular momentum $\mathbf{L}$ of the same body. ${ }^{2}$ Summing up the angular momenta of each particle, defined by Eq. (1.31), and using Eq. (10) again, in our inertial reference frame we get

$$
\begin{equation*}
\mathbf{L} \equiv \sum \mathbf{r} \times \mathbf{p}=\sum m \mathbf{r} \times \mathbf{v}=\sum m \mathbf{r} \times\left(\mathbf{v}_{O}+\boldsymbol{\omega} \times \mathbf{r}\right)=\sum m \mathbf{r} \times \mathbf{v}_{O}+\sum m \mathbf{r} \times(\boldsymbol{\omega} \times \mathbf{r}) . \tag{6.17}
\end{equation*}
$$

We see that the momentum may be presented as a sum of two terms. The first one,

$$
\begin{equation*}
\mathbf{L}_{O} \equiv \sum m \mathbf{r} \times \mathbf{v}_{O}=M \mathbf{R} \times \mathbf{v}_{O} \tag{6.18}
\end{equation*}
$$

describes possible rotation of the center of mass about the inertial frame origin. This term evidently vanishes if the moving reference frame's origin $O$ is positioned at the center of mass. In this case we are left with only the second term, which describes the rotation of the body about its center of mass:

$$
\begin{equation*}
\mathbf{L}=\mathbf{L}_{\mathrm{rot}} \equiv \sum m \mathbf{r} \times(\boldsymbol{\omega} \times \mathbf{r}) \tag{6.19}
\end{equation*}
$$

Using one more vector algebra formula, the "bac minis cab" rule, ${ }^{3}$ we may rewrite this expression as

$$
\begin{equation*}
\mathbf{L}=\sum m\left[\omega r^{2}-\mathbf{r}(\mathbf{r} \cdot \boldsymbol{\omega})\right] \tag{6.20}
\end{equation*}
$$

Let us spell out an arbitrary Cartesian component of this vector:

[^79]\[

$$
\begin{equation*}
L_{j}=\sum m\left[\omega_{j} r^{2}-r_{j} \sum_{j^{\prime}=1}^{3} r_{j^{\prime}} \omega_{j^{\prime}}\right]=\sum m \sum_{j^{\prime}=1}^{3} \omega_{j^{\prime}}\left(r^{2} \delta_{j j^{\prime}}-r_{j} r_{j^{\prime}}\right) . \tag{6.21}
\end{equation*}
$$

\]

Changing the order of summations, and comparing the result with Eq. (16), we see that the angular momentum may be conveniently expressed via the same matrix elements $I_{j j}$, as the rotational kinetic energy:

Angular momentum

$$
\begin{equation*}
L_{j}=\sum_{j^{\prime}=1}^{3} I_{i j j^{\prime}} \omega_{j^{\prime}} \tag{6.22}
\end{equation*}
$$

Since $\mathbf{L}$ and $\omega$ are both legitimate vectors (meaning that they describe physical vectors independent on the reference frame choice), their connection, the matrix of elements $I_{j j^{\prime}}$, is a legitimate tensor. This fact, and the symmetry of the tensor $\left(I_{j j^{\prime}}=I_{j^{\prime} j}\right)$, which is evident from its definition (16), allow the tensor to be further simplified. In particular, mathematics tells us that by a certain choice of the axis orientation, any symmetric tensor may be reduced to a diagonal form

$$
\begin{equation*}
I_{i j j^{\prime}}=I_{j} \delta_{i j j^{\prime}}, \tag{6.23}
\end{equation*}
$$

where, in our case

Principal moments of inertia

Rotational energy and angular momentum in principal axes

$$
\begin{equation*}
I_{j}=\sum m\left(r^{2}-r_{j}^{2}\right)=\sum m\left(r_{j^{\prime}}^{2}+r_{j^{\prime \prime}}^{2}\right)=\sum m \rho_{j}^{2} \tag{6.24}
\end{equation*}
$$

$\rho_{j}$ being the distance of the particle from the $j$-th axis, i.e. the length of the perpendicular dropped from the point to that axis. The axes of such special coordinate system are called the principal axes, while the diagonal elements $I_{j}$ given by Eq. (24), the principal moments of inertia of the body. In such a special reference frame, Eqs. (15) and (22) are reduced to very simple forms:

$$
\begin{gather*}
T_{\mathrm{rot}}=\sum_{j=1}^{3} \frac{I_{j}}{2} \omega_{j}^{2},  \tag{6.25}\\
L_{j}=I_{j} \omega_{j} . \tag{6.26}
\end{gather*}
$$

Both these results remind the corresponding relations for the translational motion, $T_{\text {tran }}=M V^{2} / 2$ and $\mathbf{P}=$ $M V$, with the angular velocity $\omega$ replacing the "linear" velocity $\mathbf{V}$, and the tensor of inertia playing the role of scalar mass $M$. However, let me emphasize that even in the specially selected coordinate system, with axes pointing in principal directions, the analogy is incomplete, and rotation is generally more complex than translation, because the measures of inertia, $I_{j}$, are generally different for each principal axis.

Let me illustrate this fact on a simple but instructive system of three similar massive particles fixed in the vertices of an equilateral triangle (Fig. 3).

Fig. 6.3. Principal moments of inertia: a simple case study.

Due to symmetry of the configuration, one of the principal axes has to pass through the center of mass $O$, perpendicular to the plane of the triangle. For the corresponding principal moment of inertia, Eq. (24) readily yields $I_{3}=3 m \rho^{2}$. If we want to express the result in terms of the triangle side $a$, we may notice that due to system's symmetry, the angle marked in Fig. 3 equals $\pi / 6$, and from the corresponding right triangle, $a / 2=\rho \cos (\pi / 6) \equiv \rho \sqrt{ } 3 / 2$, giving $\rho=a / \sqrt{ } 3$, so that, finally, $I_{3}=m a^{2}$.

Another way to get the same result is to use the following general axis shift theorem, which may be rather useful - especially for more complex cases. Let us relate the inertia tensor components $I_{j j}$, and $I^{\prime}{ }_{j j}$, , calculated in two reference frames - one in the center of mass $O$, and another one displaced by a certain vector $\mathbf{d}$ (Fig. 4a), so that for an arbitrary point, $\mathbf{r}^{\prime}=\mathbf{r}+\mathbf{d}$. Plugging this relation into Eq. (16), we get

$$
\begin{align*}
I_{j j^{\prime}}^{\prime} & =\sum m\left[(\mathbf{r}+\mathbf{d})^{2} \delta_{i j^{\prime}}-\left(r_{j}+d_{j}\right)\left(r_{j^{\prime}}+d_{j^{\prime}}\right)\right] \\
& =\sum m\left[\left(r^{2}+2 \mathbf{r} \cdot \mathbf{d}+d^{2}\right) \delta_{j j^{\prime}}\left(r_{j} r_{j^{\prime}}+r_{j} d_{j^{\prime}}+r_{j^{\prime}} d_{j}+d_{j} d_{j^{\prime}}\right)\right] . \tag{6.27}
\end{align*}
$$

Since in the center-of-mass frame, all sums $\sum m r_{j}$ equal zero, we may use Eq. (16) to finally obtain

$$
\begin{equation*}
I_{j j^{\prime}}^{\prime}=I_{j j^{\prime}}+M\left(\delta_{j j^{\prime}} d^{2}-d_{j} d_{j^{\prime}}\right) \tag{6.28}
\end{equation*}
$$

Rotation
axis
shift

In particular, this equation shows that if the shift vector $\mathbf{d}$ is perpendicular to one (say, $j$-th) of the principal axes (Fig. 4b), i.e. $d_{j}=0$, then Eq. (28) is reduced to a very simple formula:

$$
\begin{equation*}
I_{j}^{\prime}=I_{j}+M d^{2} \tag{6.29}
\end{equation*}
$$

(a)
(b)

Fig. 6.4. (a) General reference frame shift from the center of mass, and (b) a shift perpendicular to one of the principal axes.

Returning to the system shown in Fig. 3, let us perform such a shift so that the new ("primed") axis passes through the location of one of the particles, still perpendicular to particles' plane. Then the contribution of that particular mass to the primed moment of inertia vanishes, and $I_{3}=2 \mathrm{ma}^{2}$. Now, returning to the center of mass and applying Eq. (29), we get $I_{3}=I_{3}-M \rho^{2}=2 m a^{2}-(3 m)(a / \sqrt{ } 3)^{2}=m a^{2}$, i.e. the same result as above.

The symmetry situation inside the triangle plane is somewhat less evident, so let us start with calculating the moments of inertia for the axes shown vertical and horizontal in Fig. 3. From Eq. (24) we readily get:

$$
\begin{equation*}
I_{1}=2 m h^{2}+m \rho^{2}=m\left[2\left(\frac{a}{2 \sqrt{3}}\right)^{2}+\left(\frac{a}{\sqrt{3}}\right)^{2}\right]=\frac{m a^{2}}{2}, \quad I_{2}=2 m\left(\frac{a}{2}\right)^{2}=\frac{m a^{2}}{2} \tag{6.30}
\end{equation*}
$$

where I have taken into account the fact that the distance $h$ from the center of mass and any side of the triangle is $h=\rho \sin (\pi / 6)=\rho / 2=a / 2 \sqrt{3}$. We see that $I_{1}=I_{2}$, and mathematics tells us that in this case any in-plane axis (passing through the center of mass $O$ ) may be considered as principal, and has the same moment of inertia. A rigid body with this property, $I_{1}=I_{2} \neq I_{3}$, is called the symmetric top. (The last direction is called the main principal axis of the system.)

Despite the name, the situation may be even more symmetric in the so-called spherical tops, i.e. highly symmetric systems whose principal moments of inertia are all equal,

$$
\begin{equation*}
I_{1}=I_{2}=I_{3} \equiv I \tag{6.31}
\end{equation*}
$$

Spherical
top:
definition
and description

Mathematics says that in this case the moment of inertia for rotation about any axis (but still passing through the center of mass) is equal to the same $I$. Hence Eqs. (25) and (26) are further simplified for any direction of vector $\omega$ :

$$
\begin{equation*}
T_{\mathrm{rot}}=\frac{I}{2} \omega^{2}, \quad \mathbf{L}=I \omega \tag{6.32}
\end{equation*}
$$

thus making the analogy of rotation and translation complete. (As will be discussed in the next section, the analogy is also complete if the rotation axis is fixed by external constraints.)

An evident example of a spherical top is a uniform sphere or spherical shell; a less obvious example is a uniform cube - with masses either concentrated in vertices, or uniformly spread over the faces, or uniformly distributed over the volume. Again, in this case any axis passing through the center of mass is principal, and has the same principal moment of inertia. For a sphere, this is natural; for a cube, rather surprising - but may be confirmed by a direct calculation.

### 6.3. Fixed-axis rotation

Now we are well equipped for a discussion of rigid body's rotational dynamics. The general equation of this dynamics is given by Eq. (1.38), which is valid for dynamics of any system of particles - either rigidly connected or not:

$$
\begin{equation*}
\dot{\mathbf{L}}=\boldsymbol{\tau} \tag{6.33}
\end{equation*}
$$

where $\tau$ is the net torque of external forces. Let us start exploring this equation from the simplest case when the axis of rotation, i.e. the direction of vector $\omega$, is fixed by some external constraints. Let us direct axis $z$ along this vector; then $\omega_{x}=\omega_{y}=0$. According to Eq. (22), in this case, the $z$-component of the angular momentum,

$$
\begin{equation*}
L_{z}=I_{z z} \omega_{z}, \tag{6.34}
\end{equation*}
$$

where $I_{z z}$, though not necessarily one of the principal momenta of inertia, still may be calculated using Eq. (24):

$$
\begin{equation*}
I_{z z}=\sum m \rho_{z}^{2}=\sum m\left(x^{2}+y^{2}\right) \tag{6.35}
\end{equation*}
$$

with $\rho_{z}$ being the distance of each particle from the rotation axis z. According to Eq. (15), the rotational kinetic energy in this case is just

$$
\begin{equation*}
T_{\text {rot }}=\frac{I_{z z}}{2} \omega_{z}^{2} . \tag{6.36}
\end{equation*}
$$

Moreover, it is straightforward to use Eqs. (12), (17), and (28) to show that if the rotation axis is fixed, Eqs. (34)-(36) are valid even if the axis does not pass through the center of mass - if only distances $\rho_{z}$ are now measured from that axis. (The proof is left for reader's exercise.)

As a result, we may not care about other components of vector $\mathbf{L},{ }^{4}$ and use just one component of Eq. (33),

$$
\begin{equation*}
\dot{L}_{z}=\tau_{z}, \tag{6.37}
\end{equation*}
$$

because it, when combined with Eq. (34), completely determines the dynamics of rotation:

$$
\begin{equation*}
I_{z z} \dot{\omega}_{z}=\tau_{z}, \text { i.e. } I_{z z} \ddot{\theta}_{z}=\tau_{z}, \tag{6.38}
\end{equation*}
$$

where $\theta_{z}$ is the angle of rotation about the axis, so that $\omega_{z}=\dot{\theta}$. Scalar relations (34), (36) and (38), describing rotation about a fixed axis, are completely similar to the corresponding formulas of 1D motion of a single particle, with $\omega_{z}$ corresponding to the usual ("linear") velocity, the angular momentum component $L_{z}$ - to the linear momentum, and $I_{z}$ - to particle's mass.

The resulting motion about the axis is also frequently similar to that of a single particle. As a simple example, let us consider what is called the physical pendulum (Fig. 5) - a rigid body free to rotate about a fixed horizontal axis $A$ that does not pass through the center of mass $O$, in the uniform gravity field $\mathbf{g}$.

Fig. 6.5. Physical pendulum. The fixed (horizontal) rotation axis $A$ is perpendicular to the plane of drawing.

Let us drop a perpendicular from point $O$ to the rotation axis, and call the corresponding vector $\mathbf{I}$ (Fig. 5). Then the torque (relative to axis $A$ ) of the forces exerted by the axis constraint is zero, and the only contribution to the net torque is due to gravity alone:

$$
\begin{equation*}
\left.\left.\boldsymbol{\tau}\right|_{\text {in } A} \equiv \sum \mathbf{r}\right|_{\text {in } A} \times \mathbf{F}=\sum\left(\mathbf{l}+\left.\mathbf{r}\right|_{\text {in } O}\right) \times m \mathbf{g}=\sum m(\mathbf{l} \times \mathbf{g})+\left.\sum m \mathbf{r}\right|_{\text {in } O} \times \mathbf{g}=M \mathbf{l} \times \mathbf{g} . \tag{6.39}
\end{equation*}
$$

(For the last transition, I have used the facts that point $O$ is the center of mass, and that vectors $\mathbf{I}$ and $\mathbf{g}$ are the same for all particles of the body.) This result shows that the torque is directed along the rotation

[^80]axis, and its (only) component $\tau_{z}$ is equal to $-M g l \sin \theta$, where $\theta$ is the angle between vectors $\mathbf{l}$ and $\mathbf{g}$, i.e. the angular deviation of the pendulum from the position of equilibrium. As a result, Eq. (38) takes the form,
\[

$$
\begin{equation*}
I_{A} \ddot{\theta}=-M g l \sin \theta, \tag{6.40}
\end{equation*}
$$

\]

where, $I_{A}$ is the moment of inertia for rotation about axis $A$ rather about the center of mass. This equation is identical to that of the point-mass (sometimes called "mathematical") pendulum, with the small-oscillation frequency

Physical pendulum's frequency

$$
\begin{equation*}
\Omega=\left(\frac{M g l}{I_{A}}\right)^{1 / 2} \tag{6.41}
\end{equation*}
$$

As a sanity check, in the simplest case when the linear size of the body is much smaller than the suspension length $l$, Eq. (35) yields $I_{A}=M l^{2}$, and Eq. (41) reduces to the well-familiar formula $\Omega=$ $(g / l)^{1 / 2}$ for the mathematical pendulum.

Now let us discuss the situations when a body not only rotates, but also moves as the whole. As we already know from our introductory chapter, the total momentum of the body,

$$
\begin{equation*}
\mathbf{P} \equiv \sum m \mathbf{v}=\sum m \dot{\mathbf{r}}=\frac{d}{d t} \sum m \mathbf{r} \tag{6.42}
\end{equation*}
$$

satisfies the $2^{\text {nd }}$ Newton law in the form (1.30). Using the definition (13) of the center of mass, the momentum may be presented as

$$
\begin{equation*}
\mathbf{P}=M \dot{\mathbf{R}}=M \mathbf{V} \tag{6.43}
\end{equation*}
$$

so Eq. (1.30) may be rewritten as
C.o.m.'s law of motion

$$
\square-2+
$$

where $\mathbf{F}$ is the vector sum of all external forces. This equation shows that the center of mass of the body moves exactly as a point particle of mass $M$, under the effect of the net force $\mathbf{F}$. In many cases this fact makes the translational dynamics of a rigid body absolutely similar to that of a point particle.

The situation becomes more complex if some of the forces contributing to the vector sum $\mathbf{F}$ depend on rotation of the same body, i.e. if its rotational and translational motions are coupled. Analysis of such coupled motion is rather straightforward if the direction of the rotation axis does not change in time, and hence Eqs. (35)-(36) are still valid. Possibly the simplest example is a round cylinder (say, a wheel) rolling on a surface without slippage (Fig. 6).

(b)

Fig. 6.6. Round cylinder rolling over (a) plane surface and (b) concave surface.

The no-slippage condition may be presented as the requirement of zero net velocity of the particular wheel point $A$ that touches the surface - in the reference frame connected to the surface. For the simplest case of plane surface (Fig. 6a), the application of Eq. (10) shows that this requirement gives the following relation between the angular velocity $\omega$ of the wheel and the linear velocity $V$ of its center:

$$
\begin{equation*}
V+r \omega=0 \tag{6.45}
\end{equation*}
$$

Such kinematic relations are essentially holonomic constraints, which reduce the number of degrees of freedom of the system. For example, without condition (45) the wheel on a plane surface has to be considered as a system with two degrees of freedom, so that its total kinetic energy (14) is a function of two independent generalized velocities, say $V$ and $\omega$ :

$$
\begin{equation*}
T=T_{\text {tran }}+T_{\mathrm{rot}}=\frac{M}{2} V^{2}+\frac{I}{2} \omega^{2} \tag{6.46}
\end{equation*}
$$

Using Eq. (45) we may eliminate, for example, the linear velocity and reduce Eq. (46) to

$$
\begin{equation*}
T=\frac{M}{2}(\omega r)^{2}+\frac{I}{2} \omega^{2}=\frac{I_{\mathrm{ef}}}{2} \omega^{2}, \quad \text { where } \quad I_{\mathrm{ef}} \equiv I+M r^{2} \tag{6.47}
\end{equation*}
$$

This result may be interpreted as the kinetic energy of pure rotation of the wheel about the instantaneous axis $A$, with $I_{\text {ef }}$ being the moment of inertia about that axis, satisfying Eq. (29).

Kinematic relations are not always as simple as Eq. (45). For example, if the wheel is rolling on a concave surface (Fig. 6b), we need relate the angular velocities of the wheel rotation about its axis $O$ (denoted $\omega$ ) and that of its axis' rotation about the center $O^{\prime}$ of curvature of the surface ( $\Omega$ ). A popular error here is to write $\Omega=-(r / R) \omega$ [WRONG!]. A prudent way to get the correct relation is to note that Eq. (45) holds for this situation as well, and on the other hand the same linear velocity of wheel's center may be expressed as $V=(R-r) \Omega$. Combining these equations, we get a (not quite evident) relation

$$
\begin{equation*}
\Omega=-\frac{r}{R-r} \omega \tag{6.48}
\end{equation*}
$$

Another famous example of the relation between the translational and rotational motion is given by the "sliding ladder" problem (Fig. 7). Let us analyze it for the simplest case of negligible friction, and ladder's thickness small in comparison with its length $l$.

Fig. 6.7. Sliding ladder problem.

In order to use the Lagrangian formalism, we may write the kinetic energy of the ladder as the sum (14) of the translational and rotational parts:

$$
\begin{equation*}
T=\frac{M}{2}\left(\dot{X}^{2}+\dot{Y}^{2}\right)+\frac{I}{2} \dot{\alpha}^{2}, \tag{6.49}
\end{equation*}
$$

where $X$ and $Y$ are the Cartesian coordinates of its center of mass in an inertial reference frame, and $I$ is the moment of inertia for rotation about the $z$-axis passing through the center of mass. (For the uniformly-distributed mass, an elementary integration of Eq. (35) yields $I=M l^{2} / 12$ ). In the reference frame with the center in the corner $O$, both $X$ and $Y$ may be simply expressed via angle $\alpha$ :

$$
\begin{equation*}
X=\frac{l}{2} \cos \alpha, \quad Y=\frac{l}{2} \sin \alpha \tag{6.50}
\end{equation*}
$$

(The easiest way to obtain these relations is to notice that the dashed line in Fig. 7 has slope $\alpha$ and length $l / 2$.) Plugging these expressions into Eq. (49), we get

$$
\begin{equation*}
T=\frac{I_{\mathrm{ef}}}{2} \dot{\alpha}^{2}, \quad I_{\mathrm{ef}} \equiv I+M\left(\frac{l}{2}\right)^{2}=\frac{1}{3} M l^{2} . \tag{6.51}
\end{equation*}
$$

Since the potential energy of the ladder in the gravity field may be also expressed via the same angle,

$$
\begin{equation*}
U=M g Y=M g \frac{l}{2} \sin \alpha \tag{6.52}
\end{equation*}
$$

$\alpha$ may be conveniently used as the (only) generalized coordinate of the system. Even without writing the Lagrangian equation of motion for that coordinate explicitly, we may notice that since the Lagrangian function $(T-U)$ does not depend on time explicitly, and the kinetic energy (51) is a quadratichomogeneous function of the generalized velocity $\dot{\alpha}$, the full mechanical energy,

$$
\begin{equation*}
E \equiv T+U=\frac{I_{\mathrm{ef}}}{2} \dot{\alpha}^{2}+M g \frac{l}{2} \sin \alpha=\frac{M g l}{2}\left(\frac{l \dot{\alpha}^{2}}{3 g}+\sin \alpha\right), \tag{6.53}
\end{equation*}
$$

is conserved and gives us the first integral of motion. Moreover, Eq. (53) shows that the system's energy (and hence dynamics) is identical to that of a physical pendulum with an unstable fixed point $\alpha_{1}=\pi / 2$, stable fixed point at $\alpha_{2}=-\pi / 2$, and frequency

$$
\begin{equation*}
\Omega=\left(\frac{3 g}{2 l}\right)^{1 / 2} \tag{6.54}
\end{equation*}
$$

of small oscillations near the latter point. (Of course, that fixed point cannot be reached in the simple geometry shown in Fig. 7, where ladder's hitting the floor would change its equations of motion).

### 6.4. Free rotation

Now let us proceed to more complex case when the rotation axis is not fixed. A good illustration of the complexity arising is this case comes from the simplest case of a rigid body left alone, i.e. not subjected to external forces and hence its potential energy $U$ is constant. Since in this case, according to Eq. (44), the center of mass moves (as measured from any inertial reference frame) with a constant velocity, we can always use an convenient inertial reference frame with the center at that point. From the point of view of such frame, the body's motion is a pure rotation, and $T_{\text {tran }}=0$. Hence, the system's Lagrangian equals just the rotational energy (15), which is, first, a quadratic-homogeneous function of
components $\omega_{j}$ (that may be taken for generalized velocities), and, second, does not depend on time explicitly. As we know from Chapter 2, in this case the energy is conserved. For the components of vector $\omega$ in the principal axes, this means

$$
\begin{equation*}
T_{\mathrm{rot}}=\sum_{j=1}^{3} \frac{I_{j}}{2} \omega_{j}^{2}=\mathrm{const} . \tag{6.55}
\end{equation*}
$$

Next, as Eq. (33) shows, in the absence of external forces the angular momentum $\mathbf{L}$ of the body is conserved as well. However, though we can certainly use Eq. (26) to present this fact as

$$
\begin{equation*}
\mathbf{L}=\sum_{j=1}^{3} I_{j} \omega_{j} \mathbf{n}_{j}=\text { const } \tag{6.56}
\end{equation*}
$$

Rotational energy's conservation
where $\mathbf{n}_{j}$ are the principal axes of inertia, this does not mean that components $\omega_{j}$ of the angular velocity vector $\omega$ are constant, because the principal axes are fixed relative to the rigid body, and hence may rotate with it.

Before going after these complications, let us briefly mention two conceptually trivial, but practically very important, particular cases. The first is a spherical top $\left(I_{1}=I_{2}=I_{3}=I\right)$. In this case Eqs. (55) and (56) imply that all components of vector $\omega=\mathbf{L} / I$, i.e. both the magnitude and the direction of the angular velocity are conserved, for any initial spin. In other words, the body conserves its rotation speed and axis direction, as measured in an inertial frame.

The most obvious example is a spherical planet. For example, our Mother Earth, rotating about its axis with angular velocity $\omega=2 \pi /(1$ day $) \approx 7.3 \times 10^{-5} \mathrm{~s}^{-1}$, keeps its axis at a nearly constant angle of $23^{\circ} 27^{\prime}$ to the ecliptic pole, i.e. the axis normal to the plane of its motion around the Sun. (In Sec. 6 below, we will discuss some very slow motions of this axis, due to gravity effects.)

Spherical tops are also used in the most accurate gyroscopes, usually with gas or magnetic suspension in vacuum. If done carefully, such systems may have spectacular stability. For example, the gyroscope system of the Gravity Probe B satellite experiment, flown in 2004-2005, was based on quartz spheres - round with precision of about 10 nm and covered by superconducting thin films (which have enabled their magnetic suspension and SQUID monitoring). The whole system was stable enough to measure that the so-called geodetic effect in general relativity (essentially, the space curving by Earth's mass), resulting in the axis precession by just 6.6 arcseconds per year, i.e. with a precession frequency of just $\sim 10^{-11} \mathrm{~s}^{-1}$, agrees with theory with a record $\sim 0.3 \%$ accuracy. ${ }^{5}$

The second simple case is that of the "symmetric top" $\left(I_{1}=I_{2} \neq I_{3}\right)$, with the initial vector $\mathbf{L}$ aligned with the main principal axis. In this case, $\omega=\mathbf{L} / I_{3}=$ const, so that the rotation axis is conserved. ${ }^{6}$ Such tops, typically in the shape of a flywheel (rotor) supported by a "gimbal" system (Fig. 8), are broadly used in more common gyroscopes, core parts of automatic guidance systems, for

[^81]example, in ships, airplanes, missiles, etc. Even if the ship's hull wobbles, the suspended gyroscope sustains its direction relative to Earth (which is sufficiently inertial for these applications). ${ }^{7}$

Fig. 6.8. Typical gyroscope. (Adapted from http://en.wikipedia.org/wiki/Gyroscope.)

However, in the general case with no such special initial alignment, the dynamics of symmetric tops is more complex. In this case, vector $\mathbf{L}$ is still conserved, including its direction, but vector $\omega$ is not. Indeed, let us direct axis $\mathbf{n}_{2}$ perpendicular to the common plane of vectors $\mathbf{L}$ and the instantaneous direction $\mathbf{n}_{3}$ of the main principal axis (in Fig. 9, the plane of drawing); then, in that particular instant, $L_{2}=0$. Now let us recall that in a symmetric top, axis $\mathbf{n}_{2}$ is a principal one. According to Eq. (26) with $j$ $=2$, the corresponding component $\omega_{2}$ has to be equal to $L_{2} / I_{2}$, so it vanishes. This means that vector $\omega$ lies in this plane (the common plane of vectors $\mathbf{L}$ and $\mathbf{n}_{3}$ ) as well - see Fig. 9a.

(b)

Fig. 6.9. Free rotation of a symmetric top: (a) the general configuration of vectors, and (b) calculating the free precession frequency.

Now consider any point of the body, located on axis $\mathbf{n}_{3}$, and hence within plane $\left[\mathbf{n}_{3}, \mathbf{L}\right]$. Since $\omega$ is the instantaneous axis of rotation, according to Eq. (9), the point has instantaneous velocity $\mathbf{v}=\boldsymbol{\omega} \times \mathbf{r}$ directed normally to that plane. Since this is true for each point of the main axis (besides only one, with $\mathbf{r}=0$, i.e. the center of mass, which does not move), this axis as a whole has to move perpendicular to the common plane of vectors $\mathbf{L}, \omega$, and $\mathbf{n}_{3}$. Since such conclusion is valid for any moment of time, it means that vectors $\omega$ and $\mathbf{n}_{3}$ rotate about the space-fixed vector $\mathbf{L}$ together, with some angular velocity $\omega_{\text {pre }}$, at each moment staying in one plane. This effect is usually called the free precession (or "torque-

[^82]free", or "regular") precession, and has to be clearly distinguished it from the completely different effect of the torque-induced precession which will be discussed in the next section.

In order to calculate $\omega_{\text {pre }}$, let us present the instant vector $\omega$ as a sum of not its Cartesian coordinates (as in Fig. 9a), but rather of two non-orthogonal vectors directed along $\mathbf{n}_{3}$ and $\mathbf{L}$ (Fig. 9b):

$$
\begin{equation*}
\boldsymbol{\omega}=\omega_{\mathrm{rot}} \mathbf{n}_{3}+\omega_{\mathrm{pre}} \mathbf{n}_{L}, \quad \mathbf{n}_{L} \equiv \frac{\mathbf{L}}{L} . \tag{6.57}
\end{equation*}
$$

It is clear from Fig. 9 b that $\omega_{\text {rot }}$ has the meaning of the angular velocity of body rotation of the body about its main principal axis, while $\omega_{\text {pre }}$ is the angular velocity of rotation of that axis about the constant direction of vector $\mathbf{L}$, i.e. the frequency of precession. Now the latter frequency may be readily calculated from the comparison of two panels of Fig. 9, by noticing that the same angle $\theta$ between vectors $\mathbf{L}$ and $\mathbf{n}_{3}$ participates in two relations:

$$
\begin{equation*}
\sin \theta=\frac{L_{1}}{L}=\frac{\omega_{1}}{\omega_{\mathrm{pre}}} \tag{6.58}
\end{equation*}
$$

Since axis $\mathbf{n}_{1}$ is principal, we may use Eq. (26) for $j=1$, i.e. $L_{1}=I_{1} \omega_{1}$, to eliminate $\omega_{1}$ from Eq. (58), and get a very simple formula

$$
\begin{equation*}
\omega_{\mathrm{pre}}=\frac{L}{I_{1}} . \tag{6.59}
\end{equation*}
$$

[^83]This result shows that the precession frequency is constant and independent of the alignment of vector $\mathbf{L}$ with the main principal axis $\mathbf{n}_{3}$, while the amplitude of this motion (characterized by angle $\theta$ ) does depend on the alignment, and vanishes if $\mathbf{L}$ is parallel to $\mathbf{n}_{3} .{ }^{8}$ Note also that if all principal moments of inertia are of the same order, $\omega_{\text {pre }}$ is of the same order as the total angular velocity $\omega=|\omega|$ of rotation.

Now, let us briefly discuss the free precession in the general case of an "asymmetric top", i.e. a body with $I_{1} \neq I_{2} \neq I_{3}$. In this case the effect is more complex because here not only the direction but also the magnitude of the instantaneous angular velocity $\omega$ may evolve in time. If we are only interested in the relation between the instantaneous values of $\omega_{j}$ and $L_{j}$, i.e. the "trajectories" of vectors $\omega$ and $\mathbf{L}$ as observed from the reference frame $\left\{\mathbf{n}_{1}, \mathbf{n}_{2}, \mathbf{n}_{3}\right\}$ of the principal axes of the body (rather than an explicit law of their time evolution), they may be found directly from the conservation laws. (Let me emphasize again that vector $\mathbf{L}$, being constant in an inertial frame, generally evolves in the frame rotating with the body.) Indeed, Eq. (55) may be understood as the equation of an ellipsoid in Cartesian coordinates $\left\{\omega_{1}\right.$, $\left.\omega_{2}, \omega_{3}\right\}$, so that for free body, vector $\omega$ has to stay on the surface of that ellipsoid. ${ }^{9}$ On the other hand, since the reference frame rotation preserves the length of any vector, the magnitude (but not direction!) of vector $\mathbf{L}$ is also an integral of motion in the moving frame, and we can write

$$
\begin{equation*}
L^{2} \equiv \sum_{j=1}^{3} L_{j}^{2}=\sum_{j=1}^{3} I_{j}^{2} \omega_{j}^{2}=\text { const } \tag{6.60}
\end{equation*}
$$

[^84]Hence the trajectory of vector $\omega$ follows the closed curve formed by the intersection of two ellipsoids, (55) and (60). It is evident that this trajectory is generally "taco-edge-shaped", i.e. more complex than a plane circle but never very complex either.

The same argument may be repeated for vector $\mathbf{L}$, for whom the first form of Eq. (60) descries a sphere, and Eq. (55), another ellipsoid:

$$
\begin{equation*}
T_{\mathrm{rot}}=\sum_{j=1}^{3} \frac{1}{2 I_{j}} L_{j}^{2}=\text { const } . \tag{6.61}
\end{equation*}
$$

On the other hand, if we are interested in the trajectory of vector $\omega$ in an inertial frame (in which vector $\mathbf{L}$ stays still), we may note that the general relation (15) for the same rotational energy $T_{\text {rot }}$ may also be rewritten as

$$
\begin{equation*}
T_{\mathrm{rot}}=\frac{1}{2} \sum_{j=1}^{3} \omega_{j} \sum_{j^{\prime}=1}^{3} I_{i j^{\prime}} \omega_{j^{\prime}} \tag{6.62}
\end{equation*}
$$

But according to the Eq. (22), the second sum in the right-hand part is nothing more than $L_{j}$, so that

$$
\begin{equation*}
T_{\mathrm{rot}}=\frac{1}{2} \sum_{j=1}^{3} \omega_{j} L_{j}=\frac{1}{2} \boldsymbol{\omega} \cdot \mathbf{L} . \tag{6.63}
\end{equation*}
$$

This equation shows that for a free body ( $T_{\text {rot }}=$ const, $\mathbf{L}=$ const), even is vector $\omega$ changes in time, its end point should stay within a plane perpendicular to angular momentum $\mathbf{L}$. (Earlier, we have seen that for the particular case of the symmetric top - see Fig. 9b, but for an asymmetric top, the trajectory of the end point may not be circular.)

If we are interested not only in the trajectory of vector $\omega$, but also its explicit evolution in time, it may be calculated using the general Eq. (33) presented in principal components $\omega_{j}$. For that, we have to recall that Eq. (33) is only valid in an inertial reference frame, while the frame $\left\{\mathbf{n}_{1}, \mathbf{n}_{2}, \mathbf{n}_{3}\right\}$ may rotate with the body and hence is generally not inertial. We may handle this problem by applying to vector $\mathbf{L}$ the general relation (8):

$$
\begin{equation*}
\left.\frac{d \mathbf{L}}{d t}\right|_{\text {in lab }}=\left.\frac{d \mathbf{L}}{d t}\right|_{\text {in mov }}+\boldsymbol{\omega} \times \mathbf{L} . \tag{6.64}
\end{equation*}
$$

Combining it with Eq. (33), in the moving frame we get

$$
\begin{equation*}
\frac{d \mathbf{L}}{d t}+\boldsymbol{\omega} \times \mathbf{L}=\boldsymbol{\tau} \tag{6.65}
\end{equation*}
$$

where $\tau$ is the external torque. In particular, for the principal-axis components $L_{j}$, related to components $\omega_{j}$ by Eq. (26), Eq. (65) is reduced to a set of three scalar Euler equations

$$
\begin{equation*}
I_{j} \dot{\omega}_{j}+\left(I_{j^{\prime \prime}}-I_{j^{\prime}}\right) \omega_{j^{\prime}} \omega_{j^{\prime \prime}}=\tau_{j} \tag{6.66}
\end{equation*}
$$

where the set of indices $\left\{j, j^{\prime}, j^{\prime \prime}\right\}$ has to follow the usual "right" order-e.g., $\{1,2,3\}$, etc. ${ }^{10}$

[^85]In order to get a feeling how do the Euler equations work, let us return to the case of a free symmetric top ( $\tau_{1}=\tau_{2}=\tau_{3}=0, I_{1}=I_{2} \neq I_{3}$ ). In this case, $I_{1}-I_{2}=0$, so that Eq. (66) with $j=3$ yields $\omega_{3}$ $=$ const, while the equations for $j=1$ and $j=2$ take the simple form

$$
\begin{equation*}
\dot{\omega}_{1}=-\Omega_{\mathrm{pre}} \omega_{2}, \quad \dot{\omega}_{2}=\Omega_{\mathrm{pre}} \omega_{1}, \tag{6.67}
\end{equation*}
$$

where $\Omega_{\text {pre }}$ is a constant determined by the system parameters and initial conditions:

$$
\begin{equation*}
\Omega_{\mathrm{pre}} \equiv \omega_{3} \frac{I_{3}-I_{1}}{I_{1}} \tag{6.68}
\end{equation*}
$$

Obviously, Eqs. (67) have a sinusoidal solution with frequency $\Omega_{\text {pre }}$, and describe uniform rotation of vector $\omega$, with that frequency, about the main axis $\mathbf{n}_{3}$. This is just another presentation of the torque-free precession analyzed above, this time as observed from the rotating body. Evidently, $\Omega_{\text {pre }}$ is substantially different from the frequency $\omega_{\text {pre }}(59)$ of the precession as observed from the lab frame; for example, the former frequency vanishes for the spherical top (with $I_{1}=I_{2}=I_{3}$ ), while the latter frequency tends to the rotation frequency.

Unfortunately, for the rotation of an asymmetric top (i.e., an arbitrary rigid body), when no component $\omega_{j}$ is conserved, the Euler equations (66) are strongly nonlinear even in the absence of the external torque, and a discussion of their solutions would take more time than I can afford. ${ }^{11}$

### 6.5. Torque-induced precession

The dynamics of rotation becomes even more complex in the presence of external forces. Let us consider the most important and counter-intuitive effect of torque-induced precession, for the simplest case of an axially-symmetric body (which is a particular case of the symmetric top, $I_{1}=I_{2} \neq I_{3}$ ) rapidly spinning about his symmetry axis, and supported at some point $A$ of that axis, that does not coincide with the center of mass $O$ - see Fig. 10. Without external forces, such top would retain the direction of its rotation axis that would always coincide with the direction of the angular momentum:

$$
\begin{equation*}
\mathbf{L}=I_{3} \mathbf{\omega}=I_{3} \omega_{\mathrm{rot}} \mathbf{n}_{3} \tag{6.69}
\end{equation*}
$$

(a)

(b)

[^86]The uniform gravity field creates bulk-distributed forces that, as we know from the analysis of the physical pendulum in Sec. 3, are equivalent to a single force $M \mathbf{g}$ applied in the center of mass - in Fig. 10, point $O$. The torque of the force relative to the support point $A$ is

$$
\begin{equation*}
\boldsymbol{\tau}=\left.\mathbf{r}_{O}\right|_{\text {in } A} \times M \mathbf{g}=M / \mathbf{n}_{3} \times \mathbf{g} . \tag{6.70}
\end{equation*}
$$

Hence the general equation (33) of the angular momentum (valid in the inertial "lab" frame, in which point $A$ rests) becomes

Precession: equation

$$
\begin{equation*}
\dot{\mathbf{L}}=M l \mathbf{n}_{3} \times \mathbf{g} . \tag{6.71}
\end{equation*}
$$

Despite the apparent simplicity of this (exact!) equation, its analysis is straightforward only in the limit of relatively high rotation velocity $\omega_{\text {rot }}$ or, alternatively, very small torque. In this limit, we may, in the $0^{\text {th }}$ approximation, still use Eq. (69) for $\mathbf{L}$. Then Eq. (71) shows that vector $\dot{\mathbf{L}}$ is perpendicular to both $\mathbf{n}_{3}$ (and hence $\mathbf{L}$ ) and $\mathbf{g}$, i.e. lies within the horizontal plane, and is perpendicular to the horizontal component $\mathbf{L}_{x y}$ of vector $\mathbf{L}$ - see Fig. 10b. Since the magnitude of this vector is constant, $|\dot{\mathbf{L}}|=m g l \sin \theta$, vector $\mathbf{L}$ (and hence the body's main axis) rotates about the vertical axis with angular velocity

Precession: frequency

$$
\begin{equation*}
\omega_{\mathrm{pre}}=\frac{|\dot{\mathbf{L}}|}{L_{x y}}=\frac{M g l \sin \theta}{L \sin \theta}=\frac{M g l}{L}=\frac{M g l}{I_{3} \omega_{\mathrm{rot}}} . \tag{6.72}
\end{equation*}
$$

Thus, very counter-intuitively, the fast-rotating top "does not want to" follow the external, vertical force and, in addition to fast spinning about the symmetry axis $\mathbf{n}_{3}$, also performs a revolution, called the torque-induced precession, about the vertical axis. Note that, similarly to the free-precession frequency (59), the torque-induced precession frequency (72) does not depend on the initial (and sustained) angle $\theta$. However, the torque-induced precession frequency is inversely (rather than directly) proportional to $\omega$, and is typically much lower. This relative slowness is also required for the validity of our simple theory of this effect. Indeed, in our approximate treatment we have used Eq. (69), i.e. neglected precession's contribution to the angular momentum vector $\mathbf{L}$. This is only possible if the contribution is relatively small, $I \omega_{\text {pre }} \ll I_{3} \omega_{\text {rot }}$, where $I$ is a certain effective moment of inertia for the precession (to be worked out later). Using our result (72), this condition may be rewritten as

$$
\begin{equation*}
\omega_{\mathrm{rot}} \gg\left(\frac{M g l I}{I_{3}^{2}}\right)^{1 / 2} \tag{6.73}
\end{equation*}
$$

For a body of not too extreme proportions, i.e. with all linear dimensions of the order of certain length $l$, all inertia moments are of the order of $M l^{2}$, so that the right-hand part of Eq. (73) is of the order of $(g / l)^{1 / 2}$, i.e. comparable with the eigenfrequency of the same body as the physical pendulum, i.e. at the absence of fast rotation.

In order to develop a qualitative theory that could take us beyond such approximate treatment, the Euler equations (66) may be used, but are not very convenient. A better approach, suggested by the same L. Euler, is to introduce a set of three independent angles between the principal axes $\left\{\mathbf{n}_{1}, \mathbf{n}_{2}, \mathbf{n}_{3}\right\}$ bound to the rigid body, and axes $\left\{\mathbf{n}_{x}, \mathbf{n}_{y}, \mathbf{n}_{z}\right\}$ of an inertial reference frame (Fig. 11), and then express the basic equation (33) of rotation, via these angles. There are several possible options for the definition of
such angles, ${ }^{12}$ Fig. 11 shows the set of Euler angels, most convenient for discussion of fast rotation. As one can see at the figure, the first Euler angle, $\theta$, is the usual polar angle measured from axis $\mathbf{n}_{z}$ to axis $\mathbf{n}_{3}$. The second one is the azimuthal angle $\varphi$, measured from axis $\mathbf{n}_{x}$ to the so-called line of nodes formed by the intersection of planes $\left[\mathbf{n}_{x}, \mathbf{n}_{y}\right]$ and $\left[\mathbf{n}_{1}, \mathbf{n}_{2}\right]$. The last Euler angle, $\psi$, is measured within plane [ $\mathbf{n}_{1}, \mathbf{n}_{2}$ ], from the line of nodes to axis $\mathbf{n}_{1}$. In the simple picture of the force-induced precession of a symmetric top, which was derived above, angle $\theta$ is constant, angle $\psi$ changes very rapidly, with the rotation velocity $\omega_{\text {rot }}$, while angle $\varphi$ grows with the precession frequency $\omega_{\text {pre }}(72)$.
 the Euler angles.

Now we can express the principal-axes components of the instantaneous angular velocity vector, $\omega_{1}, \omega_{2}$, and $\omega_{3}$, as measured in the lab reference frame, in terms of the Euler angles. It may be easily done calculating, from Fig. 11, the contributions to the change of Euler angles to each principal axis, and then adding them up. The result is

$$
\begin{aligned}
& \omega_{1}=\dot{\varphi} \sin \theta \sin \psi+\dot{\theta} \cos \psi, \\
& \omega_{2}=\dot{\varphi} \sin \theta \cos \psi-\dot{\theta} \sin \psi, \\
& \omega_{3}=\dot{\varphi} \cos \theta+\dot{\psi}
\end{aligned}
$$

These formulas allow the expression of the kinetic energy of rotation (25) and the angular momentum components (26) in terms of the generalized coordinates $\theta, \varphi$, and $\psi$, and use then powerful Lagrangian formalism to derive their equations of motion. This is especially simple to do in the case of symmetric tops (with $I_{1}=I_{2}$ ), because plugging Eqs. (74) into Eq. (25) we get an expression,

$$
\begin{equation*}
T_{\mathrm{rot}}=\frac{I_{1}}{2}\left(\dot{\theta}^{2}+\dot{\varphi}^{2} \sin ^{2} \theta\right)+\frac{I_{3}}{2}(\dot{\varphi} \cos \theta+\dot{\psi})^{2}, \tag{6.75}
\end{equation*}
$$

which does not include explicitly either $\varphi$ or $\psi$. (This reflects the fact that for a symmetric top we can always select axis $\mathbf{n}_{1}$ to coincide with the line of nodes, and hence take $\psi=0$ at the considered moment of time. Note that this trick does not mean we can take $\dot{\psi}=0$, because axis $\mathbf{n}_{1}$, as observed from the inertial reference frame, moves!) Now we should not forget that at the torque-induced precession, the center of mass moves as well (see Fig. 10), so that according to Eq. (14), the total kinetic energy of the body is the sum of two terms,

[^87]\[

$$
\begin{equation*}
T=T_{\mathrm{rot}}+T_{\mathrm{tran}}, \quad T_{\mathrm{tran}}=\frac{M}{2} V^{2}=\frac{M}{2} l^{2}\left(\dot{\theta}^{2}+\dot{\varphi}^{2} \sin ^{2} \theta\right), \tag{6.76}
\end{equation*}
$$

\]

while the potential energy is just

$$
\begin{equation*}
U=\text { Mgl } \cos \theta+\text { const } \tag{6.77}
\end{equation*}
$$

Now we could readily write the Lagrangian equations of motion for the Euler angles, but it is better to immediately notice that according to Eqs. (75)-(77), the Lagrangian function, $T-U$, does not depend explicitly on "cyclic" coordinates $\varphi$ and $\psi$, so that the corresponding generalized momenta are conserved:

$$
\begin{gather*}
p_{\varphi} \equiv \frac{\partial T}{\partial \dot{\varphi}}=I_{A} \dot{\varphi} \sin ^{2} \theta+I_{3}(\dot{\varphi} \cos \theta+\dot{\psi}) \cos \theta=\text { const },  \tag{6.78}\\
p_{\psi} \equiv \frac{\partial T}{\partial \dot{\psi}}=I_{3}(\dot{\varphi} \cos \theta+\dot{\psi})=\text { const }, \tag{6.79}
\end{gather*}
$$

where, according to Eq. (29), $I_{A} \equiv I_{1}+M l^{2}$ is just the body's moment of inertia for rotation about a horizontal axis passing through the support point $A$. According to the last of Eqs. (74), $p_{\psi}$ is just $L_{3}$, the angular momentum's component along the rotating axis $\mathbf{n}_{3}$. On the other hand, by its definition $p_{\varphi}$ is $L_{z}$, the same vector L's component along the static axis z. (Actually, we could foresee in advance the conservation of both these components of $\mathbf{L}$, because vector (70) of the external torque is perpendicular to both $\mathbf{n}_{3}$ and $\mathbf{n}_{\mathrm{z}}$.) Using these notions, and solving the simple system of linear equations (78)-(79) for the angle derivatives, we get

$$
\begin{equation*}
\dot{\varphi}=\frac{L_{z}-L_{3} \cos \theta}{I_{A} \sin ^{2} \theta}, \quad \dot{\psi}=\frac{L_{3}}{I_{3}}-\frac{L_{z}-L_{3} \cos \theta}{I_{A} \sin ^{2} \theta} \cos \theta \tag{6.80}
\end{equation*}
$$

One more conserved quantity in this problem is the full mechanical energy ${ }^{13}$

$$
\begin{equation*}
E \equiv T+U=\frac{I_{A}}{2}\left(\dot{\theta}^{2}+\dot{\varphi}^{2} \sin ^{2} \theta\right)+\frac{I_{3}}{2}(\dot{\varphi} \cos \theta+\dot{\psi})^{2}+M g l \cos \theta . \tag{6.81}
\end{equation*}
$$

Plugging Eqs. (80) into Eq. (81), we get a first-order differential equation for angle $\theta$, which may be presented in the following physically transparent form:

$$
\begin{equation*}
\frac{I_{A}}{2} \dot{\theta}^{2}+U_{\mathrm{ef}}(\theta)=E, \quad U_{\mathrm{ef}}(\theta) \equiv \frac{\left(L_{z}-L_{3} \cos \theta\right)^{2}}{2 I_{A} \sin ^{2} \theta}+\frac{L_{3}^{2}}{2 I_{3}}+M g l \cos \theta+\text { const } . \tag{6.82}
\end{equation*}
$$

Thus, similarly to the planetary problems considered in Sec. 3.5 , the symmetric top precession has been reduced (without any approximations!) to a 1 D problem of motion of one of its degrees of freedom, the polar angle $\theta$, in an effective potential $U_{\text {ef }}(\theta)$, which is the sum of the real potential energy $U(77)$ and a contribution from the kinetic energy of motion along two other angles. In the absence of rotation about axes $\mathbf{n}_{z}$ and $\mathbf{n}_{3}$ (i.e., $L_{z}=L_{3}=0$ ), Eq. (82) is reduced to the first integral of the equation (40) of motion of a physical pendulum. If the rotation is present, then (besides the case of special initial

[^88]conditions when $\theta(0)=0$ and $\left.L_{z}=L_{3}\right),{ }^{14}$ the first contribution to $U_{\text {ef }}(\theta)$ diverges at $\theta \rightarrow 0$ and $\pi$, so that the effective potential energy has a minimum at some finite value $\theta_{0}$ of the polar angle $\theta$.

If the initial angle $\theta(0)$ equals this $\theta_{0}$, i.e. if the initial effective energy is equal to its minimum value $U_{\text {eff }}\left(\theta_{0}\right)$, the polar angle remains constant through the motion: $\theta(t)=\theta_{0}$. This corresponds to the pure torque-induced precession whose angular velocity is given by the first of Eqs. (80):

$$
\begin{equation*}
\omega_{\mathrm{pre}} \equiv \dot{\varphi}=\frac{L_{z}-L_{3} \cos \theta_{0}}{I_{A} \sin ^{2} \theta_{0}} . \tag{6.83}
\end{equation*}
$$

The condition for finding $\theta_{0}, d U_{\mathrm{ef}} / d \theta=0$, is a transcendent algebraic equation that cannot be solved analytically for arbitrary parameters. However, in the high spinning speed limit (73), this is possible. Indeed, in this limit the potential energy contribution to $U_{\text {ef }}$ is small, and we may analyze its effect by successive approximations. In the $0^{\text {th }}$ approximation, i.e. at $\mathrm{Mgl}=0$, the minimum of $U_{\text {ef }}$ is evidently achieved at $\cos \theta_{0}=L_{z} / L_{3}$, giving zero precession frequency (83). In the next, $1^{\text {st }}$ approximation, we may require that at $\theta=\theta_{0}$, the derivative of first term in the right-hand part of Eq. (82) for $U_{\text {ef }}$ over $\cos \theta$, equal to $-L_{z}\left(L_{z}-L_{3} \cos \theta\right) / I_{A} \sin ^{2} \theta,{ }^{15}$ is cancelled with that of the gravity-induced term, equal to Mgl . This immediately yields $\omega_{\text {pre }}=\left(L_{z}-L_{3} \cos \theta_{0}\right) / I_{A} \sin ^{2} \theta_{0}=\mathrm{Mgl} / L_{3}$, so that taking $L_{3}=I_{3} \omega_{\text {rot }}$ (as we may in the high spinning speed limit), we recover the simple expression (72).

The second important result that readily follows from Eq. (82) is the exact expression the threshold value of the spinning speed for a vertically rotating top $\left(\theta=0, L_{z}=L_{3}\right)$. Indeed, in the limit $\theta$ $\rightarrow 0$ this expression may be readily simplified:

$$
\begin{equation*}
U_{\mathrm{ef}}(\theta) \approx \mathrm{const}+\left(\frac{L_{3}^{2}}{8 I_{A}}-\frac{M g l}{2}\right) \theta^{2} . \tag{6.84}
\end{equation*}
$$

This formula shows that if $\omega_{3}=L_{3} / I_{3}$ (i.e. the angular velocity that was called $\omega_{\text {rot }}$ in the approximate theory) is higher than the following threshold value,

$$
\begin{equation*}
\omega_{\mathrm{th}} \equiv 2\left(\frac{M g l I_{A}}{I_{3}^{2}}\right)^{1 / 2} \tag{6.85}
\end{equation*}
$$

then the coefficient at $\theta^{2}$ in Eq. (84) is positive, so that $U_{\text {ef }}$ has a stable minimum at $\theta_{0}=0$. On the other hand, if $\omega_{3}$ is decreased below $\omega_{\mathrm{th}}$, the fixed point becomes unstable, so that the top falls down. Note that if we take $I=I_{A}$ in condition (73) of the approximate treatment, it acquires a very simple sense: $\omega_{\text {rot }}$ $\gg \omega_{\mathrm{th}}$.

Finally, Eqs. (82) give a natural description of one more phenomenon. If the initial energy is larger than $U_{\text {ef }}\left(\theta_{0}\right)$, angle $\theta$ oscillates between two classical turning points on both sides of the fixed point $\theta_{0}$. The law and frequency of these oscillations may be found exactly as in Sec. 3.3 - see Eqs. (3.27) and (3.28). At $\omega_{3} \gg \omega_{\mathrm{th}}$, this motion is a fast rotation of the symmetry axis $\mathbf{n}_{3}$ of the body about its average position performing the slow precession. These oscillations are called nutations, but

[^89]physically they are absolutely similar to the free precession that was analyzed in the previous section, and the order of magnitude of their frequency is still given by Eq. (59).

It may be proved that small energy dissipation (not taken into account in our analysis) leads first to a decay of nutations, then to a slower drift of the precession angle $\theta_{0}$ to zero and, finally, to a gradual decay of the spinning speed $\omega_{3}$ until it reaches the threshold (85) and the top falls down.

### 6.6. Non-inertial reference frames

Before moving on to the next chapter, let us use the results of our discussion of rotation kinematics in Sec. 1 to complete the analysis of transfer between two reference frames, started in the introductory Chapter 1 - see Fig. 1.2. Indeed, the differentiation rule described by Eq. (8) and derived for an arbitrary vector $\mathbf{A}$ enables us to relate not only radius-vectors, but also the velocities and accelerations of a particle as measured in two reference frames: the "lab" frame $O$ ' (which will be later assumed inertial) and the "moving" (possibly rotating) frame $O-$ see Fig. 12.

Fig. 6.12. General case of transfer between two reference frames.

As this picture shows, even if frame $O$ rotates relative to the lab frame, the radius-vectors are still related, at any moment of time, by the simple Eq. (1.7). In the notation of Fig. 12 it reads

$$
\begin{equation*}
\left.\mathbf{r}^{\prime}\right|_{\text {in lab }}=\left.\mathbf{r}_{O}\right|_{\text {in lab }}+\left.\mathbf{r}\right|_{\text {in lab }} . \tag{6.86}
\end{equation*}
$$

However, as was discussed in Sec. 1, for velocities the general addition rule is already more complex. In order to find it, let us differentiate Eq. (86) over time:

$$
\begin{equation*}
\left.\frac{d}{d t} \mathbf{r}^{\prime}\right|_{\text {in lab }}=\left.\frac{d}{d t} \mathbf{r}_{O}\right|_{\text {in lab }}+\left.\frac{d}{d t} \mathbf{r}\right|_{\text {in lab }} . \tag{6.87}
\end{equation*}
$$

The left-hand part of this relation is evidently particle's velocity as measured in the lab frame, and the first term in the right-hand part of Eq. (87) is the velocity of point $O$, as measured in the same frame. The last term is more complex: we need to differentiate vector $\mathbf{r}$ that connects point $O$ with the particle (Fig. 12), considering how its evolution looks from the lab frame. Due to the possible mutual rotation of frames $O$ and $O$ ', that term may not be zero even if the particle does not move relative to frame $O$.

Fortunately, we have already derived the general Eq. (8) to analyze situations exactly like this one. Taking $\mathbf{A}=\mathbf{r}$, we may apply it to the last term of Eq. (87), to get

$$
\begin{equation*}
\left.\mathbf{v}\right|_{\text {in lab }}=\left.\mathbf{v}_{O}\right|_{\text {in lab }}+(\mathbf{v}+\boldsymbol{\omega} \times \mathbf{r}) \tag{6.88}
\end{equation*}
$$

where $\omega$ is the instantaneous angular velocity of an imaginary rigid body connected to the moving reference frame (or we may say, of the frame as such), an $\mathbf{v}$ is $d \mathbf{r} / d t$, as measured in the moving frame $O$, (Here and later in this section, all vectors without indices imply their observation from the moving frame.) Relation (88), on one hand, is a natural generalization of Eq. (10) for $\mathbf{v} \neq 0$; on the other hand, if $\omega=0$, it is reduced to simple Eq. (1.8) for the translational motion of frame $O$.

Now, in order to calculate acceleration, me may just repeat the trick: differentiate Eq. (88) over time, and then use Eq. (8) again, now for vector $\mathbf{A}=\mathbf{v}+\omega \times \mathbf{r}$. The result is

$$
\begin{equation*}
\left.\left.\mathbf{a}\right|_{\text {in lab }} \equiv \mathbf{a}_{o}\right|_{\text {in lab }}+\frac{d}{d t}(\mathbf{v}+\boldsymbol{\omega} \times \mathbf{r})+\boldsymbol{\omega} \times(\mathbf{v}+\boldsymbol{\omega} \times \mathbf{r}) . \tag{6.89}
\end{equation*}
$$

Carrying out the differentiation in the second term, we finally get the goal equation,

$$
\begin{equation*}
\left.\left.\mathbf{a}\right|_{\text {in lab }} \equiv \mathbf{a}_{o}\right|_{\text {in lab }}+\mathbf{a}+\dot{\boldsymbol{\omega}} \times \mathbf{r}+2 \boldsymbol{\omega} \times \mathbf{v}+\boldsymbol{\omega} \times(\boldsymbol{\omega} \times \mathbf{r}), \tag{6.90}
\end{equation*}
$$

where a is particle's acceleration, as measured in the moving frame. Evidently, Eq. (90) is a natural generalization of the simple Eq. (1.9) to the rotating frame case.

Now let the lab frame $O$ ' be inertial; then the $2^{\text {nd }}$ Newton law for a particle of mass $m$ is

$$
\begin{equation*}
\left.m \mathbf{a}\right|_{\text {in lab }}=\mathbf{F}, \tag{6.91}
\end{equation*}
$$

where $\mathbf{F}$ is the vector sum of all forces action on the particle. This is simple and clear; however, in many cases it is much more convenient to work in a non-inertial reference frames. For example, describing most phenomena on Earth's surface, in is rather inconvenient to use a reference frame resting on the Sun (or in the galactic center, etc.). In order to understand what we should pay for the convenience of using the moving frame, we may combine Eqs. (90) and (91) to write

$$
\begin{equation*}
m \mathbf{a}=\mathbf{F}-\left.m \mathbf{a}_{o}\right|_{\text {in lab }}-m \boldsymbol{\omega} \times(\boldsymbol{\omega} \times \mathbf{r})-2 m \boldsymbol{\omega} \times \mathbf{v}-m \dot{\boldsymbol{\omega}} \times \mathbf{r} . \tag{6.92}
\end{equation*}
$$

This result may be interpreted in the following way: if we want to use the $2^{\text {nd }}$ Newton law's analog in a non-inertial reference frame, we have to add, to the real net force $\mathbf{F}$ acting on a particle, four pseudoforce terms, called inertial forces, all proportional to particle's mass. Let us analyze them, while always remembering that these are just mathematical terms, not real forces. (In particular, it would be futile to seek for the $3^{\text {rd }}$ Newton law's counterpart for an inertial force.)

The first term, $-\left.m \mathbf{a}_{0}\right|_{\text {in }}$ lab, is the only one not related to rotation, and is well known from the undergraduate mechanics. (Let me hope the reader remembers all these weight-in-the-moving-elevator problems.) Despite its simplicity, this term has subtle and interesting consequences. As an example, let us consider a planet, such as our Earth, orbiting a star and also rotating about its own axis - see Fig. 13. The bulk-distributed gravity forces, acting on a planet from its star, are not quite uniform, because they obey the $1 / r^{2}$ gravity law (1.16a), and hence are equivalent to a single force applied to a point $A$ slightly offset from the planet's center of mass $O$ toward the star. For a spherically-symmetric planet, points $O$ and $A$ would be exactly aligned with the direction toward the star. However, real planets are not absolutely rigid, so that, due to the centrifugal "force" (to be discussed shortly), their rotation about their own axis makes them slightly elliptic - see Fig. 13. (For our Earth, this equatorial bulge is about 10 km in each direction.) As a result, the net gravity force does create a small torque relative to the center of mass $O$. On the other hand, repeating all the arguments of this section for a body (rather than a point), we may see that, in the reference frame moving with the planet, the inertial "force" $-\mathrm{Ma}_{O}$ (which is of
course equal to the total gravity force and directed from the star) is applied exactly to the center of mass and does not create a torque. As a result, this pair of forces creates a torque $\tau$ perpendicular to both the direction toward the star and the vector connecting points $O$ and $A$. (In Fig. 13, the torque vector is perpendicular to the plane of drawing). If angle $\delta$ between the planet's "polar" axis of rotation and the direction towards the star was fixed, then, as we have seen in the previous section, this torque would induce a slow axis precession about that direction. However, as a result of orbital motion, angle $\delta$ oscillates in time much faster (once a year) between values $(\pi / 2+\varepsilon)$ and $(\pi / 2-\varepsilon)$, where $\varepsilon$ is the axis tilt, i.e. angle between the polar axis (direction of vectors $\mathbf{L}$ and $\omega_{\text {rot }}$ ) and the normal to the ecliptic plane of the planet's orbit. (For the Earth, $\varepsilon \approx 23.4^{\circ}$.) A straightforward averaging over these fast oscillations ${ }^{16}$ shows that the torque leads to the polar axis precession about the axis perpendicular to the ecliptic plane, keeping angle $\varepsilon$ constant. For the Earth, the period, $T_{\text {pre }}=2 \pi / \omega_{\text {pre }}$, of this precession of the equinoxes (or "precession of the equator"), corrected to the substantial effect of Moon's gravity, is close to 26,000 years.

Fig. 6.13. Axial precession of a planet (with the equatorial bulge and the force line offset strongly exaggerated).

Returning to Eq. (92), the direction of the second term of its right-hand part, $\mathbf{F}_{c}=-m \omega \times(\omega \times \mathbf{r})$, called the centrifugal force, is always perpendicular to, and directed out of the instantaneous rotation axis - see Fig. 14.

Indeed, vector $\omega \times \mathbf{r}$ is perpendicular to both $\omega$ and $\mathbf{r}$ (in Fig. 14, normal to the picture plane and directed from the reader) and has magnitude $\omega r \sin \theta=\omega \rho$, where $\rho$ is the distance of the particle from the rotation axis. Hence the outer vector product, with the account of the minus sign, is normal to the rotation axis $\omega$, directed out from the axis, and equal to $\omega^{2} r \sin \theta=\omega^{2} \rho$. The "centrifugal force" is of

[^90]course just the result of the fact that the centripetal acceleration $\omega^{2} \rho$, explicit in the inertial reference frame, disappears in the rotating frame. For a typical location of the Earth ( $\rho \sim R_{\mathrm{E}} \approx 6 \times 10^{6} \mathrm{~m}$ ), with its angular velocity $\omega_{\mathrm{E}} \approx 10^{-4} \mathrm{~s}^{-1}$, the acceleration is rather considerable, of the order of $3 \mathrm{~cm} / \mathrm{s}^{2}$, i.e. $\sim 0.003$ $g$, and is responsible, in particular, for the largest part of the equatorial bulge mentioned above.

As an example of using the centrifugal "force" concept, let us return again to our "testbed" problem on the bead sliding along a rotating ring - see Figs. 1.5 and 2.1. In the non-inertial reference frame attached to the ring, we have to add, to real forces $m \mathbf{g}$ and $\mathbf{N}$ acting on the bead, the horizontal centrifugal "force" ${ }^{17}$ directed out of the rotation axis, with magnitude $m \omega^{2} \rho$. In the notations of Fig. 2.1, its component tangential to the ring equals $m \omega^{2} \rho \cos \theta=m \omega^{2} R \sin \theta \cos \theta$, and hence the Cartesian component of Eq. (92) along this direction is

$$
\begin{equation*}
m a=-m g \sin \theta+m \omega^{2} R \sin \theta \cos \theta . \tag{6.93}
\end{equation*}
$$

With $a=R \ddot{\theta}$, this gives us the equation of motion equivalent to Eq. (2.25), which had been derived in Sec. 2.2 (in the inertial frame) using the Lagrangian formalism.

The third term in the right-hand part of Eq. (92) is the so-called Coriolis force, ${ }^{18}$ which exists only if the particle moves in the rotating reference frame. Its physical sense may be understood by considering a projectile fired horizontally, say from the North Pole. From the point of view of the Earthbased observer, it will a subject of an additional Coriolis force $\mathbf{F}_{\mathrm{C}}=-2 m \omega \times \mathbf{v}$, directed westward, with magnitude $2 m \omega_{E} v$, where $\mathbf{v}$ is the main, southward component of the velocity. This force would cause the westward acceleration $a=2 \omega_{\mathrm{E}} \mathrm{V}$, and the resulting eastward deviation growing with time as $d=a t^{2} / 2$ $=\omega_{\mathrm{E}} v t^{2}-$ see Fig. 15. (This formula is exact only if $d$ is much smaller than the distance $r=v t$ passed by the projectile.) On the other hand, from the point of view of the inertial-frame observer, the projectile trajectory in the horizontal plane is a straight line, but during the flight time $t$, the Earth surface slips eastward from under the trajectory by distance $d=r \varphi=(v t)\left(\omega_{E} t\right)=\omega_{E} v t^{2}$ where $\varphi=\omega_{E} t$ is the azimuthal angle of the Earth rotation during the flight). Thus, both approaches give the same result.

Fig. 6.15. Trajectory of a projectile fired horizontally from the North Pole, from the point of view of an Earth-bound observer looking down. Circles show parallels, straight lines mark meridians.

Hence, the Coriolis "force" is just a fancy (but frequently very convenient) way of description of a purely geometric effect pertinent to rotation, from the point of view of the observer participating in it. This force is responsible, in particular, for the higher right banks of rivers in the Northern hemisphere, regardless of the direction of their flow - see Fig. 16. Despite the smallness of the Coriolis force (for a

[^91]typical velocity of the water in a river, $v \sim 1 \mathrm{~m} / \mathrm{s}$, it is equivalent to acceleration $a_{\mathrm{C}} \sim 10^{-2} \mathrm{~cm} / \mathrm{s}^{2} \sim 10^{-5}$ $g$ ), its multi-century effects may be rather prominent. ${ }^{19}$

Fig. 6.16. Coriolis "forces" due to Earth's rotation, in the Northern hemisphere.

The last, fourth term of Eq. (92), $-m \dot{\boldsymbol{\omega}} \times \mathbf{r}$, exists only when the rotation frequency changes in time, and may be interpreted as a local-position-specific addition to the first term.

Equation (92), derived above from the Newton equation (91), may be alternatively obtained from the Lagrangian approach, which also gives some important insights on energy at rotation. Let us use Eq. (88) to present the kinetic energy of the particle in an inertial frame in terms of $\mathbf{v}$ and $\mathbf{r}$ measured in a rotating frame:

$$
\begin{equation*}
T=\frac{m}{2}\left[\left.\mathbf{v}_{O}\right|_{\text {in lab }}+(\mathbf{v}+\boldsymbol{\omega} \times \mathbf{r})\right]^{2}, \tag{6.94}
\end{equation*}
$$

and use this expression to calculate the Lagrangian function. For the relatively simple case of particle motion in the field of potential forces, measured from a reference frame that performs pure rotation (so that $\mathbf{v}_{\text {O }}^{\text {in lab }}=0$ ) with a constant angular velocity $\omega$, the result is

$$
\begin{equation*}
L \equiv T-U=\frac{m}{2} v^{2}+m \mathbf{v} \cdot(\boldsymbol{\omega} \times \mathbf{r})+\frac{m}{2}(\boldsymbol{\omega} \times \mathbf{r})^{2}-U=\frac{m}{2} v^{2}+m \mathbf{v} \cdot(\boldsymbol{\omega} \times \mathbf{r})-U_{\mathrm{ef}}, \tag{6.95}
\end{equation*}
$$

where the effective potential energy, ${ }^{20}$

$$
\begin{equation*}
U_{\mathrm{ef}} \equiv U-\frac{m}{2}(\boldsymbol{\omega} \times \mathbf{r})^{2}, \tag{6.96}
\end{equation*}
$$

is just the sum of the real potential energy $U$ of the particle and the so-called centrifugal potential energy associated with the centrifugal "inertial force":

[^92]\[

$$
\begin{equation*}
\mathbf{F}_{c} \equiv-m \boldsymbol{\omega} \times(\boldsymbol{\omega} \times \mathbf{r})=-\nabla\left[-\frac{m}{2}(\boldsymbol{\omega} \times \mathbf{r})^{2}\right] . \tag{6.97}
\end{equation*}
$$

\]

Of course, the Lagrangian equations of motion derived from Eq. (95), considering the Cartesian components of $\mathbf{r}$ and $\mathbf{v}$ as generalized coordinates and velocities, coincide with Eq. (92) (with $\mathbf{a}_{\circ} \mathrm{lin}_{\mathrm{in}}=$ $\dot{\boldsymbol{\omega}}=0$, and $\mathbf{F}=-\nabla U$ ), but it is very informative to have a look at a by-product of this derivation, the generalized momentum corresponding to particle's coordinate $\mathbf{r}$ as measured in the rotating reference frame, ${ }^{21}$

$$
\begin{equation*}
\boldsymbol{p} \equiv \frac{\partial L}{\partial \mathbf{v}}=m(\mathbf{v}+\boldsymbol{\omega} \times \mathbf{r}) . \tag{6.98}
\end{equation*}
$$

According to Eq. (88), with $\left.\mathbf{v}_{O}\right|_{\text {in lab }}=0$, the expression in parentheses is just $\left.m \mathbf{v}\right|_{\text {in lab. }}$. However, from the point of view of the moving frame, i.e. not knowing about the physical sense of vector $\boldsymbol{p}=\left.m \mathbf{v}\right|_{\text {in lab }}$, we would have a reason to speak about two different momenta of the same particle, the so-called kinetic momentum $\mathbf{p}=m \mathbf{v}$ and the canonical momentum $\boldsymbol{p}=\mathbf{p}+m \omega \times \mathbf{r} .{ }^{22}$

Now let us calculate the Hamiltonian function $H$ and energy $E$ as functions of the same movingframe variables:

$$
\begin{align*}
H & \equiv \sum_{j=1}^{3} \frac{\partial L}{\partial v_{j}} v_{j}-L=\boldsymbol{p} \cdot \mathbf{v}-L=m \mathbf{v} \cdot(\mathbf{v}+\boldsymbol{\omega} \times \mathbf{r})-\left[\frac{m}{2} v^{2}+m \mathbf{v} \cdot(\boldsymbol{\omega} \times \mathbf{r})-U_{\mathrm{ef}}\right]=\frac{m v^{2}}{2}+U_{\mathrm{ef}},  \tag{6.99}\\
E & \equiv T+U=\frac{m}{2} v^{2}+m \mathbf{v} \cdot(\boldsymbol{\omega} \times \mathbf{r})+\frac{m}{2}(\boldsymbol{\omega} \times \mathbf{r})^{2}+U=\frac{m}{2} v^{2}+U_{\mathrm{ef}}+m \mathbf{v} \cdot(\boldsymbol{\omega} \times \mathbf{r})+m(\boldsymbol{\omega} \times \mathbf{r})^{2} . \tag{6.100}
\end{align*}
$$

These expressions clearly show that $E$ and $H$ are not equal. In hindsight, this is not surprising, because the kinetic energy (94), expressed in the moving-frame variables, includes a term linear in $\mathbf{v}$, and hence is not a quadratic-homogeneous function of this generalized velocity. The difference of these functions may be presented as

$$
\begin{equation*}
E-H=m \mathbf{v} \cdot(\boldsymbol{\omega} \times \mathbf{r})+m(\boldsymbol{\omega} \times \mathbf{r})^{2}=m(\mathbf{v}+\boldsymbol{\omega} \times \mathbf{r}) \cdot(\boldsymbol{\omega} \times \mathbf{r})=\left.m \mathbf{v}\right|_{\text {in lab }} \cdot(\boldsymbol{\omega} \times \mathbf{r}) . \tag{6.101}
\end{equation*}
$$

Now using the operand rotation rule again, we may transform this expression into a even simpler form: ${ }^{23}$

$$
\begin{equation*}
E-H=\boldsymbol{\omega} \cdot\left(\mathbf{r} \times\left. m \mathbf{v}\right|_{\text {in lab }}\right)=\boldsymbol{\omega} \cdot(\mathbf{r} \times \boldsymbol{p})=\left.\boldsymbol{\omega} \cdot \mathbf{L}\right|_{\text {in lab }} \tag{6.102}
\end{equation*}
$$

$E$ and $H$ at rotation

Let us evaluate this difference for our testbed problem - see Fig. 2.1. In this case, vector $\omega$ is aligned with axis $z$, so that of all Cartesian components of vector $\mathbf{L}$, only component $L_{z}$ is important for the scalar product (102). This component evidently equals $I_{z} \omega=m \rho^{2} \omega=m \omega R^{2} \sin ^{2} \theta$, so that

$$
\begin{equation*}
E-H=m \omega^{2} R^{2} \sin ^{2} \theta, \tag{6.103}
\end{equation*}
$$

[^93]i.e. the same result that follows from the direct subtraction of Eqs. (2.40) and (2.41).

The last form of Eq. (99) shows that in the rotating frame, the Hamiltonian function of a particle has a very simple physical sense. It is conserved, and hence may serve as an integral of motion, in many important situations when $\mathbf{L}$, and hence $E$, are not - our testbed problem is again a very good example.

### 6.7. Exercise problems

6.1. Calculate the principal moments of inertia for the following rigid bodies:
(i)

(ii)

(iii)

(iv)

(i) a thin, plane round hoop,
(ii) a flat uniform round disk,
(iii) a thin spherical shell, and
(iv) a uniform solid sphere.

Compare the results assuming that all the bodies have the same radius $R$ and mass $M$.
6.2. Calculate the principal moments of inertia for the following rigid bodies (see Fig. below):

(i) an equilateral triangle made of thin rods with a uniform linear mass density $\mu$,
(ii) a thin plate in the shape of an equilateral triangle, with a uniform areal mass density $\sigma$, and
(iii) a tetrahedral pyramid made of a heavy material with a uniform bulk mass density $\rho$.

Assuming that the total mass of the three bodies is the same, compare the results and give an interpretation of their difference.
6.3. Prove that Eqs. (34)-(36) are valid for rotation about a fixed axis, even if it does not pass through the center of mass, if all distances $\rho_{z}$ are measured from that axis.
6.4. The end of a uniform, thin, heavy rod of length $2 l$ and mass $m$, initially at rest, is hit by a bullet of mass $m^{\prime}$, flying with velocity $v_{0}$, which gets stuck in the stick - see Fig. on the right. Use two different approaches to calculate the velocity of the opposite end of the rod right after the collision.

6.5. A uniform ball is placed on a horizontal plane, while rotating with an angular velocity $\omega_{0}$, but having no initial linear velocity. Calculate the angular velocity after ball's slippage stops, assuming the usual simple approximation of the kinetic friction force: $F_{f}=\mu N$, where $N$ is a pressure between the surfaces, and $\mu$ is a velocity-independent coefficient.
6.6. A body may rotate about fixed horizontal axis $A$ - see Fig. 5. Find the frequency of its small oscillations, in a uniform gravity field, as a function of distance $l$ of the axis from body's center of mass $O$, and analyze the result.
6.7. A thin uniform bar of mass $M$ and length $l$ is hung on a light thread of length $l$ ' (like a "chime" bell - see Fig. on the right). Find:
(i) the equations of motion of the system (within the plane of drawing);
(ii) the eigenfrequencies of small oscillations near the equilibrium;
(iii) the distribution coefficients for each oscillation mode.

Sketch the oscillation modes for the particular case $l=l$ '.

6.8. A solid, uniform, round cylinder of mass $M$ can roll, without slipping, over a concave, round cylindrical surface of a block of mass $M^{\prime}$, in a uniform gravity field - see Fig. on the right. The block can slide without friction on a horizontal surface. Using the Lagrangian formalism,

(i) find the frequency of small oscillations of the system near the equilibrium, and
(ii) sketch the oscillation mode for the particular case $M^{\prime}=M, R^{\prime}=2 R$.
6.9. A uniform solid hemisphere of radius $R$ is placed on a horizontal plane - see Fig. on the right. Find the frequency of its small oscillations within a vertical plane, for two ultimate cases:
(i) there is no friction between the hemisphere and plane surfaces, and
(ii) the static friction is so strong that there is no slippage between
 these surfaces.
6.10. For the "sliding ladder" problem started in Sec. 3 (see Fig. 7), find the critical value $\alpha_{\mathrm{c}}$ of angle $\alpha$ at which the ladder loses contact with the vertical wall, assuming that it starts sliding from the vertical position with a negligible initial velocity.
6.11.* A rigid, straight, uniform rod of length $l$, with the lower end on a pivot, falls in a uniform gravity field - see Fig. on the right. Neglecting friction, calculate the distribution of the bending torque $\tau$ along its length, and analyze the result.

6.12. Six similar, uniform rods of length $l$ and mass $m$ are connected by light joints so that they may rotate, without friction, versus each other, forming a planar polygon. Initially, the polygon was at rest, and had the correct hexagon shape - see Fig. on the right. Suddenly, an external force $\mathbf{F}$ is applied to the middle of one rod, in the direction of hexagon's symmetry center. Calculate the accelerations: of the rod to which the force is applied (a), and of the opposite $\operatorname{rod}\left(a^{\prime}\right)$, immediately after the application of the force.

6.13. A rectangular cuboid (parallelepiped) with sides $a_{1}, a_{2}$, and $a_{3}$, made of a material with constant density $\rho$, is rotated, with a constant angular velocity $\omega$, about one of its space diagonals - see Fig. on the right. Calculate the torque $\tau$ necessary to sustain such rotation.

6.14. One end of a light shaft of length $l$ is firmly attached to the center of a uniform solid disk of radius $R \ll l$ and mass $M$, whole plane is perpendicular to the shaft. Another end of the shaft is attached to a vertical axis (see Fig. on the right) so that the shaft may rotate about the axis without friction. The disk rolls, without slippage, over a horizontal surface, so
 that the whole system rotates about the vertical axis with a constant angular velocity $\omega$. Calculate the (vertical) supporting force exerted on the disk by the surface.
6.15. An air-filled balloon is placed inside a container filled with water that moves in space, in a negligible gravity field. Suddenly, force $\mathbf{F}$ is applied to the container, pointing in a certain direction. What direction would the balloon move relative to the container?
6.16. Calculate the height of solar tides on a large ocean, using the following simplifying assumptions: the tide period ( $1 / 2$ of Earth's day) is much longer than the period of all ocean waves, the Earth (of mass $M_{\mathrm{E}}$ ) is a sphere of radius $R_{\mathrm{E}}$, and its distance $r_{\mathrm{S}}$ from the Sun (of mass $M_{\mathrm{S}}$ ) is constant and much larger than $R_{\mathrm{E}}$.
6.17.* A satellite is on a circular orbit, of radius $R$, around the Earth.
(i) Write the equations of motion of a small body as observed from the satellite, and simplify them for the case when body's motion is limited to a close vicinity of the satellite.
(ii) Use the equations to prove that at negligible external forces (in particular, negligible gravitational attraction to the satellite) the body may be placed on an elliptical trajectory around satellite's center of mass, within its plane of rotation about Earth. Calculate the ellipse's orientation and eccentricity.
6.18.* A non-spherical shape of an artificial satellite may ensure its stable angular orientation relative to Earth's surface, advantageous for many practical goals. Modeling the satellite as a strongly elongated, axially-symmetric body, moving around the Earth on a circular orbit of radius $R$, find its
stable orientation, and analyze possible small oscillations of the satellite's symmetry axis around this equilibrium position.
6.19. A thin coin of radius $r$ is rolled, with velocity $V$, on a horizontal surface without slippage. What should be coin's tilt angle $\theta$ (see Fig. on the right) for it to roll on a circle of radius $R \gg r$ ? Modeling the coin as a very thin, uniform disk, and assuming that angle $\theta$ is small, solve this problem in:

(i) an inertial ("lab") reference frame, and
(ii) the non-inertial reference frame moving with coin's center of mass (but not rotating with it).
6.20. Two planets are on the circular orbit around their common center of mass. Calculate the effective potential energy of a much lighter mass (say, a spaceship) rotating with the same angular velocity, on the line connecting the planets. Sketch the plot of function the radial dependence of $U_{\text {ef }}$ and find out the number of so-called Lagrange points is which the potential energy has local maxima. Calculate their position approximately in the limit when one of the planets is much more massive than the other one.
6.21. A small body is dropped down to the surface of Earth from height $h \ll R_{\mathrm{E}}$, without initial velocity. Calculate the magnitude and direction of its deviation from the vertical, due to the Earth rotation. Estimate the effect's magnitude for a body dropped from the Empire State Building.
6.22. Use Eq. (94) to calculate the generalized momentum and derive the Lagrange equation of motion of a particle, considering $L$ a function of $\mathbf{r}$ and $\mathbf{v}$ as measured in a non-inertial but non-rotating reference frame.

## Chapter 7. Deformations and Elasticity

The objective of this chapter is a brief discussion of small deformations of $3 D$ continuous media, with a focus on elastic properties of solids. The reader will see that deformation of solids is nontrivial even in the absence of motion, so that several key problems of statics will need to be discussed before proceeding to such dynamic phenomena as elastic waves in infinite media and thin rods.

### 7.1. Strain

Rigid bodies discussed in the previous chapter are just a particular case of continuous media. As has already been mentioned, these are systems of particles so close to each other that the system discreteness may be neglected, so that the particle displacement $\mathbf{q}$ may be considered as a continuous function of space and time. The subject of this chapter is small deviations from the rigid-body approximation discussed in Chapter 6, i.e. small deformations. The deformation smallness allows one to consider the displacement vector $\mathbf{q}$ as a function of the initial (pre-deformation) position of the particle $\mathbf{r}$, and time $t$ - just as was done in the Secs. 5.3-5.5 for 1D waves.

The first task of the deformation theory is to exclude from consideration the types of motion considered in Chapter 6, namely the translation and rotation unrelated to deformations. This means, first of all, the variables describing deformations should not depend on the part of displacement $\mathbf{q}$ that does not depend on position $\mathbf{r}$ (i.e. is common for the whole media), because that part corresponds to a translational shift rather than to a deformation (Fig. 1a). Moreover, even certain non-uniform displacements do not contribute to deformation. For example, Eq. (6.7) (with $d \mathbf{r}$ replaced with $d \mathbf{q}$ to comply with our current notation) shows that a small displacement of the type

$$
\begin{equation*}
\left.d \mathbf{q}\right|_{\text {rotation }}=d \varphi \times \mathbf{r} \tag{7.1}
\end{equation*}
$$

where $d \varphi=\omega d t$ is an infinitesimal vector common for the whole continuum, corresponds to its rotation about the direction of that vector, and has nothing to do with the body deformation (Fig. 1b).

Fig. 7.1. Two types of displacement vector distributions that are unrelated to deformation:
(a) translation and (b) rotation.

This is why in order to develop an adequate quantitative characterization of deformation, we should start with finding suitable appropriate functions of the spatial distribution of displacements, $\mathbf{q}(\mathbf{r})$, that exist only due to deformations. One of such measures is the change of distance $d l=|d \mathbf{r}|$ between two close points:

$$
\begin{equation*}
\left.(d l)^{2}\right|_{\text {after deformation }}-\left.(d l)^{2}\right|_{\text {before deformation }}=\sum_{j=1}^{3}\left(d r_{j}+d q_{j}\right)^{2}-\sum_{j=1}^{3}\left(d r_{j}\right)^{2}, \tag{7.2}
\end{equation*}
$$

where $d q_{j}$ is the $j^{\text {th }}$ Cartesian component of the difference $d \mathbf{q}$ between the displacements $\mathbf{q}$ of the two points. If the deformation is small in the sense $|d \mathbf{q}| \ll|d \mathbf{r}|=d l$, we may keep in Eq. (2) only the terms proportional to the first power of the infinitesimal vector $d \mathbf{q}$ :

$$
\begin{equation*}
\left.(d l)^{2}\right|_{\text {after deformation }}-\left.(d l)^{2}\right|_{\text {before deformation }}=\sum_{j=1}^{3}\left[2 d r_{j} d q_{j}+\left(d q_{j}\right)^{2}\right] \approx 2 \sum_{j=1}^{3} d r_{j} d q_{j} \tag{7.3}
\end{equation*}
$$

Since $q_{j}$ is a function of 3 independent scalar arguments $r_{j}$, its differential may be presented as

$$
\begin{equation*}
d q_{j}=\sum_{j^{\prime}=1}^{3} \frac{\partial q_{j}}{\partial r_{j^{\prime}}} d r_{j^{\prime}} \tag{7.4}
\end{equation*}
$$

Coefficients $\partial q_{j} / \partial r_{j}$, may be considered as elements of a tensor ${ }^{1}$ providing a linear relation between vectors dr and dq. Plugging Eq. (4) into Eq. (2), we get

$$
\begin{equation*}
\left.(d l)^{2}\right|_{\text {after deformation }}-(d l)_{\mid \text {before deformation }}^{2}=2 \sum_{j, j^{\prime}=1}^{3} \frac{\partial q_{j}}{\partial r_{j^{\prime}}} d r_{j} d r_{j^{\prime}} . \tag{7.5}
\end{equation*}
$$

A convenience of tensor $\partial q_{j} / \partial r_{j}$, for characterizing deformations is that it automatically excludes the translation displacement (Fig. 1a) that is independent of $r_{j}$. Its drawback is that its particular components are still affected by the rotation of the body (though the sum (5) is not). Indeed, according to the vector product definition, Eq. (1) may be presented in Cartesian coordinates as

$$
\begin{equation*}
\left.d q_{j}\right|_{\text {rotation }}=\left(d \varphi_{j^{\prime}} r_{j^{\prime \prime}}-d \varphi_{j^{\prime \prime}} r_{j^{\prime}}\right) \varepsilon_{i j j^{\prime \prime}} \tag{7.6}
\end{equation*}
$$

where $\varepsilon_{i j j^{\prime} "}$ is the Levi-Civita symbol ${ }^{2}$ equal to (+1) if all indices $j, j^{\prime}$, and $j^{\prime \prime}$ are different and run in a "right" order - $\{1,2,3\}$, etc., and ( -1 ) otherwise, so that for any order of non-equal indices, $\varepsilon_{i j j} j^{\prime \prime}=-\varepsilon_{j i j j}$ ". Differentiating Eq. (6) over a particular Cartesian coordinate of vector $\mathbf{r}$, and taking into account that this partial differentiation $(\partial)$ is independent of (and hence may be swapped with) the differentiation (d) over the rotation angle $\varphi$, we get the amounts,

$$
\begin{equation*}
d\left(\frac{\partial q_{j}}{\partial r_{j^{\prime}}}\right)_{\text {rotation }}=-\varepsilon_{i j j^{\prime \prime}} d \varphi_{j^{\prime \prime}}, d\left(\frac{\partial q_{j^{\prime}}}{\partial r_{j}}\right)_{\text {rotation }}=-\varepsilon_{j j j^{\prime \prime}} d \varphi_{j^{\prime \prime}}=\varepsilon_{j j j^{\prime \prime}} d \varphi_{j "}, \tag{7.7}
\end{equation*}
$$

which may differ from 0 . However, notice that the sum of these two differentials equals zero for any $d \varphi$, which is possible only if

$$
\begin{equation*}
\left(\frac{\partial q_{j^{\prime}}}{\partial r_{j}}+\frac{\partial q_{j}}{\partial r_{j^{\prime}}}\right)_{\text {rotation }}=0, \text { for } j \neq j^{\prime} \tag{7.8}
\end{equation*}
$$

[^94]so that the full sum (5), that includes 3 such partial sums, is not affected by rotation - as we already know. This is why it is convenient to rewrite Eq. (5) in a mathematically equivalent form
\[

$$
\begin{equation*}
\left.(d l)^{2}\right|_{\text {after deformation }}-(d l)_{\mid \text {before deformation }}^{2}=2 \sum_{j, j^{\prime}=1}^{3} s_{j j^{\prime}} d r_{j} d r_{j^{\prime}}, \tag{7.9a}
\end{equation*}
$$

\]

where $s_{j j}$ are the elements of the so-called symmetrized strain tensor defined as

Strain tensor

$$
\begin{equation*}
s_{i j^{\prime}} \equiv \frac{1}{2}\left(\frac{\partial q_{j}}{\partial r_{j^{\prime}}}+\frac{\partial q_{j^{\prime}}}{\partial r_{j}}\right) \tag{7.9b}
\end{equation*}
$$

(Note that this modification does not affect the diagonal elements: $s_{j j}=\partial q_{j} / \partial r_{j}$.). The advantage of symmetrized tensor ( 9 b ) over the initial tensor $\partial q_{j} / \partial r_{j}$, is that according to Eq. (8), at pure rotation all elements of the symmetrized strain tensor vanish.

Now let us discuss the physical meaning of this tensor. At was already mentioned in Sec. 6.2, any symmetric tensor may be diagonalized by an appropriate selection of the reference frame axes. In such principal axes, $s_{j j^{\prime}}=s_{j j} \delta_{j j^{\prime}}$, so that Eq. (4) takes the simple form

$$
\begin{equation*}
d q_{j}=\frac{\partial q_{j}}{\partial r_{j}} d r_{j}=s_{i j} d r_{j} \tag{7.10}
\end{equation*}
$$

We may use this expression to calculate the change of each side of an infinitesimal cuboid (parallelepiped) with sides $d q_{j}$ parallel to the principal axes:

$$
\begin{equation*}
\left.d r_{j}\right|_{\text {after deformation }}-\left.d r_{j}\right|_{\text {before deformation }} \equiv d q_{j}=s_{j j} d r_{j}, \tag{7.11}
\end{equation*}
$$

and of cuboid's volume $d V=d r_{1} d r_{2} d r_{3}$ :

$$
\begin{equation*}
\left.d V\right|_{\text {after deformation }}-\left.d V\right|_{\text {before deformation }}=\prod_{j=1}^{3}\left(d r_{j}+s_{j j} d r_{j}\right)-\prod_{j=1}^{3} d r_{j}=d V\left[\prod_{j=1}^{3}\left(1+s_{j j}\right)-1\right], \tag{7.12}
\end{equation*}
$$

Since all our analysis is only valid in the linear approximation in small $s_{j j}$, Eq. (12) is reduced to

$$
\begin{equation*}
\left.d V\right|_{\text {after deformation }}-\left.d V\right|_{\text {before deformation }} \approx d V \sum_{j=1}^{3} s_{j j} \equiv d V \operatorname{Tr}(\mathrm{~s}), \tag{7.13}
\end{equation*}
$$

where $\operatorname{Tr}(\text { trace })^{3}$ of any matrix (in particular, tensor) is the sum of its diagonal elements; in our case ${ }^{4}$

$$
\begin{equation*}
\operatorname{Tr}(\mathrm{s}) \equiv \sum_{j=1}^{3} s_{j j} \tag{7.14}
\end{equation*}
$$

So, the diagonal components of the tensor characterize medium's compression/extension; then what is the meaning of the off-diagonal components of the tensor? It may be illustrated on the simplest example of a purely shear deformation, shown in Fig. 2 (the geometry is assumed to be uniform along axis $z$ ). In this case, all displacements (assumed small) have just one Cartesian component, in Fig. 2

[^95]along axis $x$ : $\mathbf{q}=\mathbf{n}_{x} \alpha y$ (with $\alpha \ll 1$ ), so that the only nonvanishing component of the initial strain tensor $\partial q_{j} / \partial r_{j}$, is $\partial q_{x} / \partial y=\alpha$, and the symmetrized tensor (9b) is
\[

\mathrm{s}=\left($$
\begin{array}{ccc}
0 & \alpha / 2 & 0  \tag{7.15}\\
\alpha / 2 & 0 & 0 \\
0 & 0 & 0
\end{array}
$$\right)
\]

Evidently, the change (13) of volume vanishes in this case. Thus, off-diagonal elements of tensor s characterize shear deformations.

Fig. 7.2. Example of a pure shear.

To conclude this section, let me note that Eq. (9) is only valid in Cartesian coordinates. For the solution of some important problems, especially those with a spherical or axial symmetry, it is frequently convenient to express six different components of the symmetric strain tensor via three components of the displacement vector $\mathbf{q}$ in either spherical or cylindrical coordinates. A straightforward differentiation, using the definition of such coordinates, ${ }^{5}$ yields, in particular, the following formulas for the diagonal elements of the tensor in the local mutually orthogonal coordinates that are directed along unit vectors - either $\left\{\mathbf{n}_{r}, \mathbf{n}_{\theta}, \mathbf{n}_{\varphi}\right\}$ or $\left\{\mathbf{n}_{\rho}, \mathbf{n}_{\varphi,}, \mathbf{n}_{z}\right\}$ - at the given point:
(i) in the spherical coordinates:

$$
\begin{equation*}
s_{r r}=\frac{\partial q_{r}}{\partial r}, \quad s_{\theta \theta}=\frac{q_{r}}{r}+\frac{1}{r} \frac{\partial q_{\theta}}{\partial \theta}, \quad s_{\varphi \varphi}=\frac{q_{r}}{r}+\frac{q_{\theta}}{r} \frac{\cos \theta}{\sin \theta}+\frac{1}{r \sin \theta} \frac{\partial q_{\varphi}}{\partial \varphi} ; \tag{7.16}
\end{equation*}
$$

(ii) in the cylindrical coordinates:

$$
\begin{equation*}
s_{\rho \rho}=\frac{\partial q_{\rho}}{\partial \rho}, \quad s_{\varphi \varphi}=\frac{q_{\rho}}{\rho}+\frac{1}{\rho} \frac{\partial q_{\varphi}}{\partial \varphi}, \quad s_{z z}=\frac{\partial q_{z}}{\partial z} . \tag{7.17}
\end{equation*}
$$

These expressions, that will be used below for solution of some problems for symmetrical geometries, may be a bit counter-intuitive. Indeed, Eq. (16) shows that even for a purely radial, axiallysymmetric deformation, $\mathbf{q}=\mathbf{n}_{r} q(r)$, diagonal angular components of strain do not vanish: $s_{\theta \theta}=s_{\varphi \varphi}=q / r$. (According to Eq. (17), in cylindrical coordinates, the same effect is exhibited by the only angular component of the tensor.) Note, however, that these relations describe a very simple geometric effect: the change of the lateral distance $r d \gamma \ll r$ between two close points with the same distance $r$ from a central point, at a small change of $r$ that keeps the angle $d \gamma$ between their radius-vectors $\mathbf{r}$ constant.

[^96]
### 7.2. Stress

Now let us discuss the forces that cause deformations. Internal forces acting inside (i.e. between arbitrarily defined parts of) a continuous media may be also characterized by a tensor. This stress tensor, ${ }^{6}$ with elements $\sigma_{j j}$, relates components of the elementary vector $d \mathbf{F}$ of the force acting on an elementary area $d A$ of an (possibly, imaginary) interface between two parts of a continuous media with elementary vector $d \mathbf{A}=\mathbf{n} d A$ normal to the area (Fig. 3):

Stress tensor

$$
\begin{equation*}
d F_{j}=\sum_{j^{\prime}=1}^{3} \sigma_{i j^{\prime}} d A_{j^{\prime}} \tag{7.18}
\end{equation*}
$$

The usual sign convention here is to take the outer normal $d \mathbf{n}$, i.e. to direct $d \mathbf{A}$ out of "our" part of the continuum, i.e. the part on which the calculated force $d \mathbf{F}$ is exerted.

Fig. 7.3. Definition of vectors $d \mathbf{A}$ and $d \mathbf{F}$.

In some cases the stress tensor's structure is very simple. For example, as will be discussed in detail in the next chapter, static or frictionless fluids may only provide a force normal to any surface and usually directed toward "our" part of the body, so that

$$
\begin{equation*}
d \mathbf{F}=-P d \mathbf{A}, \quad \text { i.e. } \sigma_{i j^{\prime}}=-P \delta_{i j^{\prime}}, \tag{7.19}
\end{equation*}
$$

where scalar $P$ (in most cases positive) is called pressure, and generally depends on both the spatial position and time. This type of stress, with $P>0$, is frequently called the hydrostatic compression - even if it takes place in solids.

However, in the general case the stress tensor also has off-diagonal terms, which characterize shear stress. For example, if the shear strain shown in Fig. 2 is caused by a pair of forces $\pm \mathbf{F}$, they create internal forces $F_{x} \mathbf{n}_{x}$, with $F_{x}>0$ if we speak about the force acting upon a part of the sample below the imaginary horizontal interface we are discussing. In order to avoid horizontal acceleration of each horizontal slice of the sample, the forces should not depend on $y$, i.e. $F_{x}=$ const $=F$. Superficially, it may look that this is the only nonvanishing component of the stress tensor is $d F_{x} / d A_{y}=F / A=$ const, so that tensor is asymmetric, in contrast to the strain tensor (15) of the same system. Note, however, that the pair of forces $\pm \mathbf{F}$ creates not only the shear stress, but also a nonvanishing rotating torque $\tau=-F h \mathbf{n}_{z}$ $=-\left(d F_{x} / d A_{y}\right) A h \mathbf{n}_{z}=-\left(d F_{x} / d A_{y}\right) V \mathbf{n}_{z}$, where $V=A h$ is sample's volume. So, if we want to perform a static stress experiment, i.e. avoid sample's rotation, we need to apply some other forces, e.g., a pair of vertical forces creating an equal and opposite torque $\tau^{\prime}=\left(d F_{y} / d A_{x}\right) V \mathbf{n}_{z}$, implying that $d F_{y} / d A_{x}=d F_{x} / d A_{y}$ $=F / A$. As a result, the stress tensor becomes symmetric, and similar in structure to the symmetrized strain tensor (15):

[^97]\[

\sigma=\left($$
\begin{array}{ccc}
0 & F_{0} / A & 0  \tag{7.20}\\
F_{0} / A & 0 & 0 \\
0 & 0 & 0
\end{array}
$$\right)
\]

In many situations, the body may be stressed not only by forces applied to their surfaces, but also by some volume-distributed (bulk) forces $d \mathbf{F}=\mathbf{f} d V$, whose certain effective bulk density $\mathbf{f}$. (The most evident example of such forces is gravity. If its field is uniform as described by Eq. (1.16b), then $\mathbf{f}=\rho \mathbf{g}$, where $\rho$ is the mass density.) Let us derive the key formula describing the correct summation of the surface and bulk forces. For that, consider again an infinitesimal cuboid with sides $d r_{j}$ parallel to the corresponding coordinates axes (Fig. 4) - now not necessarily the principal axes of the stress tensor.

Fig. 7.4. Deriving Eq. (23).

If elements $\sigma_{j j}$, of the tensor do not depend on position, the force $d \mathbf{F}^{\left(j^{\prime}\right)}$ acting on $j$ '-th face of the cuboid is exactly balanced by the equal and opposite force acting on the opposite face, because vectors $d \mathbf{A}^{\left(j^{\prime}\right)}$ of these faces are equal and opposite. However, if $\sigma_{j j}$, is a function of $\mathbf{r}$, then the net force $d\left(d \mathbf{F}^{\left(j^{\prime}\right)}\right)$ does not vanish. Using the expression for to the $j$, th contribution to sum (18), in the first order in $d \mathbf{r}$, the $j^{\text {th }}$ components of this vector is

$$
\begin{equation*}
d\left(d F_{j}^{\left(j^{\prime}\right)}\right)=d\left(\sigma_{i j^{\prime}} d A_{j^{\prime}}\right)=\frac{\partial \sigma_{i j^{\prime}}}{\partial r_{j^{\prime}}} d r_{j^{\prime}} d A_{j^{\prime}}=\frac{\partial \sigma_{i j^{\prime}}}{\partial r_{j^{\prime}}} d V \tag{7.21}
\end{equation*}
$$

where cuboid's volume $d V=d r_{j} \cdot d A_{j^{\prime}}$ does not depend on $j^{\prime}$. The addition these force components for all three pairs of cuboid faces, i.e. the summation of Eqs. (21) for all 3 values of the upper index $j$ ', yields the following relation for the $j^{\text {th }}$ component of the net force exerted on the cuboid:

$$
\begin{equation*}
d\left(d F_{j}\right)=\sum_{j^{\prime}=1}^{3} d\left(d F_{j}^{\left(j^{\prime}\right)}\right)=\sum_{j^{\prime}=1}^{3} \frac{\partial \sigma_{i j^{\prime}}}{\partial r_{j^{\prime}}} d V . \tag{7.22}
\end{equation*}
$$

Since any volume may be broken into such infinitesimal cuboids, Eq. (22) shows that the space-varying stress is equivalent to a volume-distributed force $d \mathbf{F}_{\mathrm{ef}}=\mathbf{f}_{\mathrm{ef}} d V$, whose effective (not real!) bulk density $\mathbf{f}_{\mathrm{ef}}$ has the following Cartesian components

$$
\begin{equation*}
\left(f_{\mathrm{ef}}\right)_{j}=\sum_{j^{\prime}=1}^{3} \frac{\partial \sigma_{i j^{\prime}}}{\partial r_{j^{\prime}}} \tag{7.23}
\end{equation*}
$$

so that in the presence of genuinely bulk forces $d \mathbf{F}=\mathbf{f} d V$, densities $\mathbf{f}_{\text {ef }}$ and $\mathbf{f}$ just add up.
Let us use this addition rule to spell out the $2^{\text {nd }}$ Newton law for a unit volume of a continuous medium:

$$
\begin{equation*}
\rho \frac{\partial^{2} \mathbf{q}}{\partial t^{2}}=\mathbf{f}_{\mathrm{ef}}+\mathbf{f} . \tag{7.24}
\end{equation*}
$$

Using Eq. (23), the $j^{\text {th }}$ Cartesian component of Eq. (24) may be presented as

Medium dynamics equation

$$
\begin{equation*}
\rho \frac{\partial^{2} q_{j}}{\partial t^{2}}=\sum_{j^{\prime}=1}^{3} \frac{\partial \sigma_{i j^{\prime}}}{\partial r_{j^{\prime}}}+f_{j} \tag{7.25}
\end{equation*}
$$

This is the key equation of medium's dynamics, which will be repeatedly used below.
For solution of some problems, it is also convenient to have a general expression for work $\delta W$ of the stress forces at a virtual deformation $\delta \mathbf{q}$ - understood in the same variational sense as the virtual displacement $\delta \mathbf{r}$ in Sec. 2.1. Using the equivalence between the stress forces and the effective bulk forces with density $\mathbf{f}_{\mathrm{ef}}$, for any volume $V$ of the media we may write

$$
\begin{equation*}
\delta W=\int_{V} \mathbf{f}_{\mathrm{ef}} \cdot \delta \mathbf{q} d V=\sum_{j=1}^{3} \int_{V}\left(f_{\mathrm{ef}}\right)_{j} \delta q_{j} d V=\sum_{j, j^{\prime}=1}^{3} \int_{V} \frac{\partial \sigma_{i j^{\prime}}}{\partial r_{j^{\prime}}} \delta q_{j} d^{3} r . \tag{7.28}
\end{equation*}
$$

Let us take this integral by parts for a volume so large that deformations $\delta q_{j}$ on its surface are negligible. Then, swapping the operations of variations and spatial differentiation (just like it was done with the time derivative in Sec. 2.1), we get

$$
\begin{equation*}
\delta W=-\sum_{j, j^{\prime}=1}^{3} \int_{V} \sigma_{i j^{\prime}} \delta \frac{\partial q_{j}}{\partial r_{j^{\prime}}} d^{3} r . \tag{7.29}
\end{equation*}
$$

Assuming that tensor $\sigma_{j j}$, is symmetric, we may rewrite this expression as

$$
\begin{equation*}
\delta W=-\frac{1}{2} \sum_{j, j^{\prime}=1}^{3} \int_{V}\left(\sigma_{i j j^{\prime}} \delta \frac{\partial q_{j}}{\partial r_{j^{\prime}}}+\sigma_{j j^{\prime} j} \delta \frac{\partial q_{j}}{\partial r_{j^{\prime}}}\right) d^{3} r . \tag{7.30}
\end{equation*}
$$

Now, swapping indices $j$ and $j$ ' in the second expression, we finally get

$$
\begin{equation*}
\delta W=-\frac{1}{2} \sum_{j, j^{\prime}=1}^{3} \int_{V} \delta\left(\frac{\partial q_{j}}{\partial r_{j^{\prime}}} \sigma_{j j^{\prime}}+\frac{\partial q_{j^{\prime}}}{\partial r_{j}} \sigma_{j j^{\prime}}\right) d^{3} r=-\sum_{j, j^{\prime}=1}^{3} \int_{V} \sigma_{i j^{\prime}} \delta s_{j j^{\prime}} d^{3} r, \tag{7.31}
\end{equation*}
$$

where $s_{j j}$ are the components of strain tensor ( 9 b ). It is natural to rewrite this important formula as

Work of
stress forces

$$
\begin{equation*}
\delta W=\int_{V} \delta w(\mathbf{r}) d^{3} r, \quad \text { where } \delta w(\mathbf{r}) \equiv-\sum_{j, j^{\prime}=1}^{3} \sigma_{j j^{\prime}} \delta s_{j j^{\prime}} \tag{7.32}
\end{equation*}
$$

and interpret the locally-defined scalar function $\delta w(\mathbf{r})$ as the work of stress forces per unit volume, due to the small variation of the deformation.

### 7.3. Hooke's law

In order to form a complete system of equations describing media dynamics, one needs to complement Eq. (25) with an appropriate material equation describing the relation between the stress tensor $\sigma_{j j}$, and the deformation $\mathbf{q}$ described (in the small deformation limit) by the strain tensor $s_{j j}$. This
relation depends on the medium, and generally may be rather complex. Even leaving alone various anisotropic solids (e.g., crystals) and macroscopically-inhomogeneous materials (like ceramics or sand), strain typically depends not only on the current value of stress (possibly in a nonlinear way), but also on the previous history of stress application. Indeed, if strain exceeds a certain plasticity threshold, atoms (or nanocrystals) may slip to their new positions and never come back even if the strain is reduced. As a result, deformations become irreversible - see Fig. 5.

Fig. 7.5. Typical relation between stress and strain in solids (schematically).

Only below the thresholds of nonlinearity and plasticity (which are typically close to each other), strain is nearly proportional to stress, i.e. obeys the famous Hooke's law. ${ }^{7}$ However, even in this elastic range the law is not quite simple, and even for an isotropic medium is described not by one but by two constants, called elastic moduli. The reason for that is that most elastic materials resist the strain accompanied by the volume change (say, the hydrostatic compression) differently from how they resist the shear deformation. In order to describe this difference, let us first present the symmetrized strain tensor ( 9 b ) in the mathematically equivalent form

$$
\begin{equation*}
s_{i j j^{\prime}}=\left(s_{j j^{\prime}}-\frac{1}{3} \delta_{i j j^{\prime}} \operatorname{Tr}(\mathrm{s})\right)+\left(\frac{1}{3} \delta_{i j^{\prime}} \operatorname{Tr}(\mathrm{s})\right) . \tag{7.33}
\end{equation*}
$$

According to Eq. (13), the traceless tensor in the first parentheses of Eq. (33) does not give any contribution to the volume change, e.g., may be used to characterize purely shear deformation, while the second one describes the hydrostatic compression alone. Hence we may expect that the stress tensor may be presented (again, in the elastic deformation range only!) as

$$
\begin{equation*}
\sigma_{i j^{\prime}}=2 \mu\left(s_{j j^{\prime}}-\frac{1}{3} \operatorname{Tr}(\mathrm{~s}) \delta_{i j^{\prime}}\right)+3 K\left(\frac{1}{3} \operatorname{Tr}(\mathrm{~s}) \delta_{i j j^{\prime}}\right), \tag{7.34}
\end{equation*}
$$

## Hooke's law

where $K$ and $\mu$ are some constants. ${ }^{8}$ Indeed, experiments show that Hooke's law in this form is followed, at small strain, by all isotropic elastic materials. In accordance with the above discussion, constant $\mu$ (in some texts, denoted as $G$ ) is called the shear modulus, while constant $K$ (sometimes called $B$ ), the bulk modulus. Two columns of Table 1 below show the approximate values of these moduli for typical representatives of several major classes of materials. ${ }^{9}$

[^98]To better appreciate these values, let us first discuss the physical meaning of $K$ and $\mu$, using two simple examples of elastic deformation. For that it is convenient first to solve the set of 9 (or rather 6 different) linear equations (34) for $s_{j j}$. This is easy to do, due to the simple structure of these equations: they relate components $\sigma_{j j^{\prime}}$ and $s_{j j^{\prime}}$ with the same indices, besides the involvement of the tensor trace. This slight complication may be readily overcome by noticing that according to Eq. (34),

$$
\begin{equation*}
\operatorname{Tr}(\sigma) \equiv \sum_{j=1}^{3} \sigma_{j j}=3 K \operatorname{Tr}(\mathrm{~s}), \text { i.e. } \operatorname{Tr}(\mathrm{s})=\frac{1}{3 K} \operatorname{Tr}(\sigma) \tag{7.35}
\end{equation*}
$$

Plugging this result into Eq. (34) and solving it for $s_{i j}$, we readily get the reciprocal relation, which may be presented in a similar form:

$$
\begin{equation*}
s_{i j^{\prime}}=\frac{1}{2 \mu}\left(\sigma_{j j^{\prime}}-\frac{1}{3} \operatorname{Tr}(\sigma) \delta_{j j^{\prime}}\right)+\frac{1}{3 K}\left(\frac{1}{3} \operatorname{Tr}(\sigma) \delta_{i j j^{\prime}}\right) . \tag{7.36}
\end{equation*}
$$

Table 7.1. Elastic moduli, density, and sound velocities of a few representative materials (approximate values)

| Material | $K(\mathrm{GPa})$ | $\mu(\mathrm{GPa})$ | $E(\mathrm{GPa})$ | $v$ | $\rho\left(\mathrm{~kg} / \mathrm{m}^{3}\right)$ | $v_{l}(\mathrm{~m} / \mathrm{s})$ | $v_{t}(\mathrm{~m} / \mathrm{s})$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Diamond $^{(\mathrm{a})}$ | 600 | 450 | 1,100 | 0.20 | 3,500 | 1,830 | 1,200 |
| Hardened steel $^{\text {L }}$ | 170 | 75 | 200 | 0.30 | 7,800 | 5,870 | 3,180 |
| Water $^{(\mathrm{b})}$ | 2.1 | 0 | 0 | 0.5 | 1,000 | 1,480 | 0 |
| Air $^{(\mathrm{b})}$ | 0.00010 | 0 | 0 | 0.5 | 1.2 | 332 | 0 |

${ }^{(a)}$ Averages over crystallographic directions ( $\sim 10 \%$ anisotropy).
${ }^{(b)}$ At the so-called ambient conditions $\left(T=20^{\circ} \mathrm{C}, P=1 \mathrm{bar} \equiv 10^{5} \mathrm{~Pa}\right)$.

Now let us apply Hooke's law, in the form of Eqs. (34) or (36), to two simple situations in which the strain and stress tensors may be found without formulating the exact differential equations of the elasticity theory and boundary conditions for them. (That will be the subject of the next section.) The first experiment is the hydrostatic compression when the stress tensor is diagonal, and all its diagonal components are equal - see Eq. (19). ${ }^{10}$ For this case Eq. (36) yields

$$
\begin{equation*}
s_{i j^{\prime}}=-\frac{P}{3 K} \delta_{i j j^{\prime}}, \tag{7.37}
\end{equation*}
$$

which means that regardless of the shear modulus, the strain tensor is also diagonal, with all diagonal components equal. According to Eqs. (11) and (13), this means that all linear dimensions of the body are reduced by a similar fraction, so that its shape is preserved, while the volume is reduced by

[^99]\[

$$
\begin{equation*}
\frac{\Delta V}{V}=\sum_{j=1}^{3} s_{j j}=-\frac{P}{K} \tag{7.38}
\end{equation*}
$$

\]

This equation clearly shows the physical sense of the bulk modulus $K$ as the reciprocal compressibility.
As Table 1 shows, the values of $K$ may be dramatically different for various materials, and that even for such "soft stuff" as water this modulus in actually rather high. For example, even at the bottom of the deepest, $10-\mathrm{km}$ ocean well ( $P \approx 10^{3} \mathrm{bar} \approx 0.1 \mathrm{GPa}$ ), water density increases by just about $5 \%$. As a result, in most human-scale experiments, water may be treated as incompressible - a condition that will be widely used in the next chapter. Many solids are even much less compressible - see the first two rows of Table 1.

The most compressible media are gases. For a gas, certain background pressure $P$ is necessary just for containing it within certain volume $V$, so that Eq. (38) is only valid for small increments of pressure, $\Delta P$ :

$$
\begin{equation*}
\frac{\Delta V}{V}=-\frac{\Delta P}{K} \tag{7.39}
\end{equation*}
$$

Moreover, gas compression also depends on thermodynamic conditions. (For most condensed media, the temperature effects are very small.) For example, at ambient conditions most gases are reasonably well described by the equation of state for the model called the ideal classical gas:

$$
\begin{equation*}
P V=N k_{\mathrm{B}} T, \quad \text { i.e. } P=\frac{N k_{\mathrm{B}} T}{V} . \tag{7.40}
\end{equation*}
$$

where $N$ is the number of molecules in volume $V$, and $k_{\mathrm{B}} \approx 1.38 \times 10^{-23} \mathrm{~J} / \mathrm{K}$ is the Boltzmann constant. ${ }^{11}$ For a small volume change $\Delta V$ at constant temperature, this equation gives

$$
\begin{equation*}
\left.\Delta P\right|_{T=\text { const }}=-\frac{N k_{B} T}{V^{2}} \Delta V=-\frac{P}{V} \Delta V, \quad \text { i.e. }\left.\frac{\Delta V}{V}\right|_{T=\text { const }}=-\frac{\Delta P}{P} . \tag{7.41}
\end{equation*}
$$

Comparing this expression with Eq. (37), we get a remarkably simple result for the isothermal compression of gases,

$$
\begin{equation*}
\left.K\right|_{T=\mathrm{const}}=P, \tag{7.42}
\end{equation*}
$$

which means in particular that the bulk modulus listed in Table 1 is actually valid, at the ambient conditions, for almost any gas. Note, however, that the change of thermodynamic conditions (say, from isothermal to adiabatic ${ }^{12}$ ) may affect gas' compressibility.

Now let us consider the second, rather different, fundamental experiment: a pure shear deformation shown in Fig. 2. Since the traces of matrices (15) and (20), which describe this experiment, are equal to 0 , for their off-diagonal elements Eq. (34) gives simply $\sigma_{j j^{\prime}}=2 \mu s_{j j^{\prime}}$, so that the deformation angle $\alpha$ (see Fig. 2) is just

$$
\begin{equation*}
\alpha=\frac{1}{\mu} \frac{F}{A} . \tag{7.43}
\end{equation*}
$$

[^100]Notice that the angle does not depend on thickness $h$ of the sample, though of course the maximal linear deformation $q_{x}=\alpha h$ is proportional to the thickness. Naturally, as Table 1 shows, for all fluids (liquids and gases) $\mu=0$, because they cannot resist static shear stress.

However, not all experiments, even the apparently simple ones, involve just either $K$ or $\mu$. Let us consider stretching a long elastic rod of a small and uniform cross-section of area $A$ - the so-called tensile stress experiment shown in Fig. 6. ${ }^{13}$

Fig. 7.6. Tensile stress experiment.

Though the deformation of the rod near its clamped ends depends on the exact way forces $\mathbf{F}$ are applied (we will discuss this issue later on), we may expect that over most of its length the tension forces are directed virtually along the rod, $d \mathbf{F}=F_{z} \mathbf{n}_{z}$, and hence, with the coordinate choice shown in Fig. 6, $\sigma_{x j}=$ $\sigma_{y j}=0$ for all $j$, including the diagonal elements $\sigma_{x x}$ and $\sigma_{y y}$. Moreover, due to the open lateral surfaces, on which, evidently, $d F_{x}=d F_{y}=0$, there cannot be an internal stress force of any direction, acting on any elementary internal boundary parallel to these surfaces. This means that $\sigma_{z x}=\sigma_{z y}=0$. So, of all components of the stress tensor only one, $\sigma_{z z}$, is not equal to zero, and for a uniform sample, $\sigma_{z z}=$ const $=F / A$. For this case, Eq. (36) shows that the strain tensor is also diagonal, but with different diagonal elements:

$$
\begin{gather*}
s_{z z}=\left(\frac{1}{9 K}+\frac{1}{3 \mu}\right) \sigma_{z z},  \tag{7.44}\\
s_{x x}=s_{y y}=\left(\frac{1}{9 K}-\frac{1}{6 \mu}\right) \sigma_{z z} . \tag{7.45}
\end{gather*}
$$

Since the tensile stress is most common in engineering (and physical experiment) practice, both combinations of the elastic moduli participating in these two relations have deserved their own names. In particular, the constant in Eq. (44) is usually denoted as $1 / E$ (but in many texts, as $1 / Y$ ), where $E$ is called the Young's modulus:

Young's modulus

$$
\begin{equation*}
\frac{1}{E} \equiv \frac{1}{9 K}+\frac{1}{3 \mu}, \quad \text { i.e. } E \equiv \frac{9 K \mu}{3 K+\mu} \tag{7.46}
\end{equation*}
$$

As Fig. 6 shows, in the tensile stress geometry $s_{z z} \equiv \partial q_{z} / \partial z=\Delta L / L$, so that the Young's modulus scales the linear relation between the relative extension of the rod and the force applied per unit area: ${ }^{14}$

$$
\begin{equation*}
\frac{\Delta L}{L}=\frac{1}{E} \frac{F}{A} . \tag{7.47}
\end{equation*}
$$

[^101]The third column of Table 1 shows the values of this modulus for two well-known solids: diamond (with the highest known value of $E$ of all bulk materials ${ }^{15}$ ) and the steel (physically, a solid solution of $\sim 10 \%$ of carbon in iron) used in construction. Again, for fluids the Young's modulus vanishes - as it follows from Eq. (46) with $\mu=0$.

I am confident that the reader of these notes has been familiar with Eq. (44), in the form of Eq. (47), from his or her undergraduate studies. However, most probably this cannot be said about its counterpart, Eq. (45), which shows that at the tensile stress, rod's cross-section dimension also change. This effect is usually characterized by the following dimensionless Poisson's ratio:

$$
\begin{equation*}
-\frac{s_{x x}}{s_{z z}}=-\frac{s_{y y}}{s_{z z}}=-\left(\frac{1}{9 K}-\frac{1}{6 \mu}\right) /\left(\frac{1}{9 K}+\frac{1}{3 \mu}\right)=\frac{1}{2} \frac{3 K-2 \mu}{3 K+\mu} \equiv v \tag{7.48}
\end{equation*}
$$

According to this formula, for realistic materials with $K>0, \mu \geq 0$, values of $v$ may vary from (1) to $(+1 / 2)$, but for the vast majority of materials, ${ }^{16}$ they are between 0 and $1 / 2-$ see Table 1 . The lower limit is reached in porous materials like cork whose lateral dimensions almost do not change at the tensile stress. Some soft materials like rubber present the opposite case: $v \approx 1 / 2$. Since according to Eqs. (13), (44) and (45), the volume change is

$$
\begin{equation*}
\frac{\Delta V}{V}=s_{x x}+s_{y y}+s_{z z}=\frac{1}{E} \frac{F}{A}(1-2 v) \tag{7.49}
\end{equation*}
$$

such materials virtually do not change their volume at the tensile stress. The ultimate limit of this trend, $\Delta V / V=0$, is provided by fluids and gases, because their Poisson ratio $v$ is exactly equal to $1 / 2$. (This follows from Eq. (48) with $\mu=0$.) However, for most practicable construction materials such as steel (see Table 1) the change (49) of volume is as high as $\sim 40 \%$ of that of the length.

Due to the clear physical sense of coefficients $E$ and $v$, they are frequently used as a pair of independent elastic moduli, instead of $K$ and $\mu$. Solving Eqs. (46) and (48) for $K$ and $\mu$, we get

$$
\begin{equation*}
K=\frac{E}{3(1-2 v)}, \quad \mu=\frac{E}{2(1+v)} . \tag{7.50}
\end{equation*}
$$

Using these formulas, the two (equivalent) formulations of Hooke's law, expressed by Eqs. (34) and (36), may be rewritten as

$$
\begin{align*}
\sigma_{j j^{\prime}} & =\frac{E}{1+v}\left(s_{i j^{\prime}}+\frac{v}{1-2 v} \operatorname{Tr}(\mathrm{~s}) \delta_{i j^{\prime}}\right),  \tag{7.51a}\\
s_{i j^{\prime}} & =\frac{1+\sigma}{E}\left(\sigma_{j j^{\prime}}-\frac{v}{1+v} \operatorname{Tr}(\sigma) \delta_{i j^{\prime}}\right) . \tag{7.51b}
\end{align*}
$$

The linear relation between the strain and stress tensor allows one to calculate the potential energy $U$ of an elastic medium due to its elastic deformation. Indeed, to each infinitesimal part of this

[^102]strain increase, we may apply Eq. (32), with the work $\delta W$ of the surface forces equal to $-\delta U$. Let us slowly increase the deformation from a completely unstrained state (in which we may take $U=0$ ) to a certain strained state, in the absence of bulk forces $\mathbf{f}$, keeping the deformation type, i.e. the relation between the elements of the stress tensor intact. In this case, all elements of tensor $\sigma_{j j}$, are proportional to the same single parameter characterizing the stress (say, the total applied force), and according to Hooke's law, all elements of tensor $s_{j^{\prime} j}$ are proportional to that parameter as well. In this case, integration over the variation yields the final value ${ }^{17}$
\[

$$
\begin{equation*}
U=\int_{V} u(\mathbf{r}) d^{3} r, \quad u(\mathbf{r})=\frac{1}{2} \sum_{j, j^{\prime}=1}^{3} \sigma_{i j^{\prime}} S_{j^{\prime j}} \tag{7.52}
\end{equation*}
$$

\]

Evidently, $u(\mathbf{r})$ may be interpreted as the volume density of the potential energy of the elastic deformation.

### 7.4. Equilibrium

Now we are fully equipped to discuss dynamics of elastic deformations, but let us start with statics. The static (equilibrium) state may be described by requiring the right-hand part of Eq. (25) to vanish. In order to find the elastic deformation, we need to plug $\sigma_{i j}$, from the Hooke's law (51a), and then express elements $s_{j j}$, via the displacement distribution - see Eq. (9). For a uniform material, the result is ${ }^{18}$

$$
\begin{equation*}
\frac{E}{2(1+v)} \sum_{j^{\prime}=1}^{3} \frac{\partial^{2} q_{j}}{\partial r_{j^{\prime}}^{2}}+\frac{E}{2(1+v)(1-2 v)} \sum_{j^{\prime}=1}^{3} \frac{\partial^{2} q_{j^{\prime}}}{\partial r_{j} \partial r_{j^{\prime}}}+f_{j}=0 . \tag{7.53}
\end{equation*}
$$

Taking into account that the first sum in Eq. (53) is just the $j^{\text {th }}$ component of $\nabla^{2} \mathbf{q}$, while the second sum is the $j^{\text {th }}$ component of $\nabla(\nabla \cdot \mathbf{q})$, we see that all three equations (53) for three Cartesian components $(j=$ 1,2 and 3 ) of the deformation vector $\mathbf{q}$, may be conveniently merged into one vector equation

$$
\begin{equation*}
\frac{E}{2(1+v)} \nabla^{2} \mathbf{q}+\frac{E}{2(1+v)(1-2 v)} \nabla(\nabla \cdot \mathbf{q})+\mathbf{f}=0 \tag{7.54}
\end{equation*}
$$

Equation of elastic equilibrium

For some applications, it is more convenient to recast this equation to another form, using vector identity ${ }^{19} \nabla^{2} \mathbf{q}=\nabla(\nabla \cdot \mathbf{q})-\nabla \times(\nabla \times \mathbf{q})$. The result is

$$
\begin{equation*}
\frac{E(1-v)}{(1+v)(1-2 v)} \nabla(\nabla \cdot \mathbf{q})-\frac{E}{2(1+v)} \nabla \times(\nabla \times \mathbf{q})+\mathbf{f}=0 . \tag{7.55}
\end{equation*}
$$

It is interesting that in problems without volume-distributed forces $(\mathbf{f}=0)$, the Young's modulus $E$ cancels! Even more fascinating, in this case the equation may be re-written in a form not involving the Poisson ratio $v$ either. Indeed, acting by operator $\nabla$ on the remaining terms of Eq. (55), we get a surprisingly simple equation

[^103]\[

$$
\begin{equation*}
\nabla^{2}(\nabla \cdot \mathbf{q})=0 . \tag{7.56}
\end{equation*}
$$

\]

A natural question here is how do the elastic moduli affect the deformation distribution if they do not participate in the differential equation describing it. The answer is two-fold. If what is fixed at the body boundary are deformations, then the moduli are irrelevant, because the deformation distribution through the body does not depend on them. On the other hand, if the boundary conditions fix stress (or a combination of stress and strain), then the elastic constants creep into the solution via the recalculation of these conditions into the strain.

As a simple but representative example, let us find the deformation distribution in a (generally, thick) spherical shell under the effect of different pressures fixed inside and outside it (Fig. 7a).

Fig. 7.7. Spherical shell problem: (a) the general case and (b) the thin shell limit.

Due to the spherical symmetry of the problem, the deformation is obviously sphericallysymmetric and radial, $\mathbf{q}=q(r) \mathbf{n}_{r}$, i.e. is completely described by one scalar function $q(r)$. Since the curl of such a radial vector field is zero, ${ }^{20}$ Eq. (55) is reduced to

$$
\begin{equation*}
\nabla(\nabla \cdot \mathbf{q})=0 \tag{7.57}
\end{equation*}
$$

This equation means that the divergence of function $q(r)$ is constant within the shell. In spherical coordinates this means ${ }^{21}$

$$
\begin{equation*}
\frac{1}{r^{2}} \frac{d}{d r}\left(r^{2} q\right)=\text { const. } \tag{7.58}
\end{equation*}
$$

Naming this constant $3 a$ (with the numerical factor chosen for later notation convenience), and integrating Eq. (58), we get its solution,

$$
\begin{equation*}
q(r)=a r+\frac{b}{r^{2}} \tag{7.59}
\end{equation*}
$$

that also includes another integration constant $b$.
To complete the analysis, we have to determine constants $a$ and $b$ from the boundary conditions. According to Eq. (19),

$$
\sigma_{r r}= \begin{cases}-P_{1}, & r=R_{1},  \tag{7.60}\\ -P_{2}, & r=R_{2} .\end{cases}
$$

[^104]In order to relate this stress to strain, let us use Hooke's law, but for that, we first need to calculate the strain tensor components for the deformation distribution (59). Using Eqs. (16), we get

$$
\begin{equation*}
s_{r r}=\frac{\partial q}{\partial r}=a-2 \frac{b}{r^{3}}, \quad s_{\theta \theta}=s_{\varphi \varphi}=\frac{q}{r}=a+\frac{b}{r^{3}}, \tag{7.61}
\end{equation*}
$$

so that $\operatorname{Tr}(\mathrm{s})=3 a$. Plugging these relations into Eq. (51a) for $\sigma_{r r}$, we get

$$
\begin{equation*}
\sigma_{r r}=\frac{E}{1+v}\left[\left(a-2 \frac{b}{r^{3}}\right)+\frac{v}{1-2 v} 3 a\right] . \tag{7.62}
\end{equation*}
$$

Now plugging this relation into Eqs. (60), we get a system of two linear equations for coefficients $a$ and b. Solving this system, we get:

$$
\begin{equation*}
a=\frac{1-2 v}{E} \frac{P_{1} R_{1}^{3}-P_{2} R_{2}^{3}}{R_{2}^{3}-R_{1}^{3}}, \quad b=\frac{1+v}{2 E} \frac{\left(P_{1}-P_{2}\right) R_{1}^{3} R_{2}^{3}}{R_{2}^{3}-R_{1}^{3}} . \tag{7.63}
\end{equation*}
$$

Formulas (59) and (63) give a complete solution of our problem. It is rich in contents and deserves at least some analysis. First of all, note that according to Eq. (50), coefficient ( $1-2 \sigma$ )/E in the expression for $a$ is just $1 / 3 K$, so that the first term in Eq. (59) for deformation is just the hydrostatic compression. In particular, the second of Eqs. (63) shows that if $R_{1}=0$, then $b=0$. Thus for a solid sphere we have only the hydrostatic compression that was discussed in the previous section. Perhaps less intuitively, making two pressures equal gives the same result (hydrostatic compression) for arbitrary $R_{2}>R_{1}$.

However, in the general case $b \neq 0$, so that the second term in the deformation distribution (59), which describes the shear deformation, ${ }^{22}$ is also substantial. In particular, let us consider the important thin-shell limit $R_{2}-R_{1} \equiv t \ll R_{1,2} \equiv R$ - see Fig. 7b. In this case, $q\left(R_{1}\right) \approx q\left(R_{2}\right)$ is just the change of the shell radius $R$, for which Eqs. (59) and (63) (with $R_{2}{ }^{3}-R_{1}{ }^{3} \approx 3 R^{2} t$ ) give

$$
\begin{equation*}
\Delta R \equiv q(R) \approx a R+\frac{b}{R^{2}} \approx \frac{\left(P_{1}-P_{2}\right) R^{2}}{3 t}\left(\frac{1-2 v}{E}+\frac{1+v}{2 E}\right)=\left(P_{1}-P_{2}\right) \frac{R^{2}}{t} \frac{1-v}{2 E} . \tag{7.64}
\end{equation*}
$$

Naively, one could think that at least in this limit the problem could be analyzed by elementary means. For example, the total force exerted by the pressure difference $\left(P_{1}-P_{2}\right)$ on the diametrical crosssection of the shell (see, e.g., the dashed line in Fig. 7b) is $F=\pi R^{2}\left(P_{1}-P_{2}\right)$, giving the stress,

$$
\begin{equation*}
\sigma=\frac{F}{A}=\frac{\pi R^{2}\left(P_{1}-P_{2}\right)}{2 \pi R t}=\left(P_{1}-P_{2}\right) \frac{R}{2 t}, \tag{7.65}
\end{equation*}
$$

directed along shell's walls. One can check that this simple formula may be indeed obtained, in this limit, from the strict expressions for $\sigma_{\theta \theta}$ and $\sigma_{\varphi \varphi}$, following from the general treatment carried out above. However, if we try now to continue this approach by using the simple relation (47) to find the small change $R s_{z z}$ of sphere's radius, we would arrive at a result with the structure of Eq. (64), but without factor $(1-v)<1$ in the numerator. The reason for this error (which may be as significant as $\sim 30 \%$ for typical construction materials - see Table 1) is that Eq. (47), while being valid for thin rods of arbitrary cross-section, is invalid for thin broad sheets, and in particular the thin shell in our problem.

[^105]Indeed, while at the tensile stress both lateral dimensions of a thin rod may contract freely, in our problem all dimensions of the shell are under stress - actually, under much more tangential stress than the radial one. ${ }^{23}$

### 7.5. Rod bending

The general approach to the static deformation analysis, outlined in the beginning of previous section, may be simplified not only for symmetric geometries, but also for the uniform thin structures such as thin plates ("membranes" or "sheets") and thin rods. Due to the shortage of time, in this course I will demonstrate typical approaches to such systems only on the example of thin rods. (The theory of membrane deformation is very much similar.) Besides the tensile stress analyzed in Sec. 3, two other major deformations of rods are bending and torsion. Let us start from a "local" analysis of bending caused by a pair of equal and opposite external torques $\tau= \pm \mathbf{n}_{y} \tau_{y}$ perpendicular to the rod axis $z$ (Fig. 8), assuming that the rod is "quasi-uniform", i.e. that on the scale of this analysis (comparable with linear scale $a$ of the cross-section) its material parameters and cross-section $A$ do not change substantially.

Fig. 7.8. This rod bending, in a local reference frame (specific for each cross-section).

Just as in the tensile stress experiment (Fig. 6), at bending the components of the stress forces $d \mathbf{F}$, normal to the rod length, have to equal zero on the surface of the rod. Repeating the arguments made for the tensile stress discussion, we arrive at the conclusion that only one diagonal component of the tensor (in Fig. 8, $\sigma_{z z}$ ) may differ from zero:

$$
\begin{equation*}
\sigma_{i j j^{\prime}}=\delta_{j z} \sigma_{z z} . \tag{7.66}
\end{equation*}
$$

However, in contrast to the tensile stress, at pure static bending the net force along the rod has to vanish:

$$
\begin{equation*}
F_{z}=\int_{A} \sigma_{z z} d^{2} r=0, \tag{7.67}
\end{equation*}
$$

so that $\sigma_{z z}$ has to change sign at some point of axis $x$ (in Fig. 8, selected to lay in the plane of the bent rod). Thus, the bending deformation may be viewed as a combination of stretching some layers of the rod (bottom layers in Fig. 8) with compression of other (top) layers.

Since it is hard to find more about the stress distribution from these general considerations, let us turn over to strain, assuming that the rod's cross-section is virtually constant on the length of the order of its cross-section size. From the above presentation of bending as a combination of stretching and compression, it evident that the longitudinal deformation $q_{z}$ has to vanish along some neutral line on the

[^106]rod's cross-section - in Fig. 8, represented by the dashed line. ${ }^{24}$ Selecting the origin of coordinate $x$ on this line, and expanding the relative deformation in the Taylor series in $x$, due to the cross-section smallness, we may limit ourselves to the linear term:
\[

$$
\begin{equation*}
s_{z z} \equiv \frac{d q_{z}}{d z}=-\frac{x}{R} . \tag{7.68}
\end{equation*}
$$

\]

Here constant $R$ has the sense of the curvature radius of the bent rod. Indeed, on a small segment $d z$ the cross-section turns by a small angle $d \varphi_{y}=-d q_{z} / x$ (Fig. 8b). Using Eq. (68), we get $d \varphi_{y}=d z / R$, which is the usual definition of the curvature radius $R$ in the differential geometry, for our special choice of the coordinate axes. ${ }^{25}$

Expressions for other components of the strain tensor are harder to guess (like at the tensile stress, not all of them are equal to zero!), but what we already know about $\sigma_{z z}$ and $s_{z z}$ is already sufficient to start formal calculations. Indeed, plugging Eq. (66) into the Hooke's law in the form (51b), and comparing the result for $s_{z z}$ with Eq. (68), we find

$$
\begin{equation*}
\sigma_{z z}=-E \frac{x}{R} . \tag{7.69}
\end{equation*}
$$

From the same Eq. (51b), we could also find the transverse components of the strain tensor, and see that they are related to $s_{z z}$ exactly as at the tensile stress:

$$
\begin{equation*}
s_{x x}=s_{y y}=-v S_{z z}, \tag{7.70}
\end{equation*}
$$

and then, integrating these relations along the cross-section of the rod, find the deformation of the crosssection shape. More important for us, however, is the calculation of the relation between rod's curvature and the net torque acting on a given cross-section (of area $A$ and orientation $d A_{z}>0$ ):

$$
\begin{equation*}
\tau_{y} \equiv \int_{A}(\mathbf{r} \times d \mathbf{F})_{y}=-\int_{A} x \sigma_{z z} d^{2} r=\frac{E}{R} \int_{A} x^{2} d^{2} r=\frac{E I_{y}}{R}, \tag{7.71}
\end{equation*}
$$

where $I_{y}$ is a geometric constant defined as

$$
\begin{equation*}
I_{y} \equiv \int_{A} x^{2} d x d y \tag{7.72}
\end{equation*}
$$

Note that this factor, defining the bending rigidity of the rod, grows as fast as $a^{4}$ with the linear scale $a$ of the cross-section. ${ }^{26}$

In these expressions, $x$ has to be counted from the neutral line. Let us see where exactly does this line pass through rod's cross-section. Plugging result (69) into Eq. (67), we get the condition defining the neutral line:

[^107]\[

$$
\begin{equation*}
\int_{A} x d x d y=0 \tag{7.73}
\end{equation*}
$$

\]

This condition allows a simple interpretation. Imagine a thin sheet of some material, with a constant mass density $\sigma$ per unit area, cut in the form of rod's cross-section. If we place a reference frame into its center of mass, then, by its definition,

$$
\begin{equation*}
\sigma \int_{A} \mathbf{r} d x d y=0 \tag{7.74}
\end{equation*}
$$

Comparing this condition with Eq. (73), we see that one of neutral lines has to pass through the center of mass of the sheet, which may be called the "center of mass of the cross-section". Using the same analogy, we see that integral $I_{y}$ (72) may be interpreted as the moment of inertia of the same imaginary sheet of material, with $\sigma$ formally equal to 1 , for its rotation about the neutral line - see Eq. (6.24). This analogy is so convenient that the integral is usually called the moment of inertia of the cross-section and denoted similarly - just as has been done above. So, our basic result (71) may be re-written as

$$
\begin{equation*}
\frac{1}{R}=\frac{\tau_{y}}{E I_{y}} \tag{7.75}
\end{equation*}
$$

This relation is only valid if the deformation is small in the sense $R \gg a$. Still, since the deviations of the rod from its unstrained shape may accumulate along its length, Eq. (75) may be used for calculations of global deviations arbitrary on the scale of $a$. In order to describe such deformations, this equation has to be complemented by conditions of balance of the bending forces and torques. Unfortunately, this requires a bit more of differential geometry than I have time for, and I will only discuss this procedure for the simplest case of relatively small deviations $q \equiv q_{x}$ of the rod from its initial straight shape, which will be used for axis $z$ (Fig. 9a), by some bulk-distributed force $\mathbf{f}=\mathbf{n}_{x} f_{x}(z)$. (The simplest example is a uniform gravity field, for which $f_{x}=-\rho g=$ const.) Note that in the forthcoming discussion the reference frame will be global, i.e. common for the whole rod, rather than local (pertaining to each cross-section) as in the previous analysis - cf. Fig. 8.

(a)

Fig. 7.9. Global picture of rod bending: (a) forces acting on a small fragment of a rod and (b) two bending problem examples, each with two typical, different boundary conditions.

First of all, we may write an evident differential equation for the average vertical force $\mathbf{F}=$ $\mathbf{n}_{x} F_{x}(z)$ acting of the part of the rod located to the left of its cross-section located at point $z$. This equation expresses the balance of vertical forces acting on a small fragment $d z$ of the rod (Fig. 9a), necessary for the absence of its linear acceleration: $F_{x}(z+d z)-F_{x}(z)+f_{x}(z) A d z=0$, giving

$$
\begin{equation*}
\frac{d F_{x}}{d z}=-f_{x} A \tag{7.76}
\end{equation*}
$$

Note that this vertical component of the internal forces has been neglected at our derivation of Eq. (75), and hence our final results will be valid only if the ratio $F_{x} / A$ is much less than the magnitude of $\sigma_{z z}$ described by Eq. (69). However, these lateral forces create the very torque $\tau=\mathbf{n}_{y} \tau_{y}$ that causes the bending, and thus have to be taken into account at the analysis of the global picture. This re-calculation is expressed by the balance of torque components acting on the same rod fragment of length $d z$, necessary for the absence of its angular acceleration:

$$
\begin{equation*}
\frac{d \tau_{y}}{d z}=-F_{x} \tag{7.77}
\end{equation*}
$$

These two equations of dynamics (or rather statics) should be complemented by two geometric relations. The first of them is $d \varphi_{y} / d z=1 / R$, which has already been discussed. We may immediately combine it with the basic result (75) of the local analysis, getting:

$$
\begin{equation*}
\frac{d \varphi_{y}}{d z}=\frac{\tau_{y}}{E I_{y}} \tag{7.78}
\end{equation*}
$$

The final equation is the geometric relation evident from Fig. 9a:

$$
\begin{equation*}
\frac{d q_{x}}{d z}=\varphi_{y} \tag{7.79}
\end{equation*}
$$

which is (as all expressions of our simple analysis) only valid for small bending angles, $\left|\varphi_{y}\right| \ll 1$.
Four differential equations (76)-(79) are sufficient for the full solution of the weak bending problem, if complemented by appropriate boundary conditions. Figure $9 b$ shows four most frequently met conditions. Let us solve, for example, the problem shown on the top panel of Fig. 9 b : bending of a rod, clamped in a wall on one end, under its own weight. Considering, for the sake of simplicity, a uniform rod, ${ }^{27}$ we may integrate equations (70), (72)-(74) one by one, each time using the appropriate boundary conditions. To start, Eq. (76), with $f_{x}=-\rho g$, yields

$$
\begin{equation*}
F_{x}=\rho g A z+\text { const }=\rho g A(z-L), \tag{7.80}
\end{equation*}
$$

where the integration constant has been selected to satisfy the right-end boundary condition: $F_{x}=0$ at $z$ $=L$. As a sanity check, at the left wall $(z=0), F_{x}=-\rho g A L=-m g$, meaning that the whole weight of the rod is exerted on the wall - fine.

Next, plugging Eq. (80) into Eq. (77) and integrating, we get

$$
\begin{equation*}
\tau_{y}=-\frac{\rho g A}{2}\left(z^{2}-2 L z\right)+\mathrm{const}=-\frac{\rho g A}{2}\left(z^{2}-2 L z+L^{2}\right)=-\frac{\rho g A}{2}(z-L)^{2}, \tag{7.81}
\end{equation*}
$$

where the integration constant's choice ensures the second right-boundary condition: $\tau_{y}=0$ at $z=L$. Proceeding in the same fashion to Eq. (78), we get

[^108]\[

$$
\begin{equation*}
\varphi_{y}=-\frac{\rho g A}{2 E I_{y}} \frac{(z-L)^{3}}{3}+\text { const }=-\frac{\rho g A}{6 E I_{y}}\left[(z-L)^{3}+L^{3}\right] \tag{7.82}
\end{equation*}
$$

\]

where the integration constant is selected to satisfy the clamping condition at the left end of the rod: $\varphi_{y}$ $=0$ at $z=0$. (Note that this is different from the support condition, illustrated on the lower panel of Fig. 9 b , which allows the angle at $z=0$ to be finite but requires the torque to vanish.) Finally, integrating Eq. (79) with $\varphi_{y}$ given by Eq. (82), we get rod's global deformation law,

$$
\begin{equation*}
q_{x}(z)=-\frac{\rho g A}{6 E I_{y}}\left[\frac{(z-L)^{4}}{4}+L^{3} z+\text { const }\right]=-\frac{\rho g A}{6 E I_{y}}\left[\frac{(z-L)^{4}}{4}+L^{3} z-\frac{L^{4}}{4}\right] \tag{7.83}
\end{equation*}
$$

where the integration constant is selected to satisfy the second left-boundary condition: $q=0$ at $z=0$. So, the bending law is sort of complex even in this very simple problem. It is also remarkable how fast does the end's displacement grow with the increase of rod's length:

$$
\begin{equation*}
q_{x}(L)=-\frac{\rho g A L^{4}}{8 E I_{y}} \tag{7.84}
\end{equation*}
$$

To conclude the solution, let us discuss the validity of this result. First, the geometric relation (79) is only valid if $\left|\varphi_{y}(L)\right| \ll 1$, and hence if $\left|q_{x}(L)\right| \ll L$. Next, the local formula Eq. (78) is valid if $1 / R=\tau(L) / E I_{y} \ll 1 / a \sim A^{-1 / 2}$. Using results (81) and (84), we see that the latter condition is equivalent to $\left|q_{x}(L)\right| \ll L^{2} / a$, i.e. is weaker, because all our analysis has been based on the assumption that $L \gg a$.

Another point of concern may be that the off-diagonal stress component $\sigma_{x z} \sim F_{x} / A$, that is created by the vertical gravity forces, has been ignored in our local analysis. For that approximation to be, this component must be much smaller than the diagonal component $\sigma_{z z} \sim a E / R=a \tau / I_{y}$ taken into account in that analysis. Using Eqs. (80) and (81), we are getting the following estimates: $\sigma_{x z} \sim \rho g L, \sigma_{z z}$ $\sim a \rho g A L^{2} / I_{y} \sim a^{3} \rho g L^{2} / I_{y}$. According to its definition (72), $I_{y}$ may be crudely estimated as $a^{4}$, so that we finally get the following simple condition: $a \ll L$, which has been assumed from the very beginning.

### 7.6. Rod torsion

One more class of analytically solvable elasticity problems is torsion of quasi-uniform, straight rods by a couple of axially-oriented torques $\tau=\mathbf{n}_{z} \tau_{z}$ (Fig. 10).

Fig. 7.10. Rod torsion.

Here the main goal of the local analysis is to relate torque $\tau_{z}$ to parameter $\kappa$ in the relation

$$
\begin{equation*}
\frac{d \varphi_{z}}{d z}=\kappa \tag{7.85}
\end{equation*}
$$

If the deformation is elastic and small (in the sense $\kappa a \ll 1$, where $a$ is again the characteristic size of rod's cross-section), $\kappa$ is proportional to $\tau_{z}$, and their ratio,

Torsional rigidity $C$

$$
\begin{equation*}
C \equiv \frac{\tau_{z}}{\kappa}=\frac{\tau_{z}}{d \varphi_{z} / d z}, \tag{7.86}
\end{equation*}
$$

is called the torsional rigidity of the rod. Our task is to calculate the rigidity.
As the first guess (as we will see below, of a limited validity), one may assume that the torsion does not change the shape or size of the cross-section, but leads just to the mutual rotation of crosssections about certain central line. Using a reference frame with the origin on that line, this assumption immediately allows the calculation of components of the displacement vector $d \mathbf{q}$, by using Eq. (6) with $d \boldsymbol{\varphi}=\mathbf{n}_{\mathrm{z}} d \varphi_{z}:$

$$
\begin{equation*}
d q_{x}=-y d \varphi_{z}=-\kappa y d z, \quad d q_{y}=x d \varphi_{z}=\kappa x d z, \quad d q_{z}=0 \tag{7.87}
\end{equation*}
$$

From here, we can calculate all Cartesian components (9) of the strain tensor:

$$
\begin{equation*}
s_{x x}=s_{y y}=s_{z z}=0, \quad s_{x y}=s_{y x}=0, \quad s_{x z}=s_{z x}=-\frac{\kappa}{2} y, \quad s_{y z}=s_{z y}=\frac{\kappa}{2} x . \tag{7.88}
\end{equation*}
$$

The first of these equalities means that volume does not change, i.e. we are dealing with a pure shear deformation. As a result, all nonvanishing components of the stress tensor, calculated from Eqs. (34), ${ }^{28}$ are proportional to the shear modulus alone:

$$
\begin{equation*}
\sigma_{x x}=\sigma_{y y}=\sigma_{z z}=0, \quad \sigma_{x y}=\sigma_{y x}=0, \quad \sigma_{x z}=\sigma_{z x}=-\mu k y, \quad \sigma_{y z}=\sigma_{z y}=\mu \kappa x . \tag{7.89}
\end{equation*}
$$

Now it is straightforward to use this result to calculate the full torque as an integral over the cross-section area $A$ :

$$
\begin{equation*}
\tau_{z} \equiv \int_{A}(\mathbf{r} \times d \mathbf{F})_{z}=\int_{A}\left(x d F_{y}-y d F_{x}\right)=\int_{A}\left(x \sigma_{y z}-y \sigma_{x z}\right) d x d y . \tag{7.90}
\end{equation*}
$$

Using Eq. (89), we get $\tau_{\mathrm{z}}=\mu \kappa I_{z}$, i.e.

$$
\begin{equation*}
C=\mu I_{z}, \quad \text { where } \quad I_{z} \equiv \int_{A}\left(x^{2}+y^{2}\right) d x d y . \tag{7.91}
\end{equation*}
$$

Again, just as in the case of thin rod bending, we have got an integral similar to a moment of inertia, this time for rotation about axis $z$ passing through a certain point of the cross-section. For any axially-symmetric cross-section, this evidently should be the central point. Then, for example, for the practically important case of a round pipe with internal radius $R_{1}$ and external radius $R_{2}$, Eq. (91) yields

$$
\begin{equation*}
C=\mu 2 \pi \int_{R_{1}}^{R_{2}} \rho^{3} d \rho=\frac{\pi}{2} \mu\left(R_{2}^{4}-R_{1}^{4}\right) . \tag{7.92}
\end{equation*}
$$

In particular, for the solid rod of radius $R$ this gives torsional rigidity $C=(\pi / 2) \mu R^{4}$, while for a hollow pipe of small thickness $t \ll R$, Eq. (92) is reduced to

[^109]\[

$$
\begin{equation*}
C=2 \pi \mu R^{3} t \tag{7.93}
\end{equation*}
$$

\]

Note that per unit cross-section area $A$ (and hence per unit mass) this rigidity is twice higher that of a solid rod:

$$
\begin{equation*}
\left.\frac{C}{A}\right|_{\text {thin round pipe }}=\mu R^{2}>\left.\frac{C}{A}\right|_{\text {solid round rod }}=\frac{1}{2} \mu R^{2} . \tag{7.94}
\end{equation*}
$$

This fact is the basis of a broad use of thin pipes in construction.
However, for rods with axially-asymmetric cross-sections, Eq. (91) gives wrong results. For example, for a narrow rectangle of area $A=w t$ with $t \ll w$, it yields $C=\mu t w^{3} / 12$ [WRONG!], even functionally different from the correct result - cf. Eq. (106) below. The reason of the failure of the above analysis is that does not describe possible bending $q_{z}$ of rod's cross-section in the direction along the rod. (For axially-symmetric rods, such bending is evidently forbidden by the symmetry, so that Eq. (91) is valid, and results (92)-(94) are absolutely correct.) Let us describe ${ }^{29}$ this, rather counter-intuitive effect by taking

$$
\begin{equation*}
q_{z}=\kappa \psi(x, y) \tag{7.95}
\end{equation*}
$$

(where $\psi$ is some function to be determined), but still keeping Eq. (87) for two other components of the displacement vector. The addition of $\psi$ does not change the equality to zero of the diagonal components of the strain tensor, as well as of $s_{x y}=s_{y x}$, but contributes to other off-diagonal components:

$$
\begin{equation*}
s_{x z}=s_{z x}=\frac{\kappa}{2}\left(-y+\frac{\partial \psi}{\partial x}\right), \quad s_{y z}=s_{z y}=\frac{\kappa}{2}\left(x+\frac{\partial \psi}{\partial y}\right), \tag{7.96}
\end{equation*}
$$

and hence to the corresponding elements of the stress tensor:

$$
\begin{equation*}
\sigma_{x z}=\sigma_{z x}=\mu \kappa\left(-y+\frac{\partial \psi}{\partial x}\right), \quad \sigma_{y z}=\sigma_{z y}=\mu \kappa\left(x+\frac{\partial \psi}{\partial y}\right) . \tag{7.97}
\end{equation*}
$$

Now let us find the requirement imposed on function $\psi(x, y)$ by the fact that the stress force component parallel to rod's axis,

$$
\begin{equation*}
d F_{z}=\sigma_{z x} d A_{x}+\sigma_{z y} d A_{y}=\mu \kappa d A\left[\left(-y+\frac{\partial \psi}{\partial x}\right) \frac{d A_{x}}{d A}+\left(x+\frac{\partial \psi}{\partial y}\right) \frac{d A_{y}}{d A}\right] \tag{7.98}
\end{equation*}
$$

has to vanish at rod's surface(s), i.e. at each border of its cross-section. Coordinates $\{x, y\}$ of points at a border may be considered functions of the arc $l$ of that line - see Fig. 11. As this figure shows, the elementary area ratios participating in Eq. (98) may be readily expressed via derivatives of functions $x(l)$ and $y(l): d A_{x} / d A=\sin \alpha=d y / d l, d A_{y} / d A=\cos \alpha=-d x / d l$, so that we may write

$$
\begin{equation*}
\left[\left(-y+\frac{\partial \psi}{\partial x}\right)\left(\frac{d y}{d l}\right)+\left(x+\frac{\partial \psi}{\partial y}\right)\left(-\frac{d x}{d l}\right)\right]_{\mathrm{border}}=0 \tag{7.99}
\end{equation*}
$$

Introducing, instead of $\psi$, a new function $\chi(x, y)$, defined by its derivatives as

[^110]\[

$$
\begin{equation*}
\frac{\partial \chi}{\partial x} \equiv \frac{1}{2}\left(-x-\frac{\partial \psi}{\partial y}\right), \quad \frac{\partial \chi}{\partial y} \equiv \frac{1}{2}\left(-y+\frac{\partial \psi}{\partial x}\right), \tag{7.100}
\end{equation*}
$$

\]

we may rewrite condition (99) as

$$
\begin{equation*}
\left.2\left(\frac{\partial \chi}{\partial y} \frac{d y}{d l}+\frac{\partial \chi}{\partial x} \frac{d x}{d l}\right)_{\text {border }} \equiv 2 \frac{d \chi}{d l}\right|_{\text {border }}=0 \tag{7.101}
\end{equation*}
$$

so that function $\chi$ should be constant at each border of the cross-section.

Fig. 7.11. Deriving Eq. (101).

In particular, for a singly-connected cross-section, limited by just one continuous border line, the constant is arbitrary, because according to Eqs. (100), its choice does not affect the longitudinal deformation function $\psi(x, y)$ and hence the deformation as the whole. Now let use the definition (100) of function $\chi$ to calculate the 2D Laplace operator of this function:

$$
\begin{equation*}
\nabla_{x, y}^{2} \chi \equiv \frac{\partial^{2} \chi}{\partial^{2} x}+\frac{\partial^{2} \chi}{\partial^{2} y}=\frac{1}{2} \frac{\partial}{\partial x}\left(-x-\frac{\partial \psi}{\partial y}\right)+\frac{1}{2} \frac{\partial}{\partial y}\left(-y+\frac{\partial \psi}{\partial y}\right)=-1 . \tag{7.102}
\end{equation*}
$$

This a 2D Poisson equation (frequently met, for example, in electrostatics), but with a very simple, constant right-hand part. Plugging Eqs. (100) into Eqs. (97), and those into Eq. (90), we may express torque $\tau$, and hence the torsional rigidity $C$, via the same function:

$$
\begin{equation*}
C \equiv \frac{\tau_{z}}{\kappa}=-2 \mu \int_{A}\left(x \frac{\partial \chi}{\partial x}+y \frac{\partial \chi}{\partial y}\right) d x d y \tag{7.103a}
\end{equation*}
$$

Sometimes, it is easier to use this result in one of its two different forms. The first of them may be readily obtained from Eq. (103a) using integration by parts:

$$
\begin{align*}
C & =-2 \mu\left(\int d y \int x d \chi+\int d x \int y d \chi\right)=-2 \mu\left[\int d y\left(x \chi_{\text {border }}-\int \chi d x\right)+\int d x\left(y \chi_{\text {border }}-\int \chi d y\right)\right] \\
& =4 \mu\left[\int_{A} \chi d x d y-\chi_{\text {border }} \int_{A} d x d y\right], \tag{7.103b}
\end{align*}
$$

while the proof of one more form,

$$
\begin{equation*}
C=4 \mu \int_{A}\left(\nabla_{x, y} \chi\right)^{2} d x d y \tag{7.103c}
\end{equation*}
$$

is left for reader's exercise.
Thus, if we need to know rod's rigidity alone, it is sufficient to calculate function $\chi(x, y)$ from Eq. (102) with boundary condition (101), and plug it into any of Eqs. (103). Only if we are also curious about the longitudinal deformation (95) of the cross-section, we may continue by using Eq. (100) to find function $\psi(x, y)$. Let us see how does this general result work for the two examples discussed above. For the round cross-section of radius $R$, both the Poisson equation (102) and the boundary condition, $\chi=$ const at $x^{2}+y^{2}=R^{2}$, are evidently satisfied by the axially-symmetric function

$$
\begin{equation*}
\chi=-\frac{1}{4}\left(x^{2}+y^{2}\right)+\text { const. } \tag{7.104}
\end{equation*}
$$

For this case, either of Eqs. (103) yields

$$
\begin{equation*}
C=4 \mu \int_{A}\left[\left(-\frac{1}{2} x\right)^{2}+\left(-\frac{1}{2} y\right)^{2}\right] d x d y=\mu \int_{A}\left(x^{2}+y^{2}\right) d^{2} r \tag{7.105}
\end{equation*}
$$

i.e. the same result (91) that we had for $\psi=0$. Indeed, plugging Eq. (104) into Eqs. (100), we see that in this case $\partial \psi / \partial x=\partial \psi / \partial y=0$, so that $\psi(x, y)=$ const, i.e. the cross-section is not bent. (As we have discussed in Sec. 1, a uniform translation $d q_{z}=\kappa \psi=$ const does not give any deformation.)

Now, turning to a rod with a narrow rectangular cross-section wt with $t \ll w$, we may use this strong inequality to solve the Poisson equation (102) approximately, neglecting the derivative along the wider dimension (say, $y$ ). The remaining 1 D differential equation $d^{2} \chi / d^{2} x=-1$, with boundary conditions $\left.\chi\right|_{x=+t / 2}=\left.\chi\right|_{x=-t / 2}$ has an evident solution $\chi=-x^{2} / 2+$ const. Plugging this expression into any form of Eq. (103), we get the correct result for the torsional rigidity:

$$
\begin{equation*}
C=\frac{1}{6} \mu w t^{3} . \tag{7.106}
\end{equation*}
$$

Now let us have a look at the cross-section bending law (95) for this particular case. Using Eqs. (100), we get

$$
\begin{equation*}
\frac{\partial \psi}{\partial y}=-x-2 \frac{\partial \chi}{\partial x}=x, \quad \frac{\partial \psi}{\partial x}=y+2 \frac{\partial \chi}{\partial y}=y . \tag{7.107}
\end{equation*}
$$

Integrating these differential equations over the cross-section, and taking the integration constant (again, not contributing to the deformation) for zero, we get a beautifully simple result:

$$
\begin{equation*}
\psi=x y, \quad \text { i.e. } q_{z}=\kappa x y . \tag{7.108}
\end{equation*}
$$

It means that the longitudinal deformation of the rod has a "propeller bending" form: while the regions near the opposite corners (sitting on the same diagonal) of the cross-section bend toward one direction of axis $z$, corners on the other diagonal bend in the opposite direction. (This qualitative conclusion remains valid for rectangular cross-sections with any aspect ratio $t / w$.)

For rods with several surfaces, i.e. with cross-sections limited by several boundaries (say, hollow pipes), the boundary conditions for function $\chi(x, y)$ require a bit more care, and Eq. (103b) has to be modified, because the function may be equal to a different constant at each boundary. Let me leave the calculation of the torsional rigidity for this case for reader's exercise.

### 7.7. 3D acoustic waves

Now moving to elastic dynamics, we may start with Eq. (24) that may be transformed into the vector form exactly as this was done for the static case in the beginning of Sec. 4. Comparing Eqs. (24) and (54), we immediately see that the result may be presented as
 dynamics equation

$$
\begin{equation*}
\rho \frac{\partial^{2} \mathbf{q}}{\partial t^{2}}=\frac{E}{2(1+v)} \nabla^{2} \mathbf{q}+\frac{E}{2(1+v)(1-2 v)} \nabla(\nabla \cdot \mathbf{q})+\mathbf{f}(\mathbf{r}, t) \tag{7.109}
\end{equation*}
$$

Let us use this general equation for analysis of probably the most important type of timedependent deformations: elastic waves. First, let us address the simplest case of a virtually infinite, uniform elastic medium, without any external forces $\mathbf{f}$. In this case, due to the linearity and homogeneity of the resulting equation of motion, and in clear analogy with the 1 D case (see Sec. 5.3), we may look for a particular time-dependent solution in the form of a sinusoidal, linearly-polarized, plane wave

3D plane, sinusoidal wave

$$
\begin{equation*}
\mathbf{q}(\mathbf{r}, t)=\operatorname{Re}\left[\mathbf{a} e^{i(\mathbf{k} \cdot \mathbf{r}-\omega t)}\right], \tag{7.110}
\end{equation*}
$$

where $\mathbf{a}$ is the constant complex amplitude of a wave (now a vector!), and $\mathbf{k}$ is the wave vector whose magnitude is equal to the wave number $k$. The direction of these two vectors should be clearly distinguished: while a determined wave's polarization, i.e. the direction of the particle displacements, vector $\mathbf{k}$ is directed along the spatial gradient of the full phase of the wave

$$
\begin{equation*}
\Psi \equiv \mathbf{k} \cdot \mathbf{r}-\omega t+\arg a, \tag{7.111}
\end{equation*}
$$

i.e. along the direction of the wave front propagation.

The importance of the angle between these two vectors may be readily seen from the following simple calculation. Let us point axis $z$ of an (inertial) reference frame along the direction of vector $\mathbf{k}$, and axis $x$ in such direction that vector $\mathbf{q}$, and hence a lie within the $\{x, z\}$ plane. In this case, all variables may change only along that axis, i.e. $\nabla=\mathbf{n}_{\mathrm{z}}(\partial / \partial z)$, while the amplitude vector may be presented as the sum of just two Cartesian components:

$$
\begin{equation*}
\mathbf{a}=a_{x} \mathbf{n}_{x}+a_{z} \mathbf{n}_{z} . \tag{7.112}
\end{equation*}
$$

Let us first consider a longitudinal wave, ${ }^{30}$ with the particle motion along the wave direction: $a_{x}$ $=0, a_{z}=a$. Then vector $\mathbf{q}$ in Eq. (109), describing that wave, has only one ( $z$ ) component, so that $\nabla \cdot \mathbf{q}=$ $d q_{z} / d z$ and $\nabla(\nabla \cdot \mathbf{q})=\mathbf{n}_{z}\left(\partial^{2} \mathbf{q} / \partial z^{2}\right)$, and the Laplace operator gives the same expression: $\nabla^{2} \mathbf{q}=\mathbf{n}_{z}\left(\partial^{2} \mathbf{q} / \partial z^{2}\right)$. As a result, Eq. (109), with $\mathbf{f}=0$, yields

$$
\begin{equation*}
\rho \frac{\partial^{2} q_{z}}{\partial t^{2}}=\left[\frac{E}{2(1+v)}+\frac{E}{2(1+v)(1-2 v)}\right] \frac{\partial^{2} q_{z}}{\partial z^{2}}=\frac{E(1-v)}{(1+v)(1-2 v)} \frac{\partial^{2} q_{z}}{\partial z^{2}} . \tag{7.113}
\end{equation*}
$$

Plugging the plane-wave solution (110) into this equation, we see that it is indeed satisfied if the wave number and wave frequency are related as

[^111]\[

$$
\begin{equation*}
\omega=v_{l} k, \quad v_{l}^{2}=\frac{E(1-v)}{(1+v)(1-2 v) \rho}=\frac{K+(4 / 3) \mu}{\rho} \tag{7.114}
\end{equation*}
$$

\]

This expression allows a simple interpretation. Let us consider a static experiment, similar to the tensile test experiment shown in Fig. 6, but with a sample much wider than $L$ in both directions perpendicular to the force. Then the lateral contraction is impossible, and we can calculate the only finite stress component, $\sigma_{z z}$, directly from Eq. (34) with $\operatorname{Tr}(\mathrm{s})=s_{z z}$ :

$$
\begin{equation*}
\sigma_{z z}=2 \mu\left(s_{z z}-\frac{1}{3} s_{z z}\right)+3 K\left(\frac{1}{3} s_{z z}\right)=\left(K+\frac{4}{3} \mu\right) s_{z z} . \tag{7.115}
\end{equation*}
$$

We see that the numerator in Eq. (114) is nothing more than the static elastic modulus for such a uniaxial deformation, and it is recalculated into the velocity exactly as the spring constant in the 1D waves considered in Sec. 5.3 - cf. Eq. (5.32). ${ }^{31}$ Thus, the longitudinal acoustic waves are just simple waves of uniaxial extension/compression along the propagation axis. Formula (114) becomes especially simple in fluids, where $\mu=0$, and the wave velocity is described by well-known expression

$$
\begin{equation*}
v_{l}=\left(\frac{K}{\rho}\right)^{1 / 2} \tag{7.116}
\end{equation*}
$$

Note, however, that for gases, with their high compressibility and temperature sensitivity, the value of $K$ participating in this formula may differ, at high frequencies, from that given by Eq. (42), because the fast compressions/extensions of gas are nearly adiabatic rather than isothermal. This difference is noticeable in Table 1 which, in particular, lists the values of $v_{l}$ for some representative materials.

Now let us consider an opposite case of transverse waves with $a_{x}=a, a_{z}=0$. In such a wave, the displacement vector is perpendicular to $z$, so that $\nabla \cdot \mathbf{q}=0$, and the second term in the right-hand part of Eq. (109) vanishes. On the contrary, the Laplace operator acting on such vector still gives the same nonzero contribution, $\nabla^{2} \mathbf{q}=n_{z}\left(\partial^{2} \mathbf{q} / \partial z^{2}\right)$, to Eq. (109), so that the equation yields

$$
\begin{equation*}
\rho \frac{\partial^{2} q_{x}}{\partial t^{2}}=\frac{E}{2(1+v)} \frac{\partial^{2} q_{x}}{\partial z^{2}} \tag{7.117}
\end{equation*}
$$

and instead of Eq. (114) we now get

$$
\begin{equation*}
\omega=v_{t} k, \quad v_{t}^{2}=\frac{E}{2(1+v) \rho}=\frac{\mu}{\rho} . \tag{7.118}
\end{equation*}
$$

Longitudinal waves: velocity in fluids

Longitudinal waves: velocity
the strain tensor $s_{j j}$, has no diagonal components, $\operatorname{Tr}(\mathrm{s})=0$, so that $\mu$ is the only elastic modulus actively participating in the Hooke's law (34).

In particular, fluids cannot carry transverse waves at all (formally, their velocity (118) vanishes), because they do not resist shear deformations. For all other materials, longitudinal waves are faster than the transverse ones. Indeed, for all known materials the Poisson ratio is positive, so that the velocity ratio that follows from Eqs. (114) and (118),

$$
\begin{equation*}
\frac{v_{l}}{v_{t}}=\left(\frac{2-2 v}{1-2 v}\right)^{1 / 2}, \tag{7.119}
\end{equation*}
$$

is above $\sqrt{ } 2 \approx 1.4$. For the most popular construction materials, with $\lambda \approx 0.3$, the ratio is about $2-$ see Table 1.

Let me emphasize again that for both longitudinal and transverse waves the relation between the wave number and frequency is linear: $\omega=v k$. As has already been discussed in Sec. 5.3, in this case of acoustic waves (or just "sound") there is no dispersion, i.e. a transverse or longitudinal wave of more complex form, consisting of several (or many) Fourier components of the type (110), preserves its form during propagation: ${ }^{33}$

$$
\begin{equation*}
\mathbf{q}(z, t)=\mathbf{q}(z-v t, 0) . \tag{7.120}
\end{equation*}
$$

As one may infer from the analysis in Sec. 5.3, the dispersion would be back at very high (hypersound) frequencies where the wave number $k$ becomes of the order of the reciprocal distance between the particles of the medium (e.g., atoms or molecules), and hence the approximation of the medium as a continuum, used through this chapter, became invalid.

As we already know from Sec. 5.3, besides the velocity, an important parameter characterizing waves of each type is the wave impedance $Z$ of the medium, for acoustic waves frequently called the acoustic impedance. Generalizing Eq. (5.44) to the 3D case, we may define the impedance as the ratio of the force per unit area (i.e. the corresponding component of the stress tensor) exerted by the wave, to particles' velocity. For example, for the longitudinal waves, propagating in the positive/negative direction along $z$ axis,

$$
\begin{equation*}
Z_{l} \equiv \mp \frac{\sigma_{z z}}{\partial q_{z} / \partial t}=\mp \frac{\sigma_{z z}}{s_{z z}} \frac{s_{z z}}{\partial q_{z} / \partial t}=\mp \frac{\sigma_{z z}}{s_{z z}} \frac{\partial q_{z} / \partial z}{\partial q_{z} / \partial t} . \tag{7.121}
\end{equation*}
$$

Plugging in Eqs. (110), (114), and (115), we get

$$
\begin{equation*}
Z_{l}=\left[\left(K+\frac{4}{3} \mu\right) \rho\right]^{1 / 2} \tag{7.122}
\end{equation*}
$$

in a clear analogy with Eq. (5.45). Similarly, for the transverse wave, the appropriately modified definition, $Z_{t} \equiv \mp \sigma_{x z} /\left(\partial q_{x} / \partial z\right)$, yields

$$
\begin{equation*}
Z_{t}=(\mu \rho)^{1 / 2} \tag{7.123}
\end{equation*}
$$

[^112]Just like in the 1D waves, one role of impedance is to scale the power carried by the wave. For plane 3D waves in infinite media, with their infinite wave front area, it is more appropriate to speak it is more appropriate to speak about power density, i.e. power $p=d \not \mathcal{P} d A$ per unit area of the front, and characterize it by not only its magnitude,

$$
\begin{equation*}
p=\frac{d \mathbf{F}}{d A} \cdot \frac{\partial \mathbf{q}}{\partial t} \tag{7.124}
\end{equation*}
$$

but also the direction of the energy propagation, that (for a plane wave in an isotropic medium) coincides with the direction of the wave vector $\mathbf{k}: \boldsymbol{p} \equiv \boldsymbol{\sim} \mathbf{n}_{\mathbf{k}}$. Using definition (18) of the stress tensor, we may present the Cartesian components of this Umov vector ${ }^{34}$ as

$$
\begin{equation*}
\boldsymbol{p}_{j}=\sum_{j^{\prime}} \sigma_{i j^{\prime}} \frac{\partial q_{j^{\prime}}}{\partial t} \tag{7.125}
\end{equation*}
$$

Returning to plane waves propagating along axis $z$, and acting exactly like in Sec. 5.3, for both the longitudinal and transverse waves we arrive at the following 3D analog Eq. (5.46),

$$
\begin{equation*}
p_{z}=\frac{\omega^{2} Z}{2} a a^{*} \tag{7.126}
\end{equation*}
$$

with $Z$ being the corresponding impedance - either $Z_{l}$ or $Z_{t}$.
Just as in 1D case, one more important effect in which the notion of impedance is crucial is wave reflection from at an interface between two media. The two boundary conditions, necessary for the analysis of these processes, may be obtained from the continuity of vectors $\mathbf{q}$ and $d \mathbf{F}$. (The former condition is evident, while the latter one may be obtained by applying the $2^{\text {nd }}$ Newton law to the infinitesimal volume $d V=d A d z$, where segment $d z$ straddles the boundary.) Let us start from the simplest case of the normal incidence on a plane interface between two uniform media with different elastic moduli and mass densities. Due to the symmetry, it is evident that the incident longitudinal/transverse wave may only excite longitudinal/transverse reflected and transferred waves, but not the counterpart wave type. Thus we can literally repeat all the calculations of Sec. 5.4, again arriving at the fundamental relations (5.53) and (5.54), with the only replacement of $Z$ and $Z$ ' with the corresponding values of either $Z_{l}(121)$ or $Z_{t}(123)$. Thus, at the normal incidence the wave reflection is determined solely by the acoustic impedances of the media, while the sound velocities are not involved.

The situation, however, becomes more involved at a nonvanishing incidence angle $\theta^{(i)}$ (Fig. 12), where the transmitted wave is generally also refracted, i.e. propagates under a different angle, $\theta^{(r)} \neq \theta^{(i)}$, to the interface. Moreover, at $\theta^{(i)} \neq 0$ the directions of particle motion (vector $\mathbf{q}$ ) and of the stress forces (vector $d \mathbf{F}$ ) in the incident wave are neither exactly parallel nor exactly perpendicular to the interface, and thus this wave serves as an actuator for reflected and refracted waves of both types - see Fig. 12. (It shows the particular case when the incident wave is transverse.) The corresponding four angles, $\theta_{t}^{(r)}$, $\theta_{t}^{(r)}, \theta_{l}^{\prime}$ ' $\theta_{t}^{\prime}$, may be readily related to $\theta^{(i)}$ by the "kinematic" condition that the incident wave, as well as

[^113]the reflected and refracted waves of both types should have the same spatial distribution along the interface plane, i.e. for the material particles participating in all five waves. According to Eq. (110), the necessary boundary condition is the equality of the tangential components (in Fig. 12, $k_{x}$ ), of all five wave vectors:
\[

$$
\begin{equation*}
k_{t} \sin \theta_{t}^{(r)}=k_{l} \sin \theta_{l}^{(r)}=k_{l}^{\prime} \sin \theta_{l}^{\prime}=k_{t}^{\prime} \sin \theta_{t}^{\prime}=k_{x} \equiv k_{t} \sin \theta_{t}^{(i)} . \tag{7.127}
\end{equation*}
$$

\]

Since the acoustic wave vectors, at fixed frequency, are inversely proportional to the corresponding wave velocities, we immediately get the following relations:

$$
\begin{equation*}
\theta_{t}^{(r)}=\theta_{t}^{(i)}, \quad \frac{\sin \theta_{l}^{(r)}}{v_{l}}=\frac{\sin \theta_{l}^{\prime}}{v_{l}^{\prime}}=\frac{\sin \theta_{t}^{\prime}}{v_{t}^{\prime}}=\frac{\sin \theta_{t}^{(i)}}{v_{t}} \tag{7.128}
\end{equation*}
$$

so that generally all 4 angles are different. (In optics, the latter relation, reduced to just one equality for the only possible, transverse waves, is known as the Snell law.) These relations show that, just like in optics, the direction of a wave propagating into a medium with lower velocity is closer to the normal (axis $z$ ). In particular, this means that if $v^{\prime}>v$, the acoustic waves, at larger angles of incidence, may exhibit the effect of total internal reflection, so well known from optics ${ }^{35}$, when the refracted wave vanishes. In addition, Eqs. (128) show that in acoustics, a reflected longitudinal wave, with velocity $v_{l}>$ $v_{t}$, may vanish at sufficiently large angles of transverse wave incidence.

Fig. 7.12. "Kinematic" condition of acoustic wave reflection and refraction.

All these fact automatically follow from general expressions for amplitudes of the reflected and refracted waves via the amplitude of the incident wave. These relations are straightforward to derive (again, from the continuity of vectors $\mathbf{q}$ and $d \mathbf{F}$ ), but since they are much more bulky then those in the electromagnetic wave theory (where they are called the Fresnel formulas ${ }^{36}$ ), I would not have time/space for spelling them up. Let me only note that, in contrast to the case of normal incidence, these relations involve 8 media parameters: the values of impedances $Z, Z^{\prime}$, and velocities $v, v$ ' on both sides of the interface, and for both the longitudinal and transverse waves.

There is another factor that makes boundary acoustic effects more complex. Within certain frequency ranges, interfaces (and in particular surfaces) of elastic solids may sustain so-called surface

[^114]acoustic waves (SAW), in particular, the Rayleigh waves and Love waves. ${ }^{37}$ The main feature that distinguishes such waves from their bulk (longitudinal and transverse) counterparts is that the particle displacement amplitude is maximal at the interface and decays exponentially into the bulk of both adjacent media. The characteristic depth of this penetration is of the order of, though not exactly equal to the wavelength.

In the Rayleigh waves, the particle displacement vector $\mathbf{q}$ has two components: one longitudinal (and hence parallel to the interface along which the wave propagates) and another transverse (perpendicular to the interface). In contrast to the bulk waves discussed above, the components are coupled (via their interaction with the interface) and as a result propagate with a single velocity $v_{\mathrm{R}}$. As a result, the trajectory of each particle in the Rayleigh wave is an ellipse in the plane perpendicular to the interface. A straightforward analysis ${ }^{38}$ of the Rayleigh waves on the surface of an elastic solid (i.e. its interface with vacuum) yields the following equation for $v_{R}$ :

$$
\begin{equation*}
\left(2-\frac{v_{R}^{2}}{v_{t}^{2}}\right)^{4}=16\left(1-\frac{v_{R}^{2}}{v_{t}^{2}}\right)^{2}\left(1-\frac{v_{R}^{2}}{v_{l}^{2}}\right)^{2} . \tag{7.129}
\end{equation*}
$$

According to this formula, and Eqs. (114) and (118), for realistic materials with $0<\sigma<1 / 2$, the Rayleigh waves are slightly (by 4 to 13\%) slower than the bulk transverse waves - and hence substantially slower than the bulk longitudinal waves.

In contrast, the Love waves are purely transverse, with vector $\mathbf{q}$ oriented parallel to the interface. However, the interaction of these waves with the interface reduces their velocity $v_{\mathrm{L}}$ in comparison with that $\left(v_{t}\right)$ of the bulk transverse waves, keeping it in the narrow interval between $v_{t}$ and $v_{\mathrm{R}}$ :

$$
\begin{equation*}
v_{\mathrm{R}}<v_{\mathrm{L}}<v_{t}<v_{l} \tag{7.130}
\end{equation*}
$$

The practical importance of surface acoustic waves is that their amplitude decays very slowly with distance $r$ from their point-like source: $a \propto 1 / r^{1 / 2}$, while any bulk waves decay much faster, as $a \propto$ $1 / r$. (Indeed, in the latter case power $\mathcal{P} \propto a^{2}$, emitted by such source, is distributed over a spherical surface area proportional to $r^{2}$, while in the former case all the power goes into a thin surface circle whose length scales as $r$.) At least two areas of applications of the surface acoustic waves have to be mentioned: in geophysics (for earthquake detection and Earth crust seismology), and electronics (for signal processing, with a focus on frequency filtering). Unfortunately, I cannot dwell on these interesting topics and I have to refer the reader to special literature. ${ }^{39}$

### 7.8. Elastic waves in restricted geometries

From what we have discussed in the end of the last section, it should be pretty clear that generally the propagation of acoustic waves in elastic bodies of finite size may be very complicated. There is, however, one important limit in which several important results may be readily obtained. This is the limit of (relatively) low frequencies, where the wavelength is much larger than at least one

[^115]dimension of a system. Let us consider, for example, various waves that may propagate along thin rods, in this case "thin" meaning that the characteristic size $a$ of rod's cross-section is much smaller than not only the length of the rod, but also the wavelength $\lambda=2 \pi / k$. In this case there is a considerable range of distances $z$ along the rod,
\[

$$
\begin{equation*}
a \ll \Delta z \ll \lambda \tag{7.131}
\end{equation*}
$$

\]

in which we can neglect the dynamic effects due to medium inertia, and apply results of our earlier static analyses.

For example, for a longitudinal wave of stress, which is essentially a wave of periodic tensile extensions and compressions of the rod, within range (131) we can use the static relation (44):

$$
\begin{equation*}
\sigma_{z z}=E s_{z z} . \tag{7.132}
\end{equation*}
$$

For what follows, it is easier to use the general equation of elastic dynamics not in its vector form (109), but rather in the precursor, Cartesian-component form (25), with $f_{j}=0$. For plane waves propagating along axis $z$, only one component (with $j^{\prime} \rightarrow z$ ) of the sum in the right-hand part of this equation is nonvanishing, and it is reduced to

$$
\begin{equation*}
\rho \frac{\partial^{2} q_{j}}{\partial^{2} t^{2}}=\frac{\partial \sigma_{j z}}{\partial z} . \tag{7.133}
\end{equation*}
$$

In our current case of longitudinal waves, all components of the stress tensor but $\sigma_{z z}$ are equal to zero. With $\sigma_{z z}$ from Eq. (132), and using the definition $s_{z z}=\partial q_{z} / \partial z=\partial q_{z} / \partial z$, Eq. (133) is reduced to a very simple wave equation,

$$
\begin{equation*}
\rho \frac{\partial^{2} q_{z}}{\partial^{2} t^{2}}=E \frac{\partial^{2} q_{z}}{\partial z^{2}} \tag{7.134}
\end{equation*}
$$

which shows that the velocity of such tensile waves is

Tensile waves: velocity

$$
\begin{equation*}
v=\left(\frac{E}{\rho}\right)^{1 / 2} \tag{7.135}
\end{equation*}
$$

Comparing this result with Eq. (114), we see that the tensile wave velocity, for any medium with $\sigma>0$, is lower than the velocity $v_{l}$ of longitudinal waves in the bulk of the same material. The reason for this difference in simple: in thin rods, the cross-section is free to oscillate (e.g., shrink in the longitudinal extension phase of the passing wave), ${ }^{40}$ so that the effective force resisting the longitudinal deformation is smaller than in a border-free space. Since (as clearly visible from the wave equation), the scale of the force gives the scale of $v^{2}$, this difference translates into slower waves in rods. Of course as wave frequency is increased, at $k a \sim 1$ there is a (rather complex and cross-section-depending) crossover from Eq. (135) to Eq. (114).

Proceeding to transverse waves in rods, let us first have a look at long bending waves, with vector $\mathbf{q}=\mathbf{n}_{x} q_{x}$ (with axis $x$ along the bending direction - see Fig. 8) being approximately constant in the whole cross-section. In this case, the only component of the stress tensor contributing to the net transverse force $F_{x}$ is $\sigma_{x z}$, so that the integral of Eq. (133) over the cross-section is

[^116]\[

$$
\begin{equation*}
\rho A \frac{\partial^{2} q_{x}}{\partial t^{2}}=\frac{\partial F_{x}}{\partial z}, \quad F_{x}=\int_{A} \sigma_{x z} d A . \tag{7.136}
\end{equation*}
$$

\]

Now, if Eq. (131) is satisfied, we again may use static local relations (77)-(79), with all derivatives $d / d z$ duly replaced with their partial form $\partial / \partial z$, to express force $F_{x}$ via the bending deformation $q_{x}$. Plugging these relations into each other one by one, we arrive at a very unusual differential equation

$$
\begin{equation*}
\rho A \frac{\partial^{2} q_{x}}{\partial t^{2}}=-E I_{y} \frac{\partial^{4} q_{x}}{\partial z^{4}} . \tag{7.137}
\end{equation*}
$$

Looking for its solution in the form of a sinusoidal wave (110), we get a nonlinear dispersion relation: ${ }^{41}$

$$
\begin{equation*}
\omega=\left(\frac{E I_{y}}{\rho A}\right)^{1 / 2} k^{2} \tag{7.138}
\end{equation*}
$$

Such relation means that the bending waves are not acoustic at any frequency, and cannot be characterized by a single velocity that would be valid for all wave numbers $k$, i.e. for all spatial Fourier components of a waveform. According to our discussion in Sec. 5.3, such strongly dispersive systems cannot pass non-sinusoidal waveforms too far without changing their waveform very considerably.

This situation changes, however, if the rod has an initial uniform longitudinal stress $\sigma_{z z}=T / A$ (where force $T$ is usually called tension), on whose background the transverse waves propagate. To analyze its effect, let us redraw Fig. 6, for a minute neglecting the bending stress - see Fig. 13.

Fig. 7.13. Additional forces in a thin rod ("string"), due to background tension $T$.

Still sticking to the limit of small angles $\varphi$, the additional vertical component $d \tau_{x}$ of the net force acting on a small rod fragment of length $d z$ is $\tau_{x}(z-d z)-T_{x}(z)=T \varphi_{y}(z+d z)-T \varphi_{y}(z) \approx T\left(\partial \varphi_{y} / \partial z\right) d z$, so that $\partial F_{x} / \partial z=T\left(\partial \varphi_{y} / \partial z\right)$. With the geometric relation (79) in its partial-derivative form $\partial q_{x} / \partial z=\varphi_{y}$, this additional term becomes $T\left(\partial^{2} q_{x} / \partial z^{2}\right)$. Adding it to the right-hand part of into Eq. (137), we get the following dispersion relation

$$
\omega^{2}=\frac{1}{\rho A}\left(E I_{y} k^{4}+7 k^{2}\right)
$$

[^117]At low $k$ (and hence low frequencies), it describes acoustic waves with the "guitar string" velocity that should be well known to the reader from undergraduate courses:

$$
\begin{equation*}
v^{2}=\frac{T}{\rho A} \tag{7.140}
\end{equation*}
$$

where the denominator is nothing else than the linear mass density. However, as the frequency grows, Eq. (139) describes a crossover to highly-dispersive bending waves (138).

Now let us consider the so-called torsional waves that are essentially the dynamic propagation of the torsional deformation discussed in Sec. 6. The easiest way to describe these waves, again within the limits given by Eq. (131), is to write the equation of rotation of a small segment $d z$ of the rod about axis $z$, passing through the "center of mass" of its cross-section, under the difference of torques $\tau=\mathbf{n}_{z} \tau_{z}$ applied on its ends - see Fig. 10:

$$
\begin{equation*}
\rho I_{z} d z \frac{\partial^{2} \varphi_{z}}{\partial t^{2}}=d \tau_{z} \tag{7.141}
\end{equation*}
$$

where $I_{z}$ is the "moment of inertia" defined by Eq. (91), which now, after its multiplication by $\rho d z$, i.e. by the mass per unit area, has turned into the real moment of inertia of a $d z$-thick slice of the rod. Dividing both parts by $d z$, using the static local relation (86), $\tau_{z}=C \kappa=C\left(\partial \varphi_{z} / \partial z\right)$, we get the following differential equation

$$
\begin{equation*}
\rho I_{z} \frac{\partial^{2} \varphi_{z}}{\partial t^{2}}=C \frac{\partial^{2} \varphi_{z}}{\partial z^{2}} . \tag{7.142}
\end{equation*}
$$

Just as Eqs. (114), (118), (135) and (140), this equation describes an acoustic (dispersion-free) wave that propagates with frequency-independent velocity

Torsional waves: velocity

$$
\begin{equation*}
v=\left(\frac{C}{\rho I_{z}}\right)^{1 / 2} \tag{7.143}
\end{equation*}
$$

As we have seen in Sec. 6, for rods with axially-symmetric cross-sections, the torsional rigidity $C$ is described by the simple equation (91), $C=\mu I_{z}$, so that expression (143) is reduced to Eq. (118) for the transverse waves in infinite media. The reason for this similarity is simple: in a torsional wave, particles oscillate along small arcs (Fig. 14a), so that if the rod's cross-section is round, the stress-free surface does not perturb or modify the motion in any way, and hence does not affect the transverse velocity.

(b)

Fig. 7.14. Particle trajectories in two different transverse waves with the same velocity: (a) torsional waves in a thin round rod and (b) circularly-polarized waves in an infinite (or very broad) sample.

This fact raises an interesting issue of the relation between the torsional and circularly-polarized waves. Indeed, in Sec. 7, I have not emphasized enough that Eq. (118) is valid for a transverse wave polarized in any direction perpendicular to vector $\mathbf{k}$ (in our notation, directed along axis $z$ ). In particular, this means that such waves are doubly-degenerate: any isotropic elastic medium can carry simultaneously two non-interacting transverse waves propagating in the same direction with the same velocity (118), with mutually perpendicular linear polarizations (directions of vector a), for example, directed along axes $x$ and $y$. If both waves are sinusoidal (110), with the same frequency, each point of the medium participates in two simultaneous sinusoidal motions within the $[x, y]$ plane:

$$
\begin{equation*}
q_{x}=\operatorname{Re}\left[a_{x} e^{i(k z-\omega t)}\right]=A_{x} \cos \Psi, \quad q_{y}=\operatorname{Re}\left[a_{y} e^{i(k z-\omega t)}\right]=A_{y} \cos (\Psi+\varphi), \tag{7.144}
\end{equation*}
$$

where $\Psi \equiv k z-\omega t+\varphi_{x}$, and $\varphi \equiv \varphi_{y}-\varphi_{x}$. Trigonometry tells us that the trajectory of such motion on the $[x, y]$ plane is an ellipse (Fig. 15), so that such waves are called elliptically-polarized. The most important particular cases of such polarization are:
(i) $\varphi=0$ or $\pi$. a linearly-polarized wave, with vector a turned by angle $\theta=\tan ^{-1}\left(A_{y} / A_{x}\right)$ from axis $x$; and
(ii) $\varphi= \pm \pi / 2$ and $A_{x}=A_{y}$ : circularly polarized waves, with the right or left polarization, respectively.

The circularly polarized waves play an important role in quantum mechanics, where such waves may be most naturally quantized, with elementary excitations (in the case of mechanical waves we are discussing, called phonons) having either positive or negative angular momentum $L_{z}= \pm \hbar$.

Now comparing the trajectories of particles in the torsional wave in a thin round rod (or pipe) and the circularly-polarized wave in a broad sample (Fig. 14), we see that, despite the same wave propagation velocity, these transverse waves are rather different. In the former case (Fig. 14a) each particle moves back and forth along an arc, with the arc length different for different particles (and vanishing at rod's center). On the other hand, in a circularly-polarized, plane wave all particles move along similar, circular trajectories.

Fig. 7.15. Trajectory of a particle of an infinite medium with elliptically-polarized transverse wave, within the plane perpendicular to the direction of wave propagation.

In conclusion, let me briefly mention the opposite limit, when the size of the body, from whose boundary are completely reflected, ${ }^{42}$ is much larger than the wavelength. In this case, the waves

[^118]propagate almost as in an infinite 3D medium (Sec. 7), and the most important new effect is the finite numbers of wave modes in the body. Repeating 1D analysis of Sec. 5.4 for each dimension of a 3D cuboid of volume $V=L_{1} L_{2} L_{3}$ (for example, using the Born-Karman boundary conditions in each dimension), we obtain Eq. (5.59) for the spectrum of components of wave vector $\mathbf{k}$ along each side. This means that all possible wave vectors are located in nodes of a rectangular 3D mesh with steps $2 \pi / L_{j}$ in each direction, and hence with the $k$-space ("reciprocal space") volume

Reciprocal volume per wave vector

$$
\begin{equation*}
V_{k}=\frac{2 \pi}{L_{1}} \frac{2 \pi}{L_{2}} \frac{2 \pi}{L_{3}}=\frac{(2 \pi)^{3}}{V} \tag{7.145}
\end{equation*}
$$

per each vector. It is possible (though not quite as straightforward as it is sometimes assumed) to prove that this relation is valid regardless of the shape of volume $V$. Hence the number of different wave vectors within the reciprocal space volume $d^{3} k \gg V_{k}$ is

$$
\begin{equation*}
d N=\frac{d^{3} k}{V_{k}}=\frac{V}{(2 \pi)^{3}} d^{3} k \gg 1 \tag{7.146a}
\end{equation*}
$$

In quantum mechanics, this relation takes the form of the density of quantum states in $k$-space:

$$
\begin{equation*}
g_{k} \equiv g \frac{d N}{d^{3} k}=\frac{g V}{(2 \pi)^{3}} \tag{7.146b}
\end{equation*}
$$

where $g$ is the number of possible different quantum states with the same de Broglie wave vector $\mathbf{k}$. In this form, Eq. (146) is ubiquitous in physics. ${ }^{43}$ For phonons, formed from quantization of one longitudinal mode, and two transverse modes with different polarizations, $g=3$.

### 7.9. Exercise problems

7.1. A uniform thin sheet of an isotropic, elastic material is compressed, along its thickness $t$, by two plane, parallel, broad (of area $A \gg t^{2}$ ) rigid surfaces - see Fig. on the right. Assuming no slippage between the sheet and the surfaces, calculate the relative compression ($\Delta t / t)$ as a function of the compressing force. Compare the result with
 that for the tensile stress, given by Eq. (47).
7.2. A thin, wide sheet of an isotropic, elastic material is clamped in two rigid, plane, parallel surfaces that are pulled apart with force $F$. Find the relative extension $\Delta L / L$ of the sheet in the direction of the force, and its relative compression $\Delta t / t$ in the perpendicular direction, and compare the results with Eqs. (47)-(48) for the tensile stress, and the solution of Problem 1.
the impedance of a longitudinal wave in a typical metal (say, steel) is almost two orders of magnitude higher than that in air, ensuring their virtually full reflection from the surface.
${ }^{43}$ See, e.g., EM Secs. 7.7 and 7.9, and QM Sec. 1.5.
7.3. Calculate the radial extension $\Delta R$ of a thin, long, round cylindrical pipe under the effect of its rotation with a constant angular velocity $\omega$ about its symmetry axis (see Fig. on the right), in terms of the elastic moduli $E$ and $\nu$, assuming that pressure both inside and outside the pipe is negligible.

7.4. A long, uniform rail with the cross-section shown in Fig. on the right, is being bent with the same (small) torque twice: first within plane $x z$ and then within plane $y z$. Assuming that $t \ll L$, find the ratio of rail deformations in these two cases.

7.5. Two thin rods of the same length and mass have been made of the same elastic, isotropic material. The crosssection of one of them is a circle, while another one is an equilateral triangle - see Fig. on the right. Which of the rods is more stiff for bending along its length? Quantify the relation. Does the result depend on the bending plane
 orientation?
7.6. A thin, elastic, uniform, initially straight beam is placed on two point supports at the same height - see Fig. on the right. What support point placement minimizes the largest deviation of the beam from the horizontal line, under its own weight?
7.7. Calculate the largest compression force $T$ that may be withstood by a thin, straight, elastic rod without bucking (see Figs. on the right) for two shown cases:
(i) rod's ends are clamped, and
(ii) the rod it free to rotate about the support points.
(i)

(ii)

7.8. Calculate the potential energy of a small and slowly changing, but otherwise arbitrary bending deformation of a uniform, elastic, initially straight rod. Can the result be used to derive the dispersion relation (7.138)?
7.9.* Calculate the spring constant $d F / d L$ of a coil spring made of a uniform, elastic wire, with circular crosssection of diameter $d$, wound as a dense round spiral of $N$ $\gg 1$ turns of diameter $D \gg d$ - see Fig. on the right. Comment on the type of material's deformation.

7.10. The coil discussed in Problem 9 is now used as what is sometimes called the torsion spring - see Fig. on the right. Find the corresponding spring constant $d \tau / d \varphi$, where $\tau$ is the torque of external forces $\mathbf{F}$ relative the center of the coil (point $O$ ).

7.11. Use Eqs. (101) and (102) to recast Eq. (103b) for the torsional rigidity $C$ into the form given by Eq. (103c).
7.12. ${ }^{*}$ Generalize Eq. (103b) to the case of rods with more than one cross-section boundary. Use the result to calculate the torsional rigidity of a thin round pipe, and compare it with Eq. (93).
7.13. Calculate the potential energy of a small but otherwise arbitrary torsional deformation $\varphi_{z}(z)$ of a uniform, straight, elastic rod.
7.14. A steel wire with the circular cross-section of a $3-\mathrm{mm}$ diameter is stretched with a constant force of 10 N and excited at frequency 1 kHz by an actuator that excites all modes of longitudinal and transverse waves. Which wave has the highest group velocity? Accept the following parameters for steel (see Table 7.1): $E=170 \mathrm{GPa}, \sigma=0.30, \rho=7.8 \mathrm{~g} / \mathrm{cm}^{3}$.
7.15. Define and calculate appropriate wave impedances for (i) tensile and (ii) torsional waves in a thin rod. Use the results to calculate what fraction of each wave's power is reflected from the connection of a long rod with round cross-section to a similar rod, but with twice larger diameter - see Fig.
 on the right.

## Chapter 8. Fluid Mechanics

This chapter describes the basic notions of mechanics of fluids, discusses a few core problems of statics and dynamics of ideal and viscous fluids, and gives a very brief review of such a complex phenomenon as turbulence. Also, the viscous fluid flow is used to give an elementary introduction to numerical methods of partial differential equation solution - whose importance extends well beyond this particular field.

### 8.1. Hydrostatics

The mechanics of fluids (the class of materials that includes both liquids and gases) is both more simple and more complex than that of the elastic solids, with the simplicity falling squarely to the domain of statics - often called hydrostatics, because water has always been the main fluid for the human race and hence for science and engineering. Indeed, fluids are, by definition, the media that cannot resist static shear deformations. There are two ways to express this fact. First, we can formally take the shear modulus $\mu$, describing this resistance, to be equal zero. Then the Hooke's law (7.34) shows that the stress tensor is diagonal:

$$
\begin{equation*}
\sigma_{i j^{\prime}}=\delta_{j j^{\prime}} \sigma_{i j} . \tag{8.1}
\end{equation*}
$$

Alternatively, the same conclusion may be reached by looking at the stress tensor definition (7.19) and saying that in the absence of shear stress, the elementary interface $d \mathbf{F}$ has to be perpendicular to the area element $d A$, i.e. parallel to vector $d \mathbf{A}$.

Moreover, in fluids at equilibrium, all three diagonal components $\sigma_{j j}$ of the stress tensor have to be equal. To prove that, it is sufficient to single out (mentally rather than physically) from a fluid a small volume in the shape of a right prism, with mutually perpendicular faces normal to the two directions we are interested in (Fig. 1, along axes $x$ and $y$ ).

The prism is in equilibrium if each Cartesian component of the total force acting on all its faces nets to zero. For the $x$-component this balance is $\sigma_{x x} d A_{x}-\left(\sigma_{\alpha \alpha} d A\right) \cos \alpha=0$. However, from the geometry (Fig. 1), $d A_{x}=d A \cos \alpha$, and the above balance condition yields $\sigma_{\alpha \alpha}=\sigma_{x x}$. A similar argument for the vertical forces gives $\sigma_{\alpha \alpha}=\sigma_{y y}$, so that $\sigma_{x x}=\sigma_{y y}$. Since such equality holds for any pair of diagonal components of the stress tensor, $\sigma_{j j}$, all three of them have to be equal. This common component is usually represented as $(-P)$, because in the vast majority of cases, parameter $P$, called pressure, is positive. Thus we arrive at the key relation (which has already been mentioned in Ch .7 ):

$$
\begin{equation*}
\sigma_{i j^{\prime}}=-P \delta_{i j^{\prime}} \tag{8.2}
\end{equation*}
$$

In the absence of bulk forces, pressure should be constant through the volume of fluid, due to symmetry. Let us see how this result is affected by bulk forces. With the simple stress tensor (2), the general condition of equilibrium of a continuous medium, expressed by Eq. (7.25) with zero left-hand part, becomes just

$$
\begin{equation*}
-\frac{\partial P}{\partial r_{j}}+f_{j}=0 \tag{8.3}
\end{equation*}
$$

and may be re-written in a convenient vector form:

$$
\begin{equation*}
-\nabla P+\mathbf{f}=0 \tag{8.4}
\end{equation*}
$$

In the simplest case of a heavy fluid, with mass density $\rho$, in a uniform gravity field, $\mathbf{f}=\rho \mathbf{g}$, and the equation of equilibrium becomes,

$$
\begin{equation*}
-\nabla P+\rho \mathbf{g}=0 \tag{8.5}
\end{equation*}
$$

with only one nonvanishing component (vertical, near the Earth surface). If, in addition, the fluid may be considered incompressible, with its density $\rho$ constant, ${ }^{1}$ this equation may be readily integrated to give the so-called Pascal equation: ${ }^{2}$

$$
\begin{equation*}
P+\rho g y=\text { const } \tag{8.6}
\end{equation*}
$$

where $y$ is the vertical coordinate, with the direction opposite to that of vector $\mathbf{g}$.
Let me hope that this equation, and its simple applications (including buoyant force calculations using the Archimedes principle), are well familiar to the reader from his or her undergraduate physics courses, so that I may save time by skipping their discussion. I would only like to note, that the integration of Eq. (4) may be more complex in the case if the bulk forces $\mathbf{f}$ depend on position, ${ }^{3}$ and/or if the fluid is substantially compressible. In the latter case, Eq. (4) should be solved together with the media-specific equation of state $\rho=\rho(P)$ describing the compressibility law - whose example is given by Eq. (7.40) for ideal gases: $\rho \equiv m N / V=m P / k_{\mathrm{B}} T$, where $m$ is the mass of one gas molecule.

### 8.2. Surface tension effects

Besides the bulk (volume-distributed) forces, one more possible source of pressure is surface tension. This effect results from the difference between the potential energy of atomic interactions on the interface between two different fluids and that in their bulks, and thus may be described by an additional potential energy

$$
\begin{equation*}
U_{i}=\gamma A, \tag{8.7}
\end{equation*}
$$

[^119]where $A$ is the interface area, and $\gamma$ is called the surface tension constant (or just the "surface tension"), evidently of the dimensionality of $\mathrm{J} / \mathrm{m}^{2}$, i.e. $\mathrm{N} / \mathrm{m}$. For a stable interface of any two fluids, $\gamma$ is always positive. ${ }^{4}$ In the absence of other forces, the surface tension makes a liquid drop spherical to minimize its surface area at fixed volume.

For the analysis of the surface tension effects in the presence of other forces, it is convenient to reduce it to a certain additional effective pressure drop $\Delta P_{\text {ef }}$ at the interface. In order to calculate $\Delta P_{\text {ef }}$, let us consider the condition of equilibrium of a small part $d A$ of a smooth interface between two fluids (Fig. 2), in the absence of bulk forces.

Fig. 8.2. Deriving the Young-Laplace formula (10).

If pressures $P_{1,2}$ on two sides of the interface are different, the work of stress forces on fluid 1 at a small virtual displacement $\delta \mathbf{r}=\mathbf{n} \delta r$ of the interface (where $\mathbf{n}=d \mathbf{A} / d A$ is the unit vector normal to the interface) equals ${ }^{5}$

$$
\begin{equation*}
\delta W=d A \delta r\left(P_{1}-P_{2}\right) . \tag{8.8}
\end{equation*}
$$

For equilibrium, this work has to be compensated by an equal change of the interface energy, $\delta U_{i}=$ $\gamma \delta(d A)$. Differential geometry tells us that in the linear approximation in $\delta r$, the relative change of the elementary surface area, corresponding to a fixed solid angle $d \Omega$, may be expressed as

$$
\begin{equation*}
\frac{\delta(d A)}{d A}=\frac{\delta r}{R_{1}}+\frac{\delta r}{R_{2}} \tag{8.9}
\end{equation*}
$$

where $R_{1,2}$ are the so-called principal radii of the interface curvature. ${ }^{6}$ Combining Eqs. (7)-(9), we get the Young-Laplace formula ${ }^{7}$

[^120]\[

$$
\begin{equation*}
P_{1}-P_{2}=\Delta P_{\mathrm{ef}} \equiv \gamma\left(\frac{1}{R_{1}}+\frac{1}{R_{2}}\right) . \tag{8.10}
\end{equation*}
$$

\]

In particular, this formula shows that the additional pressure created by surface tension inside a spherical drop of a liquid, of radius $R$, equals $2 \gamma / R$, i.e. decreases with $R$. In contrast, according to Eqs. (5)-(6), the effects of bulk forces, for example gravity, grow as $\rho g R$. The comparison of these two pressure components shows that if the drop radius (or more generally, the characteristic linear size of a fluid sample) is much larger than the so-called capillary length

$$
\begin{equation*}
a_{c} \equiv\left(\frac{2 \gamma}{\rho g}\right)^{1 / 2} \tag{8.11}
\end{equation*}
$$

the surface tension may be safely ignored - as will be done in the following sections of this chapter, besides a brief discussion of Eq. (48). For the water surface, or more exactly its interface with air at ambient conditions, $\gamma \approx 0.073 \mathrm{~N} / \mathrm{m}$, while $\rho \approx 1,000 \mathrm{~kg} / \mathrm{m}^{3}$, so that $a_{c} \approx 4 \mathrm{~mm}$.

On the other hand, in very narrow tubes, such as blood capillary vessels with radius $a \sim 1 \mu \mathrm{~m}$, i.e. $a \ll a_{c}$, the surface tension effects are very important. The key notion for the analysis of these effects is the equilibrium contact angle $\theta_{\mathrm{c}}$ (also called the "wetting angle") at the edge of a liquid wetting a solid - see Fig. 3.

Fig. 8.5. Contact angles for (a) hydrophilic and (b) hydrophobic surfaces.

According to its definition (7), constant $\gamma$ may be interpreted as a force (per unit length of the interface boundary) directed along the interface and trying to reduce its area. As a result, the balance of horizontal components of the three such forces, shown in Fig. 3, immediately yields

$$
\begin{equation*}
\gamma_{\mathrm{sl}}+\gamma_{\mathrm{lg}} \cos \theta_{\mathrm{c}}=\gamma_{\mathrm{sg}}, \tag{8.12}
\end{equation*}
$$

where the indices at constants $\gamma$ correspond to three possible interfaces between the liquid, solid and gas. For the so-called hydrophilic surfaces that "like to be wet" by this particular liquid (not necessarily water), meaning that $\gamma_{\mathrm{sl}}<\gamma_{\mathrm{sg}}$, this relation yields $\cos \theta_{\mathrm{c}}>0$, i.e. $\theta_{\mathrm{c}}<\pi / 2-$ the situation shown in Fig. 3a. On the other hand, for hydrophobic surfaces with $\gamma_{\mathrm{sl}}>\gamma_{\mathrm{sg}}$, Young's equation (12) yields larger contact angles, $\theta_{\mathrm{c}}>\pi / 2-$ see Fig. 3b.

Let us use this notion to solve the simplest but perhaps the most important problem of this field find the height $h$ of the fluid column in a narrow vertical tube made of a hydrophilic material, lifted by the surface tension forces, assuming its internal surface to be a round cylinder of radius $a-$ see Fig. 4. Inside an incompressible fluid, pressure drops with height according to the Pascal equation (6), so that just below the surface, $P \approx P_{0}-\rho g h$, where $P_{0}$ is the background (e.g., atmospheric) pressure. This means that at $a \ll h$ the pressure variation along the concave surface (called the meniscus) of the liquid
is negligible, so that according to the Young-Poisson equation (10) the sum $\left(1 / R_{1}+1 / R_{2}\right)$ has to be virtually constant along the surface. Due to the axial symmetry of the problem, this means that the surface has to be a part of a sphere. ${ }^{8}$ From the contact angle definition, radius $R$ of the sphere is equal to $a / \cos \theta_{\mathrm{c}}-$ see Fig. 4.

Fig. 8.4. Liquid rise in a vertical capillary tube.

Plugging this relation into Eq. (10) with $P_{1}-P_{2}=\rho g h$, we get the following equation for $h$ :

$$
\begin{equation*}
\rho g h=\frac{2 \gamma \cos \theta_{\mathrm{c}}}{a} . \tag{8.13a}
\end{equation*}
$$

In hindsight, this result might be obtained more directly - by requiring the total weight $\rho g V=\rho g\left(\pi a^{2} h\right)$ of the lifted liquid's column to be equal to the vertical component $F \cos \theta_{\mathrm{c}}$ of the full surface tension force $F=\gamma p$ acting on the perimeter $p=2 \pi a$ of the meniscus. Using the definition (11) of the capillary length $a_{c}$, Eq. (13a) may be presented as the so-called Jurin rule:

$$
\begin{equation*}
h=\frac{a_{c}^{2}}{a} \cos \theta_{\mathrm{c}} \leq \frac{a_{c}^{2}}{a} \tag{8.13b}
\end{equation*}
$$

according to our initial assumption $h \gg a$, Eq. (13) is only valid for narrow tubes, with radius $a \ll a_{c}$. This capillary rise is the basic mechanism of lifting water with nutrients from roots to the branches and leaves of plants, so that the tallest tree height is practically established by the Jurin rule (13), with $\cos \theta_{c}$ $\approx 1$ and the pore radius $a$ limited from below by a few microns, because of the viscosity effects restricting the fluid discharge - see Sec. 5 below and in particular the Poiseuille formula (60).

### 8.3. Kinematics

In contrast to the stress tensor, which is useful and simple - see Eq. (2), the strain tensor is not a very useful notion in fluid mechanics. Indeed, besides a very few situations, ${ }^{9}$ typical problems of this field involve fluid flow, i.e. a state when velocity of fluid particles has some nonzero time average. This means that the trajectory of each individual particle is a long line, and the notion of its displacement $\mathbf{q}$

[^121]becomes impracticable. However, particle's velocity $\mathbf{v} \equiv d \mathbf{q} / d t$ is a much more useful notion, especially if it is considered as a function the observation point $\mathbf{r}$ and (generally) time $t$. In an important class of fluid dynamics problem, the so-called stationary (or "steady", or "static") flow, the velocity defined in this way does not depend on time, $\mathbf{v}=\mathbf{v}(\mathbf{r})$.

There is, however, a price to pay for the convenience of this notion: namely, due to the difference between vectors $\mathbf{q}$ and $\mathbf{r}$, particle's acceleration $\mathbf{a}=d^{2} \mathbf{q} / d t^{2}$ (that participates, in particular, in the $2^{\text {nd }}$ Newton law) cannot be calculated just as a time derivative of velocity $\mathbf{v}(\mathbf{r}, t)$. This fact is evident, for example, for the static flow case, in which the acceleration of individual fluid particles may be very significant even if $\mathbf{v}(\mathbf{r})$ does not depend on time - just think about the acceleration of a drop of water flowing over the Niagara Falls rim, first accelerating fast and then virtually stopping below, while the water velocity $\mathbf{v}$ at every particular point, as measured from a bank-based reference frame, is nearly constant. Thus the main task of fluid kinematics is to express a via $\mathbf{v}(\mathbf{r}, t)$; let us do this.

Since each Cartesian component $v_{j}$ of the velocity has to be considered as a function of four independent scalar variables, three Cartesian components $r_{j^{\prime}}$ of vector $\mathbf{r}$ and time $t$, its full time derivative may be presented as

$$
\begin{equation*}
\frac{d v_{j}}{d t}=\frac{\partial v_{j}}{\partial t}+\sum_{j^{\prime}=1}^{3} \frac{\partial v_{j}}{\partial r_{j^{\prime}}} \frac{d r_{j^{\prime}}}{d t} \tag{8.14}
\end{equation*}
$$

Let us apply this general relation to a specific set of infinitesimal changes $\left\{d r_{1}, d r_{2}, d r_{3}\right\}$ that follows a small displacement $d \mathbf{q}$ of a certain particular particle of the fluid, $d \mathbf{r}=d \mathbf{q}=\mathbf{v} d t$, i.e.

$$
\begin{equation*}
d r_{j}=v_{j} d t \tag{8.15}
\end{equation*}
$$

In this case $d v_{j} / d t$ is the $j$-th component $a_{j}$ of the particle's acceleration a, so that Eq. (14) yields the following key relation of fluid kinematics:

$$
\begin{equation*}
a_{j}=\frac{\partial v_{j}}{\partial t}+\sum_{j^{\prime}=1}^{3} v_{j^{\prime}} \frac{\partial v_{j}}{\partial r_{j^{\prime}}} \tag{8.16a}
\end{equation*}
$$

Using operator $\nabla$, this result may be rewritten in the following compact vector form: ${ }^{10}$

$$
\begin{equation*}
\mathbf{a}=\frac{\partial \mathbf{v}}{\partial t}+(\mathbf{v} \cdot \nabla) \mathbf{v} \tag{8.16b}
\end{equation*}
$$

This relation already signals the main technical problem of the fluid dynamics: many equations involving particle's acceleration are nonlinear in velocity, excluding such a powerful tool the linear superposition principle from the applicable mathematical arsenal.

One more basic relation of the fluid kinematics is the so-called continuity equation, which is essentially just the differential version of the mass conservation law. Let us mark, inside a fluid flow, an arbitrary volume $V$ limited by stationary (time-independent) surface $S$. The total mass of the fluid inside the volume may change only due to its flow though the boundary:

[^122]\[

$$
\begin{equation*}
\frac{d M}{d t} \equiv \frac{d}{d t} \int_{V} \rho d^{3} r=-\int_{S} \rho v_{n} d^{2} r \equiv-\int_{S} \rho \mathbf{v} \cdot d \mathbf{A}, \tag{8.17a}
\end{equation*}
$$

\]

where the elementary area vector $d \mathbf{A}$ is defined just as in Sec. 7.2 - see Fig. 5.

Fig. 8.5. Deriving the continuity equation.

Using the same the same divergence theorem that has been used several times in this course, ${ }^{11}$ the surface integral in Eq. (17a) may be transformed into the integral of $\nabla(\rho \mathbf{v})$ over volume $V$, so that this relation may be rewritten as

$$
\begin{equation*}
\int_{V}\left(\frac{\partial \rho}{\partial t}+\nabla \cdot \mathbf{j}\right) d^{3} r=0 \tag{8.17b}
\end{equation*}
$$

where vector $\mathbf{j} \equiv \rho \mathbf{v}$ defined is called either the mass flux density or the mass current. Since Eq. (17b) is valid for an arbitrary volume, the function under the integral has to vanish at any point:

$$
\begin{equation*}
\frac{\partial \rho}{\partial t}+\nabla \cdot \mathbf{j}=0 \tag{8.18}
\end{equation*}
$$

Note that such continuity equation is valid not only for mass, but for other conserved physics quantities (e.g., the electric charge, quantum-mechanical probability, etc.), with the proper re-definition of $\rho$ and $\mathbf{j} .{ }^{12}$

### 8.4. Dynamics: Ideal fluids

Let us start our discussion of fluid dynamics from the simplest case when the stress tensor obeys the simple expression (2) even at the fluid motion. Physically, this means that fluid viscosity effects, including mechanical energy loss, are negligible. (We will discuss the conditions of this assumption in the next section.) Then the equation of motion of such an ideal fluid (essentially the $2^{\text {nd }}$ Newton law for its unit volume) may be obtained from Eq. (7.25) using the simplifications of its right-hand part, discussed in Sec. 1:

$$
\begin{equation*}
\rho \mathbf{a}=-\nabla P+\mathbf{f} . \tag{8.19}
\end{equation*}
$$

Now using the basic kinematic relation (16), we arrive at the following Euler equation: ${ }^{13}$

[^123]\[

$$
\begin{equation*}
\rho \frac{\partial \mathbf{v}}{\partial t}+\rho(\mathbf{v} \cdot \nabla) \mathbf{v}=-\nabla P+\mathbf{f} \tag{8.20}
\end{equation*}
$$

\]

Generally this equation has to be solved together with the continuity equation (11) and equation of state of the particular fluid, $\rho=\rho(P)$. However, as we have already discussed, in many situations the compressibility of water and other important fluids is very low and may be ignored, so that $\rho$ may be treated as a given constant. Moreover, in many cases the bulk forces $\mathbf{f}$ are conservative and may be presented as a gradient of a certain potential function $u(\mathbf{r})$ - the potential energy per unit volume:

$$
\begin{equation*}
\mathbf{f}=-\nabla u \tag{8.21}
\end{equation*}
$$

for example, for a uniform gravity field, $u=\rho g h$. In this case the right-hand part of Eq. (20) becomes $\nabla(P+u)$. For these cases, it is beneficial to recast the left-hand of that equation as well, using the following well-know identity of vector algebra ${ }^{14}$

$$
\begin{equation*}
(\mathbf{v} \cdot \nabla) \mathbf{v}=\nabla\left(\frac{v^{2}}{2}\right)-\mathbf{v} \times(\nabla \times \mathbf{v}) \tag{8.22}
\end{equation*}
$$

As a result, the Euler equation takes the form

$$
\begin{equation*}
\rho \frac{\partial \mathbf{v}}{\partial t}-\rho \mathbf{v} \times(\nabla \times \mathbf{v})+\nabla\left(P+u+\rho \frac{v^{2}}{2}\right)=0 . \tag{8.23}
\end{equation*}
$$

In a stationary flow, the first term of this equation vanishes. If the second term, describing fluid's vorticity, is zero as well, then Eq. (23) has the first integral of motion,

$$
\begin{equation*}
P+u+\frac{\rho}{2} v^{2}=\text { const } \tag{8.24}
\end{equation*}
$$

called the Bernoulli equation. Numerous examples of application of Eq. (24) to simple problems of stationary flow in pipes, in the Earth gravity field (giving $u=\rho g h$ ), should be well known to the reader, so I hope I can skip their discussion without much harm.

In the general case an ideal fluid may have vorticity, so that Eq. (24) is not always valid. Moreover, due to absence of viscosity in an ideal fluid, the vorticity, once created, does not decrease along the streamline - the fluid particle's trajectory, to which the velocity is tangential in every point. ${ }^{15}$ Mathematically, this fact ${ }^{16}$ is expressed by the following Kelvin theorem: $(\nabla \times \mathbf{v}) \cdot d \mathbf{A}=$ const along any small contiguous group of streamlines crossing an elementary area $d A .{ }^{17}$

In many important cases the vorticity of fluid is negligible. For example, if a solid body of arbitrary shape is embedded into an ideal fluid that is uniform (meaning, by definition, that $\mathbf{v}(\mathbf{r}, t)=\mathbf{v}_{0}=$

[^124]const) at large distances, its vorticity is zero everywhere. (Indeed, since $\nabla \times \mathbf{v}$ at the uniform flow, the vorticity is zero at distant points of any streamline, and according to the Kelvin theorem, should equal zero everywhere.) In this case the velocity, as any curl-free vector field, may be presented as a gradient of some effective potential function,
\[

$$
\begin{equation*}
\mathbf{v}=-\nabla \phi \tag{8.25}
\end{equation*}
$$

\]

Such potential flow may be described by a simple differential equation. Indeed, the continuity equation (18) for a steady flow of an incompressible fluid is reduced to $\nabla \cdot \mathbf{v}=0$. Plugging Eq. (25) into this relation, we get the scalar Laplace equation,

$$
\begin{equation*}
\nabla^{2} \phi=0 \tag{8.26}
\end{equation*}
$$

which should be solved with appropriate boundary conditions. For example, the fluid flow may be limited by solid bodies inside which that the fluid cannot penetrate. Then the fluid velocity at these boundaries should not have a normal component:

$$
\begin{equation*}
\frac{\partial \phi}{\partial n}=0 . \tag{8.27}
\end{equation*}
$$

On the other hand, at large distances from the body in question the fluid flow is known, e.g., uniform:

$$
\begin{equation*}
\nabla \phi=-\mathbf{v}_{0}, \quad \text { at } r \rightarrow \infty . \tag{8.28}
\end{equation*}
$$

As the reader may already know (for example, from a course of electrodynamics ${ }^{18}$ ), the Laplace equation (26) is readily solvable analytically in several simple (symmetric) but important situations. Let us consider, for example, the case of a round cylinder, with radius $R$, immersed into a flow with the initial velocity $\mathbf{v}_{0}$ perpendicular to the cylinder axis (Fig. 6). ${ }^{19}$

For this problem, it is natural to use cylindrical coordinates with axis $z$ parallel to cylinder's axis. In this case the velocity distribution is evidently independent of $z$, so that we may simplify the general expression of the Laplace operator in cylindrical coordinates ${ }^{20}$ by taking $\partial / \partial \mathrm{z}=0$. As a result, Eq. (26) is reduced to ${ }^{21}$

$$
\begin{equation*}
\frac{1}{\rho} \frac{\partial}{\partial \rho}\left(\rho \frac{\partial \phi}{\partial r}\right)+\frac{1}{\rho^{2}} \frac{\partial^{2} \phi}{\partial \theta^{2}}=0, \quad \text { at } \rho \geq R . \tag{8.29}
\end{equation*}
$$

The general solution of this equation may be obtained using the variable separation method: ${ }^{22}$

$$
\begin{equation*}
\phi=a_{0}+b_{0} \ln \rho+\sum_{n=1}^{\infty}\left(c_{n} \cos n \varphi+s_{n} \sin n \varphi\right)\left(a_{n} \rho^{n}+b_{n} \rho^{-n}\right), \tag{8.30}
\end{equation*}
$$

[^125]where coefficients $a_{n}$ and $b_{n}$ have to be found from the boundary conditions (27) and (28). Choosing axis $x=r \cos \varphi$ to be parallel to vector $\mathbf{v}_{0}$ (Fig. 6a) we may rewrite these the conditions in the form
\[

$$
\begin{gather*}
\frac{\partial \phi}{\partial \rho}=0, \text { at } \rho=R,  \tag{8.31}\\
\phi \rightarrow-v_{0} \rho \cos \varphi+\phi_{0}, \text { at } \rho \gg R, \tag{8.32}
\end{gather*}
$$
\]

where $\phi_{0}$ is an arbitrary constant, which does not affect the velocity distribution, and may be taken for zero. The latter condition is incompatible with all terms of Eq. (30) except the term with $n=1$ (with $s_{1}=$ 0 and $c_{1} a_{1}=-v_{0}$ ), so it is reduced to

$$
\begin{equation*}
\phi=\left(-v_{0} \rho+\frac{c_{1} b_{1}}{\rho}\right) \cos \varphi \tag{8.33}
\end{equation*}
$$

Now, plugging this solution into Eq. (31), we get $c_{1} b_{1}=-v_{0} R^{2}$, so that, finally,

$$
\begin{equation*}
\phi=-v_{0}\left(\rho+\frac{R^{2}}{\rho}\right) \cos \varphi \tag{8.34}
\end{equation*}
$$

(a)
(b)

Fig. 8.6. Flow of ideal, incompressible fluid around a round cylinder: (a) equipotential surfaces and (b) streamlines.

Figure 6a shows the surfaces of constant velocity potential $\phi$. In order to find the fluid velocity, it is easier to rewrite result (34) in the Cartesian coordinates $x=\rho \cos \varphi, y=\rho \sin \varphi$ :

$$
\begin{equation*}
\phi=-v_{0} x\left(1+\frac{R^{2}}{\rho^{2}}\right)=-v_{0} x\left(1+\frac{R^{2}}{x^{2}+y^{2}}\right) . \tag{8.35}
\end{equation*}
$$

From this equation, we may readily calculate the Cartesian components $v_{x}=-\partial \phi / \partial x$ and $v_{y}=-\partial \phi / \partial y$ of the fluid velocity. Figure 6 b shows particle streamlines. ${ }^{23}$ One can see that the largest potential gradient, and hence the maximum speed, is achieved at points near the vertical diameter ( $\rho=R, \varphi= \pm \pi / 2$ ), where

$$
\begin{equation*}
v=v_{x}=-\left.\frac{\partial \phi}{\partial x}\right|_{\substack{R=r, x=0}}=2 v_{0} . \tag{8.36}
\end{equation*}
$$

Now the pressure distribution may now be found from the Bernoulli equation (24). For $u(\mathbf{r})=0$, it shows that the pressure reaches maximum at the ends of the longitudinal diameter $y=0$, while at the ends of the transverse diameter $x=0$, where the velocity is largest, it is less by $2 \rho v_{0}{ }^{2}$ (where $\rho$ is the fluid density again - sorry for the notation jitters!) Note that the distributions of both velocity and pressure are symmetric about the transverse axis $x=0$, so that the fluid flow does not create any net drag force in its direction. This result, which stems from the conservation of the mechanical energy of an ideal fluid, remains valid for a solid body of arbitrary shape moving inside an infinite volume of such ideal fluid - the so-called D'Alambert paradox. However, if a body moves near ideal fluid's surface, its energy may be transformed into that of surface waves, and the drag becomes possible.

Speaking about the surface waves in a gravity field ${ }^{24}$, their description is one more classical problem of the ideal fluid dynamics. Let us consider an open surface of an ideal fluid of density $\rho$ in a uniform gravity field $\mathbf{f}=\rho \mathbf{g}=-\rho g \mathbf{n}_{y}-$ see Fig. 7. If the wave amplitude $A$ is sufficiently small, we can neglect the nonlinear term $(\mathbf{v} \cdot \nabla) \mathbf{v} \propto A^{2}$ in the Euler equation (20) in comparison with the first term, $\partial \mathbf{v} / \partial t$, that is linear in $A$. For a wave with frequency $\omega$ and wavenumber $k$, particle's velocity $\mathbf{v}=d \mathbf{q} / d t$ is of the order of $\omega A$, so that this approximation is legitimate if $\omega^{2} A \gg k(\omega A)^{2}$, i.e. when

$$
\begin{equation*}
k A \ll 1 \tag{8.37}
\end{equation*}
$$

i.e. when the wave amplitude is much smaller than its wavelength $\lambda=2 \pi / k$. By this assumption, we may neglect the fluid vorticity effects, and again use Eq. (25) and (for an incompressible fluid) Eq. (26).

Fig. 8.7. Small "plane" surface wave on a deep fluid. Dashed lines show fluid particle trajectories. (For clarity, the displacement amplitude $A \equiv(k / \omega) \Phi_{0}$ is strongly exaggerated.)
ion (26) in the natural form of a 1D sinusoidal
wave, ${ }^{25}$

[^126]\[

$$
\begin{equation*}
\phi=\operatorname{Re}\left[\Phi(y) e^{i(k z-\omega t)}\right], \tag{8.38}
\end{equation*}
$$

\]

we get a simple equation

$$
\begin{equation*}
\frac{d^{2} \Phi}{d y^{2}}-k^{2} \Phi=0 \tag{8.39}
\end{equation*}
$$

with an exponential solution (decaying, as it has to, at $y \rightarrow-\infty$ ) $\Phi=\Phi_{0} \exp \{k y\}$, so that Eq. (38) becomes

$$
\begin{equation*}
\phi=\operatorname{Re}\left[\Phi_{0} e^{k y} e^{i(k z-\omega t)}\right]=\Phi_{0} e^{k y} \cos (k z-\omega t) \tag{8.40}
\end{equation*}
$$

where the last form is valid if $\Phi_{0}$ is real - which may be always arranged by a proper selection of origins of $z$ and/or $t$. Note that the rate of wave decay with depth is exactly equal to the wavenumber of its propagation along the surface. Because of that, the trajectories of fluid particles are exactly circular. Indeed, using Eqs. (25) and (40) (with amplitude) to calculate velocity components,

$$
\begin{equation*}
v_{x}=0, \quad v_{y}=-\frac{\partial \phi}{\partial y}=-k \Phi_{0} e^{k y} \cos (k z-\omega t), \quad v_{z}=-\frac{\partial \phi}{\partial z}=k \Phi_{0} e^{k y} \sin (k z-\omega t) \tag{8.41}
\end{equation*}
$$

we see that they have equal real amplitudes, and are phase-shifted by $\pi / 2$. This result becomes even more clear if we use the velocity definition $\mathbf{v}=d \mathbf{q} / d t$ to integrate Eqs. (41) over time to recover the particle displacement law $\mathbf{q}(t)$. Due to the strong inequality (37), the integration may be done at fixed $y$ and $z$ :

$$
\begin{equation*}
q_{y}=\frac{k}{\omega} \Phi_{0} e^{k y} \sin (k z-\omega t), \quad q_{z}=\frac{k}{\omega} \Phi_{0} e^{k y} \cos (k z-\omega t) . \tag{8.42}
\end{equation*}
$$

Note that the phase of oscillations of $v_{z}$ coincides with that of $q_{y}$. It means, in particular, that at wave's top ("crest"), fluid particles are moving in the direction of wave's propagation - see arrows in Fig. 7.

It is remarkable that all this picture follows from the Laplace equation alone! The "only" remaining feature to calculate is the dispersion law $\omega(k)$, and for that we need to combine Eq. (40) with what remains, in our linear approximation, of the Euler equation (23). In this approximation, and with the bulk force potential $u=\rho g y$, this equation is reduced to

$$
\begin{equation*}
\nabla\left(-\rho \frac{\partial \phi}{\partial t}+P+\rho g y\right)=0 \tag{8.43}
\end{equation*}
$$

This equation means that the function in the parentheses is constant in space; at the surface, it should equal to pressure $P_{0}$ above the surface (say, the atmospheric pressure), that we assume to be constant. This means that on the surface, the contributions to $P$ that come from the first and the third term in Eq. (43), should compensate each other. Let us take the average surface position for $y=0$; then the surface with waves is described by relation $y=q_{y}-$ see Fig. 7. Due to the strong relation (37), which means $k\left|q_{y}\right|$ $\ll 1$, we can use Eqs. (40) and (42) with $y=0$, so that the above compensation condition yields

$$
\begin{equation*}
-\rho \omega \Phi_{0} \sin (k z-\omega t)+\rho g \frac{k}{\omega} \Phi_{0} \sin (k z-\omega t)=0 \tag{8.44}
\end{equation*}
$$

This condition is identically satisfied on the whole surface (and for any $\Phi_{0}$ ) as soon as

$$
\begin{equation*}
\omega^{2}=g k \tag{8.45}
\end{equation*}
$$

this equality giving the dispersion relation we were looking for.
Looking at this surprisingly simple result (which includes just one constant, g), note, first of all, that it does not involved fluid's density. This is not too much surprising, because due to the weak equivalence principle, particle masses always drop out of the results of problems involving gravitational forces alone. Second, the dispersion law (45) is strongly nonlinear, and in particular does not have the acoustic wave limit. This means that the surface wave propagation is strongly dispersive, with the phase velocity $\omega / k \propto 1 / \omega$ diverging at $\omega \rightarrow 0$. This divergence is an artifact of our assumption of the infinite fluid thickness. A rather straightforward generalization of the above calculations to a layer of finite thickness $h$, using the additional boundary condition $\left.v_{y}\right|_{y=-h}=0$, yields the following modified dispersion relation,

$$
\begin{equation*}
\omega^{2}=g k \tanh k h . \tag{8.46}
\end{equation*}
$$

It shows that relatively long waves, with $\lambda \gg h$, i.e. with $k h \ll 1$, propagate without dispersion (i.e. have $\omega / k=$ const $\equiv v$ ), with velocity

$$
\begin{equation*}
v=(g h)^{1 / 2} . \tag{8.47}
\end{equation*}
$$

For the Earth oceans, this velocity is rather high, approaching $300 \mathrm{~m} / \mathrm{s}$ (!) for $h=10 \mathrm{~km}$. This result explains, in particular, the very fast propagation of tsunami waves.

In the opposite limit of very short waves (large $k$ ), Eq. (45) also does not give a good description of experimental data, due to the effects of surface tension (see Sec. 2 above). Using Eq. (8.10), it is easy (and hence left for the reader :-) to show that their account leads (at $k h \gg 1$ ) to the following modification of Eq. (45):

$$
\begin{equation*}
\omega^{2}=g k+\frac{\gamma k^{3}}{\rho} . \tag{8.48}
\end{equation*}
$$

According to this formula, the surface tension is important at wavelengths smaller than the capillary constant $a_{s}$ given by Eq. (11). Much shorter waves, for whom Eq. (48) yields $\omega \propto k^{3 / 2}$, are called the capillary waves - or just "ripples".

All these generalizations are still limited to potential forces, and do not allow one to describe energy loss, in particular the attenuation of either bulk or surface waves in fluids. For that, as well as for the drag force description, we need to proceed to the effects of viscosity.

### 8.5. Dynamics: Viscous fluids

Fluid viscosity of many fluids, at not too high velocities, may be described surprisingly well by adding, to the static stress tensor (2), additional components proportional to velocity $\mathbf{v} \equiv d \mathbf{q} / d t$ :

$$
\begin{equation*}
\sigma_{j j^{\prime}}=-P \delta_{i j j^{\prime}}+\widetilde{\sigma}_{j j^{\prime}}(\mathbf{v}) \tag{8.49}
\end{equation*}
$$

Since the Hooke law (7.34) has taught us about the natural structure of such a tensor in the case of stress proportional to displacement $\mathbf{q}$, we may expect a similar expression with replacement $\mathbf{q} \rightarrow \mathbf{v}=d \mathbf{q} / d t$ :

$$
\begin{equation*}
\tilde{\sigma}_{i j j^{\prime}}=2 \eta\left(e_{i j}-\frac{1}{3} \delta_{i j j^{\prime}} \operatorname{Tr}(\mathrm{e})\right)+3 \varsigma\left(\frac{1}{3} \delta_{i j j^{2}} \operatorname{Tr}(\mathrm{e})\right), . \tag{8.50a}
\end{equation*}
$$

where $e_{i j}$ are the elements of the symmetrized strain derivative tensor:

$$
\begin{equation*}
e_{i j j^{\prime}} \equiv \frac{d s_{i j^{\prime}}}{d t}=\frac{1}{2}\left(\frac{\partial v_{j}}{\partial r_{j^{\prime}}}+\frac{\partial v_{j^{\prime}}}{\partial r_{j}}\right) . \tag{8.50b}
\end{equation*}
$$

Experiment confirms that Eq. (50) gives a good description of the viscosity effects in a broad range of isotropic fluids. Coefficient $\eta$ is called either the shear viscosity, or the dynamic viscosity, or just viscosity, while $\zeta$ is called the second (or bulk) viscosity.

In the most frequent case of a virtually incompressible fluid, $\operatorname{Tr}(\mathrm{u})=d[\operatorname{Tr}(\mathrm{~s})] / d t=(d V / d t) / V=0$, so that the term proportional to $\zeta$ vanishes, and $\eta$ is the only important viscosity parameter. ${ }^{26}$ Table 1 shows the approximate values of the viscosity, together with the mass density $\rho$, for several common fluids. One can see that $\eta$ may vary in extremely broad limits; the extreme cases are glasses (somewhat counter-intuitively, these amorphous materials are not stable solids even at room temperature, but rather may "flow", though extremely slowly, until they eventually crystallize) and liquid helium. ${ }^{27}$

Table 8.1. Important parameters of several representative fluids (approximate values)

| Fluid (all at 300 K , besides the helium) | $\eta(\mathrm{mPa} \cdot \mathrm{s})$ | $\rho\left(\mathrm{kg} / \mathrm{m}^{3}\right)$ |
| :--- | :---: | :---: |
| Glasses | $10^{21}-10^{24}$ | $2,200-2,500$ |
| Machine oils (SAE 10W - 40 W) | $65-320$ | 900 |
| Water | 0.89 | 1,000 |
| Mercury | 1.53 | 13,530 |
| Liquid helium 4 (at 4.2K, $\left.10^{5} \mathrm{~Pa}\right)$ | 0.019 | 130 |
| Air $\left(\right.$ at $\left.10^{5} \mathrm{~Pa}\right)$ | 0.018 | 1.3 |

Incorporating the additional components of $\sigma_{j j}$, to the equation (20) of fluid motion, absolutely similarly to how it was done at the derivation of Eq. (7.109) of the elasticity theory, with the account of Eq. (16) we arrive at the famous Navier-Stokes equation: ${ }^{28}$

$$
\begin{equation*}
\rho \frac{\partial \mathbf{v}}{\partial t}+\rho(\mathbf{v} \cdot \nabla) \mathbf{v}=-\nabla P+\mathbf{f}+\eta \nabla^{2} \mathbf{v}+\left(\varsigma+\frac{\eta}{3}\right) \nabla(\nabla \cdot \mathbf{v}) \tag{8.51}
\end{equation*}
$$

The apparent simplicity of this equation should not mask an enormous range of phenomena, notably including turbulence (see the next section), that are described by it, and the complexity of its

[^127]solutions even for some simple geometries. In most problems interesting for practice the only option is to use numerical methods, but due to the large number of parameters ( $\rho, \eta, \zeta$, plus geometrical parameters of the involved bodies, plus the distribution of bulk forces $\mathbf{f}$, plus boundary conditions), this way is strongly plagued by the "curse of dimensionality" that was discussed in Sec. 4.8.

Let us see how does the Navier-Stokes equation work, on several simple examples. As the simplest case, let us consider the so-called Couette flow caused in an incompressible fluid layer between two wide, horizontal plates (Fig. 8) by mutual sliding of the plates with a constant relative velocity $\mathbf{v}_{0}$.

Fig. 8.8. The simplest problem of the viscous fluid flow.

Let us assume a laminar (vorticity-free) fluid flow. (As will be discussed in the next section, this assumption is only valid within certain limits.) Then we may use the evident symmetry of the problem, to take, in the reference frame shown in Fig. $8, \mathbf{v}=\mathbf{n}_{z} v(y)$. Let the bulk forces be vertical, $\mathbf{f}=\mathbf{n}_{y} f$, so they do not give an additional drive to fluid flow. Then for the stationary flow $(\partial \mathbf{v} / \partial t=0)$, the vertical, $y$-component of the Navier-Stokes equation is reduced to the static Pascal equation (3), showing that the pressure distribution is not affected by the plate (and fluid) motion. In the horizontal, $z$-component of the equation only one term, $\nabla^{2} v$, survives, so that for the only Cartesian component of velocity we get the 1D Laplace equation

$$
\begin{equation*}
\frac{d^{2} v}{d y^{2}}=0 \tag{8.52}
\end{equation*}
$$

In contract to the ideal fluid (see, e.g., Fig. 6b), the relative velocity of a viscous fluid and a solid wall it flows by should approach zero at the wall, ${ }^{29}$ so that Eq. (52) should be solved with boundary conditions

$$
v= \begin{cases}0, & \text { at } y=0  \tag{8.53}\\ v_{0}, & \text { at } y=d\end{cases}
$$

Using the evident solution of this boundary problem, $v(y)=(y / d) v_{0}$, illustrated by arrows in Fig. 8, we can now calculate the horizontal drag force acting on a unit area of each plate. For the bottom plate,

$$
\begin{equation*}
\frac{F_{z}}{A_{y}}=\left.\sigma_{z y}\right|_{y=0}=\left.\eta \frac{\partial v}{\partial y}\right|_{y=0}=\eta \frac{v_{0}}{d} . \tag{8.54}
\end{equation*}
$$

(For the top plate, the derivative $\partial v / \partial y$ has the same value, but the sign of $d A_{y}$ has to be changed to reflect the direction of the outer normal to the solid surface, so that we get a similar force but with the

[^128]negative sign.) The well-known result (54) is often used, in undergraduate courses, for a definition of the dynamic viscosity $\eta$, and indeed shows its physical meaning very well.

As the next, slightly less trivial example let us consider the so-called Poiseuille problem ${ }^{30}$ of the relation between the constant external pressure gradient $\chi \equiv-\partial P / \partial z$ applied along a round pipe with internal radius $R$ (Fig. 9) and the so-called discharge $Q$ - defined as the mass of fluid flowing through pipe's cross-section per unit time.

Fig. 8.9. The Poiseuille problem.

Again assuming a laminar flow, we can involve the problem uniformity along the $z$ axis and its axial symmetry to infer that $\mathbf{v}=\mathbf{n}_{z} v(\rho)$, and $P=-\chi z+f(\rho, \varphi)+$ const (where $\rho=\{\rho, \varphi\}$ is the 2D radiusvector rather than fluid density), so that the Navier-Stokes equation (51) for an incompressible fluid (with $\nabla \cdot \mathbf{v}=0$ ) is reduced to a 2D Poisson equation

$$
\begin{equation*}
\eta \nabla_{2}^{2} v=-\chi . \tag{8.55}
\end{equation*}
$$

After spelling out the 2D Laplace operator in polar coordinates for our axially-symmetric case $\partial / \partial \varphi=0$, Eq. (55) becomes a simple ordinary differential equation,

$$
\begin{equation*}
\eta \frac{1}{\rho} \frac{d}{d \rho}\left(\rho \frac{d v}{d \rho}\right)=-\chi \tag{8.56}
\end{equation*}
$$

that has to be solved at the segment $0 \leq \rho \leq R$, with the following boundary conditions:

$$
\begin{array}{ll}
v=0, & \text { at } \rho=R \\
\frac{d v}{d \rho}=0, & \text { at } \rho=0 \tag{8.57}
\end{array}
$$

(The latter condition is required by the axial symmetry.) A straightforward double integration yields:

$$
\begin{equation*}
v=\frac{\chi}{4 \eta}\left(R^{2}-\rho^{2}\right) \tag{8.58}
\end{equation*}
$$

so that the integration of the mass flow density over the cross-section of the pipe,

$$
\begin{equation*}
Q \equiv \int_{A} \rho v d^{2} r=2 \pi \rho \frac{\chi}{4 \eta} \int_{0}^{R}\left(R^{2}-\rho^{\prime 2}\right) \rho^{\prime} d \rho^{\prime}, \tag{8.59}
\end{equation*}
$$

immediately gives us the so-called Poiseuille (or "Hagen-Poiseuille") law for the fluid discharge:

$$
\begin{equation*}
Q=\frac{\pi}{8} \rho \frac{\chi}{\eta} R^{4} \tag{8.60}
\end{equation*}
$$

[^129]where (sorry!) $\rho$ is the mass density again.

Fig. 8.10. Application of the finitedifference method with a very coarse mesh (with step $h=a / 2$ ) to the problem of viscous fluid flow in a pipe with a square cross-section.

Of course, not for each cross-section shape the 2D Poisson equation (55) is so readily solvable. For example, consider a very simple, square-shape cross-section with side $a$ (Fig. 10). For it, it is natural to use the Cartesian coordinates, so that Eq. (55) becomes

$$
\begin{equation*}
\frac{\partial^{2} v}{\partial x^{2}}+\frac{\partial^{2} v}{\partial y^{2}}=-\frac{\chi}{\eta}=\mathrm{const}, \quad \text { for } 0 \leq x, y \leq a \tag{8.61}
\end{equation*}
$$

and has to be solved with boundary conditions

$$
\begin{equation*}
v=0, \quad \text { at } x, y=0, a . \tag{8.62}
\end{equation*}
$$

For this boundary problem, analytical methods ${ }^{31}$ give answers in the form of infinite sums (series) that ultimately require computers for their plotting and comprehension. Let me use this pretext to discuss how explicitly numerical methods may be used for such problems - or any partial differential equations involving the Laplace operator. The simplest of them is the finite-difference method ${ }^{32}$ in which the function to be calculated, $f\left(r_{1}, r_{2}, \ldots\right)$, is represented by its values in discrete points of a rectangular grid (frequently called mesh) of the corresponding dimensionality (Fig. 11).

## (a)

(b)

Fig. 8.11. Idea of the finitedifference method in (a) one and (b) two dimensions.

In Sec. 4.7, we have already discussed how to use such a grid to approximate the first derivative - see Eq. (4.98). Its extension to the second derivative is straightforward - see Fig. 11a:

[^130]\[

$$
\begin{equation*}
\frac{\partial^{2} f}{\partial r_{j}^{2}}=\frac{\partial}{\partial r_{j}}\left(\frac{\partial f}{\partial r_{j}}\right) \approx \frac{1}{h}\left(\frac{\partial f}{\partial r_{j \rightarrow}}-\frac{\partial f}{\partial r_{j_{\leftarrow}}}\right) \approx \frac{1}{h}\left[\frac{f_{\rightarrow}-f}{h}-\frac{f-f_{\leftarrow}}{h}\right]=\frac{f_{\rightarrow}+f_{\leftarrow}-2 f}{h^{2}} . \tag{8.63}
\end{equation*}
$$

\]

The relative error of this approximation is of the order of $h^{2} \partial^{4} / \partial r_{j}^{4}$, quite acceptable in many cases. As a result, the left-hand part of Eq. (61), treated on a square mesh with step $h$ (Fig. 11b), may be presented as the so-called 5-point scheme:

$$
\begin{equation*}
\frac{\partial^{2} v}{\partial x^{2}}+\frac{\partial^{2} v}{\partial y^{2}} \approx \frac{v_{\rightarrow}+v_{\leftarrow}-2 v}{h^{2}}+\frac{v_{\uparrow}+v_{\downarrow}-2 v}{h^{2}}=\frac{v_{\rightarrow}+v_{\leftarrow}+v_{\uparrow}+v_{\downarrow}-4 v}{h^{2}} . \tag{8.64}
\end{equation*}
$$

(The generalization to the 7-point scheme, appropriate for 3D problems, is straightforward.)
Let us apply this scheme to the pipe with the square cross-section, using an extremely coarse mesh with step $h=a / 2$ (Fig. 10). In this case the fluid velocity $v$ should equal zero on the walls, i.e. in all points of the five-point scheme (Fig. 11b) except for the central point (in which velocity is evidently the largest), so that Eqs. (61) and (64) yield ${ }^{33}$

$$
\begin{equation*}
\frac{0+0+0+0-4 v_{\max }}{(a / 2)^{2}} \approx-\frac{\chi}{\eta}, \quad \text { i.e. } v_{\max } \approx \frac{1}{16} \frac{\chi a^{2}}{\eta} \tag{8.65}
\end{equation*}
$$

The resulting expression for the maximal velocity is only $\sim 20 \%$ different from the exact value. Using a slightly finer mesh with $h=a / 4$, which gives a readily solvable system of 3 linear equations for 3 different velocity values (the exercise highly recommended to the reader), brings us within a couple percent from the exact result. This shows that such "numerical" methods may be more efficient practically than the "analytical" ones, even if the only available tool is a calculator app on your smartphone rather than an advanced computer.

Of course, many practical problems of fluid dynamics do require high-performance computing, especially in conditions of turbulence (see the next section) with its complex, irregular spatial-temporal structure. In these conditions, the finite-difference approach may become unsatisfactory, because is implies the same accuracy of derivative approximation through the whole volume. A more powerful (but also much more complex for implementation) approach is the finite-element method in which the discrete point mesh is based on triangles with uneven sides, and is (in most cases, automatically) generated in accordance with the system geometry - see Fig. 12. Unfortunately I do not have time for going into the details of that method, so the reader is referred to the special literature on this subject. ${ }^{34}$

Before proceeding to our next topic, let me note one more important problem that is analytically solvable using the Navier-Stokes equation (51): a slow motion of a solid sphere of radius $R$, with a constant velocity $\mathbf{v}_{0}$, through an incompressible viscous fluid - or equivalently, a slow flow of the fluid (uniform at large distances) around an immobile sphere. Indeed, in the limit $v \rightarrow 0$, the second term in the left-hand part of this equation is negligible (just as at the surface wave analysis in Sec. 3), and the equation takes the form

[^131]\[

$$
\begin{equation*}
-\nabla P+\eta \nabla^{2} \mathbf{v}=0 \tag{8.66}
\end{equation*}
$$

\]

which should be complemented with the incompressibility condition $\nabla \cdot \mathbf{v}=0$ and boundary conditions

$$
\begin{align*}
& \mathbf{v}=0, \text { at } r=R, \\
& \mathbf{v} \rightarrow \mathbf{v}_{0}, \text { at } r \rightarrow \infty . \tag{8.67}
\end{align*}
$$

In spherical coordinates, with the polar axis directed along vector $\mathbf{v}_{0}$, this boundary problem has the axial symmetry (so that $\partial \mathbf{v} / \partial \varphi=0$ and $v_{\varphi}=0$ ), and allows the following analytical solution:

$$
\begin{equation*}
v_{r}=v_{0} \cos \theta\left(1-\frac{3 R}{2 r}+\frac{R^{3}}{2 r^{2}}\right), \quad v_{\theta}=-v_{0} \sin \theta\left(1-\frac{3 R}{4 r}-\frac{R^{3}}{4 r^{2}}\right) . \tag{8.68}
\end{equation*}
$$

Fig. 8.12. Typical finite-element mesh generated automatically for an object of complex geometry in this case, a plane wing's cross-section. (Figure adapted from www.mathworks.com.)

Calculating pressure from Eq. (66), and integrating it over the surface of the sphere it is now straightforward to obtain the famous Stokes formula for the drag force acting on the sphere:

$$
\begin{equation*}
F=6 \pi \eta R v_{0} \tag{8.69}
\end{equation*}
$$

Historically, this formula has played an important role in the first precise (with accuracy better than 1\%) calculation of the fundamental electric charge $e$ by R. Millikan and H. Fletcher from their famous oil drop experiments in 1909-1913.

### 8.6. Turbulence

The Stokes formula (69), whose derivation is limited to low velocities at that the nonlinear term $(\mathbf{v} \cdot \nabla) \mathbf{v}$ could be neglected, become invalid if the fluid velocity is increased. For example, Fig. 13 shows the drag coefficient defined as

$$
\begin{equation*}
C_{D} \equiv \frac{F}{\rho v_{0}^{2} A / 2} \tag{8.70}
\end{equation*}
$$

where $A$ is the cross-section of the body as seen from the fluid flow direction, for a sphere of radius $R$ (so that $A=\pi R^{2}$ ), as a function of the so-called Reynolds number, ${ }^{35}$ for this particular geometry defined as

$$
\begin{equation*}
R e \equiv \frac{\rho v_{0}(2 R)}{\eta}=\frac{\rho v_{0} D}{\eta} \tag{8.71}
\end{equation*}
$$

Fig. 8.13. The drag coefficient for a sphere and a round thin disk as functions of the Reynolds number.
Adapted from F. Eisner, Das Widerstandsproblem, Proc. $3^{\text {rd }}$ Int. Cong. On Appl. Mech., Stockholm, 1931.

In this notation, the Stokes formula (69) reads $C_{D}=24 / R e$. One can see this formula is only valid at $R e \ll 1$, while at larger velocities the drag force becomes substantially higher than that prediction, and its dependence on velocity very complicated, so that only its general, semi-quantitative features may be readily understood from simple arguments. ${ }^{36}$

The reason for this complexity is a gradual development of very intricate, time-dependent fluid patterns, called turbulence, rich with vortices - for an example, see Fig. 14. These vortices are especially pronounced in the region behind the moving body (so-called wake), while the region before the body is virtually unperturbed. Figure 14 indicates that turbulence exhibits rather different behaviors in an extremely broad range of velocities (i.e. values of $R e$ ), and sometimes changes rather abruptly see, for example, the significant drag drop at $R e \approx 5 \times 10^{5}$.
${ }^{35}$ This notion was introduced in 1851 by the same G. Stokes, but eventually named after O. Reynolds who popularized it three decades later.
${ }^{36}$ For example, Fig. 13 shows that, within a very broad range of Reynolds numbers, from $\sim 10^{2}$ to $\sim 3 \times 10^{5}, C_{D}$ for sphere is of the order of (and for a flat disk, remarkably close to) unity. This level, i.e., the approximate equality $F$ $\approx \rho v_{0}{ }^{2} A / 2$, may be understood (in the picture where the object is moved by an external force $F$ with velocity $\mathrm{v}_{0}$ through a fluid which is initially at rest) as the equality of force's power $F v_{0}$ and fluid's kinetic energy $\left(\rho v_{0}{ }^{2} / 2\right) V$ created in volume $V=v_{0} A$ in unit time. This relation would be exact if the object gave velocity $v_{0}$ to each and every fluid particle its cross-section runs into, for example by dragging all such particles behind itself. In reality, much of this kinetic energy goes into vortices - see Fig. 14 and its discussion below.

Fig. 8.14. Snapshot of the turbulent tail (wake) behind a sphere moving in a fluid with a high Reynolds number, showing the so-called von Kármán vortex street. A nice animation of such a pattern may be found at http://en.wikipedia.org/wiki/Reynolds number.

In order to understand the conditions of this phenomenon, let us estimate the scale of various terms in the Navier-Stokes equation (51) for the generic case of a body with characteristic size $l$ moving in an otherwise static, incompressible fluid, with velocity $v$. In this case the characteristic time scale of possible non-stationary phenomena is given by the ratio $l / v,{ }^{37}$ so that we arrive at the following estimates:

$$
\begin{array}{lcccc}
\text { Equation term: } & \rho \frac{\partial \mathbf{v}}{\partial t} & \rho(\mathbf{v} \cdot \nabla) \mathbf{v} & \mathbf{f} & \eta \nabla^{2} \mathbf{v} \\
\text { Order of magnitude: } & \rho \frac{v^{2}}{l} & \rho \frac{v^{2}}{l} & \rho g & \eta \frac{v}{l^{2}} \tag{8.72}
\end{array}
$$

(I have skipped term $\nabla P$, because as we saw in the previous section, in typical fluid flow problems it balances the viscosity term, and hence is of the same order of magnitude.) This table shows that relative importance of the terms may be characterized by two dimensionless ratios. ${ }^{38}$

The first of them is the so-called Froude number

$$
\begin{equation*}
F \equiv \frac{\rho v^{2} / l}{\rho g}=\frac{v^{2}}{l g}, \tag{8.73}
\end{equation*}
$$

[^132]which characterizes the relative importance of bulk gravity - or, upon an appropriate modification, other bulk forces. In most practical problems (with the important exception of surface waves, see Sec. 4 above) $F \gg 1$, so that the gravity effects may be neglected.

Much more important is another ratio, the Reynolds number (71), in the general case defined as

$$
\begin{equation*}
R e \equiv \frac{\rho v^{2} / l}{\eta v / l^{2}}=\frac{\rho v l}{\eta} \tag{8.74}
\end{equation*}
$$

Reynolds number
which is a measure of the relative importance of the fluid particle's inertia in comparison with the viscosity effects. ${ }^{39}$ Thus, it is not quite surprising that for a sphere, the role of the vorticity-creating term $(\mathbf{v} \cdot \nabla) \mathbf{v}$ becomes noticeable already at $R e \sim 1-$ see Fig. 13. Much more surprising is the onset of turbulence in systems where the laminar (turbulence-free) flow is formally an exact solution to the Navier-Stokes equation for any $R e$. For example, at $R e>R e_{t} \approx 2,100$ (with $l=2 R$ and $v=v_{\max }$ ) the laminar flow in a round pipe, described by Eq. (58), becomes unstable, and the resulting turbulence decreases the fluid discharge $Q$ in comparison with the Poiseuille law (60). Even more strikingly, the critical value of $R e$ is rather insensitive to the pipe wall roughness.

Since $R e \gg 1$ in many real-life situations, ${ }^{40}$ turbulence is very important for practice. However, despite nearly a century of intensive research, there is no general, quantitative analytical theory of this phenomenon, ${ }^{41}$ and most results are still obtained either by rather approximate analytical treatments, or by the numerical solution of the Navier-Stokes equations using the approaches discussed in the previous section, or in experiments (e.g., on scaled models ${ }^{42}$ in wind tunnels).

Unfortunately, due to the time/space restrictions, for a more detailed discussion of these results I have to refer the reader to more specialized literature, ${ }^{43}$ and will conclude the chapter with a brief discussion of just one issue: can the turbulence be "explained by a singe mechanism"? (In other words, can it be reduced, at least on a semi-quantitative level, to a set of simpler phenomena that are commonly considered "well understood"?) Apparently the answer in no, ${ }^{44}$ though nonlinear dynamics of simpler systems may provide some useful insights.

At the middle of the past century, the most popular qualitative explanation of turbulence had been the formation of an "energy cascade" that would transfer energy from larger to smaller vortices. With our background, it is easier to retell that story in the time-domain language (with velocity $v$ serving

[^133]as the conversion factor), using the fact that in a rotating vortex each component of the particle radiusvector oscillates in time, so that to some extent the vortex plays the role of an oscillatory motion mode. Let us consider the passage of a solid body between the two, initially close, small parts of fluid. The body pushes them apart, but after its passage these partial volumes are free to return to their initial positions. However, the domination of inertia effects at motion with $R e \gg 1$ means that the volumes continue to "oscillate" for a while about those equilibrium positions. (Since elementary volumes of an incompressible fluid cannot merge, these oscillations take the form of rotating vortices.)

Now, from Sec. 4.8 we know that intensive oscillations in a system with quadratic nonlinearity, in this case provided by the convective term $(\mathbf{v} \cdot \nabla) \mathbf{v}$, are equivalent, for small perturbations, to the oscillation of the system parameters at the corresponding frequency. On the other hand, the discussion in Sec. 5.5 shows that in a system with two oscillatory degrees of freedom, a periodic parameter change with frequency $\omega_{p}$ may lead to non-degenerate parametric excitation of oscillations with frequencies $\omega_{1,2}$ satisfying relation $\omega_{1}+\omega_{2}=\omega_{p}$. Moreover, the spectrum of oscillations in such system also has higher combinational frequencies such as $\left(\omega_{p}+\omega_{1}\right)$, thus pushing the oscillation energy up the frequency scale. In the presence of other oscillatory modes, these oscillations may in turn produce, via the same nonlinearity, even higher frequencies, etc. In a fluid, the spectrum of these "oscillatory modes" (actually, vortex structures) is essentially continuous, so that the above arguments make very plausible a sequential transfer of energy to a broad spectrum of modes - whose frequency spectrum is limited from above by the energy dissipation due to viscosity. When excited, these modes interact (in particular, phase-lock) through system's nonlinearity, creating the complex motion we call turbulence.

Though not having much quantitative predictive power, such handwaving explanations, which are essentially based on the excitation of a large number of effective degrees of freedom, had been dominating the fluid dynamics reviews until the mid-1960s. At that point, the discovery (or rather rediscovery) of quasi-random motion in classical dynamic systems with just a few degrees of freedom altered the discussion substantially. Since this phenomenon, called the deterministic chaos, extends well beyond the fluid dynamics, and I will devote to it a separate (albeit short) next chapter, and in its end briefly return to the discussion of turbulence.

### 8.7. Exercise problems

8.1. A solid round cylinder of radius $r$ is let to float in a water inside the glass, also of a round cylindrical form with radius $R$ - see Fig. on the right, which shows the water levels before and after the submersion, and some vertical dimensions of the system. Calculate the buoyant force $F$ exerted by water on the floating body.

Hint: This is just a fast check whether the reader understands the Archimedes principle correctly.

8.2. Pressure $P$ under a free water surface crudely obeys the Pascal law, Eq. (6). Find the firstorder corrections to this result, due to small compressibility of water.

8.3. Find the stationary shape of the open surface of an incompressible, heavy fluid rotated about a vertical axis with a constant angular velocity $\omega$ - see Fig. on the right.
8.4.* Calculate the shape of the surface of an incompressible fluid of density $\rho$ near a vertical plane wall, in a uniform gravity field - see Fig. on the right. In particular, find the height $h$ of liquid's rise at the wall surface as a function of the contact angle $\theta_{c}$.

8.5.* A soap film with surface tension $\gamma$ is stretched between two similar, coaxial, thin, round rings of radius $R$, separated by distance $d$-see Fig. on the right. Neglecting gravity, calculate the equilibrium shape of the film, and the force needed for keeping it stretched.

8.6. A solid sphere of radius $R$ is kept in a steady, vorticity-free flow of an ideal incompressible fluid, with velocity $v_{0}$. Find the spatial distribution of velocity and pressure, and in particular their extremal values. Compare the results with those obtained in Sec. 4 for a round cylinder.
8.7.* A small source, located at distance $d$ from a plane wall of a container filled with an ideal, incompressible fluid of density $\rho$, injects additional fluid isotropically, at a constant mass current ("discharge") $Q \equiv d M / d t$ - see Fig. on the right. Calculate fluid's velocity distribution, and its pressure on the wall, created by the flow.

Hint: Recall the charge image method in electrostatics, ${ }^{45}$ and contemplate its possible analog.

8.8. Derive Eq. (46) for surface waves on a finite-thickness layer of a heavy liquid.
8.9. Derive Eq. (48) for the capillary waves ("ripples").
8.10.* Derive a 2D differential equation describing propagation of waves on the surface of a broad layer, of constant thickness $h$, of an ideal, incompressible fluid, and use it to calculate the longest standing wave modes and frequencies in a layer covering a spherical planet of radius $R \gg h$.

[^134]Hint: The second assignment requires some familiarity with the basic properties of spherical harmonics. ${ }^{46}$
8.11. Calculate the velocity distribution and dispersion relation of waves propagating along the horizontal interface of two ideal, incompressible fluids of different densities.
8.12. Calculate the energy of a monochromatic, plane surface wave on an, ideal, incompressible, deep fluid, and the power it carries (per unit width of wave's front).
8.13. Use the finite-difference approximation for the Laplace operator, with mesh $h=a / 4$, to find the maximum velocity and total mass flow $Q$ of a viscous, incompressible fluid through a long pipe with a square-shaped cross-section of side $a$. Compare the results with those described in Sec. 4 for:
(i) the same problem with mesh $h=a / 2$, and
(ii) a pipe with circular cross-section of the same area.
8.14. A layer, of thickness $h$, of a heavy, viscous, incompressible fluid flows down a long and wide incline plane, under its own weight - see Fig. on the right. Find the stationary velocity distribution profile, and the total fluid discharge (per unit width.)

8.15. Calculate the drag torque exerted on a unit length of a solid round cylinder of radius $R$ that rotates about its axis, with angular velocity $\omega$, inside an incompressible fluid with viscosity $\eta$.
8.16. Calculate the tangential force (per unit area) exerted by incompressible fluid, with density $\rho$ and viscosity $\eta$, on a broad solid plane placed over its surface and forced to oscillate, along the surface, with amplitude $a$ and frequency $\omega$.
8.17. A massive barge, with a flat bottom of area $A$, floats in shallow water, with clearance $h \ll A^{1 / 2}$ (see Fig. on the right). Calculate the time dependence of barge's velocity $V(t)$, and the water velocity profile, after the barge's engine has been turned off. Discuss the limits of large and
 small values of the dimensionless parameter $M / \rho A h$.
8.18.* Derive a general expression for mechanical energy loss rate in a viscous incompressible fluid that obeys the Navier-Stokes equation, and use this expression to calculate the attenuation coefficient of surface waves, assuming that the viscosity is small (quantify this condition).

[^135]8.19. Use the Navier-Stokes equation to calculate the attenuation coefficient for a plane, sinusoidal acoustic wave.

## Chapter 9. Deterministic Chaos

This chapter gives a very brief review of chaotic phenomena in deterministic maps and dynamic systems with and without dissipation, and an even shorter discussion of the possible role of chaos in fluid turbulence.

### 9.1. Chaos in maps

Chaotic behavior of dynamic systems ${ }^{1}$ (sometimes called the deterministic chaos) has become broadly recognized ${ }^{2}$ after the publication of a 1963 paper by E. Lorenz who was examining numerical solutions of the following system of three nonlinear, ordinary differential equations,

Lorenz system

$$
\begin{align*}
& \dot{q}_{1}=a_{1}\left(q_{2}-q_{1}\right), \\
& \dot{q}_{2}=a_{2} q_{1}-q_{2}-q_{1} q_{3},  \tag{9.1}\\
& \dot{q}_{3}=q_{1} q_{2}-a_{3} q_{3},
\end{align*}
$$

as a rudimentary model for heat transfer through a horizontal liquid layer between two solid plates. (Experiment shows that if the bottom plate is kept hotter than the top one, the liquid may exhibit turbulent convection.) He has found that within a certain range of constants $a_{1,2,3}$, the solutions of Eq. (1) follow complex, unpredictable, non-repeating trajectories in the 3D $q$-space. Moreover, the resulting functions $q_{j}(t)$ (where $j=1,2,3$ ) are so sensitive to initial conditions $q_{j}(0)$ that at sufficiently large times $t$, solutions corresponding to slightly different initial conditions are completely different.

Very soon it was realized that such behavior is typical for even simpler mathematical objects called maps, so that I will start my discussion of chaos from these objects. A 1D map is essentially a rule for finding the next number $q_{n+1}$ of a sequence, in the simplest case using only its last known value $q_{n}$, in a discrete series numbered by integer index $n$. The most famous example is the so-called logistic map: ${ }^{3}$

Logistic
map

$$
\begin{equation*}
q_{n+1}=f\left(q_{n}\right) \equiv r q_{n}\left(1-q_{n}\right) \tag{9.2}
\end{equation*}
$$

The basic properties of this map may be understood using the (hopefully, self-explanatory) graphical presentation shown in Fig. 1.4 One can readily see that at $r<1$ (Fig. 1a) the sequence rapidly converges to the trivial fixed point $q^{(0)}=0$, because each next value of $q$ is less than the previous one. However, if $r$ is increased above 1 (as in the example shown in Fig. 1b), fixed point $q^{(0)}$ becomes unstable. Indeed, at $q_{n} \ll 1$, map (2) yields $q_{n+1}=r q_{n}$, so that at $r>1$, values $q_{n}$ grow with each iteration. Instead of the unstable point $q^{(0)}=0$, in the range $1<r<r_{1}$, where $r_{1} \equiv 3$, the map has a stable fixed point, $q^{(1)}$, that may be found by plugging this value into both parts of Eq. (2):

[^136]\[

$$
\begin{equation*}
q^{(1)}=r q^{(1)}\left(1-q^{(1)}\right), \tag{9.3}
\end{equation*}
$$

\]

giving $q^{(1)}=(1-1 / r)-$ see the left branch of the plot shown in Fig. 2.

Fig. 9.1. Graphical analysis of the logistic map for: (a) $r<1$ and (b) $r>1$.

Fig. 9.2. Fixed points and chaotic regions of the logistic map. The plot is adapted from http://en.wikipedia.org/wiki/Lo gistic map; a very nice live simulation of the map is also available on this Web site.

At $r>r_{1}=3$, the plot gets thicker: here the fixed point $q^{(1)}$ also becomes unstable. To prove that, let us take $q_{n}=q^{(1)}+\tilde{q}_{n}$, assume that deviation $\tilde{q}_{n}$ from the fixed point $q^{(1)}$ is small, and linearize map (3) in $\widetilde{q}_{n}$, just as we repeatedly did for differential equations earlier in this course. The result is

$$
\begin{equation*}
\widetilde{q}_{n+1}=\left.\frac{d f}{d q}\right|_{q=q^{(1)}} \widetilde{q}_{n}=r\left(1-2 q^{(1)}\right) \widetilde{q}_{n}=(2-r) \widetilde{q}_{n} . \tag{9.4}
\end{equation*}
$$

It shows that $0<2-r<1$, i.e. $1<r<2$, deviations $\widetilde{q}_{n}$ decrease monotonically. At $-1<2-r<0$, i.e. in the range $2<r<3$, the deviation signs alternate but the magnitude still decreases (as in a stable focus - see Sec. 4.6). However, at $-1<2-r$, i.e. $r>r_{1}=3$, the deviations are growing by magnitude, while still changing sign, at each step. Since Eq. (2) has no other fixed points, this means that at $n \rightarrow \infty$, values
$q_{n}$ do not converge to one point; rather, within the range $r_{1}<r<r_{2}$, they approach a limit cycle of alternation of two points, $q_{+}^{(2)}$ and $q_{-}^{(2)}$ that satisfy the following system of algebraic equations

$$
\begin{equation*}
q_{+}^{(2)}=f\left(q_{-}^{(2)}\right), q_{-}^{(2)}=f\left(q_{+}^{(2)}\right) \tag{9.5}
\end{equation*}
$$

(These points are also plotted in Fig. 2, as functions of parameter $r$.) What has happened at point $r_{1}$ is called the period-doubling bifurcation. The story repeats at $r=r_{2}=1+\sqrt{ } 6 \approx 3.45$ where the system goes from the 2-point limit cycle to a 4-point cycle, then at point $r=r_{3} \approx 3.54$ at that the limit cycle becomes consisting of 8 alternating points, etc. Most remarkably, the period-doubling bifurcation points $r_{n}$, at that the number of points in the limit cycle doubles from $2^{n-1}$ points to $2^{n}$ points, become closer and closer. Numerical calculations have shown that these points obey the following asymptotic behavior: sequence

$$
\begin{equation*}
r_{n} \rightarrow r_{\infty}-\frac{C}{\delta^{n}}, \quad \text { where } r_{\infty}=3.5699 \ldots, \quad \delta=4.6692 \ldots \tag{9.6}
\end{equation*}
$$

Parameter $\delta$ is called the Feigenbaum constant; for other maps, and some dynamic systems (see the next section), period-doubling sequences follow a similar law, but with different parameter $\delta$.

More important for us, however, is what happens at $r>r_{\infty}$. Numerous numerical experiments, repeated with increasing precision, ${ }^{5}$ have confirmed that here the system is fully disordered, with no reproducible limit cycle, though (as Fig. 2 shows) at $r \approx r_{\infty}$, all sequential values $q_{n}$ are still confined to a few narrow regions. ${ }^{6}$ However, as parameter $r$ is increased well beyond $r_{\infty}$, these regions broaden and merge. This the so-called full, or well-developed chaos, with no apparent order at all. ${ }^{7}$

The most important feature of chaos (in this and any other system) is the exponential divergence of trajectories. For a 1 D map, this means that even if the initial conditions $q_{1}$ in two map implementations differ by a very small amount $\Delta q_{1}$, the difference $\Delta q_{n}$ between the corresponding sequences $q_{n}$ is growing (on the average) exponentially with $n$. Such exponents may be used to characterize chaos. Indeed, let us assume that $\Delta q_{1}$ is so small that $N$ first values $q_{n}$ are relatively close to each other. Then an evident generalization of the first of Eqs. (4) to an arbitrary point $q_{n}$ is

$$
\begin{equation*}
\Delta q_{n+1}=e_{n} \Delta q_{n},\left.\quad e_{n} \equiv \frac{d f}{d q}\right|_{q=q_{n}} . \tag{9.7}
\end{equation*}
$$

Using this result iteratively for $N$ steps, we get

$$
\begin{equation*}
\Delta q_{N}=\Delta q_{1} \prod_{n=1}^{N} e_{n}, \quad \text { so that } \ln \left|\frac{\Delta q_{N}}{\Delta q_{1}}\right|=\sum_{n=1}^{N} \ln \left|e_{n}\right| . \tag{9.8}
\end{equation*}
$$

[^137]Numerical experiments show that in most chaotic regimes, at $N \rightarrow \infty$ such a sum fluctuates about an average, which grows as $\lambda N$, with parameter

$$
\begin{equation*}
\lambda=\lim _{\Delta q_{1} \rightarrow 0} \lim _{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^{N} \ln \left|e_{n}\right|, \tag{9.9}
\end{equation*}
$$

Lyapunov exponent
called the Lyapunov exponent, ${ }^{8}$ being independent on the initial conditions. The bottom panel in Fig. 3 shows it as a function of the parameter $r$ for the logistic map (2).

Fig. 9.3. The Lyapunov exponent for the logistic map. Adapted from the monograph by Schuster and Just (cited below). © WileyVCH Verlag GmbH \& Co. KGaA.

Note that at $r<r_{\infty}, \lambda$ is negative, indicating trajectory's stability, besides points $r_{1}, r_{2}, \ldots$ where $\lambda$ would become positive if the limit cycle change had not brought it back to the negative territory. However, at $r>r_{\infty}, \lambda$ becomes positive, returning the negative values only in limited intervals of stable limit cycles. It is evident that in numerical experiments (which dominate the studies of the deterministic chaos) the Lyapunov exponent may be used as a good measure of chaos' "depth". ${ }^{9}$

Despite all the abundance of results published for particular maps, ${ }^{10}$ and several interesting general observations (like the existence of the Feigenbaum bifurcation sequences), to the best of my knowledge nobody can yet predict the patterns like those shown in Fig. 2 and 3, from just looking at the map rule itself, i.e. without carrying out actual numerical experiments with in. Unfortunately the situation with chaos in other systems is not much better.

[^138]
### 9.2. Chaos in dynamic systems

Proceeding to the discussion of chaos in dynamic systems, it is more natural, with our background, to illustrate this discussion not with the Lorenz' system Eqs. (1), but with the system of equations describing a dissipative pendulum driven by a sinusoidal external force, which was repeatedly discussed in Chapter 4. Introducing two new variables, the normalized momentum $p \equiv \dot{q} / \omega_{0}$ and the external force's full phase $\psi \equiv \omega t$, we may rewrite Eq. (4.42) describing the pendulum,

$$
\begin{equation*}
\ddot{q}+2 \delta \ddot{q}+\omega_{0}^{2} \sin q=f_{0} \cos \omega t \tag{9.10a}
\end{equation*}
$$

in a form similar to Eq. (1), i.e. as a system of three first-order ordinary differential equations:

$$
\begin{align*}
\dot{q} & =\omega_{0} p, \\
\dot{p} & =-\omega_{0} \sin q-2 \delta p+\left(f_{0} / \omega_{0}\right) \cos \psi,  \tag{9.10b}\\
\dot{\psi} & =\omega .
\end{align*}
$$

Figure 4 several results of numerical solution of Eq. (10). ${ }^{11}$ In all cases, the internal parameters $\delta$ and $\omega_{0}$ of the system, and the external force amplitude $f_{0}$ are fixed, while the external frequency $\omega$ is gradually changed. For the case shown on the top panel, the system still tends to a stable periodic solution, with low contents of higher harmonics. If the external force frequency is reduced by a just few percent, the $3^{\text {rd }}$ subharmonic may be excited. (This effect has already been discussed in Sec. $4.8-$ see, e.g., Fig. 4.15.) The next panel shows that just a very small further reduction of frequency leads to a new tripling of the period, i.e. the generation of a complex waveform with the $9^{\text {th }}$ subharmonic. Finally, even a minor further change of parameters leads to oscillations without any visible period, e.g., chaos.

In order to trace this transition, direct observation of the oscillation waveforms $q(t)$ is not very convenient, and trajectories on the phase plane $[q, p]$ also become messy if plotted for many periods of the external frequency. In situations like this, the Poincaré (or "stroboscopic") plane, already discussed in Sec. 4.6, is much more useful. As a reminder, this is essentially just the phase plane [ $q, p$ ], but with the points highlighted only once a period, e.g., at $\psi=2 \pi n$, with $n=1,2, \ldots$ On this plane, periodic oscillations of frequency $\omega$ are presented just as one fixed point - see, e.g. the top panel in the right column of Fig. 4. The beginning of the $3^{\text {rd }}$ subharmonic generation, shown on the next panel, means tripling of the oscillation period, and is reflected on the Poincare plane by splitting the fixed point into three. It is evident that this transition is similar to the period-doubling bifurcation in the logistic map, besides the fact (already discussed in Sec. 4.8) that in systems with an asymmetric nonlinearity, such as the pendulum (10), the $3^{\text {rd }}$ subharmonic is easier to excite. From this point, the $9^{\text {th }}$ harmonic generation (shown on the $3^{\text {rd }}$ panel of Fig. 4), i.e. one more splitting of the points on the Poincaré plane, may be understood as one more step on the Feigenbaum-like route to chaos - see the bottom panel of that figure.

So, the transition to chaos in dynamic systems may be at least qualitatively similar to than in 1D maps, with the similar law (6) for the critical values of some parameter $r$ of the system (in Fig. 4, frequency $\omega$ ), though generally with a different value of exponent $\delta$. Moreover, it is evident that we can always consider the first two differential equations of system (10b) as a 2D map that relates the vector $\left\{q_{n+1}, p_{n+1}\right\}$ of the coordinate and velocity, measured at $\psi=2 \pi(n+1)$, with the previous value $\left\{q_{n}, p_{n}\right\}$

[^139]of that vector (reached at $\psi=2 \pi n$ ). Unfortunately this similarity also implies that chaos in dynamical systems is at least as complex, and it as little understood, as in maps.

Fig. 9.4. Oscillations in a pendulum with weak damping, $\delta / \omega_{0}=0.1$, driven by a sinusoidal external force with a fixed effective amplitude $f_{0} / \omega_{0}{ }^{2}=1$, and several close values of the frequency (listed on the panels). Left column: oscillation waveforms $q(t)$ recorded after certain initial transient intervals. Right column: representations of the same processes on the Poincaré plane of variables $[p, q]$.

For example, Fig. 5 shows (a part of) the state diagram of the externally-driven pendulum, with the red bar marking the route to chaos traced in Fig. 4, and shading/hatching styles marking different regimes. One can that the pattern is at least as complex as that shown in Figs. 2 and 3, and besides a few features, ${ }^{12}$ is equally unpredictable from the form of the equation.

Fig. 9.5. Phase diagram of an externally-driven pendulum with $\delta / \omega_{0}=0.1$. Regions of oscillations with the basic period are not shaded. The notation for other regions is as follows. Doted: subharmonic generation; cross-hatched: chaos; hatched: chaos or basic period (depending on the initial conditions); hatchdotted: basic period or subharmonics. Solid lines show boundaries of single-regime regions, while dashed lines are boundaries of regions in which several types of motion are possible, depending on history. (Figure courtesy V. Kornev.)

Are there any valuable general results concerning chaos in dynamic systems? The most important (though an almost evident) result is that this phenomenon is impossible in any system described by one or two first-order differential equations with right-hand parts independent of time. Indeed, let us start with a single equation

$$
\begin{equation*}
\dot{q}=f(q) \tag{9.11}
\end{equation*}
$$

where $f(q)$ is any single-valued function. This equation may be directly integrated to give

$$
\begin{equation*}
t=\int^{q} \frac{d q^{\prime}}{f\left(q^{\prime}\right)}+\text { const } \tag{9.12}
\end{equation*}
$$

showing that the relation between $q$ and $t$ is unique and hence does not leave place for chaos.
Now, let us explore the system of two such equations:

$$
\begin{align*}
& \dot{q}_{1}=f_{1}\left(q_{1}, q_{2}\right)  \tag{9.13}\\
& \dot{q}_{2}=f_{2}\left(q_{1}, q_{2}\right)
\end{align*}
$$

Consider its phase plane shown schematically in Fig. 6. In a "usual" system, the trajectories approach either some fixed point (Fig. 6a) describing static equilibrium, or a limit cycle (Fig. 6b) describing periodic oscillations. (Both notions are united by the term attractor, because they "attract" trajectories launched from various initial conditions.) However, phase plane trajectories of a chaotic system of

[^140]equations that describe real physical variables (which cannot tend to infinity), should be confined to a limited phase plane area, and simultaneously cannot start repeating each other. (This topology is frequently called the strange attractor.) For that, 2D trajectories need to cross - see, e.g., point $A$ in Fig. $6 c$.

Fig. 9.6. Attractors in dynamical systems: (a) a fixed point, (b) a limit cycle, and (c) a strange attractor.
However, in the case described by Eqs. (13), this is clearly impossible, because according to these equations, the tangent slope on the phase plane is a unique function of point coordinates $\left\{q_{1}, q_{2}\right\}$ :

$$
\begin{equation*}
\frac{d q_{1}}{d q_{2}}=\frac{f_{1}\left(q_{1}, q_{2}\right)}{f_{2}\left(q_{1}, q_{2}\right)} \tag{9.14}
\end{equation*}
$$

Thus, in this case the deterministic chaos is impossible. ${ }^{13}$ It becomes, however, readily possible if the right-hand parts of a system similar to Eq. (13) depend either on other variables of the system or time. For example, if we consider the first two differential equations of system (10b), in the case $f_{0}=0$ they have the structure of the system (13) and hence chaos is impossible, even at $\delta<0$ when (as we know from Sec. 4.4) the system allows self-excitation of oscillations - leading to a limit-cycle attractor. However, if $f_{0} \neq 0$, this argument does not work any longer and (as we have already seen) the system may have a strange attractor - which is, for dynamic systems, a synonym for the deterministic chaos. Thus, chaos is possible in dynamic systems that may be described by three or more differential equations of the first order. ${ }^{14}$

### 9.3. Chaos in Hamiltonian systems

The last analysis is of course valid for Hamiltonian systems, which are just a particular type of dynamic systems. However, one may wonder whether these systems, that feature at least one first integral of motion, $H=$ const, and hence are more "ordered" than the systems discussed above, can exhibit chaos at all. The question is yes, because such systems still can have mechanisms for an exponential growth of a small initial perturbation.

[^141]As the simplest way to show it, let us consider a so-called mathematical billiard, i.e. a ballistic particle (a "ball") moving freely by inertia on a horizontal plane surface ("table") limited by rigid impenetrable walls. In this idealized model of the usual game of billiards, ball's velocity $\mathbf{v}$ is conserved when it moves on the table, and when it runs into a wall, the ball is elastically reflected from it as from a mirror, ${ }^{15}$ with the reversal of the sign of the normal velocity $v_{n}$, and conservation of the tangential velocity $v_{\tau}$, and hence without any loss of its kinetic (and hence the full) energy

$$
\begin{equation*}
E=H=T=\frac{m}{2} v^{2}=\frac{m}{2}\left(v_{n}^{2}+v_{\tau}^{2}\right) \tag{9.15}
\end{equation*}
$$

This model, while being a legitimate 2D dynamic system, ${ }^{16}$ allows geometric analyses for several simple table shapes. The simplest case is a rectangular billiard of area $a \times b$ (Fig. 7), whose analysis may be readily carried out by the replacement of each ball reflection event with the mirror reflection of the table in that wall - see dashes lines in panel (a).

Fig. 9.7. Ball motion on a rectangular billiard at (a) a commensurate, and (b) an incommensurate launch angle.

Such analysis (left for reader' pleasure :-) shows that if the tangent of the ball launching angle $\varphi$ is commensurate with the side length ratio,

$$
\begin{equation*}
\tan \varphi= \pm \frac{m}{n} \frac{b}{a} \tag{9.16}
\end{equation*}
$$

where $n$ and $m$ are non-negative integers without common integer multipliers, the ball returns exactly to the launch point $O$, after bouncing $m$ times from each wall of length $a$, and $n$ times from each wall of length $b$. (Red lines in Fig. 7a show an example of such trajectory for $n=m=1$, while blue lines, for $m$ $=3, n=1$.) Thus the larger is the sum $(m+n)$, the more complex is such closed trajectory - "orbit".

Finally, if $(n+m) \rightarrow \infty$, i.e. $\tan \varphi$ and $b / a$ are incommensurate (meaning that their ratio is an irrational number), the trajectory covers all the table area, and the ball never returns exactly into the launch point. Still, this is not the real chaos. Indeed, a small shift of the launch point shifts all the trajectory fragments by the same displacement. Moreover, at any time $t$, each of Cartesian components $v_{j}(t)$ of the ball's velocity (with coordinate axes parallel to the table sides) may take only two values, $\pm v_{j}(0)$, and hence may vary only as much as the initial velocity is being changed.

[^142]In 1963, Ya. Sinai showed that the situation changes completely if an additional wall, in the shape of a circle, is inserted into the rectangular billiard (Fig. 8). For most initial conditions, ball's trajectory eventually runs into the circle (see the red line on panel (a) as an example), and the further trajectory becomes essentially chaotic. Indeed, let us consider ball's reflection from the circle-shaped wall - Fig. 8 b . Due to the conservation of the tangential velocity, and the sign change of the normal velocity component, the reflection obeys the mechanical analog of the Snell law (cf. Fig. 7.12 and its discussion): $\theta_{r}=\theta_{i}$. Figure 8 b shows that as the result, a small difference $\delta \varphi$ between the angles of two close trajectories (as measured in the lab system), doubles by magnitude at each reflection from the curved wall. This means that the small deviation grows along the ball trajectory as

$$
\begin{equation*}
|\delta \varphi(N)| \sim|\delta \varphi(0)| \times 2^{N}=|\delta \varphi(0)| e^{N \ln 2} \tag{9.17}
\end{equation*}
$$

where $N$ is the number of reflections from the convex wall. ${ }^{17}$ As we already know, such exponential divergence of trajectories, with a positive Lyapunov exponent, is the sign of deterministic chaos. ${ }^{18}$

(a)

(b)

Fig. 9.8. (a) Motion on a Sinai billiard table, and (b) the mechanism of the exponential divergence of close trajectories.

The most important new feature of the dynamic chaos in Hamiltonian systems is its dependence on initial conditions. (In the systems discussed in the previous two previous sections, that lack the integrals of motion, the initial conditions are rapidly "forgotten", and the chaos is usually characterized after cutting out the initial transient period - see, e.g., Fig. 4.) Indeed, even a Sinai billiard allows periodic motion, along closed orbits, at certain initial conditions - see the blue and green lines in Fig. 8a as examples. Thus the chaos "depth" in such systems may be characterized by the "fraction" 19 of the phase space of initial parameters (for a 2D billiard, the 3D space of initial values of $x, y$, and $\varphi$ ) resulting in chaotic trajectories.

This conclusion is also valid for Hamiltonian systems that are met in experiments more frequently than the billiards, for example, coupled nonlinear oscillators without damping. Perhaps, the

[^143]earliest and the most popular example is the so-called Hénon-Heiles system, ${ }^{20}$ which may be descrbed by the following Lagrangian function:
\[

$$
\begin{equation*}
L=\frac{m_{1}}{2}\left(\dot{q}_{1}^{2}-\omega_{1}^{2} q_{1}^{2}\right)+\frac{m_{2}}{2}\left(\dot{q}_{2}^{2}-\omega_{2}^{2} q_{2}^{2}\right)-\varepsilon\left(q_{1}^{2}-\frac{1}{3} q_{2}^{2}\right) q_{2} . \tag{9.18}
\end{equation*}
$$

\]

HénonHeiles system

It is straightworward to use Eq. (18) to derive the Lagrangian equations of motion,

$$
\begin{align*}
& m_{1}\left(\ddot{q}_{1}+\omega_{1}^{2} q_{1}\right)=-2 \varepsilon q_{1} q_{2}, \\
& m_{2}\left(\ddot{q}_{2}+\omega_{2}^{2} q_{2}\right)=-\varepsilon\left(q_{1}^{2}-q_{2}^{2}\right), \tag{9.19}
\end{align*}
$$

and find its first integral of motion (physically, the energy conservation law):

$$
\begin{equation*}
H=E=\frac{m_{1}}{2}\left(\dot{q}_{1}^{2}+\omega_{1}^{2} q_{1}^{2}\right)+\frac{m_{2}}{2}\left(\dot{q}_{2}^{2}+\omega_{2}^{2} q_{2}^{2}\right)+\varepsilon\left(q_{1}^{2}-\frac{1}{3} q_{2}^{2}\right) q_{2}=\text { const } . \tag{9.20}
\end{equation*}
$$

In the conext of our discussions in Chapter 4 and 5, Eqs. (19) may be readily interpreted as those describing two oscillators, with small-oscillation eigenfrequencies $\omega_{1}$ and $\omega_{2}$, nonlinearly coupled only as described by the terms in the right-hand parts of the equations. This means that as the oscillation amplitudes $A_{1,2}$, and hence the total energy $E$ of the system, tend to zero, the oscillator subsystems are virtually independent, each performing sinusoidal oscillations at its own frequency. This observation suggestes a convenient way to depict the system motion. ${ }^{21}$ Let us consider a Poincaré plane for one of the oscillators (say, with coordinate $q_{2}$ ), similar to that discussed in Sec. 2 above, with the only difference is that (because of the absence of an explicit function of time in system's equations), the trajectory on the $\left[q_{2}, \dot{q}_{2}\right]$ plane is highlighted at the moments when $q_{1}=0$.

Let us start from the limit $A_{1,2} \rightarrow 0$, when oscillations of $q_{2}$ are virtually sinusoidal. As we already know (see Fig. 4.9 and its discussion), if the representation point highlighting was perfectly synchronous with frequency $\omega_{2}$ of the oscillations, there would be only one point on the Poincaré plane - see, e.g. the right top plane in Fig. 4. However, at the $q_{1}$ - initiated highlighting, there is not such synchronism, so that each period, a different point of the elliptical (at the proper scaling of the velocity, circular) trajectory is highlighted, so that the resulting points, for certain initial conditions, reside on a circle of radius $A_{2}$. If we now vary the initial conditions, i.e. redistribute the initial energy between the oscillators, but keep the total energy $E$ constant, on the Poincaré plane we get a series of ellipses.

Now, if the initial energy is increased, nonlinear interaction of the oscillations start to deform these ellipses, causing also their crossings - see, e.g., the top left panel of Fig. 9. Still, below a certain threshold value of $E$, all Poincaré points belonging to a certain initial condition sit on a single closed

[^144]contour. Moreover, these contours may be calculated approximately, but with a pretty good accuracy, using a straighforward generalization of the small parameter method discussed in Sec. 4.2.22

However, starting from some value of energy, certain initial conditions lead to series of points scattered over final-area parts of the Poincaré plane - see the top right panel of Fig. 9. This means that the corresponding oscillations $q_{2}(t)$ do not repeat from one (quasi-) period to the next one -cf . Fig. 4 for the dissipative, forced pendulum. This is chaos. ${ }^{23}$ However, some other initial conditions still lead to closed contours. This feature is similar to Sinai billiards, and is typical for Hamiltonian systems. As the energy is increased, the larger and larger part of the Poincare plane belongs to the chaotic motion, signifying deeper and deeper chaos.

[^145]
### 9.4. Chaos and turbulence

This extremely short section consists of essentially just one statement, extending the discussion in Sec. 8.5. The (re-) discovery of the deterministic chaos in systems with just a few degrees of freedom in the 1960s changed the tone of debates concerning origins of turbulence very considerably. At first, an extreme point of view that equated the notions of chaos and turbulence, became the debate's favorite. ${ }^{24}$ However, after an initial excitement, a significant evidence of the Landau-style mechanisms, involving many degrees of freedom, has been rediscovered and could not be ignored any longer. To the best knowledge of this author, who is a very distant albeit interested observer of that field, most experimental and numerical-simulation data carry features of both mechanisms, so that the debate continues. ${ }^{25}$ Due to the age difference, most readers of these notes have much better chances than the author to see where will this discussion end (if it does :-). ${ }^{26}$

### 9.5. Exercise problems

9.1. Generalize the reasoning of Sec. 1 to an arbitrary 1 D map $q_{n+1}=f\left(q_{n}\right)$, with function $f(q)$ differentiable at all points of interest. In particular, derive the condition of stability of an $N$-point limit cycle $q^{(1)} \rightarrow q^{(2)} \rightarrow \ldots \rightarrow q^{(N)} \rightarrow q^{(1)}$.
9.2. Use the stability condition, derived in Problem 9.1, to analyze chaos excitation in the socalled tent map:

$$
f(q)=\left\{\begin{array}{ll}
r q, & \text { for } 0 \leq q \leq 1 / 2, \\
r(1-q), & \text { for } 1 / 2 \leq q \leq 1,
\end{array} \quad \text { with } 0 \leq r \leq 2\right.
$$

9.3. A dynamic system is described by the following system of ordinary differential equations:

$$
\begin{aligned}
& \dot{q}_{1}=-q_{1}+a_{1} q_{2}^{3}, \\
& \dot{q}_{2}=a_{2} q_{2}-a_{3} q_{2}^{3}+a_{4} q_{2}\left(1-q_{1}^{2}\right) .
\end{aligned}
$$

Can it exhibit chaos at some set of constant parameters $a_{1-} a_{4}$ ?
9.4. A periodic function of time has been added to the right-hand part of the first equation of the system considered in the previous problem. Is chaos possible now?

[^146]

## Chapter 10. A Bit More of Analytical Mechanics

This concluding chapter reviews two alternative approaches to analytical mechanics, whose main advantage is a closer parallel to quantum mechanics in general and to its quasiclassical (WKB) approximation in particular. One of them, the Hamiltonian formalism, is also used to derive an important asymptotic result, the adiabatic invariance, for classical systems with slowly changing parameters.

### 10.1. Hamilton equations

Throughout this course we have seen how useful the analytical mechanics, in its Lagrangian form, may be invaluable for solving various particular problems of classical mechanics. Now let us discuss several alternative formulations ${ }^{1}$ that may not be much more useful for this purpose, but shed light on possible extensions of classical mechanics, most importantly to quantum mechanics.

As was already discussed in Sec. 2.3, the partial derivative $p_{j} \equiv \partial L / \partial \dot{q}_{j}$ participating in the Lagrange equations (2.19)

$$
\begin{equation*}
\frac{d}{d t} \frac{\partial L}{\partial \dot{q}_{j}}-\frac{\partial L}{\partial q_{j}}=0, \tag{10.1}
\end{equation*}
$$

may be considered as the generalized momentum corresponding to generalized coordinate $q_{j}$, and the full set of this momenta may be used to define the Hamiltonian function (2.32):

$$
\begin{equation*}
H \equiv \sum_{j} p_{j} \dot{q}_{j}-L \tag{10.2}
\end{equation*}
$$

Now let us rewrite the full differential of this function ${ }^{2}$ in the following form:

$$
\begin{align*}
d H & =d\left(\sum_{j} p_{j} \dot{q}_{j}-L\right)=\sum_{j}\left[d\left(p_{j}\right) \dot{q}_{j}+p_{j} d\left(\dot{q}_{j}\right)\right]-d L \\
& =\sum_{j}\left[d\left(p_{j}\right) \dot{q}_{j}+p_{j} d\left(\dot{q}_{j}\right)\right]-\left[\frac{\partial L}{\partial t} d t+\sum_{j}\left(\frac{\partial L}{\partial q_{j}} d\left(q_{j}\right)+\frac{\partial L}{\partial \dot{q}_{j}} d\left(\dot{q}_{j}\right)\right)\right] . \tag{10.3}
\end{align*}
$$

According to the definition of the generalized momentum, the second terms of each sum over $j$ cancel, while according to the Lagrange equation (1), the derivative $\partial L / \partial q_{j}$ is just $\dot{p}_{j}$, so that

$$
\begin{equation*}
d H=-\frac{\partial L}{\partial t} d t+\sum_{j}\left(\dot{q}_{j} d p_{j}-\dot{p}_{j} d q_{j}\right) . \tag{10.4}
\end{equation*}
$$

So far, this is just a universal identity. Now comes the main trick of Hamilton's approach: let us consider $H$ a function of the following independent arguments: time $t$, the generalized coordinates $q_{j}$,

[^147]and the generalized momenta $p_{j}$ (rather than generalized velocities). With this commitment, the general rule of differentiation of a function of several arguments gives
\[

$$
\begin{equation*}
d H=\frac{\partial H}{\partial t} d t+\sum_{j}\left(\frac{\partial H}{\partial q_{j}} d q_{j}+\frac{\partial H}{\partial p_{j}} d p_{j}\right) \tag{10.5}
\end{equation*}
$$

\]

where $d t, d q_{j}$, and $d p_{j}$ are independent differentials. Since Eq. (5) should be valid for any choice of these argument differentials, it should hold in particular if the differentials correspond to the real law of motion, for which Eq. (4) is valid as well. The comparison of Eqs. (4) and (5) gives us three relations:

$$
\begin{align*}
& \frac{\partial H}{\partial t}=-\frac{\partial L}{\partial t} .  \tag{10.6}\\
& \dot{q}_{j}=\frac{\partial H}{\partial p_{j}}, \\
& \dot{p}_{j}=-\frac{\partial H}{\partial q_{j}} . \tag{10.7}
\end{align*}
$$

Comparing the first of them with Eq. (2.35), we see that

$$
\begin{equation*}
\frac{d H}{d t}=\frac{\partial H}{\partial t}, \tag{10.8}
\end{equation*}
$$

meaning that function $H\left(t, q_{j}, p_{j}\right)$ can change in time only via its explicit dependence on $t$. Eqs. (7) are even more substantial: provided that such function $H\left(t, q_{j}, p_{j}\right)$ has been calculated, they give us two firstorder differential equations (called the Hamilton equations) for the time evolution of the generalized coordinate and generalized momentum of each degree of freedom of the system. ${ }^{3}$

Let us have a look at these equations for the simplest case of a system with one degree of freedom, with the simple Lagrangian function (3.3):

$$
\begin{equation*}
L=\frac{m_{\mathrm{ef}}}{2} \dot{q}^{2}-U_{\mathrm{ef}}(q, t) \tag{10.9}
\end{equation*}
$$

In this case, $p \equiv \partial L / \partial \dot{q}=m_{\text {ef }} \dot{q}$, and $H \equiv p \dot{q}-L=m_{\text {ef }} \dot{q}^{2} / 2+U_{\text {ef }}(q, t)$. In order to honor our new commitment, we need to express the Hamiltonian function explicitly via $t, q$ and $p$ (rather than $\dot{q}$ ):

$$
\begin{equation*}
H=\frac{p^{2}}{2 m_{\mathrm{ef}}}+U_{\mathrm{ef}}(q, t) . \tag{10.10}
\end{equation*}
$$

Now we can spell out Eqs. (7) for this particular case:

$$
\begin{equation*}
\dot{q}=\frac{\partial H}{\partial p}=\frac{p}{m_{\mathrm{ef}}} \tag{10.11}
\end{equation*}
$$

[^148]\[

$$
\begin{equation*}
\dot{p}=-\frac{\partial H}{\partial q}=-\frac{\partial U_{\mathrm{ef}}}{\partial q} . \tag{10.12}
\end{equation*}
$$

\]

While the first of these equations just repeats the definition of the generalized momentum corresponding to coordinate $q$, the second one gives the equation of momentum change. Differentiating Eq. (11) over time, and plugging Eq. (12) into the result, we get:

$$
\begin{equation*}
\ddot{q}=\frac{\dot{p}}{m_{\mathrm{ef}}}=-\frac{1}{m_{\mathrm{ef}}} \frac{\partial U_{\mathrm{ef}}}{\partial q} . \tag{10.13}
\end{equation*}
$$

So, we have returned to the same equation (3.4) that had been derived from the Lagrangian approach.
Thus, the Hamiltonian formalism does not give much new for the solution of most problems of classical mechanics. (This is why I have postponed its discussion until the very end of this course.) Moreover, since the Hamiltonian function $H\left(t, q_{j}, p_{j}\right)$ does nor include generalized velocities explicitly, the phenomenological introduction of dissipation in this approach is less straightforward than that in the Lagrangian equations whose precursor form (2.17) is valid for dissipative forces as well. However, the Hamilton equations (7), which treat the generalized coordinates and momenta in a manifestly symmetric way, are aesthetically appealing and heuristically fruitful. This is especially true in the cases where these arguments participate in $H$ in a similar way. For example, for the very important case of a dissipationfree harmonic oscillator, for which $U_{\text {ef }}=\kappa_{\text {ef }} q^{2} / 2$, Eq. (10) gives the famous symmetric form

$$
\begin{equation*}
H=\frac{p^{2}}{2 m_{\mathrm{ef}}}+\frac{\kappa_{\mathrm{ef}} x^{2}}{2}=\frac{p^{2}}{2 m_{\mathrm{ef}}}+\frac{m_{\mathrm{ef}} \omega_{0}^{2} x^{2}}{2}, \quad \text { where } \omega_{0}^{2} \equiv \frac{\kappa_{\mathrm{ef}}}{m_{\mathrm{ef}}} . \tag{10.14}
\end{equation*}
$$

The Hamilton equations (7) for this system preserve the symmetry, especially evident if we introduce the normalized momentum $\rho \equiv p / m_{\text {ef }} \omega_{0}$ (already used in Secs. 4.3 and 9.2):

$$
\begin{equation*}
\frac{d q}{d t}=\omega_{0} \rho, \quad \frac{d \rho}{d t}=-\omega_{0} q . \tag{10.15}
\end{equation*}
$$

More practically, the Hamilton approach gives additional tools for the search for the integrals of motion. In order to see that, let us consider the full time derivative of an arbitrary function $f\left(t, q_{j}, p_{j}\right)$ :

$$
\begin{equation*}
\frac{d f}{d t}=\frac{\partial f}{\partial t}+\sum_{j}\left(\frac{\partial f}{\partial q_{j}} \dot{q}_{j}+\frac{\partial f}{\partial p_{j}} \dot{p}_{j}\right) \tag{10.16}
\end{equation*}
$$

Plugging in $\dot{q}_{j}$ and $\dot{p}_{j}$ from the Hamilton equations (7), we get

Dynamics of arbitrary variable

$$
\begin{equation*}
\frac{d f}{d t}=\frac{\partial f}{\partial t}+\sum_{j}\left(\frac{\partial H}{\partial p_{j}} \frac{\partial f}{\partial q_{j}}-\frac{\partial H}{\partial q_{j}} \frac{\partial f}{\partial p_{j}}\right)=\frac{\partial f}{\partial t}+\{H, f\} \tag{10.17}
\end{equation*}
$$

where the last term in the right-hand part is the so-called Poisson bracket ${ }^{4}$ that is defined, for two arbitrary functions $f\left(t, q_{j}, p_{j}\right)$ and $g\left(t, q_{j}, p_{j}\right)$, as

Poisson bracket

$$
\begin{equation*}
\{g, f\} \equiv \sum_{j}\left(\frac{\partial g}{\partial p_{j}} \frac{\partial f}{\partial q_{j}}-\frac{\partial f}{\partial p_{j}} \frac{\partial g}{\partial q_{j}}\right) \tag{10.18}
\end{equation*}
$$

[^149]From this definition, one can readily verify that besides evident relations $\{f, f\}=0$ and $\{f, g\}=-\{g, f\}$, the Poisson brackets obey the following important Jacobi identity:

$$
\begin{equation*}
\{f,\{g, h\}\}+\{g,\{h, f\}\}+\{h,\{f, g\}\}=0 . \tag{10.19}
\end{equation*}
$$

Now let us use these relations for a search for integrals of motion. First, equation (17) shows that if a function $f$ does not depend on time explicitly, and

$$
\begin{equation*}
\{H, f\}=0 \tag{10.20}
\end{equation*}
$$

then $d f / d t=0$, i.e. function $f$ is an integral of motion.
Moreover, if we already know two integrals of motion, say $f$ and $g$, then function

$$
\begin{equation*}
F \equiv\{f, g\} \tag{10.21}
\end{equation*}
$$

is also an integral of motion - the so-called Poisson theorem. In order to prove it, we may use the Jacobi identity (19) with $h=H$. Now using Eq. (17) to express the Poisson brackets $\{g, H\},\{H, g\}$, and $\{H$, $\{f$, $g\}\}=\{H, F\}$ via the full and partial time derivatives of functions $f, g$, and $F$, we get

$$
\begin{equation*}
\left\{f, \frac{\partial g}{\partial t}-\frac{d g}{d t}\right\}+\left\{g, \frac{d f}{d t}-\frac{\partial f}{\partial t}\right\}+\frac{d F}{d t}-\frac{\partial F}{\partial t}=0 \tag{10.22}
\end{equation*}
$$

so that if $f$ and $g$ are indeed integrals of motion, i.e., $d f / d t=d g / d t=0$, then

$$
\begin{equation*}
\frac{d F}{d t}=\frac{\partial F}{\partial t}+\left\{g, \frac{\partial f}{\partial t}\right\}-\left\{f, \frac{\partial g}{\partial t}\right\}=\frac{\partial F}{\partial t}-\left[\left\{\frac{\partial f}{\partial t}, g\right\}+\left\{f, \frac{\partial g}{\partial t}\right\}\right] \tag{10.23}
\end{equation*}
$$

Plugging Eq. (21) into the first term of the right-hand part of this equation, and differentiating it by parts, we get $d F / d t=0$, i.e. $F$ is indeed an integral of motion as well.

Finally, one more important role of the Hamilton formalism is that it allows one to trace the close connection between the classical and quantum mechanics. Indeed, using Eq. (18) to calculate the Poisson brackets of the generalized coordinates and momenta, we readily get

$$
\begin{equation*}
\left\{q_{j}, q_{j^{\prime}}\right\}=0, \quad\left\{p_{j}, p_{j^{\prime}}\right\}=0, \quad\left\{q_{j}, p_{j^{\prime}}\right\}=-\delta_{i j^{\prime}} \tag{10.24}
\end{equation*}
$$

In quantum mechanics, ${ }^{5}$ operators of these quantities ("observables") obey commutation relations

$$
\begin{equation*}
\left[\hat{q}_{j}, \hat{q}_{j^{\prime}}\right]=0, \quad\left[\hat{p}_{j}, \hat{p}_{j^{\prime}}\right]=0, \quad\left[\hat{q}_{j}, \hat{p}_{j^{\prime}}\right]=i \hbar \delta_{j j^{\prime}}, \tag{10.25}
\end{equation*}
$$

where the definition of the commutator, $[\hat{g}, \hat{f}] \equiv \hat{g} \hat{f}-\hat{f} \hat{g}$, is to a certain extent ${ }^{6}$ similar to that (18) of the Poisson bracket. We see that the classical relations (24) are similar to quantum-mechanical relations (25) if we following parallel has been made:

$$
\begin{equation*}
\{g, f\} \leftrightarrow \frac{i}{\hbar}[\hat{g}, \hat{f}] . \tag{10.26}
\end{equation*}
$$

[^150]This analogy extends well beyond Eqs. (24)-(25). For example, making replacement (26) in Eq. (17), we get

$$
\begin{equation*}
\frac{d \hat{f}}{d t}=\frac{\partial \hat{f}}{\partial t}+\frac{i}{\hbar}[\hat{H}, \hat{f}], \quad \text { i.e. } i \hbar \frac{d \hat{f}}{d t}=i \hbar \frac{\partial \hat{f}}{\partial t}+[\hat{f}, \hat{H}] \tag{10.27}
\end{equation*}
$$

which is the correct equation of operator evolution in the Heisenberg picture of quantum mechanics. ${ }^{7}$
This analogy implies, in particular, that the quantum-mechanical operators (and the matrices used for their representation in a particular basis) should satisfy the same identities including Eq. (17).

### 10.2. Adiabatic invariance

One more application of the Hamiltonian formalism in classical mechanics is the solution of the following problem. ${ }^{8}$ Earlier in the course, we already studied some effects of time variation of parameters of a single oscillator (Sec. 4.5) and coupled oscillators (Sec. 5.5). However, those discussions were focused on the case when the parameter variation frequency is comparable with the initial oscillation frequency (or frequencies) of the system. Another practically important case is when some system's parameter (let us call it $\lambda$ ) is changed much more slowly (adiabatically ${ }^{9}$ ),

$$
\begin{equation*}
\left|\frac{\lambda}{\lambda}\right| \ll \frac{1}{\tau} \tag{10.28}
\end{equation*}
$$

where $\tau$ is a typical time period of oscillations in the system. Let us consider a 1 D system whose Hamiltonian $H(q, p, \lambda)$ depends on time only via the slow (28) evolution of parameter $\lambda=\lambda(t)$, and whose initial energy restricts system's motion to a finite coordinate interval - see Fig. 3.2c.

Then, as we know from Sec. 3.3, if parameter $\lambda$ is constant, the system performs a periodic (though not necessarily sinusoidal) motion back and forth axis $q$, or, in a different language, along a closed trajectory on the phase plane $[q, p]$ - see Fig. $1 .{ }^{10}$ According to Eq. (8), in this case $H$ is constant on the trajectory. (In order to distinguish this particular value from the Hamiltonian function as such, I will assume that this constant coincides with the full mechanical energy $E$, like is does for Hamiltonian (10), though this assumption is not necessary for the calculation made below.)

The oscillation period $\tau$ may be calculated as a contour integral along this closed trajectory:

$$
\begin{equation*}
T \equiv \int_{0}^{\tau} d t=\oint \frac{d t}{d q} d q=\oint \frac{1}{\dot{q}} d q . \tag{10.29}
\end{equation*}
$$

Using the first of the Hamilton equations (7), we may now present this integral as

[^151]\[

$$
\begin{equation*}
\tau=\oint \frac{1}{\partial H / \partial p} d q \tag{10.30}
\end{equation*}
$$

\]

At each given point $q, H=E$ is a function of $p$ alone, so that we may flip the partial derivative in the denominator just as a full derivative, and rewrite Eq. (30) as

$$
\begin{equation*}
\tau=\oint \frac{\partial p}{\partial E} d q . \tag{10.31}
\end{equation*}
$$

For the particular Hamiltonian (10), this relation is immediately reduced to Eq. (3.27) in the form of a contour integral:

$$
\begin{equation*}
\tau=\left(\frac{m_{\mathrm{ef}}}{2}\right)^{1 / 2} \oint \frac{1}{\left[E-U_{\mathrm{ef}}(q)\right]^{1 / 2}} d q \tag{10.32}
\end{equation*}
$$

Fig. 10.1. Phase-plane representation of periodic oscillations of a 1D Hamiltonian system, for two values of energy (schematically).

Superficially, it looks that these formulas may be also used to find the motion period change when parameter $\lambda$ is being changed adiabatically, for example, by plugging known functions $m_{\mathrm{ef}}(\lambda)$ and $U_{\text {ef }}(q, \lambda)$ into Eq. (32). However, there is no guarantee that energy $E$ in that integral would stay constant as the parameter change, and indeed we will see below that this is not necessarily the case. Even more interestingly, in the most important case of the harmonic oscillator ( $U_{\mathrm{ef}}=\kappa_{\mathrm{e} f} q^{2} / 2$ ), whose oscillation period $\tau$ does not depend on $E$ (see Eq. (3.29) and its discussion), its variation in the adiabatic limit (28) may be readily predicted: $T(\lambda)=2 \pi / \omega_{0}(\lambda)=2 \pi\left[m_{\mathrm{ef}}(\lambda) / \kappa_{\mathrm{ef}}(\lambda)\right]^{1 / 2}$, but the dependence of the oscillation energy $E$ (and hence the oscillation amplitude) on $\lambda$ is not immediately obvious.

In order to address this issue, let us use Eq. (8) (with $E=H$ ) to present the energy change with $\lambda(t)$, i.e. in time, as

$$
\begin{equation*}
\frac{d E}{d t}=\frac{\partial H}{\partial t}=\frac{\partial H}{\partial \lambda} \frac{d \lambda}{d t} . \tag{10.33}
\end{equation*}
$$

Since we are interested in a very slow (adiabatic) time evolution of energy, we can average Eq. (33) over fast oscillations in the system, for example over one oscillation period $\tau$, treating $d \lambda / d t$ as a constant during this averaging. ${ }^{11}$ The averaging yields

[^152]\[

$$
\begin{equation*}
\frac{\overline{d E}}{d t} \approx \frac{d \lambda}{d t} \frac{\overline{\partial H}}{\partial \lambda}=\frac{d \lambda}{d t} \frac{1}{T} \int_{0}^{\tau} \frac{\partial H}{\partial \lambda} d t . \tag{10.34}
\end{equation*}
$$

\]

Transforming the time integral to the contour one, just as we did at the transition from Eq. (29) to Eq. (30), and using Eq. (31) for $T$, we get

$$
\begin{equation*}
\frac{\overline{d E}}{d t}=\frac{d \lambda}{d t} \frac{\oint \frac{\partial H / \partial \lambda}{\partial H / \partial p} d q}{\oint \frac{\partial p}{\partial E} d q} \tag{10.35}
\end{equation*}
$$

At each point $q$ of the contour, $H$ is a function of not only $\lambda$, but also of $p$, which may be also $\lambda$ dependent, so that if $E$ is fixed, the partial differentiation of relation $E=H$ over $\lambda$ yields

$$
\begin{equation*}
\frac{\partial H}{\partial \lambda}+\frac{\partial H}{\partial p} \frac{\partial p}{\partial \lambda}=0, \quad \text { i.e. } \frac{\partial H / \partial \lambda}{\partial H / \partial p}=-\frac{\partial p}{\partial \lambda} . \tag{10.36}
\end{equation*}
$$

Plugging the last relation into Eq.(35), we get

$$
\begin{equation*}
\frac{\overline{d E}}{d t}=-\frac{d \lambda}{d t} \frac{\oint \frac{\partial p}{\partial \lambda} d q}{\oint \frac{\partial p}{\partial E} d q} \tag{10.37}
\end{equation*}
$$

Since the left-hand part of Eq. (37), and the derivative $d \lambda / d t$ do not depend on $q$, we may move them into the integrals over $q$ as constants, and rewrite that relation as

$$
\begin{equation*}
\oint\left(\frac{\partial p}{\partial E} \frac{\overline{d E}}{d t}+\frac{\partial p}{\partial \lambda} \frac{d \lambda}{d t}\right) d q=0 \tag{10.38}
\end{equation*}
$$

Now let us consider the following integral over the same phase-plane contour,

$$
\begin{equation*}
J \equiv \frac{1}{2 \pi} \oint p d q \tag{10.39}
\end{equation*}
$$

called the action variable. Just to understand its physical sense, let us calculate $J$ for a harmonic oscillator (14). As we know very well from Chapter 4, for such oscillator, $q=A \cos \Psi, p=-m_{\mathrm{ef}} \omega_{0} A \sin \Psi$ (with $\Psi=\omega_{0} t+$ const), so that $J$ may be easily expressed either via oscillations' amplitude $A$, or their energy $E=H=m_{\text {ef }} \omega_{0}^{2} A^{2} / 2$ :

$$
\begin{equation*}
J=\frac{1}{2 \pi} \oint p d q=\frac{1}{2 \pi} \int_{\Psi=0}^{\Psi=2 \pi}\left(-m_{\mathrm{ef}} \omega_{0} A \sin \Psi\right) d(A \cos \Psi)=\frac{1}{2 \pi} \frac{m_{\mathrm{ef}} \omega_{0}}{2} A^{2}=\frac{E}{\omega_{0}} . \tag{10.40}
\end{equation*}
$$

Returning to a general system with adiabatically changed parameter $\lambda$, let us use the definition of $J$, Eq. (39), to calculate its time derivative, again taking into account that at each point $q$ of the trajectory, $p$ is a function of $E$ and $\lambda$ :
cumbersome) proofs of Eq. (42) are still being offered in literature - see, e.g., C. Wells and S. Siklos, Eur. J. Phys. 28, 105 (2007) and/or A. Lobo et al., Eur. J. Phys. 33, 1063 (2012).

$$
\begin{equation*}
\frac{d J}{d t}=\frac{1}{2 \pi} \oint \frac{d p}{d t} d q=\frac{1}{2 \pi} \oint\left(\frac{\partial p}{\partial E} \frac{d E}{d t}+\frac{\partial p}{\partial \lambda} \frac{d \lambda}{d t}\right) d q . \tag{10.41}
\end{equation*}
$$

Within the accuracy of our approximation, in which the contour integrals (38) and (41) are calculated along a closed trajectory, factor $d E / d t$ is indistinguishable from its time average, and these integrals coincide, so that result (38) is applicable to Eq. (41) as well. Hence, we have finally arrived at a very important result: at a slow parameter variation, $d J / d t=0$, i.e. the action variable remains constant:

$$
\begin{equation*}
J=\text { const } . \tag{10.42}
\end{equation*}
$$

This is the famous adiabatic invariance. ${ }^{12}$ In particular, according to Eq. (40), in a harmonic oscillator, energy of oscillation changes proportionately to the (slowly changed) eigenfrequency.

Before moving on, let me briefly note that the adiabatic invariance is not the only application of the action variable $J$. Since the initial choice of generalized coordinates and velocities (and hence the generalized momenta) in analytical mechanics is arbitrary (see Sec. 2.1), it is almost evident that $J$ may be taken for a new generalized momentum corresponding to a certain new generalized coordinate $\Theta,{ }^{13}$ and that pair $\{J, \Theta\}$ should satisfy the Hamilton equations (7), in particular,

$$
\begin{equation*}
\frac{d \Theta}{d t}=\frac{\partial H}{\partial J} . \tag{10.43}
\end{equation*}
$$

Following the commitment of Sec. 1 (made there for the "old" arguments $q_{j}, p_{j}$ ), before the differentiation in the right-hand part in Eq. (43), $H$ should be expressed as a function of $t$, $J$, and $\Theta$. For time-independent Hamiltonian systems, $H$ is uniquely defined by $J$ - see, e.g., Eq. (40). Hence the righthand part of Eq. (43) does not depend on either $t$ or $\Theta$, so that according to that equation, $\Theta$ (called the angle variable) is a linear function of time:

$$
\begin{equation*}
\Theta=\frac{\partial H}{\partial J} t+\text { const } . \tag{10.44}
\end{equation*}
$$

For a harmonic oscillator, according to Eq. (40), derivative $\partial H / \partial J=\partial E / \partial J=\omega_{0}=2 \pi / T$, so that $\Theta$ $=\omega_{0} t+$ const. It may be shown that a more general form of this relation,

$$
\begin{equation*}
\frac{\partial H}{\partial J}=\frac{2 \pi}{\tau} \tag{10.45}
\end{equation*}
$$

is valid for an arbitrary system described by Eq. (10). Thus, Eq. (44) becomes

$$
\begin{equation*}
\Theta=2 \pi \frac{t}{T}+\text { const } \tag{10.46}
\end{equation*}
$$

[^153]To summarize, for a harmonic oscillator, the angle variable $\Theta$ is just the full phase $\Psi$ that we used so much in Ch. 4, while for an arbitrary (nonlinear) 1D oscillator, this is a convenient generalization of that notion. Due to this reason, variables $J$ and $\Theta$ present a convenient tool for discussion of certain fine points of dynamics strongly nonlinear oscillators - for whose discussion I, unfortunately, do not have time. ${ }^{14}$

### 10.3. The Hamilton principle

Now let me show that the Lagrangian equations of motion, that have been derived in Sec. 2.1 from the Newton laws, may be also obtained from the so-called Hamilton principle, namely the condition of a minimum (or rather an extremum) of the integral called action:

$$
\begin{equation*}
S \equiv \int_{t_{\mathrm{ini}}}^{t_{\mathrm{fin}}} L d t \tag{10.47}
\end{equation*}
$$

where $t_{\text {ini }}$ and $t_{\text {fin }}$ are, respectively, the initial and final moments of time, at which moments all generalized coordinates and velocities are considered fixed (not varied) - see Fig. 2.

Fig. 10.2. Deriving the Hamilton principle.

The proof of that statement is rather simple. Considering, similarly to Sec. 2.1, a possible virtual variation of the motion, described by infinitesimal deviations $\left\{\delta q_{j}(t), \delta \dot{q}_{j}(t)\right\}$ from the real motion, the necessary condition for $S$ to be minimal is

$$
\begin{equation*}
\delta S \equiv \int_{t_{\mathrm{ini}}}^{t_{\mathrm{fin}}} \delta L d t=0 \tag{10.48}
\end{equation*}
$$

where $\delta S$ and $\delta L$ are the variations of the action and the Lagrange function, corresponding to the set $\left\{\delta q_{j}(t), \delta \dot{q}_{j}(t)\right\}$. As has been already discussed in Sec. 2.1, we can use the operation of variation just as the usual differentiation (but at fixed time, see Fig. 2.1), swapping these two operations if needed see Fig. 2.3 and its discussion. Thus, we may write

$$
\begin{equation*}
\delta L=\sum_{j}\left(\frac{\partial L}{\partial q_{j}} \delta q_{j}+\frac{\partial L}{\partial \dot{q}_{j}} \delta \dot{q}_{j}\right)=\sum_{j} \frac{\partial L}{\partial q_{j}} \delta q_{j}+\sum_{j} \frac{\partial L}{\partial \dot{q}_{j}} \frac{d}{d t} \delta q_{j} . \tag{10.49}
\end{equation*}
$$

[^154]After plugging the last expression into Eq. (48), we can integrate the second term by parts:

$$
\begin{align*}
\delta S & =\int_{t_{\mathrm{ini}}}^{t_{\mathrm{fin}}} \sum_{j} \frac{\partial L}{\partial q_{j}} \delta q_{j} d t+\sum_{j}^{t_{\mathrm{fin}}} \int_{t_{\mathrm{ini}}} \frac{\partial L}{\partial \dot{q}_{j}} \frac{d}{d t} \delta q_{j} d t \\
& =\int_{t_{\mathrm{ini}}}^{t_{\mathrm{fin}}} \sum_{j} \frac{\partial L}{\partial q_{j}} \delta q_{j} d t+\sum_{j}\left[\frac{\partial L}{\partial \dot{q}_{j}} \delta q_{j}\right]_{t_{\mathrm{ini}}}^{t_{\mathrm{fin}}}-\sum_{j} \int_{t_{\mathrm{ini}}}^{t_{\mathrm{fin}}} \delta q_{j} d\left(\frac{\partial L}{\partial \dot{q}_{j}}\right)=0 . \tag{10.50}
\end{align*}
$$

Since the generalized coordinates in the initial and final points are considered fixed (not affected by the variation), all $\delta q_{j}\left(t_{\text {ini }}\right)=\delta q_{j}\left(t_{\text {fin }}\right)=0$, the second term in the right-hand part of Eq. (50) vanishes. Multiplying and dividing the last term of that part by $d t$, we finally get

$$
\begin{equation*}
\delta S=\int_{t_{\mathrm{ini}}}^{t_{\mathrm{fin}}} \sum_{j} \frac{\partial L}{\partial q_{j}} \delta q_{j} d t-\sum_{j} \int_{t_{\mathrm{ini}}}^{t_{\mathrm{fin}}} \delta q_{j} \frac{d}{d t}\left(\frac{\partial L}{\partial \dot{q}_{j}}\right) d t=-\int_{t_{\mathrm{ini}}}^{t_{\mathrm{fin}}} \sum_{j}\left[\frac{d}{d t}\left(\frac{\partial L}{\partial \dot{q}_{j}}\right)-\frac{\partial L}{\partial q_{j}}\right] \delta q_{j} d t=0 . \tag{10.51}
\end{equation*}
$$

This relation should hold for an arbitrary set of functions $\delta q_{j}(t)$, and for any time interval, so that it is only possible if the expressions in square brackets equal zero for all $j$, giving us the set of Lagrange equations (2.19). So, the Hamilton principle indeed gives the Lagrange equations of motion.

It is very useful to make the notion of action $S$, defined by Eq. (47), more transparent by calculating it for the simple case of a single particle moving in a potential field that conserves its energy $E=T+U$. In this case the Lagrangian function $L=T-U$ may be presented as

$$
\begin{equation*}
L=T-U=2 T-(T+U)=2 T-E=m v^{2}-E, \tag{10.52}
\end{equation*}
$$

with $E=$ const, so that

$$
\begin{equation*}
S=\int L d t=\int m v^{2} d t-E t+\text { const. } \tag{10.53}
\end{equation*}
$$

Presenting the expression under the remaining integral as $m \mathbf{v} \cdot \mathbf{v} d t=\mathbf{p} \cdot(d \mathbf{r} / d t) d t=\mathbf{p} \cdot d \mathbf{r}$, we finally get

$$
\begin{equation*}
S=\int \mathbf{p} \cdot d \mathbf{r}-E t+\text { const }=S_{0}-E t+\text { const } \tag{10.54}
\end{equation*}
$$

where the time-independent integral

$$
\begin{equation*}
S_{0} \equiv \int \mathbf{p} \cdot d \mathbf{r} \tag{10.55}
\end{equation*}
$$

is frequently called the abbreviated action. ${ }^{15}$
This expression may be used to establish one more connection between the classical and quantum mechanics, now in its Schrödinger picture. Indeed, in the quasiclassical (WKB) approximation of that picture ${ }^{16}$ a particle of fixed energy is described by a De Broglie wave

$$
\begin{equation*}
\Psi(\mathbf{r}, t) \propto \exp \left\{i\left(\int \mathbf{k} \cdot d \mathbf{r}-\omega t+\mathrm{const}\right)\right\}, \tag{10.56}
\end{equation*}
$$

[^155]where wavevector $\mathbf{k}$ is proportional to the particle's momentum, while frequency $\omega$, to its energy:
\[

$$
\begin{equation*}
\mathbf{k}=\frac{\mathbf{p}}{\hbar}, \quad \omega=\frac{E}{\hbar} . \tag{10.57}
\end{equation*}
$$

\]

Plugging these expressions into Eq. (56) and comparing the result with Eq. (54), we see that the WKB wavefunction may be presented as

$$
\begin{equation*}
\Psi \propto \exp \{i S / \hbar\} . \tag{10.58}
\end{equation*}
$$

Hence the Hamilton's principle (48) means that the total phase of the quasiclassical wavefunction should be minimal along particle's real trajectory. But this is exactly the so-called eikonal minimum principle well known from the optics (though valid for any other waves as well), where it serves to define the ray paths in the geometric optics limit - similar to the WKB approximation condition. Thus, the ratio $S / \hbar$ may be considered just as the eikonal, i.e. the total phase accumulation, of the de Broigle waves. ${ }^{17}$

Now, comparing Eq. (55) with Eq. (39), we see that the action variable $J$ is just the change of the abbreviated action $S_{0}$ along a single phase-plane contour (divided by $2 \pi$ ). This means that in the WKB approximation, $J$ is the number of de Broglie waves along the classical trajectory of a particle, i.e. an integer value of the corresponding quantum number. If system's parameters are changed slowly, the quantum number has to stay integer, and hence $J$ cannot change, giving a quantum-mechanical interpretation of the adiabatic invariance. It is really fascinating that a fact of classical mechanics may be "derived" (or at least understood) more easily from the quantum mechanics' standpoint. ${ }^{18}$

### 10.4. The Hamilton-Jacobi equation

Action S, defined by Eq. (47), may be used for one more formulation of classical mechanics. For that, we need one more, different commitment: $S$ to be considered a function of the following independent arguments: the final time point $t_{\text {fin }}$ (which I will, for brevity, denote as $t$ in this section), and the set of generalized coordinates (but not of the generalized velocities!) at that point:

$$
\begin{equation*}
S \equiv \int_{t_{\mathrm{ini}}}^{t} L d t=S\left[t, q_{j}(t)\right] \tag{10.59}
\end{equation*}
$$

Let us calculate a variation of this (essentially, new!) function, resulting from an arbitrary combination of variations of final values $q_{j}(t)$ of the coordinates, while keeping $t$ fixed. Formally this may be done by repeating the variation calculations described by Eqs. (49)-(52), besides that now variations $\delta q_{j}$ at the finite point $(t)$ do not necessarily equal zero. As a result, we get

$$
\begin{equation*}
\delta S=\left.\sum_{j} \frac{\partial L}{\partial \dot{q}_{j}} \delta q_{j}\right|_{t}-\int_{t_{\mathrm{ini}}}^{t} d t \sum_{j}\left[\frac{d}{d t}\left(\frac{\partial L}{\partial \dot{q}_{j}}\right)-\frac{\partial L}{\partial q_{j}}\right] \delta q_{j} . \tag{10.60}
\end{equation*}
$$

[^156]For the motion along the real trajectory, i.e. satisfying the Lagrange equations of motion, the second term of this expression equals zero. Hence Eq. (60) shows that, for (any) fixed time $t$,

$$
\begin{equation*}
\frac{\partial S}{\partial q_{j}}=\frac{\partial L}{\partial \dot{q}_{j}} \tag{10.61}
\end{equation*}
$$

But the last derivative is nothing else than the generalized momentum $p_{j}-$ see Eq. (2.31), so that

$$
\begin{equation*}
\frac{\partial S}{\partial q_{j}}=p_{j} \tag{10.62}
\end{equation*}
$$

(As a reminder, both parts of this relation refer to the final moment $t$ of the trajectory.) As a result, the full derivative of action $S\left[t, q_{j}(t)\right]$ over time takes the form

$$
\begin{equation*}
\frac{d S}{d t}=\frac{\partial S}{\partial t}+\sum_{j} \frac{\partial S}{\partial q_{j}} \dot{q}_{j}=\frac{\partial S}{\partial t}+\sum_{j} p_{j} \dot{q}_{j} \tag{10.63}
\end{equation*}
$$

Now, by the very definition (59), the full derivative $d S / d t$ is nothing more that the Lagrange function $L$, so that Eq. (63) yields

$$
\begin{equation*}
\frac{\partial S}{\partial t}=L-\sum_{j} p_{j} \dot{q}_{j} \tag{10.64}
\end{equation*}
$$

However, according to the definition (2) of the Hamiltonian function $H$, the right-hand part of Eq. (63) is just $(-H)$, so that we get an extremely simply-looking Hamilton-Jacobi equation

$$
\begin{equation*}
\frac{\partial S}{\partial t}=-H \tag{10.65}
\end{equation*}
$$

This simplicity is, however, rather deceiving, because in order to use this equation for the calculation of function $S\left(t, q_{j}\right)$ for any particular problem, the Hamiltonian function has to be first expressed as a function of time $t$, generalized coordinates $q_{j}$, and the generalized momenta $p_{j}$ (which may be, according to Eq. (62), presented just as derivatives $\partial S / \partial q_{j}$ ). Let us see how does this procedure work for the simplest case of a 1D system with the Hamiltonian function given by Eq. (10). In this case, the only generalized momentum is $p=\partial S / \partial q$, so that

$$
\begin{equation*}
H=\frac{p^{2}}{2 m_{\mathrm{ef}}}+U_{\mathrm{ef}}(q, t)=\frac{1}{2 m_{\mathrm{ef}}}\left(\frac{\partial S}{\partial q}\right)^{2}+U_{\mathrm{ef}}(q, t), \tag{10.66}
\end{equation*}
$$

and the Hamilton-Jacobi equation (65) is reduced to a partial differential equation,

$$
\begin{equation*}
\frac{\partial S}{\partial t}+\frac{1}{2 m_{\mathrm{ef}}}\left(\frac{\partial S}{\partial q}\right)^{2}+U_{\mathrm{ef}}(q, t)=0 \tag{10.67}
\end{equation*}
$$

Its solution may be readily found in the particular case of time-independent potential energy $U_{\text {ef }}$ $=U_{\text {ef }}(q)$. In this case, Eq. (67) is evidently satisfied by a variable-separated solution

$$
\begin{equation*}
S(t, q)=S_{0}(q)+\text { const } \times t \tag{10.68}
\end{equation*}
$$

Plugging this solution into Eq. (67), we see that since the sum of two last terms in the left-hand part of that equation presents the full mechanical energy $E$, the constant in Eq. (68) is nothing but ( $-E$ ). Thus for function $S_{0}$ we get an ordinary differential equation

$$
\begin{equation*}
-E+\frac{1}{2 m_{\mathrm{ef}}}\left(\frac{d S_{0}}{d q}\right)^{2}+U_{\mathrm{ef}}(q)=0 \tag{10.69}
\end{equation*}
$$

Integrating it, we get

$$
\begin{equation*}
S_{0}=\int\left\{2 m_{\mathrm{ef}}\left[E-U_{\mathrm{ef}}(q)\right]\right\}^{1 / 2} d q+\text { const }, \tag{10.70}
\end{equation*}
$$

so that, finally, the action is equal to

$$
\begin{equation*}
S=\int\left\{2 m_{\mathrm{ef}}\left[E-U_{\mathrm{ef}}(q)\right]\right\}^{1 / 2} d q-E t+\text { const. } \tag{10.71}
\end{equation*}
$$

For the case of 1D motion of a single 1D particle, i.e. for $q=x, m_{\text {ef }}=m, U_{\text {ef }}(q)=U(x)$, this solution is just the 1D case of the more general Eqs. (54)-(55), which were obtained by a much more simple way. (In particular, $S_{0}$ is just the abbreviated action.)

This particular case illustrates that the Hamilton-Jacobi equation is not the most efficient way for solution of most practical problems. However, it may be rather useful for studies of certain mathematical aspects of dynamics. ${ }^{19}$ Moreover, in the 1940s this approach was extended to a completely different field - the optimal control theory, in which the role of action $S$ is played by the so-called cost function a certain functional of a dynamic system, that should be minimized by an optical choice of a control signal - a function of time that affects system's dynamics. From the point of view of this mathematical theory, Eq. (65) is a particular case of a more general Hamilton-Jacobi-Bellman equation. ${ }^{20}$

### 10.5. Exercise problems

10.1. Derive the Hamilton equations of motion for our testbed problem (a bead on a ring rotating about its vertical diameter - see Fig. 2.1, partly reproduced on the right). Check that the equations are equivalent to those derived from the Lagrangian formalism.

10.2. Perform the same tasks as in Problem 10.1 for the system already considered in Problem 2.3, a fixed-length pendulum hanging from a horizontal support whose motion law $x_{0}(t)$ is fixed - see Fig. on the right. (No vertical plane constraint.)

[^157]10.3. Perform the same tasks as in Problems 1 and 2, for the system already considered in Problem 2.5 - a block of mass $m$ that can slide, without friction, along the inclined surface of a heavy wedge (mass $m^{\prime}$ ). The wedge is free to move, also without friction, along a horizontal surface - see Fig. on the right. (Both motions are within the vertical plane containing the steepest slope line.)

10.4. Find and solve equations of motion of a particle with the following Hamiltonian function:
$$
H=\frac{1}{2 m}(\mathbf{p}+a \mathbf{r})^{2},
$$
where $a$ is a constant scalar.
10.5. Let $L$ be the Lagrange function, and $H$ the Hamilton function, of the same system. What three of the following four statements,
(i) $\frac{d L}{d t}=0$,
(ii) $\frac{\partial L}{\partial t}=0$,
(iii) $\frac{d H}{d t}=0$,
(iv) $\frac{\partial H}{\partial t}=0$,
are equivalent? Give an example when those three equalities hold, but the forth one does not.
10.6. Calculate the Poisson brackets of the Cartesian components of the angular momentum $\mathbf{L}$ of a particle moving in a central force field and its Hamiltonian function $H$, and discuss the most important implication of the result.
10.7. After small oscillations had been initiated in a simple pendulum (Fig. on the right), the thread is being pulled up slowly, so that the pendulum length $l$ is being reduced. Neglecting dissipation,
(i) prove by a direct calculation that the oscillation energy is indeed changing proportionately to the oscillation frequency, as it follows from the constancy of the corresponding adiabatic invariant (40), and

(ii) find the $l$-dependence of amplitudes of the angular and linear deviations from the equilibrium.
10.8. The mass $m$ of a small body that performs 1D oscillations in potential $U(x)=a x^{2 n}$, with $n>$ 0 , is being changed slowly. Calculate the oscillation energy $E$ as a function of $m$.
10.9. A stiff ball is bouncing vertically from the floor of an elevator whose upward acceleration changes very slowly. Neglecting energy dissipation, calculate how much does the bounce height $h$ change during acceleration's increase from 0 to $g$.

# Part EM: Classical Electrodynamics 

Last corrections: 2019/09/05

A revised version of this material is now published by the IOP under the title "Classical Electrodynamics: Lecture notes" (Essential Advanced Physics - Volume 3, ISBN 978-0-7503-1405-3), with the model solutions of the exercise problems published under the title
"Classical Electrodynamics: Problems with solutions"
(Essential Advanced Physics - Volume 4, ISBN 978-0-7503-1408-4)

## Table of Contents

## Chapter 1. Electric Charge Interaction (20 pp.)

1.1. The Coulomb law
1.2. The Gauss law
1.3. Scalar potential and electric field energy
1.4. Exercise problems (17)

Chapter 2. Charges and Conductors ( 64 pp.)
2.1. Electric field screening
2.2. Capacitance
2.3. The simplest boundary problems
2.4. Other orthogonal coordinates
2.5. Variable separation
2.6. Charge images
2.7. Green’s functions
2.8. Numerical methods
2.9. Exercise problems (33)

## Chapter 3. Polarization of Dielectrics ( 26 pp .)

3.1. Electric dipole
3.2. Dipole media
3.3. Linear dielectrics
3.4. Molecular field effects
3.5. Electric field energy in a dielectric
3.6. Exercise problems (20)

## Chapter 4. DC Currents (14 pp.)

4.1. Continuity equation and the Kirchhoff laws
4.2. The Ohm law
4.3. Boundary problems
4.4. Dissipation power
4.5. Exercise problems (9)

Chapter 5. Magnetism (42 pp.)
5.1. Magnetic interaction of currents
5.2. Vector-potential and the Ampère law
5.3. Magnetic flux, energy, and inductance
5.4. Magnetic dipole moment, and magnetic dipole media
5.5. Magnetic materials
5.6. Systems with magnetics
5.7. Exercise problems (23)

## Chapter 6. Time-Dependent Electromagnetism (32 pp.)

6.1. Electromagnetic induction
6.2. Quasistatic approximation and skin effect
6.3. Electrodynamics of superconductivity and gauge invariance
6.4. Electrodynamics of macroscopic quantum phenomena
6.5. Inductors, transformers, and ac Kirchhoff laws
6.6. Displacement currents
6.7. Finally, the full Maxwell equation system
6.8. Exercise problems (22)

## Chapter 7. Electromagnetic Wave Propagation (66 pp.)

7.1. Plane waves
7.2. Attenuation and dispersion
7.3. Kramers-Kronig relations
7.4. Reflection
7.5. Refraction
7.6. Transmission lines: TEM waves
7.7. $H$ and $E$ waves in metallic waveguides
7.8. Dielectric waveguides and optical fibers
7.9. Resonators
7.10. Energy loss effects
7.11. Exercise problems (30)

Chapter 8. Radiation, Scattering, Interference, and Diffraction (36 pp.)
8.1. Retarded potentials
8.2. Electric dipole radiation
8.3. Wave scattering
8.4. Interference and diffraction
8.5. The Huygens principle
8.6. Diffraction on a slit
8.7. Geometrical optics placeholder
8.8. Fraunhofer diffraction from more complex scatterers
8.9. Magnetic dipole and electric quadrupole radiation
8.10. Exercise problems (20)

Chapter 9. Special Relativity (54 pp.)
9.1. Einstein postulates and the Lorentz transform
9.2. Relativistic kinematic effects
9.3. 4-vectors, momentum, mass, and energy
9.4. More on 4 -vectors and 4 -tensors
9.5. Maxwell equations in the 4 -form
9.6. Relativistic particles in electric and magnetic fields
9.7. Analytical mechanics of charged particles
9.8. Analytical mechanics of electromagnetic field
9.9. Exercise problems (34)

## Chapter 10. Radiation by Relativistic Charges (38 pp.)

10.1. Liénard-Wiechert potentials
10.2. Radiation power
10.3. Synchrotron radiation
10.4. Bremsstrahlung and Coulomb losses
10.5. Density effects and the Cherenkov radiation
10.6. Radiation's back-action
10.7. Exercise problems (12)

Additional files (available upon request):
Exercise and Test Problems with Model Solutions (220 + 69 = 289 problems; 367 pp.)

## Chapter 1. Electric Charge Interaction

This brief chapter describes the basics of electrostatics, the study of interactions between static (or slowly moving) electric charges. Much of this material should be known to the reader from his or her undergraduate studies; because of that, the explanations will be very succinct. ${ }^{1}$

### 1.1. The Coulomb law

A serious discussion of the Coulomb law ${ }^{2}$ requires a common agreement on the meaning of the following notions: ${ }^{3}$

- electric charges $q_{k}$, as revealed, most explicitly, by experimental observation of electrostatic interaction between the charged particles;
- electric charge conservation, meaning that the algebraic sum of $q_{k}$ of all particles inside any closed volume is conserved, unless the charged particles cross the volume's border; and
- a point charge, meaning the charge of an ultimately small ("point") particle whose position in space may be completely described (in a given reference frame) by its radius-vector $\mathbf{r}=\mathbf{n}_{1} r_{1}+\mathbf{n}_{2} r_{2}+$ $\mathbf{n}_{3} r_{3}$, where $\mathbf{n}_{j}$ (with $j=1,2,3$ ) are unit vectors directed along 3 mutually perpendicular axes, and $r_{j}$ are the corresponding Cartesian components of $\mathbf{r}$.

I will assume that these notions are well known to the reader - though my strong advice is to give some thought to their vital importance. Using them, the Coulomb law for the electrostatic interaction of two point charges in otherwise free space may be formulated as follows:

Coulomb
law for
2 point charges

$$
\begin{equation*}
\mathbf{F}_{k k^{\prime}}=\kappa q_{k} q_{k^{\prime}} \frac{\mathbf{r}_{k}-\mathbf{r}_{k^{\prime}}}{\left|\mathbf{r}_{k}-\mathbf{r}_{k^{\prime}}\right|^{3}} \tag{1.1}
\end{equation*}
$$

where $\mathbf{F}_{k k}$, denotes the force exerted on charge number $k$ by charge number $k$ '. This law is certainly very familiar to the reader, but several remarks may still be due:
(i) Flipping indices $k$ and $k$, we see that Eq. (1) $)^{4}$ complies with the $3^{\text {rd }}$ Newton law: the reciprocal force is equal in magnitude but opposite in direction: $\mathbf{F}_{k^{\prime} k}=-\mathbf{F}_{k k^{\prime}}$.
(ii) According to Eq. (1), the magnitude of the force, $F_{k k^{\prime}}$, is inversely proportional to the square of the distance between the two charges - the well-known undergraduate-level formulation of the Coulomb law.

[^158](iii) Since vector $\left(\mathbf{r}_{k}-\mathbf{r}_{k^{\prime}}\right)$ is directed from point $\mathbf{r}_{k}$, toward point $\mathbf{r}_{k}$ (Fig. 1), Eq. (1) implies that charges of the same sign (i.e. with $q_{k} q_{k^{\prime}}>0$ ) repulse, while those with opposite signs ( $q_{k} q_{k}<0$ ) attract each other.

Fig. 1.1. Direction of the Coulomb forces (for $q_{k} q_{k}{ }^{\prime}>0$ ).
(iv) Constant $\kappa$ in Eq. (1) depends on the system of units we use. In the Gaussian units, $\kappa$ is set to 1 , for the price of introducing a special unit of charge (the statcoulomb) that would fit the experimental data for Eq. (1), for forces $\mathbf{F}_{k k}$, measured in Gaussian units (dynes). On the other hand, in the International System ("SI") of units, the charge unit is one coulomb (abbreviated C), ${ }^{5}$ close to $3 \times 10^{9}$ statcoulombs, and $\kappa$ is different from unity: ${ }^{6}$

$$
\begin{equation*}
\kappa_{\mathrm{SI}}=\frac{1}{4 \pi \varepsilon_{0}} \equiv 10^{-7} \mathrm{c}^{2} \tag{1.2}
\end{equation*}
$$

Electric force constant

Unfortunately, the continuing struggle between zealot proponents of these two systems bears all ugly features of a religious war, with a similarly slim chances for any side to win it in any foreseeable future. In my humble view, each of these systems has its advantages and handicaps (to be noted on several occasions below), and every educated physicist should have no problem with using any of them. Following insisting recommendations of international scientific unions, I will mostly use SI units, but for readers' convenience, duplicate the most important formulas in the Gaussian units.

Besides Eq. (1), another key experimental law of electrostatics is the linear superposition principle: the electrostatic forces exerted on some point charge (say, $q_{k}$ ) by other charges do not affect each other and add up as vectors to form the net force:

$$
\begin{equation*}
\mathbf{F}_{k}=\sum_{k^{\prime} \neq k} \mathbf{F}_{k k^{\prime}}, \tag{1.3}
\end{equation*}
$$

where the summation is extended over all charges but $q_{k}$, and the partial force $\mathbf{F}_{k k}$, is described by Eq. (1). ${ }^{7}$ The fact that the sum is restricted to $k^{\prime} \neq k$ means that a point charge does not interact with itself.

[^159]This fact may look trivial from Eq. (1), whose right-hand part diverges at $\mathbf{r}_{k} \rightarrow \mathbf{r}_{k^{\prime}}$, but becomes less evident (though still true) in quantum mechanics where the charge of even an elementary particle is effectively spread around some volume, together with particle's wavefunction. ${ }^{8}$

Now we may combine Eqs. (1) and (3) to get the following expression for the net force $\mathbf{F}$ acting on some charge $q$ located at point $\mathbf{r}$ :

$$
\begin{equation*}
\mathbf{F}=q \frac{1}{4 \pi \varepsilon_{0}} \sum_{\mathbf{r}_{k} \neq \neq \mathbf{r}} q_{k^{\prime}} \frac{\mathbf{r}-\mathbf{r}_{k^{\prime}}}{\left|\mathbf{r}-\mathbf{r}_{k^{\prime}}\right|^{3}} . \tag{1.4}
\end{equation*}
$$

This equation implies that it makes sense to introduce the notion of the electric field at point $\mathbf{r}$, as an entity independent of the probe charge $q$, characterized by vector

$$
\begin{equation*}
\mathbf{E}(\mathbf{r}) \equiv \frac{\mathbf{F}}{q} \tag{1.5}
\end{equation*}
$$

formally called the electric field strength - but much more frequently, just the "electric field". In these terms, Eq. (4) becomes
Coulomb law for system of point charges

$$
\begin{equation*}
\mathbf{E}(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} \sum_{\mathbf{r}_{k}^{\prime} \neq \mathbf{r}} q_{k^{\prime}} \frac{\mathbf{r}-\mathbf{r}_{k^{\prime}}}{\left|\mathbf{r}-\mathbf{r}_{k^{\prime}}\right|^{3}} \tag{1.6}
\end{equation*}
$$

This concept is so appealing that Eq. (5) is used well beyond the boundaries of free-space electrostatics. Moreover, the notion of field becomes virtually unavoidable for description of time-dependent phenomena (such as electromagnetic waves), where the electromagnetic field shows up as a specific form of matter, with zero rest mass, and hence different from the usual "material" particles.

Many problems involve many point charges $q_{k}, q_{k^{\prime \prime}}, \ldots$, located so closely that it is possible to approximate them with a continuous charge distribution. Indeed, for a group of charges within a very small volume $d^{3} r^{\prime}$, with the linear size satisfying strong condition $d r \ll{\mathbf{r}_{k}}-\mathbf{r}_{k^{\prime}} \mid$, the geometrical factor in Eq. (6) is essentially the same. As a result, all these charges may be treated as a single charge $d Q\left(\mathbf{r}^{\prime}\right)$. Since this charge is proportional to $d^{3} r^{\prime}$, we can define the local (3D) charge density $\rho\left(\mathbf{r}^{\prime}\right)$ by relation ${ }^{9}$

$$
\begin{equation*}
\rho\left(\mathbf{r}^{\prime}\right) d^{3} r^{\prime} \equiv d Q\left(\mathbf{r}^{\prime}\right) \equiv \sum_{r_{k^{\prime}} \in d^{3} r^{\prime}} q_{k^{\prime}}, \tag{1.7}
\end{equation*}
$$

and rewrite Eq. (6) as

$$
\begin{equation*}
\mathbf{E}(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} \sum_{d^{3} r^{\prime}} d Q\left(\mathbf{r}^{\prime}\right) \frac{\mathbf{r}-\mathbf{r}^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{3}}=\frac{1}{4 \pi \varepsilon_{0}} \sum_{d^{3} r^{\prime}} \rho\left(\mathbf{r}^{\prime}\right) d^{3} r^{\prime} \frac{\mathbf{r}-\mathbf{r}^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{3}}, \tag{1.8}
\end{equation*}
$$

[^160]i.e. as the integral (over the whole volume containing all essential charges): ${ }^{10}$
\[

$$
\begin{equation*}
\mathbf{E}(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} \int \rho\left(\mathbf{r}^{\prime}\right) \frac{\mathbf{r}-\mathbf{r}^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{3}} d^{3} r^{\prime} \tag{1.9}
\end{equation*}
$$

\]

Coulomb law for continuous charge distribution

It is very convenient that Eq. (9) may be used even in the case of discrete point charges, employing the notion of Dirac's $\delta$-function, ${ }^{11}$ which is a mathematical approximation for a very sharp function equal to zero everywhere but one point, and still having a finite (unit) integral. Indeed, in this formalism, a set of point charges $q_{k^{\prime}}$ located in points $\mathbf{r}_{k^{\prime}}$ may be presented by the pseudo-continuous distribution with density

$$
\begin{equation*}
\rho\left(\mathbf{r}^{\prime}\right)=\sum_{k^{\prime}} q_{k^{\prime}} \delta\left(\mathbf{r}^{\prime}-\mathbf{r}_{k^{\prime}}\right) . \tag{1.10}
\end{equation*}
$$

Plugging this expression into Eq. (9), we come back to the discrete version (6) of the Coulomb law.

### 1.2. The Gauss law

Due to the extension to point ("discrete") charges, it may seem that Eqs. (5) and (9) is all we need for solving any problem of electrostatics. In practice, this is not quite true, first of all because the direct use of Eq. (9) frequently leads to complex calculations. Indeed, let us consider a very simple example: the electric field produced by a spherically-symmetric charge distribution with density $\rho\left(r^{\prime}\right)$. We may immediately use the problem symmetry to argue that the electric field should be also spherically-symmetric, with only one component in spherical coordinates: $\mathbf{E}(\mathbf{r})=E(r) \mathbf{n}_{r}$ where $\mathbf{n}_{r} \equiv \mathbf{r} / r$ is the unit vector in the direction of the field observation point $\mathbf{r}$ (Fig. 2).

Fig. 1.2. One of the simplest problems of electrostatics: electric field produced by a spherically-symmetric charge distribution.

Taking this direction as the polar axis of a spherical coordinate system, we can use the evident independence of the elementary radial field $d E$, created by the elementary charge $\rho\left(r^{\prime}\right) d^{3} r^{\prime}=\rho\left(r^{\prime}\right) r^{\prime 2} \sin \theta$ $d r^{\prime} d \theta^{\prime} d \varphi^{\prime}$, of the azimuth angle $\varphi^{\prime}$, and reduce integral (9) to

$$
\begin{equation*}
E=\frac{1}{4 \pi \varepsilon_{0}} 2 \pi \int_{0}^{\pi} \sin \theta^{\prime} d \theta^{\prime} \int_{0}^{\infty} r^{\prime 2} d r^{\prime} \frac{\rho\left(r^{\prime}\right)}{\left(r^{\prime \prime}\right)^{2}} \cos \theta \tag{1.11}
\end{equation*}
$$

[^161]where $\theta$ and $r "$ are the geometrical parameters marked in Fig. 2. Since they all may be readily expressed via $r^{\prime}$ and $\theta^{\prime}$ using auxiliary parameters $a$ and $h$,
\[

$$
\begin{equation*}
\cos \theta=\frac{r-a}{r^{\prime \prime}}, \quad\left(r^{\prime \prime}\right)^{2}=h^{2}+\left(r-r^{\prime} \cos \theta\right)^{2}, \quad a=r^{\prime} \cos \theta^{\prime}, \quad h=r^{\prime} \sin \theta, \tag{1.12}
\end{equation*}
$$

\]

integral (11) may be eventually reduced to an explicit integral over $r^{\prime}$ and $\theta$. and worked out analytically, but that would require some effort.

For more complex problem, integral (8) may be much more complex, defying an analytical solution. One could argue that with the present-day abundance of computers and numerical algorithm libraries, one can always resort to numerical integration. This argument may be enhanced by the fact that numerical integration is based on the replacement of the integral by a sum, and summation is much more robust to (unavoidable) discretization and rounding errors than the finite-difference schemes typical for the numerical solution of differential equations.

These arguments, however, are only partly justified, since in many cases the numerical approach runs into a problem sometimes called the curse of dimensionality, in which the last word refers to the number of input parameters of the problem to be solved, i.e. the dimensionality of its parameter space. Let us discuss this issue, because it is common for most fields of physics and, more generally, any quantitative science. ${ }^{12}$

If the number of the parameters of a problem is small, the results of its numerical solution may be of the same (and in some sense higher) value than the analytical ones. For example, if a problem has no parameters, and its result is just one number (say, $\pi^{2} / 4$ ), this "analytical" answer hardly carries more information than its numerical form $2.4674011 \ldots$ Now, if a problem has one input parameter (say, a), the result of an analytical approach in most cases may be presented as an analytical function $f(a)$. If the function is really simple, called elementary, with many properties well known (say, $f(a)=\sin a$ ), this function gives us virtually everything we want to know. However, if the function is complicated, you would need to tabulate it numerically for a set of values of parameter $a$ and possibly present the result as a plot. The same results (and the same plot) can be calculated numerically, without using analytics at all. This plot may certainly be very valuable, but since the analytical form has a potential of giving you more information (say, the values of $f(a)$ outside the plot range, or the asymptotic behavior of the function), it is hard to say that the numerics completely beat the analytics here.

Now let us assume that you have more input parameters. For two parameters (say, $a$ and $b$ ), instead of one curve you would need a family of such curves for several (sometimes many) values of $b$. Still, the plots sometimes may fit one page convenient for viewing, so it is still not too bad. Now, if you have three parameters, the full representation of the results may require many pages (maybe a book) full of curves, for four parameters we may speak about several bookshelves, for five parameters something like a library, etc. For large number of parameters, typical for many scientific problems, the number of points in the parameters space grows exponentially, even the volume of calculations necessary for the generation of this data may become impracticable, despite the dirt-cheap CPU time we have now.

Thus, despite the current proliferation of numerical methods in physics, analytical results have an ever-lasting value, and we should try to get them whenever we can. For our current problem of finding electric field generated by a fixed set of electric charges, large help comes from the Gauss law.

[^162]Let us consider a single point charge $q$ inside a smooth, closed surface $A$ (Fig. 3), and calculate product $E_{n} d^{2} r$, where $d^{2} r$ is an infinitesimal element of the surface (which may be well approximated with a plane of that area), and $E_{n}$ is the component of the electric field in that point, normal to that plane.

(b)

Fig. 1.3. Deriving the Gauss law: a point charge $q$ is (a) inside volume $V$ and (b) outside of that volume.

This component may be calculated as $E \cos \theta$, where $\theta$ is the angle between vector $\mathbf{E}$ and the unit vector $\mathbf{n}$ normal to the surface. (Equivalently, $E_{n}$ may be presented as the scalar product E.n.) Now let us notice that the product $\cos \theta d^{2} r$ is nothing more than the area $d^{2} r$ of the projection of $d^{2} r$ onto the plane perpendicular to vector $\mathbf{r}$ connecting charge $q$ with this point of the surface (Fig. 3), because the angle between the planes $d^{2} r^{\prime}$ and $d^{2} r$ is also equal to $\theta$. Using the Coulomb law for $\mathbf{E}$, we get

$$
\begin{equation*}
E_{n} d^{2} r=E \cos \theta d^{2} r=\frac{1}{4 \pi \varepsilon_{0}} \frac{q}{r^{2}} d^{2} r^{\prime} \tag{1.13}
\end{equation*}
$$

But the ratio $d^{2} r^{\prime} / r^{2}$ is nothing more than the elementary solid angle $d \Omega$ under which the areas $d^{2} r^{\prime}$ and $d^{2} r$ are seen from the charge point, so that $E_{n} d^{2} r$ may be presented as just a product of $d \Omega$ by a constant $\left(q / 4 \pi \varepsilon_{0}\right)$. Summing these products over the whole surface, we get

$$
\begin{equation*}
\oint_{S} E_{n} d^{2} r=\frac{q}{4 \pi \varepsilon_{0}} \oint_{S} d \Omega=\frac{q}{\varepsilon_{0}}, \tag{1.14}
\end{equation*}
$$

since the full solid angle equals $4 \pi$. (The integral in the left-hand part of this relation is called the flux of electric field through surface $S$.)

Equation (14) expresses the Gauss law for one point charge. However, it is only valid if the charge is located inside the volume limited by the surface. In order to find the flux created by a charge outside of the volume, we still can use Eq. (13), but to proceed we have to be careful with the signs of the elementary contributions $E_{n} d A$. Let us use the common convention to direct the unit vector $\mathbf{n}$ out of the closed volume we are considering (the so-called outer normal), so that the elementary product $E_{n} d^{2} r$ $=(\mathbf{E} \cdot \mathbf{n}) d^{2} r$ and hence $d \Omega=E_{n} d^{2} r^{\prime} / r^{2}$ is positive if vector $\mathbf{E}$ is pointing out of the volume (like in the example shown in Fig. 3a and the upper-right area in Fig. 3b), and negative in the opposite case (for example, in the lower-left area in Fig. 3b). As the latter figure shows, if the charge is located outside of the volume, for each positive contribution $d \Omega$ there is always equal and opposite contribution to the
integral. As a result, at the integration over the solid angle the positive and negative contributions cancel exactly, so that

$$
\begin{equation*}
\oint_{S} E_{n} d^{2} r=0 . \tag{1.15}
\end{equation*}
$$

The real power of the Gauss law is revealed by its generalization to the case of many charges within volume $V$. Since the calculation of flux is a linear operation, the linear superposition principle (3) means that the flux created by several charges is equal to the (algebraic) sum of individual fluxes from each charge, for which either Eq. (14) or Eq. (15) are valid, depending on the charge position (in or out of the volume). As the result, for the total flux we get:

$$
\begin{equation*}
\oint_{S} E_{n} d^{2} r=\frac{Q_{V}}{\varepsilon_{0}} \equiv \frac{1}{\varepsilon_{0}} \sum_{\mathbf{r}_{j} \in V} q_{j}=\frac{1}{\varepsilon_{0}} \int_{V} \rho\left(\mathbf{r}^{\prime}\right) d^{3} r^{\prime} \tag{1.16}
\end{equation*}
$$

where $Q_{V}$ is the net charge inside volume $V$. This is the full version of the Gauss law.
In order to appreciate the problem-solving power of the law, let us return to the problem presented in Fig. 2, i.e. a spherical charge distribution. Due to its symmetry, which had already been discussed above, if we apply Eq. (16) to a sphere of radius $r$, the electric field should be perpendicular to the sphere at each its point (i.e., $E_{n}=E$ ), and its magnitude the same at all points: $E_{n}=E=E(r)$. As a result, the flux calculation is elementary:

$$
\begin{equation*}
\oint E_{n} d^{2} r=4 \pi r^{2} E(r) . \tag{1.17}
\end{equation*}
$$

Now, applying the Gauss law (16), we get:

$$
\begin{equation*}
4 \pi r^{2} E(r)=\frac{1}{\varepsilon_{0}} \int_{r^{\prime}<r} \rho\left(r^{\prime}\right) d^{3} r^{\prime}=\frac{4 \pi}{\varepsilon_{0}} \int_{0}^{r} r^{\prime 2} \rho\left(r^{\prime}\right) d r^{\prime} \tag{1.18}
\end{equation*}
$$

so that, finally,

$$
\begin{equation*}
E(r)=\frac{1}{r^{2} \varepsilon_{0}} \int_{0}^{r} r^{\prime 2} \rho\left(r^{\prime}\right) d r^{\prime}=\frac{1}{4 \pi \varepsilon_{0}} \frac{Q(r)}{r^{2}} \tag{1.19}
\end{equation*}
$$

where $Q(r)$ is the full charge inside the sphere of radius $r$ :

$$
\begin{equation*}
Q(r) \equiv 4 \pi \int_{0}^{r} \rho\left(r^{\prime}\right) r^{\prime 2} d r^{\prime} \tag{1.20}
\end{equation*}
$$

In particular, this formula shows that the field outside of a sphere of a finite radius $R$ is exactly the same as if all its charge $Q=Q(R)$ was concentrated in the sphere's center. (Note that this important result is only valid for any spherically-symmetric charge distribution.) For the field inside the sphere, finding electric field still requires an explicit integration (20), but this 1D integral is much simpler than the 2D integral (11), and in some important cases may be readily worked out analytically. For example, if charge $Q$ is uniformly distributed inside a sphere of radius $R$,

$$
\begin{equation*}
\rho\left(r^{\prime}\right)=\rho=\frac{Q}{V}=\frac{Q}{(4 \pi / 3) R^{3}}, \tag{1.21}
\end{equation*}
$$

the integration is elementary:

$$
\begin{equation*}
E(r)=\frac{\rho}{r^{2} \varepsilon_{0}} \int_{0}^{r} r^{\prime 2} d r^{\prime}=\frac{\rho r}{3 \varepsilon_{0}}=\frac{1}{4 \pi \varepsilon_{0}} \frac{Q r}{R^{3}} . \tag{1.22}
\end{equation*}
$$

We see that in this case the field is growing linearly from the center to the sphere's surface, and only at $r$ $>R$ starts to decrease in agreement with Eq. (19) with constant $Q(r)=Q$. Another important observation is that the results for $r \leq R$ and $r \geq R$ give the same value $\left(Q / 4 \pi \varepsilon_{0} R^{2}\right)$ at the charged sphere's surface, $r=$ $R$, so that the electric field is continuous.

In order to underline the importance of the last fact, let us consider one more elementary but very important example of the Gauss law's application. Let a thin plane sheet (Fig. 4) be charged uniformly, with an areal density $\sigma=$ const (see Footnote 9 above).

Fig. 1.4. Electric field of a charged plane.

In this case, it is fruitful to use the Gauss volume in the form of a planar "pillbox" of thickness $2 z$ (where $z$ is the Cartesian coordinate perpendicular to charged plane) and certain area $A-$ see Fig. 4. Due to the symmetry of the problem, it is evident that the electric field should be: (i) directed along axis $z$, (ii) constant on each of the upper and bottom sides of the pillbox, (iii) equal and opposite on these sides, and (iv) parallel to the side surfaces of the box. As a result, the full electric field flux through the pillbox surface is just $2 A E(\mathrm{z})$, so that the Gauss law (16) yields

$$
\begin{equation*}
2 A E(\mathrm{z})=\frac{1}{\varepsilon_{0}} Q_{A}=\frac{1}{\varepsilon_{0}} \sigma A \tag{1.23}
\end{equation*}
$$

and we get a very simple but important formula

$$
\begin{equation*}
E(z)=\frac{\sigma}{2 \varepsilon_{0}}=\text { const. } \tag{1.24}
\end{equation*}
$$

Notice that, somewhat counter-intuitively, the field magnitude does not depend on the distance from the charged plane. From the point of view of the Coulomb law (5), this result may be explained as follows, the farther the observation point from the plane, the weaker the effect of each elementary charge, $d Q=\sigma d^{2} r$, but the more such elementary charges give contributions to the vertical component of vector $\mathbf{E}$.

Note also that though the magnitude $E \equiv|\mathbf{E}|$ of the electric field is constant, its vertical component $E_{z}$ changes sign at $z=0$ (Fig. 4), experiencing a discontinuity (jump) equal to $\Delta E_{z}=\sigma / \varepsilon_{0}$. This jump disappears if the surface is not charged ( $\sigma=0$ ). This statement remains true in a more general case of finite volume (but not surface!) charge density $\rho$. Returning for a minute to our charged
sphere problem, very close to its surface it may be considered planar, so that the electric field should indeed be continuous, as it is.

Admittedly, the integral form (16) of the Gauss law is immediately useful only for highly symmetrical geometries, like as in the two problems discussed above. However, it may be recast into an alternative, differential form whose field of useful applications is much wider. This form may be obtained from Eq. (16) using the divergence theorem that, according to the vector algebra, is valid for any space-differentiable vector, in particular $\mathbf{E}$, and for any volume $V$ limited by closed surface $S:{ }^{13}$

$$
\begin{equation*}
\oint_{S} E_{n} d^{2} r=\int_{V}(\nabla \cdot \mathbf{E}) d^{3} r, \tag{1.25}
\end{equation*}
$$

where $\nabla$ is the del (or "nabla") operator of spatial differentiation. ${ }^{14}$ Combining Eq. (25) with the Gauss law (16), we get

$$
\begin{equation*}
\int_{V}\left(\nabla \cdot \mathbf{E}-\frac{\rho}{\varepsilon_{0}}\right) d^{3} r=0 \tag{1.26}
\end{equation*}
$$

For a given distribution of electric charge (and hence of the electric field), this equation should be valid for any choice of volume $V$. This can hold only if the function under the integral vanishes at each point, i.e. if ${ }^{15}$

Inhomogeneous Maxwell equation for $E$

$$
\begin{equation*}
\nabla \cdot \mathbf{E}=\frac{\rho}{\varepsilon_{0}} \tag{1.27}
\end{equation*}
$$

Note that in a sharp contrast with the integral form (16), Eq. (26) is local: it relates the electric field divergence to the charge density at the same point. This equation, being the differential form of the Gauss law, is frequently called (the free-space version of) one of Maxwell equations. Another, homogeneous Maxwell equation's "embryo" may be obtained by noticing that curl of point charge's

Homogeneous Maxwell equation
for E field, and hence that of any system of charges, equals zero: ${ }^{16}$

$$
\begin{equation*}
\nabla \times \mathbf{E}=0 \tag{1.28}
\end{equation*}
$$

(We will arrive at two other Maxwell equations, for the magnetic field, in Chapter 5, and then generalize all the equations to their full, time-dependent form by the end of Chapter 6. However, Eq. (27) would stay the same.)

Just to get a better gut feeling of Eq. (27), let us apply it to the same example of a uniformly charged sphere (Fig. 2). The vector algebra tells us that the divergence of a spherically symmetric vector function $\mathbf{E}(\mathbf{r})=E(r) \mathbf{n}_{r}$ may be simply expressed in spherical coordinates: ${ }^{17}$

[^163]\[

$$
\begin{equation*}
\nabla \cdot \mathbf{E}=\frac{1}{r^{2}} \frac{d}{d r}\left(r^{2} E\right) . \tag{1.29}
\end{equation*}
$$

\]

As a result, Eq. (27) yields a linear, ordinary differential equation for the function $E(r)$ :

$$
\frac{1}{r^{2}} \frac{d}{d r}\left(r^{2} E\right)= \begin{cases}\rho / \varepsilon_{0}, & \text { for } r \leq R  \tag{1.30a}\\ 0, & \text { for } r \geq R\end{cases}
$$

that may be readily integrated on each of the segments:

$$
E(r)=\frac{1}{\varepsilon_{0}} \frac{1}{r^{2}} \times \begin{cases}\rho \int r^{2} d r=\rho r^{3} / 3+C_{1}, & \text { for } r \leq R  \tag{1.30b}\\ C_{2}, & \text { for } r \geq R\end{cases}
$$

In order to determine the integration constant $C_{1}$, we can use boundary condition $E(0)=0$. (It follows from problem's spherical symmetry: in the center of the sphere, electric field has to vanish, because otherwise, where would it be directed?) Constant $C_{2}$ may be found from the continuity condition $E(R-$ $0)=E(R+0)$, which has already been discussed above. As a result, we arrive at our previous results (19) and (22).

We can see that in this particular, highly symmetric case, using the differential form of the Gauss law is more complex than its integral form. (For our second example, shown in Fig. 4, it would be even less natural.) However, Eq. (27) and its generalizations are more convenient for asymmetric charge distributions, and invaluable in the cases where the charge distribution $\rho(\mathbf{r})$ is not known a priori and has to be found in a self-consistent way. (We will start discussing such cases in the next chapter.)

### 1.3. Scalar potential and electric field energy

One more help for solving electrostatics (and more complex) problems may be obtained from the notion of the electrostatic potential, which is just the electrostatic potential energy $U$ of a probe particle, normalized by its charge:

$$
\begin{equation*}
\phi \equiv \frac{U}{q} . \tag{1.31}
\end{equation*}
$$

## Electrostatic potential

As we know from classical mechanics, ${ }^{18}$ the notion of $U$ (and hence $\phi$ ) make sense only for the case of potential forces, for example those depending just on particle's position. Equations (6) and (8) show that, in the static situations, the electric field clearly falls into this category. For such a field, the potential energy may be defined as a scalar function $U(\mathbf{r})$ that allows the force to be calculated as its gradient (with the opposite sign):

$$
\begin{equation*}
\mathbf{F}=-\nabla U . \tag{1.32}
\end{equation*}
$$

Dividing both sides of this equation by the charge of the probe particle, and using Eqs. (5) and (31), we get ${ }^{19}$

[^164]Electrostatic field as a gradient

$$
\begin{equation*}
\mathbf{E}=-\nabla \phi \tag{1.33}
\end{equation*}
$$

In order to calculate the scalar potential, let us start from the simplest case of a single point charge $q$ placed at the origin. For it, the Coulomb law (5) takes a simple form

$$
\begin{equation*}
\mathbf{E}=\frac{1}{4 \pi \varepsilon_{0}} q \frac{\mathbf{r}}{r^{3}}=\frac{1}{4 \pi \varepsilon_{0}} q \frac{\mathbf{n}_{r}}{r^{2}} . \tag{1.34}
\end{equation*}
$$

It is straightforward to check that the last fraction in the right-hand part of this equation is equal to $\nabla(1 / r) .{ }^{20}$ Hence, according to the definition (33), for this particular case

Potential of a point charge

$$
\begin{equation*}
\phi=\frac{1}{4 \pi \varepsilon_{0}} \frac{q}{r} . \tag{1.35}
\end{equation*}
$$

(In the Gaussian units, this result is spectacularly simple: $\phi=q / r$.) Note that we could add an arbitrary constant to this potential (and indeed to any other distribution of $\phi$ discussed below) without changing the force, but it is convenient to define the potential energy to approach zero at infinity.

Before going any further, let us demonstrate how useful the notions of $U$ and $\phi$ are, on a very simple example. Let two similar charges $q$ be launched from afar, with an initial velocity $v_{0} \ll c$ each, straight toward each other (i.e. with the zero impact parameter) - see Fig. 5. Since, according to the Coulomb law, the charges repel each other with increasing force, they will stop at some minimum distance $r_{\text {min }}$ from each other, and than fly back.

Fig. 1.5. Simple problem of electric particle motion.
We could of course find $r_{\text {min }}$ directly from the Coulomb law. However, for that we would need to write the $2^{\text {nd }}$ Newton law for each particle (actually, due to the problem symmetry, they would be similar), then integrate them over time once to find the particle velocity $v$ as a function of distance, and then recover $r_{\min }$ from the requirement $v=0$. The notion of potential allows this problem to be solved in one line. Indeed, in the field of potential forces the system's total energy $E=T+U=T+q \phi$ is conserved. In our non-relativistic case, the kinetic energy $T$ is just $m v^{2} / 2$. Hence, equating the total energy of two particles in the points $r=\infty$ and $r=r_{\text {min }}$, and using Eq. (35) for $\phi$, we get

$$
\begin{equation*}
2 \frac{m v_{0}^{2}}{2}+0=0+\frac{1}{4 \pi \varepsilon_{0}} \frac{q^{2}}{r_{\min }} \tag{1.36}
\end{equation*}
$$

immediately giving us the final answer: $r_{\min }=q^{2} / 4 \pi \varepsilon_{0} m v_{0}{ }^{2}$.
Now let us calculate $\phi$ for an arbitrary configuration of charges. For a single charge in an arbitrary position (say, $\mathbf{r}_{k^{\prime}}$ ), $r$ in Eq. (35) should be evidently replaced for $\left|\mathbf{r}-\mathbf{r}_{k^{\prime}}\right|$. Now, the linear

[^165]superposition principle (3) allows for an easy generalization of this formula to the case of an arbitrary set of discrete charges,
\[

$$
\begin{equation*}
\phi(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} \sum_{\mathbf{r}_{k^{\prime}} \neq \mathbf{r}} \frac{q_{k^{\prime}}}{\left|\mathbf{r}-\mathbf{r}_{k^{\prime}}\right|} \tag{1.37}
\end{equation*}
$$

\]

Finally, using the same arguments as in Sec. 1, we can use this result to argue that in the case of an arbitrary continuous charge distribution

$$
\begin{equation*}
\phi(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} \int \frac{\rho\left(\mathbf{r}^{\prime}\right)}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} d^{3} r^{\prime} \tag{1.38}
\end{equation*}
$$

Potential of a charge distribution

Again, the notion of Dirac's delta-function allows to use the last equation for discrete charges as well, so that Eq. (38) may be considered as the general expression for the electrostatic potential.

For most practical calculations, using this expression and then applying Eq. (33) to the result, is preferable to using Eq. (9), because $\phi$ is a scalar, while $\mathbf{E}$ is a 3 D vector - mathematically equivalent to 3 scalars. Still, this approach may lead to technical problems similar to those discussed in Sec. 2. For example, applying it to the spherically-symmetric distribution of charge (Fig. 2), we get integral

$$
\begin{equation*}
\phi=\frac{1}{4 \pi \varepsilon_{0}} 2 \pi \int_{0}^{\pi} \sin \theta^{\prime} d \theta^{\prime} \int_{0}^{\infty} r^{\prime 2} d r^{\prime} \frac{\rho\left(r^{\prime}\right)}{r^{\prime \prime}} \cos \theta, \tag{1.39}
\end{equation*}
$$

which is not much simpler than Eq. (11).
The situation may be much improved by re-casting Eq. (38) into a differential form. For that, it is sufficient to plug the definition of $\phi$, Eq. (33), into Eq. (27):

$$
\begin{equation*}
\nabla \cdot(-\nabla \phi)=\frac{\rho}{\varepsilon_{0}} \tag{1.40}
\end{equation*}
$$

The left-hand part of this equation is nothing more than the Laplace operator of $\phi$ (with the minus sign), so that we get the famous Poisson equation ${ }^{21}$ for the electrostatic potential:

$$
\begin{equation*}
\nabla^{2} \phi=-\frac{\rho}{\varepsilon_{0}} \tag{1.41}
\end{equation*}
$$

Poisson equation for $\phi$
(In the Gaussian units, the Poisson equation looks like $\nabla^{2} \phi=-4 \pi \rho$.) This differential equation is so convenient for applications that even its particular case for $\rho=0$,

$$
\begin{equation*}
\nabla^{2} \phi=0 \tag{1.42}
\end{equation*}
$$

has earned a special name - the Laplace equation. ${ }^{22}$
In order to get a feeling of the Poisson equation as a problem solving tool, let us return to the spherically-symmetric charge distribution (Fig. 2) with a constant charge density $\rho$. Using the

[^166]symmetry, we can present the potential as $\phi(\mathbf{r})=\phi(r)$, and hence use the following simple expression for its Laplace operator: ${ }^{23}$
\[

$$
\begin{equation*}
\nabla^{2} \phi=\frac{1}{r^{2}} \frac{d}{d r}\left(r^{2} \frac{d \phi}{d r}\right) \tag{1.43}
\end{equation*}
$$

\]

so that for the points inside the charged sphere $(r \leq R)$ the Poisson equation yields

$$
\begin{equation*}
\frac{1}{r^{2}} \frac{d}{d r}\left(r^{2} \frac{d \phi}{d r}\right)=-\frac{\rho}{\varepsilon_{0}}, \quad \text { i.e. } \frac{d}{d r}\left(r^{2} \frac{d \phi}{d r}\right)=-\frac{\rho}{\varepsilon_{0}} r^{2} \tag{1.44}
\end{equation*}
$$

Integrating the last form of the equation over $r$ once, with the natural boundary condition $d \phi /\left.d r\right|_{r=0}=0$ (because of the condition $E(0)=0$, which has been discussed above), we get

$$
\begin{equation*}
\frac{d \phi}{d r}(r)=-\frac{\rho}{r^{2} \varepsilon_{0}} \int_{0}^{r} r^{\prime 2} d r^{\prime}=-\frac{\rho r}{3 \varepsilon_{0}}=-\frac{1}{4 \pi \varepsilon_{0}} \frac{Q r}{R^{3}} . \tag{1.45}
\end{equation*}
$$

Since this derivative is nothing more than $-E(r)$, in this formula we can readily recognize our previous result (22). Now we may like to carry out the second integration to calculate the potential itself:

$$
\begin{equation*}
\phi(r)=-\frac{Q}{4 \pi \varepsilon_{0} R^{3}} \int_{0}^{r} r^{\prime} d r^{\prime}+c_{1}=-\frac{Q r^{2}}{8 \pi \varepsilon_{0} R^{3}}+c_{1} . \tag{1.46}
\end{equation*}
$$

Before making any judgment on the integration constant $c_{1}$, let us solve the Poisson equation (in this case, just the Laplace equation) for the range outside the sphere $(r>R)$ :

$$
\begin{equation*}
\frac{1}{r^{2}} \frac{d}{d r}\left(r^{2} \frac{d \phi}{d r}\right)=0 \tag{1.47}
\end{equation*}
$$

Its first integral,

$$
\begin{equation*}
\frac{d \phi}{d r}(r)=\frac{c_{2}}{r^{2}} \tag{1.48}
\end{equation*}
$$

also gives the electric field (with the minus sign). Now using Eq. (1.45) and requiring the field to be continuous at $r=R$, we get

$$
\begin{equation*}
\frac{c_{2}}{R^{2}}=-\frac{Q}{4 \pi \varepsilon_{0} R^{2}}, \text { i.e. } \frac{d \phi}{d r}(r)=-\frac{Q}{4 \pi \varepsilon_{0} r^{2}} \tag{1.49}
\end{equation*}
$$

in an evident agreement with Eq. (19). Integrating this result again,

$$
\begin{equation*}
\phi(r)=-\frac{Q}{4 \pi \varepsilon_{0}} \int \frac{d r}{r^{2}}=\frac{Q}{4 \pi \varepsilon_{0} r}+c_{3}, \quad \text { for } r>R \tag{1.50}
\end{equation*}
$$

we can select $c_{3}=0$, so that $\phi(\infty)=0$, in accordance with the usual (though not compulsory) convention. Now we can finally determine constant $c_{1}$ in Eq. (46) by requiring that this equation and Eq. (50) give the same value of $\phi$ at the boundary $r=R$. (According to Eq. (33), if the potential had a jump, the electric field at that point would be infinite.) The final answer may be presented as

[^167]\[

$$
\begin{equation*}
\phi(r)=\frac{Q}{4 \pi \varepsilon_{0} R}\left[\frac{R^{2}-r^{2}}{2 R^{2}}+1\right], \quad \text { for } r \leq R . \tag{1.51}
\end{equation*}
$$

\]

We see that using the Poisson equation to find the electrostatic potential distribution for highly symmetric problems may be more cumbersome than directly finding the electric field - say, from the Gauss law. However, we will repeatedly see below that if the electric charge distribution is not fixed in advance, using Eq. (41) may be the only practicable way to proceed.

Returning now to the general theory of electrostatic phenomena, let us calculate potential energy $U$ of an arbitrary system of electric charges $q_{k}$. Despite the apparently straightforward relation (31) between $U$ and $\phi$, the calculation is a little bit more complex than one might think. Indeed, let us rewrite Eqs. (32), (33) for a single charge in the integral form:

$$
\begin{equation*}
U(\mathbf{r})=-\int_{\mathbf{r}_{0}}^{\mathbf{r}} \mathbf{F}\left(\mathbf{r}^{\prime}\right) \cdot d \mathbf{r}^{\prime}, \quad \text { i.e. } \quad \phi(\mathbf{r})=-\int_{\mathbf{r}_{0}}^{\mathbf{r}} \mathbf{E}\left(\mathbf{r}^{\prime}\right) \cdot d \mathbf{r}^{\prime} \tag{1.52}
\end{equation*}
$$

where $\mathbf{r}_{0}$ is some reference point. These integrals reflect the fact that the potential energy is just the work necessary to move the charge from point $\mathbf{r}_{0}$ to point $\mathbf{r}$, and clearly depend on whether the charge motion affects force $\mathbf{F}$ (and hence electric field $\mathbf{E}$ ) or not. If it does not, i.e. if the field is produced by some external charges (such fields $\mathbf{E}_{\text {ext }}$ are also called external), everything is simple indeed: using the linearity of relations (31) and (32), for the total potential energy we may write

$$
\begin{equation*}
U_{\text {ext }}=\sum_{k} q_{k} \phi_{\text {ext }}\left(\mathbf{r}_{k}\right), \quad \text { where } \phi_{\text {ext }}(\mathbf{r}) \equiv-\int_{\mathbf{r}_{0}}^{\mathbf{r}} E_{\text {ext }}\left(\mathbf{r}^{\prime}\right) \cdot d \mathbf{r}^{\prime} . \tag{1.53}
\end{equation*}
$$

Repeating the argumentation that has led us to Eq. (9), we see that for a continuously distributed charge, this sum turns into an integral:

$$
\begin{equation*}
U_{\mathrm{ext}}=\int \rho(\mathbf{r}) \phi_{\mathrm{ext}}(\mathbf{r}) d^{3} r \tag{1.54}
\end{equation*}
$$

However, if the electric field is created by the charges whose energy we are calculating, the situation is somewhat different. To calculate $U$ for this case, let us use the fact its independence of the way the charge configuration has been created, considering the following process. First, let us move one charged particle (say, $q_{1}$ ) from infinity to an arbitrary point of space ( $\mathbf{r}_{1}$ ) in the absence of other charges. During the motion the particle does not experience any force (again, the charge does not interact with itself!), so that its potential energy is the same as at infinity (with the standard choice of the arbitrary constant, zero): $U_{1}=0$. Now let us fix the position of that charge, and move another charge $\left(q_{2}\right)$ from infinity to point $\mathbf{r}_{2}$ (with velocity $v \ll c$, in order to avoid any magnetic field effects, to be discussed in Chapter 5.) This particle, during its motion, does experience the Coulomb force exerted by fixed $q_{1}$, so that according to Eq. (31), its contribution to the final potential energy

$$
\begin{equation*}
U_{2}=q_{2} \phi_{1}\left(\mathbf{r}_{2}\right) . \tag{1.55}
\end{equation*}
$$

Since the first particle was not moving during this process, the total potential energy $U$ of the system is equal to just $U_{2}$. This is exactly the equality used for writing the right-hand part of Eq. (36). (Prescribing a similar energy to charge $q_{1}$ as well would constitute an error - a very popular one, and hence having a special name, double-counting.)

Now, fixing the first two charges in points $\mathbf{r}_{1}$ and $\mathbf{r}_{2}$, respectively, and bringing in the third charge from infinity, we increment the potential energy by

$$
\begin{equation*}
U_{3}=q_{3}\left[\phi_{1}\left(\mathbf{r}_{3}\right)+\phi_{2}\left(\mathbf{r}_{3}\right)\right] \tag{1.56}
\end{equation*}
$$

I believe that at this stage it is already clear how to generalize this result to the contribution from an arbitrary ( $k$-th) charge being moved in (Fig. 6):

$$
\begin{equation*}
U_{k}=q_{k}\left[\phi_{1}\left(\mathbf{r}_{k}\right)+\phi_{2}\left(\mathbf{r}_{k}\right)+\phi_{3}\left(\mathbf{r}_{k}\right)+\ldots+\phi_{k-1}\left(\mathbf{r}_{k}\right)\right]=q_{k} \sum_{k^{\prime}<k} \phi_{k^{\prime}}\left(\mathbf{r}_{k}\right) . \tag{1.57}
\end{equation*}
$$

(Notice condition $k^{\prime}<k$, which suppresses erroneous double-counting.)

Fig. 1.6. Deriving the potential energy of a system of electric charges.

Now, summing up all the increments, for the total electrostatic energy of the system we get:

$$
\begin{equation*}
U=\sum_{k} U_{k}=\sum_{\substack{k, k^{\prime} \\\left(k^{\prime} k\right)}} q_{k} \phi_{k^{\prime}}\left(\mathbf{r}_{k}\right) . \tag{1.58}
\end{equation*}
$$

This is our final result in its generic form; it is so important that is worthy of rewriting it in two other forms. First, for its generalization to the continuous charge distribution, we may use Eq. (35) to present Eq. (58) in a more symmetric form:

$$
\begin{equation*}
U=\frac{1}{4 \pi \varepsilon_{0}} \sum_{\substack{k, k^{\prime} \\\left(k^{\prime}<k\right)}} \frac{q_{k} q_{k^{\prime}}}{\left|\mathbf{r}_{k}-\mathbf{r}_{k^{\prime}}\right|} \tag{1.59}
\end{equation*}
$$

The expression under the sum is evidently symmetric with respect to the index swap, so that it may be rewritten in a fully symmetric form,

$$
\begin{equation*}
U=\frac{1}{4 \pi \varepsilon_{0}} \frac{1}{2} \sum_{\substack{k^{\prime}, k \\\left(k^{\prime} \neq k\right)}} \frac{q_{k} q_{k^{\prime}}}{\left|\mathbf{r}_{k}-\mathbf{r}_{k^{\prime}}\right|}, \tag{1.60}
\end{equation*}
$$

which is now easily generalized to the continuous case:

$$
\begin{equation*}
U=\frac{1}{4 \pi \varepsilon_{0}} \frac{1}{2} \int d^{3} r \int d^{3} r^{\prime} \frac{\rho(\mathbf{r}) \rho\left(\mathbf{r}^{\prime}\right)}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} \tag{1.61}
\end{equation*}
$$

(As before, in this case the restriction expressed in the discrete charge case as $k \neq k$ ' is not important, because if the charge density is a continuous function, integral (61) does not diverge at point $\mathbf{r}=\mathbf{r}^{\prime}$.)

To present this result in one more form, let us notice that according to Eq. (38), the integral over $r$ ' in Eq. (61), divided by $4 \pi \varepsilon_{0}$, is just the full electrostatic potential at point $\mathbf{r}$, and hence

$$
\begin{equation*}
U=\frac{1}{2} \int \rho(\mathbf{r}) \phi(\mathbf{r}) d^{3} r . \tag{1.62}
\end{equation*}
$$

For the discrete charge case, this result becomes

$$
\begin{equation*}
U=\frac{1}{2} \sum_{k} q_{k} \phi\left(\mathbf{r}_{k}\right), \tag{1.63}
\end{equation*}
$$

but now it is important to remember that the "full" potential's value $\phi\left(\mathbf{r}_{k}\right)$ should exclude the (infinite) contribution of charge $k$ itself. Comparing the last two formulas with Eqs. (52) and (53), we see that the electrostatic energy of charge interaction, as expressed via the charge-potential product, is twice less than that of charge energy in a fixed ("external") field. This is evidently the result of the self-consistent build-up of the electric field as the charge system is being formed. ${ }^{24}$

Now comes an important conceptual question: can we locate this interaction energy in space? Expressions (60)-(63) seem to imply that contributions to $U$ come only from the regions where electric charges are located. However, one of the beautiful features of physics is that sometimes completely different interpretations of the same mathematical result are possible. In order to get an alternative view at our current result, let us write Eq. (62) for a volume $V$ so large that the electric field on the limiting surface $A$ is negligible, and plug into it the charge density expressed from the Poisson equation (41):

$$
\begin{equation*}
U=-\frac{\varepsilon_{0}}{2} \int_{V} \phi \nabla^{2} \phi d^{3} r . \tag{1.64}
\end{equation*}
$$

This expression may be integrated by parts as ${ }^{25}$

$$
\begin{equation*}
U=-\frac{\varepsilon_{0}}{2}\left[\oint_{A} \phi(\nabla \phi)_{n} d^{2} r-\int_{V}(\nabla \phi)^{2} d^{3} r\right] . \tag{1.65}
\end{equation*}
$$

According to our condition of negligible field $\mathbf{E}=-\nabla \phi$ on the surface, the first integral vanishes, and we get a very important formula

$$
\begin{equation*}
U=\frac{\varepsilon_{0}}{2} \int(\nabla \phi)^{2} d^{3} r=\frac{\varepsilon_{0}}{2} \int E^{2} d^{3} r . \tag{1.66}
\end{equation*}
$$

This result certainly invites an interpretation very much different than Eq. (62): it is natural to represent it in the following form:

$$
\begin{equation*}
U=\int u(\mathbf{r}) d^{3} r, \quad \text { with } u(\mathbf{r}) \equiv \frac{\varepsilon_{0}}{2} E^{2}(\mathbf{r}), \tag{1.67}
\end{equation*}
$$

Electric
field energy

[^168]and interpret $u(\mathbf{r})$ as the spatial density of the electric field energy, ${ }^{26}$ which is continuously distributed over all the space where the field exists - rather than just its part where the charges are located.

Let us have a look how these two alternative pictures work for our testbed problem, a uniformly charged sphere. If we start from Eq. (62), we may limit integration by the sphere volume ( $0 \leq r \leq R$ ) where $\rho \neq 0$. Using Eq. (51), and the spherical symmetry of the problem ( $d^{3} r=4 \pi r^{2} d r$ ), we get

$$
\begin{equation*}
U=\frac{1}{2} 4 \pi \int_{0}^{R} \rho \phi r^{2} d r=\frac{1}{2} 4 \pi \rho \frac{Q}{4 \pi \varepsilon_{0} R} \int_{0}^{R}\left[\frac{R^{2}-r^{2}}{2 R^{2}}+1\right] r^{2} d r=\frac{6}{5} \frac{1}{4 \pi \varepsilon_{0} R} \frac{Q^{2}}{2} . \tag{1.68}
\end{equation*}
$$

On the other hand, if we use Eq. (67), we need to integrate energy everywhere, i.e. both inside and outside of the sphere:

$$
\begin{equation*}
U=\frac{\varepsilon_{0}}{2} 4 \pi\left[\int_{0}^{R} E^{2} r^{2} d r+\int_{R}^{\infty} E^{2} r^{2} d r\right] \tag{1.69}
\end{equation*}
$$

Using Eqs. (19) and (22) for, respectively, the external and internal regions, we get

$$
\begin{equation*}
U=\frac{\varepsilon_{0}}{2} 4 \pi\left[\int_{0}^{R}\left(\frac{Q r}{4 \pi \varepsilon_{0}}\right)^{2} r^{2} d r+\int_{R}^{\infty}\left(\frac{Q}{4 \pi \varepsilon_{0} r^{2}}\right)^{2} r^{2} d r\right]=\left(\frac{1}{5}+1\right) \frac{1}{4 \pi \varepsilon_{0} R} \frac{Q^{2}}{2} . \tag{1.70}
\end{equation*}
$$

This is (fortunately :-) the same answer as given by Eq. (68), but to some extent it is more informative because it shows how exactly the electric field energy is distributed between the interior and exterior of the charged sphere. ${ }^{27}$

We see that, as we could expect, within the realm of electrostatics, Eqs. (62) and (67) are equivalent. However, when we examine electrodynamics in Chapter 6 and on, we will see that the latter equation is more general, and that it is more adequate to associate energy with the field itself rather than its sources - in our current case, electric charges.

### 1.4. Exercise problems

1.1. Calculate the electric field created by a thin, long, straight filament, electrically charged with a constant linear density $\lambda$, using two approaches:
(i) directly from the Coulomb law, and
(ii) using the Gauss law.
1.2. Two thin, straight parallel filaments, separated by distance $\rho$, carry equal and opposite uniformly distributed charges with linear density $\lambda$ - see Fig. on the right. Calculate the electrostatic force (per unit length) of the Coulomb

[^169]interaction between the wires. Compare the result with the Coulomb law for the force between the point charges, and interpret their difference.
1.3. A sphere of radius $R$, whose volume had been charged with a constant density $\rho$, is split with a very narrow, planar gap passing through its center. Find the Coulomb force between the resulting two hemispheres.
1.4. Calculate the distribution of the electrostatic potential created by a straight, thin filament of finite length $2 l$, charged with a constant linear density $\lambda$, and explore the result in the limits of very small and very large distances from the filament.
1.5. A thin plane sheet, perhaps of an irregular shape, carries an electric charge distributed over the sheet with a constant areal density $\sigma$.
(i) Express the electric field component normal to the plane, at a certain distance from it, via the solid angle $\Omega$ at which the sheet is visible from the observation point.
(ii) Use the result to calculate the field in the center of a cube, with one face charged with constant density $\sigma$.
1.6. Can one create electrostatic fields with the Cartesian components proportional to the following products of Cartesian coordinates $\{x, y, z\}$,
(i) $\{y z, x z, x y\}$,
(ii) $\{x y, x y, y z\}$,
in a finite region of space?
1.7. Distant sources have been used to create different electric fields on two sides of a wide and thin metallic membrane with a round hole of radius $R$ in it - see Fig. on the right. Besides the local perturbation created by the hole, the fields are uniform:
\[

\left.E\right|_{r \gg R}=\mathbf{n}_{z} \times $$
\begin{cases}E_{1}, & \text { at } z<0, \\ E_{2}, & \text { at } z>0 .\end{cases}
$$
\]

Prove that the system may serve as an electrostatic lens for charged particles flying along axis $z$, at distances $\rho \ll R$ from it, and calculate the focal distance $f$ of the lens. Spell out the
 conditions of validity of your result.
1.8. By direct calculation, find the average electric potential of the spherical surface of radius $R$, created by a point charge $q$ located at distance $r>R$ from the sphere's center. Use the result to prove the following general mean value theorem: the electric potential at any point is always equal to its average value on any spherical surface with the center at that point, and containing no electric charges inside it.
1.9. Calculate the electrostatic energy per unit area of the system of two thin, parallel planes with equal and opposite charges of a constant areal density $\sigma$, separated by distance $d$ - see Fig. on the right.

1.10. The system analyzed in the previous problem (two thin, parallel, oppositely charged planes) is now placed into an external, uniform, normal electric field $E_{\text {ext }}=\sigma / \varepsilon_{0}-$ see Fig. on the right. Find the forces (per unit area) acting on each plane, by two methods:
(i) directly from the electric field distribution, and
(ii) from the potential energy of the system.

1.11. A thin spherical shell of radius $R$, which had been charged with a constant areal density $\sigma$, is split into two equal halves by a very narrow, planar cut passing through sphere's center. Calculate the force of electrostatic repulsion between the resulting hemispheric shells.
1.12. Two similar thin, circular, coaxial disks of radius $R$, separated by distance $2 d$, are uniformly charged with equal and opposite areal densities $\pm \sigma$ - see Fig. on the right. Calculate and sketch the distribution of the electrostatic potential and the electric field of the disks along their common axis.

1.13. In a certain reference frame, the electrostatic potential created by some electric charge distribution, is

$$
\phi(\mathbf{r})=C\left(\frac{1}{r}+\frac{1}{2 r_{0}}\right) \exp \left\{-\frac{r}{r_{0}}\right\},
$$

where $C$ and $r_{0}$ are constants, and $r \equiv|\mathbf{r}|$ is the distance from the origin. Calculate the charge distribution in space.
1.14. A thin flat sheet, cut in a form of a rectangle of size $a \times b$, is electrically charged with a constant areal density $\sigma$. Without an explicit calculation of the spatial distribution $\phi(\mathbf{r})$ of the electrostatic potential induced by this charge, find the ratio of its values at the center and at the corners of the rectangle.

Hint: Consider partitioning the rectangle into several similar parts and using the linear superposition principle.
1.15. Explore the relation between the Laplace equation (42) and the condition of minimum of the electrostatic field energy (67).
1.16. Calculate the energy of electrostatic interaction of two spheres, of radii $R_{1}$ and $R_{2}$, each with a spherically-symmetric charge distribution, separated by distance $d>R_{1}+R_{2}$.
1.17. Prove the following reciprocity theorem of electrostatics: ${ }^{28}$ if two spatially-confined charge distributions $\rho_{1}(\mathbf{r})$ and $\rho_{2}(\mathbf{r})$ create respective distributions $\phi_{1}(\mathbf{r})$ and $\phi_{2}(\mathbf{r})$ of the electrostatic potential, then

$$
\int \rho_{1}(\mathbf{r}) \phi_{2}(\mathbf{r}) d^{3} r=\int \rho_{2}(\mathbf{r}) \phi_{1}(\mathbf{r}) d^{3} r
$$

Hint: Consider integral $\int \mathbf{E}_{1} \cdot \mathbf{E}_{2} d^{3} r$.

[^170]
## Chapter 2. Charges and Conductors

In this chapter I will start addressing the (very common) situations when the electric charge distribution in space is not known a priori, but rather should be calculated in a self-consistent way together with the electric field it creates. The simplest situations of this kind involve conductors, and lead to the so-called boundary problems in which partial differential equations are solved with appropriate boundary conditions. Such problems are also broadly used in other parts of electrodynamics (and indeed in other fields of physics as well), so that following tradition, I will use this chapter's material as a playground for a discussion of various methods of boundary problem solution, and the special functions most frequently encountered on this way.

### 2.1. Electric field screening

The basic principles of electrostatics outlined in Chapter 1 present the conceptually full solution for the problem of finding electric field (and hence Coulomb forces) induced by a charge distribution, for example, charge density $\rho(\mathbf{r})$. However, in most practical situation this function is not known but should be found self-consistently with the field. The conceptually simplest case of this type arises when certain point charges $q_{k}$ are placed near a surface of a good conductor, e.g., a metal: the electric field of these charges induces additional charges at conductor's surface, which also contribute to the field. Another important type of problems are those without space-positioned charges at all; here only the total charges of the involved conductors are fixed, but their spatial distribution inside each conductor has to be found. The full solution of such problems, of course, should satisfy Eq. (1.5) for the total field and total set of charges.

To approach the problems, I need to discuss, if only very briefly, ${ }^{1}$ the relevant physics of conductors. In the simplest macroscopic model, conductors are treated as materials having internal charged particles (e.g., electrons in metals) that are free to move under the effect of force - in particular, the force $\mathbf{F}=q \mathbf{E}$ exerted by electric field $\mathbf{E}$. In electrostatics (which specifically excludes the case dc current, to be discussed in Chapter 4 below), there should be no such motion, so that everywhere inside the conductor the electric field should vanish:

$$
\begin{equation*}
\mathbf{E}=0 \tag{2.1a}
\end{equation*}
$$ electrostatics

This is the electric field screening ${ }^{2}$ effect. According to Eq. (1.33), this condition may be rewritten in another, frequently more convenient form:

$$
\begin{equation*}
\phi=\text { const } ; \tag{2.1b}
\end{equation*}
$$

note, however, that if a problem includes several unconnected conductors, the constant in Eq. (1b) may be different for each of them.

[^171]Now let us examine what we can say about the electric field outside a conductor, within the same macroscopic model. At close proximity, any smooth surface (in our case that of a conductor) looks planar. Let us integrate Eq. (1.28) over a narrow ( $d \ll l$ ) rectangular loop $C$ encircling a part of such plane conductor's surface (see the dashed line in Fig. 1), and apply to the electric field the well-known vector algebra equality - the Stokes theorem ${ }^{3}$

$$
\begin{equation*}
\oint_{S}(\nabla \times \mathbf{E})_{n} d^{2} r=\oint_{C} \mathbf{E} \cdot d \mathbf{r}, \tag{2.2}
\end{equation*}
$$

where $S$ is the surface limited by contour $C$, in our case dominated by two straight lines of length $l$. This means that if $l$ is much smaller that the characteristic scale of field change, the right-hand part of Eq. (2) equals $\left[\left(E_{\tau}\right)_{\text {in }}-\left(E_{\tau}\right)_{\text {out }}\right] l$, where $E_{\tau}$ is field's component parallel to the surface. On the other hand, according to Eq. (1.28), the left-hand side of Eq. (2) equals zero. Hence, $E_{\tau}$ should be continuous at the surface, and in order to satisfy Eq. (1a) inside the conductor, immediately outside it, $E_{\tau}=0$ as well.

Fig. 2.1. Electric field near conductor's surface:
$E_{\tau}=0, E_{n}=\sigma / \varepsilon_{0}$.

Hence, the field just outside the conductor has be normal to its surface. In order to find this normal field, let us apply the Gauss law (1.16) to a plane pillbox of area $A$, similar to the one discussed in Sec. 1.2 - see Fig. 1.4. Due to Eq. (1), the total electric flux through the pillbox walls is now $\left(E_{n}\right)_{\text {out }} A$, so that for this surface field we get

$$
\begin{equation*}
\sigma=\varepsilon_{0}\left(E_{n}\right)_{\text {out }}=-\varepsilon_{0}(\nabla \phi)_{n} \equiv-\varepsilon_{0} \frac{\partial \phi}{\partial n} \tag{2.3}
\end{equation*}
$$

Surface charge density
where $\sigma$ is the areal density of conductor's surface charge. So, the normal component of the field is related to the surface charge density by the universal relation (3).

For the electrostatic potential the macroscopic model provides an even more simple result. Indeed, applying the latter of integrals (1.52) to a short path $d$ across the surface normal to it, we see that since $E_{n}$ is finite, the potential change $\Delta \phi$ vanishes as $d \rightarrow 0$. Hence Eq. (1b) is also valid for potential's value immediately outside conductor's surface.

Before starting to use the macroscopic model for solution of particular problems of electrostatics, let us briefly discuss its limitations. Since the argumentation leading to Eq. (3) is valid for any thickness $d$ of the Gauss pillbox, within the macroscopic model, the surface charge is located within an infinitely

[^172]thin surface layer. This is of course impossible physically: for one, this would require an infinite volume density $\rho$ of charge. In reality the charged layer (and hence the region of electric field's crossover from the finite value (3) to zero) has a nonvanishing thickness $\lambda$. At least three effects contribute to $\lambda$ :
(i) Atomic structure of matter. Within each atom, the electric field does exist and is highly nonuniform. Thus Eq. (1) is valid only for the spatial average of the field in a conductor, and cannot be taken seriously on the atomic scale $a_{0} \sim 10^{-10} \mathrm{~m} .{ }^{4}$
(ii) Thermal excitation. In conductor's bulk, the number of protons of atomic nuclei ( $n$ ) and electrons $\left(n_{e}\right)$ and per unit volume are balanced, so that the net charge density, $\rho=e\left(n-n_{e}\right)$, vanishes. ${ }^{5}$ However, if an external electric field penetrates a conductor, electrons can shift in or out of its affected part, depending on the field addition to their potential energy, $\Delta U=q_{e} \phi=-e \phi$. (Here the arbitrary constant in $\phi$ is chosen to give $\phi=0$ inside the conductor.) In classical statistics, this change is described by the Boltzmann distribution: ${ }^{6}$
\[

$$
\begin{equation*}
n_{e}(\mathbf{r})=n \exp \left\{-\frac{U(\mathbf{r})}{k_{\mathrm{B}} T}\right\}, \tag{2.4}
\end{equation*}
$$

\]

where $k_{\mathrm{B}} \approx 1.38 \times 10^{-23} \mathrm{~J} / \mathrm{K}$ is the Boltzmann constant, and $T$ is temperature in SI units (kelvins). As a result, the net charge density is

$$
\begin{equation*}
\rho(\mathbf{r})=e n\left(1-\exp \left\{\frac{e \phi(\mathbf{r})}{k_{\mathrm{B}} T}\right\}\right) . \tag{2.5}
\end{equation*}
$$

If the field did not move the atomic nuclei at all, we could plug the last formula directly into the Poisson equation (1.49). Actually, the penetrating electric field shifts the average charge of the nuclei as well. As will be discusses in the next chapter, this results in the reduction of the electric field by a media-specific dimensionless factor $\varepsilon_{r}$ (typically not too different from 1), called the dielectric constant. As a result, the Poisson equation takes the form, ${ }^{7}$

$$
\begin{equation*}
\frac{d^{2} \phi}{d z^{2}}=-\frac{\rho}{\varepsilon_{r} \varepsilon_{0}}=\frac{e n}{\varepsilon_{r} \varepsilon_{0}}\left(\exp \left\{\frac{e \phi}{k_{\mathrm{B}} T}\right\}-1\right), \tag{2.6}
\end{equation*}
$$

where we have taken advantage of the 1D geometry of the system to simplify the Laplace operator, with axis $z$ normal to the surface. Even with this simplification, Eq. (6) is a nonlinear differential equation allowing an analytical but rather bulky solution. Since our current goal is just to estimate of the field penetration depth $\lambda$, let us simplify the equation further by considering the low-field limit: $e|\phi| \sim e|E| \lambda$ $\ll k_{\mathrm{B}} T$. In this limit we can extend the exponent into the Taylor series, and limit ourselves to the two leading terms (of which the first one cancels with the unity). As a result, Eq. (6) becomes linear,

$$
\begin{equation*}
\frac{d^{2} \phi}{d z^{2}}=\frac{e n}{\varepsilon \varepsilon_{0}} \frac{e \phi}{k_{\mathrm{B}} T}, \quad \text { i.e. } \frac{d^{2} \phi}{d z^{2}}=\frac{1}{\lambda^{2}} \phi \tag{2.7}
\end{equation*}
$$

[^173]where constant $\lambda$ in this case is equal to the so-called Debye screening length $\lambda_{\mathrm{D}}$, defined by relation
\[

$$
\begin{equation*}
\lambda_{\mathrm{D}}^{2} \equiv \frac{\varepsilon_{r} \varepsilon_{0} k_{\mathrm{B}} T}{e^{2} n} . \tag{2.8}
\end{equation*}
$$

\]

Debye screening length

Equation (7) is easy to solve: it describes an exponential decrease of the electric potential, with the characteristic length $\lambda_{\mathrm{D}}: \phi \propto \exp \left\{-z / \lambda_{\mathrm{D}}\right\}$. Plugging in the fundamental constants $\varepsilon_{0}, e$, and $k_{\mathrm{B}}$, we get the following estimate: $\lambda_{\mathrm{D}}[\mathrm{m}] \approx 70\left(\varepsilon_{r} T[\mathrm{~K}] / h\left[\mathrm{~m}^{-3}\right]\right)^{1 / 2}$. According to this formula, in semiconductors at room temperature, the Debye length may be rather substantial. For example, in silicon ( $\varepsilon_{r} \approx 12$ ) doped to the charge carrier concentration $n=3 \times 10^{24} \mathrm{~m}^{-3}$ (the value typical for modern integrated circuits), ${ }^{8} \lambda_{\mathrm{D}} \approx 2$ nm , still well above the atomic size scale $a_{0}$. However, for typical good metals ( $n \sim 10^{28} \mathrm{~m}^{-3}, \varepsilon_{r} \sim 10$ ) the same formula gives an estimate $\lambda_{\mathrm{D}} \sim 4 \times 10^{-11} \mathrm{~m}$, less than $a_{0}$. In this case Eq. (8) should not be taken too literally, because it is based on the assumption of continuous charge distribution.
(iii) Quantum statistics. Actually, the last estimate is not valid for good metals (and highly doped semiconductors) for one more reason: their free electrons obey quantum (Fermi-Dirac) statistics rather that the Boltzmann distribution (4). ${ }^{9}$ As a result, at all realistic temperatures they form a degenerate quantum gas, occupying all available energy states below certain level $\varepsilon_{\mathrm{F}} \gg k_{\mathrm{B}} T$ called the Fermi energy. In these conditions, the screening of relatively low electric field ${ }^{10}$ may be described by replacing Eq. (5) with

$$
\begin{equation*}
\rho=e\left(n-n_{e}\right)=-e g\left(\varepsilon_{\mathrm{F}}\right)(-U)=-e^{2} g\left(\varepsilon_{\mathrm{F}}\right) \phi, \tag{2.9}
\end{equation*}
$$

where $g(\mathcal{\varepsilon})$ is the density of quantum states (per unit volume) at electron's energy $\varepsilon$. At the Fermi surface, the density is of the order of $n / \mathcal{E}_{\mathrm{F}} .{ }^{11}$ As a result, we again get the second of Eqs. (7), but with a different characteristic scale $\lambda$, defined by the following relation:

$$
\begin{equation*}
\lambda_{\mathrm{TF}}^{2} \equiv \frac{\varepsilon_{r} \varepsilon_{0}}{e^{2} g\left(\varepsilon_{\mathrm{F}}\right)} \sim \frac{\varepsilon_{r} \varepsilon_{0} \varepsilon_{\mathrm{F}}}{e^{2} n} \tag{2.10}
\end{equation*}
$$

and called the Thomas-Fermi screening length. Since for most good metals, $n$ is of the order of $10^{29} \mathrm{~m}^{-3}$, and $\varepsilon_{\mathrm{F}}$ is of the order of 10 eV , Eq. (10) typically gives $\lambda_{\mathrm{TF}}$ close to a few $a_{0}$, and makes the ThomasFermi screening theory valid at least semi-quantitatively.

To summarize, the electric field penetration into good conductors is limited to a depth $\lambda$ ranging from fractions of a nanometer to a few nanometers, so that for problems with the characteristic size much larger than that scale, the macroscopic boundary conditions (1) give a very good accuracy, and we will use them in the rest of this chapter. However, the reader should remember that in some situations

[^174]involving semiconductors, as well as at nanoscale experiments with metals, the electric field penetration effect should be taken into account.

### 2.2. Capacitance

Let us start with systems consisting of charged conductors alone. Our goal here is calculating the distributions of electric field $\mathbf{E}$ and potential $\phi$ in space, and the distribution of the surface charge density $\sigma$ over the conductor surfaces. However, before doing that for particular situations, let us see if there are any integral measures of these distributions, that should be our primary focus.

The simplest case is of course a single conductor in the otherwise free space. According to Eq. (1), all its volume should have a constant electrostatic potential $\phi$, evidently providing one convenient global measure of the situation. Another integral measure is evidently provided by the total charge

$$
\begin{equation*}
Q \equiv \int_{V} \rho d^{3} r=\oint_{S} \sigma d^{2} r \tag{2.11}
\end{equation*}
$$

where the latter integral is extended over the whole surface $S$ of the conductor. In the general case, what we can tell about the relation between $Q$ and $\phi$ ? At $Q=0$, there is no electric field in the system, and it is natural (though not necessary) to select the arbitrary constant in the electrostatic potential to have $\phi=0$. Then, if the conductor is charged with a finite $Q$, according to the Coulomb law, the electric field in any point of space is proportional to $Q$. Hence the electrostatic potential everywhere, including its value $\phi$ on the conductor, is also proportional to $Q$ :

$$
\begin{equation*}
\phi=p Q . \tag{2.12}
\end{equation*}
$$

The proportionality coefficient $p$, that depends on the conductor size and shape but not on $Q$, is called the reciprocal capacitance (or, not too often, "electrical elastance"). Usually, Eq. (12) is rewritten in a different form,

Selfcapacitance

$$
\begin{equation*}
Q=C \phi, \quad C \equiv \frac{1}{p} \tag{2.13}
\end{equation*}
$$

where $C$ is called self-capacitance. (Frequently, $C$ is called just capacitance, but we will soon see that for more complex situations the latter term may be too ambiguous.)

Before going to calculation of $C$, let us have a look at the electrostatic energy of a single conductor. In order to calculate it, of the several equations discussed in Chapter 1, Eq. (1.63) is most convenient, because all elementary charges $q_{k}$ are now parts of the conductor surface charge, and hence sit at the same potential $\phi$. As a result, the equation becomes very simple:

$$
\begin{equation*}
U=\frac{1}{2} \phi \sum_{k} q_{k}=\frac{1}{2} \phi Q . \tag{2.14}
\end{equation*}
$$

Moreover, using the linear relation (13), the same result may be re-written in two more forms:

> Electro-
> static energy

$$
U=\frac{Q^{2}}{2 C}=\frac{C}{2} \phi^{2}
$$

We will discuss several ways to calculate $C$ in the next sections, and right now will have a quick look at just the simplest example for which we have calculated everything necessary in the previous
chapter: a conducting sphere of radius $R$. Indeed, we already know the electric field distribution: according to Eq. (1), $E=0$ inside the sphere, while Eq. (1.19), with $Q(r)=Q$, describes the field distribution outside it. Moreover, since the latter formula is exactly the same as for the point charge placed in the sphere's center, the potential distribution in space can be obtained from Eq. (1.35) by replacing $q$ with sphere's full charge $Q$. Hence, on the surface of the sphere (and, according to Eq. (2), through its interior),

$$
\begin{equation*}
\phi=\frac{1}{4 \pi \varepsilon_{0}} \frac{Q}{R} . \tag{2.16}
\end{equation*}
$$

Comparing this result with the definition (13), for the self-capacitance we obtain ${ }^{12}$

$$
\begin{equation*}
C=4 \pi \varepsilon_{0} R=2 \pi \varepsilon_{0} D, \quad D \equiv 2 R . \tag{2.17}
\end{equation*}
$$

This formula, which should be well familiar to the reader, is convenient to get some feeling of how large the SI unit of capacitance ( 1 farad, abbreviated as F) is: the self-capacitance of Earth ( $R_{\mathrm{E}} \approx$ $6.34 \times 10^{6} \mathrm{~m}$ ) is below 1 mF ! Another important note is that while Eq. (17) is not exactly valid for a conductor of arbitrary shape, it implies an important estimate

$$
\begin{equation*}
C \sim 2 \pi \varepsilon_{0} a \tag{2.18}
\end{equation*}
$$

where $a$ is the scale of the linear size of any conductor. ${ }^{13}$
Now proceeding to a system of two conductors, we immediately see why we should be careful with the capacitance definition: one constant $C$ is insufficient to describe such system. Indeed, here we have two, generally different conductor potentials, $\phi_{1}$ and $\phi_{2}$, that may depend on both conductor charges, $Q_{1}$ and $Q_{2}$. Using the same arguments as for the one-conductor case, we may conclude that the dependence is always linear:

$$
\begin{align*}
& \phi_{1}=p_{11} Q_{1}+p_{12} Q_{2}  \tag{2.19}\\
& \phi_{2}=p_{21} Q_{1}+p_{22} Q_{2}
\end{align*}
$$

but still has to be described not with one but with four coefficients $p_{j j^{\prime}}\left(j, j^{\prime}=1,2\right)$ forming the so-called reciprocal capacitance matrix

$$
\left(\begin{array}{ll}
p_{11} & p_{12}  \tag{2.20}\\
p_{21} & p_{22}
\end{array}\right)
$$

Plugging relation (19) into Eq. (1.63), we see that the full electrostatic energy of the system may be expressed by a quadratic form:

[^175]\[

$$
\begin{equation*}
U=\frac{p_{11}}{2} Q_{1}^{2}+\frac{p_{12}+p_{21}}{2} Q_{1} Q_{2}+\frac{p_{22}}{2} Q_{2}^{2} \tag{2.21}
\end{equation*}
$$

\]

It is evident that the middle term in the right-hand part of this equation describes the electrostatic coupling of the conductors. (Without it, the energy would be just a sum of two independent electrostatic energies of conductors 1 and 2.) This is why systems with $\left|p_{12}\right|,\left|p_{21}\right| \ll p_{11}, p_{22}$ are called weakly coupled, and may be analyzed using approximate methods - see, e.g., Fig. 3 and its discussion below.

Before proceeding further, let us use the Lagrangian formalism of analytical mechanics ${ }^{14}$ to argue that the off-diagonal elements of matrix $p_{j j}$, are always equal:

$$
\begin{equation*}
p_{12}=p_{21} . \tag{2.22}
\end{equation*}
$$

Indeed, charges $Q_{1,2}$ may be taken for generalized coordinates $q_{j}(j=1,2)$ of the system; then the corresponding generalized forces may be found as

$$
\begin{equation*}
\boldsymbol{7}_{j}=-\frac{\partial U}{\partial q_{j}}=-\frac{\partial U}{\partial Q_{j}} \tag{2.23}
\end{equation*}
$$

Applying this equation to Eq. (21), we see that, for example

$$
\begin{equation*}
7_{1}=-\left(p_{11} Q_{1}+\frac{p_{12}+p_{21}}{2} Q_{2}\right) \tag{2.24}
\end{equation*}
$$

Now we may argue that dynamics of charge $Q_{j}$ should only depend on the electrostatic potential $\phi_{j}$ this charge "sees". This means, in particular, that $\phi_{1}$ should be a unique function of $\not \mathcal{I}_{1}$. Comparing Eq. (24) with the first of Eqs. (19), we see that for this to be true, Eq. (22) should indeed be valid.

Equations (19) and (21) show that for the general case of arbitrary charges $Q_{1}$ and $Q_{2}$, the system properties cannot be reduced to just one coefficient ("capacitance"). Let us consider three particular cases when such a reduction is possible.
(i) The system as the whole is electrically neutral: $Q_{1}=-Q_{2} \equiv Q$. In this case the most important function of $Q$ is the difference of conductor potentials, called voltage: ${ }^{15}$

Voltage

$$
\begin{equation*}
V \equiv \phi_{1}-\phi_{2} \tag{2.25}
\end{equation*}
$$

For that function, the subtraction of two Eqs. (19) gives

$$
\begin{equation*}
V=\frac{Q}{C_{m}}, \quad \text { with } C_{m} \equiv \frac{1}{\left(p_{11}+p_{22}\right)-\left(p_{12}+p_{21}\right)}, \tag{2.26}
\end{equation*}
$$

where coefficient $C_{m}$ is called the mutual capacitance between the conductors - or, again, just "capacitance". The same coefficient describes the electrostatic energy of the system. Indeed, plugging Eq. (25) into Eq. (21), we see that both forms of Eq. (15) are reproduced if $\phi$ is replaced with $V, Q_{1}$ with $Q$, and $C$ with $C_{m}$ :

[^176]\[

$$
\begin{equation*}
U=\frac{Q^{2}}{2 C_{m}}=\frac{C_{m}}{2} V^{2} \tag{2.27}
\end{equation*}
$$

\]

The best known system for which the mutual capacitance $C_{m}$ may be readily calculated is the plane (or "parallel-plate") capacitor, a system of two conductors separated with a narrow, plane gap (Fig. 2). Indeed, since the surface charges, that contribute to the opposite charges $\pm Q$ of the conductors in this system, attract each other, in the limit $d \ll a$ they sit entirely on the sides of the narrow gap.

Fig. 2.2. Plane capacitor.

Let us apply the Gauss law to a pillbox volume (shown by dashed line in Fig. 2) whose area is a small part of the gap (but nevertheless much larger than $d^{2}$ ), with one of the plane lids inside a conductor, and another one inside the gap. The result immediately shows that the electric field within the gap is $E=\sigma / \varepsilon_{0}$, i.e. is independent of the pillbox thickness. Integrating this field across thickness $d$ of the gap, we get $V=E d=\sigma d / \varepsilon_{0}$, so that $\sigma=\varepsilon_{0} V / d$. But this voltage should not depend on the selection of the point of the gap area. As a result, $\sigma$ should be also constant over all the gap area $A$, and hence $Q=$ $\sigma A=\varepsilon_{0} V / d$. Thus we may write $V=Q / C_{m}$, with

$$
\begin{equation*}
C_{m}=\frac{\varepsilon_{0}}{d} A \tag{2.28}
\end{equation*}
$$

[^177]Let me offer a few comments on this well-known formula. First, it is valid even if the gap is not quite planar, for example if it gently curves on a scale much larger than $d$. Second, Eq. (28) is only valid if $A \sim a^{2}$ is much larger than $d^{2}$, because its derivation ignores the electric field deviations from uniformity ${ }^{16}$ at distances $\sim d$ near the gap edges. Finally, the same condition $\left(A \gg d^{2}\right)$ assures that $C_{m}$ is much larger than the self-capacitance of each of the conductors - see Eq. (18). The opportunities given by this fact for electronic engineering and experimental physics practice are rather astonishing. For example, a very realistic $3-\mathrm{nm}$ layer of high-quality aluminum oxide (which may provide a nearly perfect electric insulation between two thin conducting films) with area of $0.1 \mathrm{~m}^{2}$ (which is a typical area of silicon wafers used in semiconductor industry) provides $C_{m} \sim 1 \mathrm{mF},{ }^{17}$ larger than the selfcapacitance of the whole planet Earth!

In the case shown in Fig. 2, the electrostatic coupling of the two conductors is evidently strong. As an opposite example of a weakly coupled system, let us consider two conducting spheres of the same radius $R$, separated by a much larger distance $d$ (Fig. 3).

[^178]

Fig. 2.3. A system of two well separated, similar conducting spheres.

In this case the diagonal components of matrix $p_{i j}$, may be approximately found from Eq. (16), i.e. by neglecting the coupling altogether:

$$
\begin{equation*}
p_{11}=p_{22} \approx \frac{1}{4 \pi \varepsilon_{0} R} . \tag{2.29}
\end{equation*}
$$

Now, if we had just one sphere (say, number 1), the electric potential at distance $d$ from its center would be given by Eq. (16): $\phi=Q_{1} / 4 \pi \varepsilon_{0} d$. Now if we move into this point a small ( $R \ll d$ ) sphere without its own charge, we may expect that its potential should not be too far from this result, so that $\phi_{2} \approx Q_{1} / 4 \pi \varepsilon_{0} d$. Comparing this expression with Eq. (19) (taken for $Q_{2}=0$ ), we get

$$
\begin{equation*}
p_{12}=p_{21} \approx \frac{1}{4 \pi \varepsilon_{0} d} \ll p_{11}, p_{22} \tag{2.30}
\end{equation*}
$$

From here and Eq. (26), the mutual capacitance

$$
\begin{equation*}
C_{m} \approx \frac{1}{p_{11}+p_{22}} \approx 2 \pi \varepsilon_{0} R . \tag{2.31}
\end{equation*}
$$

We see that (somewhat counter-intuitively), in this case $C_{m}$ does not depend substantially on the distance between the spheres, i.e. does not describe their electrostatic coupling. The off-diagonal coefficients of the reciprocal capacitance matrix (20) play this role much better - see Eq. (30).
(ii) Now let us consider the case when only one conductor of the two is charged, for example $Q_{1}$ $\equiv Q$, while $Q_{2}=0$. Then Eqs. (19) yield

$$
\begin{equation*}
\phi_{1}=p_{11} Q_{1} . \tag{2.32}
\end{equation*}
$$

Now, if we follow Eq. (13) and define $C_{j} \equiv 1 / p_{j j}$ as the partial capacitance of conductor number $j$, we see that it differs from the mutual capacitance $C_{m}$ - cf. Eq. (26). For example, in the case shown in Fig. $3, C_{1}=C_{2} \approx 4 \pi \varepsilon_{0} R \approx 2 C_{m}$.
(iii) Finally, let us consider a popular case when one of the conductors is charged by a certain charge (say, $Q_{1}=Q$ ), but the potential of another one is sustained constant, say $\phi_{2}=0 .{ }^{18}$ (This condition is especially easy to implement if the second conductor is much larger that the first one. Indeed, as the estimate (18) shows, in this case it would take much larger charge $Q_{2}$ to make potential $\phi_{2}$ comparable with $\phi_{1}$.) In this case the second of equations (19) yields $Q_{2}=-\left(p_{21} / p_{22}\right) Q_{1}$. Plugging this relation into the first of those equations, we get

[^179]\[

$$
\begin{equation*}
\phi_{1}=\left(p_{11}-\frac{p_{12} p_{21}}{p_{22}}\right) Q_{1} \tag{2.33}
\end{equation*}
$$

\]

Thus, if we treat the reciprocal of the expression in parentheses,

$$
\begin{equation*}
C_{1}^{\mathrm{ef}} \equiv\left(p_{11}-\frac{p_{12} p_{21}}{p_{22}}\right)^{-1} \tag{2.34}
\end{equation*}
$$

as the effective capacitance of the first conductor, it is generally different both from $C_{m}$ and (unless the conductors are far apart and their electrostatic coupling is negligible) from $C_{1}=1 / p_{11}$.

To summarize this section, the potential (and hence the actual capacitance) of a conductor in a two-conductor system may be very much dependent on what exactly is being done with the second conductor when the first one is charged. This is also true for multi-conductor systems (for whose description, Eqs. (19) and (21) may be readily generalized); moreover, in that case even the mutual capacitance between two selected conductors may depend on the electrostatics conditions of other components of the system.

### 2.3. The simplest boundary problems

In the general case when the electric field distribution in the free space between the conductors cannot be readily found from the Gauss law or by any other special methods, the best approach is to try to solve the differential Laplace equation (1.42), with boundary conditions (1b):

$$
\begin{equation*}
\nabla^{2} \phi=0,\left.\quad \phi\right|_{S_{k}}=\phi_{k} \tag{2.35}
\end{equation*}
$$

where $S_{k}$ is the surface of the $k$-th conductor of the system. After such boundary problem has been solved, i.e. the spatial distribution $\phi(\mathbf{r})$ has been found in all points outside the conductor, it is straightforward to use Eq. (3) to find the surface charge density, and finally the total charge

$$
\begin{equation*}
Q_{k}=\oint_{S_{k}} \sigma d^{2} r \tag{2.36}
\end{equation*}
$$

of each conductor, and hence any component of the reciprocal capacitance matrix $p_{i j}$. As an illustration, let us implement this program for three very simple problems.
(i) Plane capacitor (Fig. 2). In this case, the easiest way to solve the Laplace equation is to use linear (Cartesian) coordinates with one coordinate axis, say $z$, normal to the conductor surfaces (Fig. 4).

Fig. 2.4. Plane capacitor's geometry used for the solution of the boundary problem (35).

In these coordinates, the Laplace operator is just the sum of three second derivatives. ${ }^{19}$ It is evident that due to problem's translational symmetry in the $\{x, y\}$ plane, deep inside the gap (i.e. at the lateral distance from the edges much larger than $d$ ) the electrostatic potential may only depend on the coordinate perpendicular to the gap surfaces: $\phi(\mathbf{r})=\phi(z)$. For such a function, derivatives over $x$ and $y$ vanish, and the boundary problem (35) is reduced to a very simple ordinary differential equation

$$
\begin{equation*}
\frac{d^{2} \phi}{d z^{2}}(z)=0 \tag{2.37}
\end{equation*}
$$

with boundary conditions

$$
\begin{equation*}
\phi(0)=0, \quad \phi(d)=V . \tag{2.38}
\end{equation*}
$$

(For the sake of notation simplicity, I have used the discretion of adding a constant to the potential to make one of the potentials vanish, and also definition (25) of voltage $V$.) The general solution of Eq. (37) is a linear function: $\phi(z)=c_{1} z+c_{2}$, whose constant coefficients $c_{1,2}$ may be found, in an elementary way, from the boundary conditions (38). The final solution is

$$
\begin{equation*}
\phi=V \frac{z}{d} . \tag{2.39}
\end{equation*}
$$

From here the only nonvanishing component of the electric field is

$$
\begin{equation*}
E_{z}=-\frac{d \phi}{d z}=-\frac{V}{d}, \tag{2.40}
\end{equation*}
$$

and the surface charge of the capacitor plates

$$
\begin{equation*}
\sigma=\varepsilon_{0} E_{n}=\mp \varepsilon_{0} E_{z}= \pm \varepsilon_{0} \frac{V}{d}, \tag{2.41}
\end{equation*}
$$

where the upper and lower sign correspond to the upper and lower plate, respectively. Since $\sigma$ does not depend on coordinates $x$ and $y$, we can get the full charges $Q_{1}=-Q_{2} \equiv Q$ of the surfaces by its multiplication by the gap area $A$, giving us the again already known result (28) for the mutual capacitance $C_{m} \equiv Q / V$. I believe that this calculation, though very easy, may serve as a good introduction to the boundary problem solution philosophy.
(ii) Coaxial-cable capacitor. Coaxial cable is a system of two round cylindrical, coaxial conductors, with the cross-section shown in Fig. 5.

Fig. 2.5. Cross-section of a coaxial capacitor.

[^180]Evidently, in this case the cylindrical coordinates $\{\rho, \varphi, z\}$, with axis $z$ along the common axis of the cylinders, are most appropriate. Due to the axial symmetry of the problem, in these coordinates $\mathbf{E}(\mathbf{r})$ $=\mathbf{n}_{\rho} E(\rho), \phi(\mathbf{r})=\phi(\rho)$, so that in the general expression for the Laplace operator ${ }^{20}$ we can take $\partial / \partial \varphi=$ $\partial / \partial z=0$. As a result, only the first (radial) term of the operator survives, and the boundary problem (35) takes the form

$$
\begin{equation*}
\frac{1}{\rho} \frac{d}{d \rho}\left(\rho \frac{d \phi}{d \rho}\right)=0, \quad \phi(a)=V, \phi(b)=0 \tag{2.42}
\end{equation*}
$$

The sequential integration of this ordinary differential equation is elementary (and similar to that of the Poisson equation in spherical coordinates, performed in Sec. 1.3), giving

$$
\begin{equation*}
\frac{d \phi}{d \rho}=\frac{c_{1}}{\rho}, \quad \phi(\rho)=c_{1} \int_{a}^{\rho} \frac{d \rho^{\prime}}{\rho^{\prime}}+c_{2}=c_{1} \ln \frac{\rho}{a}+c_{2} \tag{2.43}
\end{equation*}
$$

Constants $c_{1,2}$ may be found using boundary conditions (42):

$$
\begin{equation*}
V=c_{2}, \quad 0=c_{1} \ln \frac{b}{a}+c_{2}, \tag{2.44}
\end{equation*}
$$

giving $c_{1}=-V / \ln (b / a)$, so that solution (43) takes the following form

$$
\begin{equation*}
\phi(\rho)=V\left(1-\frac{\ln (\rho / a)}{\ln (b / a)}\right) \tag{2.45}
\end{equation*}
$$

Next, for our axial symmetry the general expression for the gradient ${ }^{21}$ is reduced to the radial derivative, so that

$$
\begin{equation*}
E(\rho) \equiv-\frac{d \phi(\rho)}{d \rho}=\frac{V}{\rho \ln (b / a)} \tag{2.46}
\end{equation*}
$$

This expression, plugged into Eq. (2), allows us to find the density of conductors' surface charge. For example, for the inner electrode

$$
\begin{equation*}
\sigma_{a}=\varepsilon_{0} E_{a}=\frac{\varepsilon_{0} V}{a \ln (b / a)}, \tag{2.47}
\end{equation*}
$$

so that its full charge (per unit length of the system) is

$$
\begin{equation*}
\frac{Q}{L}=2 \pi a \sigma_{a}=\frac{2 \pi \varepsilon_{0} V}{\ln (b / a)} \tag{2.48}
\end{equation*}
$$

(It is straightforward to check that the charge of the outer electrode is equal and opposite.) Hence, by the definition of the mutual capacitance, its value per unit length is

$$
\begin{equation*}
\frac{C_{m}}{L} \equiv \frac{Q}{L V}=\frac{2 \pi \varepsilon_{0}}{\ln (b / a)} \tag{2.49}
\end{equation*}
$$

[^181]This expression shows that the total capacitance $C$ is proportional to the systems length $L$ (if $L$ $\gg a, b$ ), while being only logarithmically dependent on is the dimensions of its cross-section. Since log of a very large argument is an extremely slow function (sometimes called "quasi-constant"), if the external conductor is made large $(b \gg a)$ the capacitance diverges, but very weakly. Such a logarithmic divergence may be cut by any miniscule additional effect, for example by the finite length $L$ of the system. This allows one to get a crude but very useful estimate of self-capacitance of a single wire:

$$
\begin{equation*}
C \approx \frac{2 \pi \varepsilon_{0} L}{\ln (L / a)}, \quad \text { for } L \gg a \tag{2.50}
\end{equation*}
$$

On the other hand, if the gap between the conductors is narrow: $b=a+d$, with $d \ll a$, then $\ln (b / a)=$ $\ln (1+d / a)$ may be approximated as $d / a$, and Eq. (49) is reduced to $C_{m} \approx 2 \pi \varepsilon_{0} a L / d$, i.e. to Eq. (28) for the plane capacitor, with $A=2 \pi a L$.
(iii) Spherical capacitor. This is a system of two conductors, with the same central cross-section as the coaxial cable (Fig. 5), but now with the spherical rather than axial symmetry. This symmetry implies that we are better off using spherical coordinates, so that potential $\phi$ depends only on one of them, the distance $r$ from the common center of the conductors: $\phi(\mathbf{r})=\phi(r)$. As we already know from Sec. 1.3, in this case the general expression for the Laplace operator is reduced to its first (radial) term, so that the Laplace equation takes a simple form - see Eq. (1.47). Moreover, we have already found the general solution to this equation - see Eq. (1.50):

$$
\begin{equation*}
\phi(r)=\frac{c_{1}}{r}+c_{2}, \tag{2.51}
\end{equation*}
$$

Now acting exactly as above, i.e. determining constant $c_{1}$ from the boundary conditions $\phi(a)=V, \phi(b)=$ 0 , we get

$$
\begin{equation*}
V=c_{1}\left(\frac{1}{a}-\frac{1}{b}\right), \quad \text { so that } \quad \phi(r)=\frac{V}{r}\left(\frac{1}{a}-\frac{1}{b}\right)^{-1}+c_{2} . \tag{2.52}
\end{equation*}
$$

Next, we can use the spherical symmetry to find electric field, $\mathbf{E}(\mathbf{r})=\mathbf{n}_{r} E(r)$, with

$$
\begin{equation*}
E(r)=-\frac{d \phi}{d r}=\frac{V}{r^{2}}\left(\frac{1}{a}-\frac{1}{b}\right)^{-1} \tag{2.53}
\end{equation*}
$$

and hence its values on conductors' surfaces, and then the surface charge density $\sigma$ from Eq. (2). For example, for the inner conductor's surface,

$$
\begin{equation*}
\sigma_{a}=\varepsilon_{0} E(a)=\varepsilon_{0} \frac{V}{a^{2}}\left(\frac{1}{a}-\frac{1}{b}\right)^{-1}, \tag{2.54}
\end{equation*}
$$

so that, finally, for the full charge of that conductor we get

$$
\begin{equation*}
Q=4 \pi a^{2} \sigma=4 \pi \varepsilon_{0}\left(\frac{1}{a}-\frac{1}{b}\right)^{-1} V . \tag{2.55}
\end{equation*}
$$

(Again, the charge of the outer conductor is equal and opposite.) Now we can use the definition of the mutual capacitance to get the final result

$$
\begin{equation*}
C_{m} \equiv \frac{Q}{V}=4 \pi \varepsilon_{0}\left(\frac{1}{a}-\frac{1}{b}\right)^{-1}=4 \pi \varepsilon_{0} \frac{a b}{b-a} . \tag{2.56}
\end{equation*}
$$

For $b \gg a$, this result coincides with Eq. (17) for self-capacitance of the inner conductor. On the other hand, if the gap between two conductors is narrow, $d \equiv b-a \ll a$,

$$
\begin{equation*}
C_{m}=4 \pi \varepsilon_{0} \frac{a(a+d)}{d} \approx 4 \pi \varepsilon_{0} \frac{a^{2}}{d}, \tag{2.57}
\end{equation*}
$$

i.e. the capacitance approaches that of the planar capacitor of area $A=4 \pi a^{2}$ - as it should.

All this seems (and is) very straightforward, but let us contemplate what was the reason for such easy successes. We have managed to find such coordinate transformations, for example $\{x, y, z\} \rightarrow\{r$, $\theta, \varphi\}$ in the spherical case, that both the Laplace equation and the boundary conditions involve only one of the new coordinates (in this case, $r$ ). The necessary condition for the former fact is that the new coordinates (in this case, spherical ones) are orthogonal. This means that three vector components of differential $d \mathbf{r}$, due to small variations of the new coordinates (say, $d r, d \theta$, and $d \varphi$ ), are mutually perpendicular. If this were not so, the Laplace operator would not fall into the simple sum of three independent parts, and could not be reduced, at the proper symmetry of the problem, to just one of these components, making it readily integrable.

### 2.4. Other orthogonal coordinates

Since the cylindrical and spherical coordinates are only simplest examples of the orthogonal (or "orthogonal curvilinear") coordinates, this methodology may be extended to other coordinate systems of this type. As an example, let us have a look at the following problem: finding the self-capacitance of a thin, round conducting disk (and, as solution's by-products, the distributions of the electric field and surface charge) - see Fig. 6. The cylindrical or spherical coordinates would not give too much help here, because though they have the appropriate axial symmetry about axis $z$, they would make the boundary condition on the disk too complex (two coordinates, either $\rho$ and $z$, or $r$ and $\theta$ ).

Fig. 2.6. The thin conducting disk problem. (The crosssection of the system by the vertical plane $y=0$.)

The relief comes from noting that the disk, i.e. the area $z=0, r<R$, may be thought of as the limiting case of an axially-symmetric ellipsoid - the result of rotation of the usual ellipse about one of its axes - in our case, the vertical axis $z .{ }^{22}$ Analytically, such an ellipsoid may be described by the following equation:

[^182]\[

$$
\begin{equation*}
\frac{x^{2}+y^{2}}{a^{2}}+\frac{z^{2}}{b^{2}}=1 \tag{2.58}
\end{equation*}
$$

\]

where $a$ and $b$ are the so-called major semi-axes whose ratio determines the ellipse eccentricity (the degree of squeezing). For our problem, we will only need oblate ellipsoids with $a \geq b$; according to Eq. (58), they may be presented as surfaces of constant $\alpha$ in the system of degenerate ellipsoidal (or "spheroidal") coordinates $\{\alpha, \beta, \varphi\}$, which are related to the Cartesian coordinates as follows:

$$
\begin{align*}
& x=R \cosh \alpha \sin \beta \cos \varphi, \\
& y=R \cosh \alpha \sin \beta \sin \varphi,  \tag{2.59}\\
& z=R \sinh \alpha \cos \beta .
\end{align*}
$$

Such ellipsoidal coordinates are the evident generalization of the spherical coordinates, which correspond to the limit $\alpha \gg 1$ (i.e. $r \gg R$ ). In the opposite limit of small $\alpha$, the surface of constant $\alpha=$ 0 describes our thin disk of radius $R$. It is almost evident (and easy to prove) that coordinates (59) are also orthogonal, so that the Laplace operator may be expressed as a sum of three independent terms:

$$
\nabla^{2}=\frac{1}{R^{2}\left(\cosh ^{2} \alpha-\sin ^{2} \beta\right)} \times\left[\begin{array}{l}
\frac{1}{\cosh \alpha} \frac{\partial}{\partial \alpha}\left(\cosh \alpha \frac{\partial}{\partial \alpha}\right)  \tag{2.60}\\
+\frac{1}{\sin \beta} \frac{\partial}{\partial \beta}\left(\sin \beta \frac{\partial}{\partial \beta}\right)+\left(\frac{1}{\sin ^{2} \beta}-\frac{1}{\cosh ^{2} \alpha}\right) \frac{\partial^{2}}{\partial \varphi^{2}}
\end{array}\right]
$$

Though this expression may look a bit intimidating, let us notice that in our current problem, the boundary conditions depend only on coordinate $\alpha$ : ${ }^{23}$

$$
\begin{equation*}
\left.\phi\right|_{\alpha=0}=V,\left.\quad \phi\right|_{\alpha=\infty}=0 . \tag{2.61}
\end{equation*}
$$

Hence there is every reason to believe that the electrostatic potential in all space is the function of $\alpha$ alone. (In other words, all ellipsoids $\alpha=$ const are the equipotential surfaces.) Indeed, acting on such function $\phi(\alpha)$ by the Laplace operator (60), we see that the two last terms in the square brackets vanish, and the Laplace equation (35) is reduced to a simple ordinary differential equation

$$
\begin{equation*}
\frac{d}{d \alpha}\left[\cosh \alpha \frac{d \phi}{d \alpha}\right]=0 \tag{2.62}
\end{equation*}
$$

Integrating it twice, just as we did in the previous problems, we get

$$
\begin{equation*}
\phi(\alpha)=c_{1} \int \frac{d \alpha}{\cosh \alpha} \tag{2.63}
\end{equation*}
$$

This integral may be readily taken, for example, using the substitution $\xi \equiv \sinh \alpha$ (with $d \xi \equiv \cosh \alpha d \alpha$, $\cosh ^{2} \alpha=1+\sinh ^{2} \alpha=1+\xi^{2}$ ):

$$
\begin{equation*}
\phi(\alpha)=c_{1} \int_{0}^{\sinh \alpha} \frac{d \xi}{1+\xi^{2}}+c_{2}=c_{1} \tan ^{-1}(\sinh \alpha)+c_{2} \tag{2.64}
\end{equation*}
$$

[^183]The integration constants $c_{1,2}$ are again simply found from boundary conditions, in this case Eqs. (61), and we arrive at the final expression for the electrostatic potential:

$$
\begin{equation*}
\phi(\alpha)=V\left[1-\frac{2}{\pi} \tan ^{-1}(\sinh \alpha)\right] . \tag{2.65}
\end{equation*}
$$

This solution satisfies both the Laplace equation and the boundary conditions. Mathematicians tell us that the solution of any boundary problem of the type (35) is unique, so we do not need to look any further.

Now we may use Eq. (3) to find the surface density of electric charge, but in the case of thin disk, it is more natural to add up such densities on its top and bottom surfaces at the same distance $r=$ $\left(x^{2}+y^{2}\right)^{1 / 2}$ from the disk center (which are evidently equal, due to the problem symmetry about plane $z=$ $0): \sigma=\left.2 \varepsilon_{0} E_{n}\right|_{z=+0}$. According to Eq. (65), the electric field on the surface is

$$
\begin{equation*}
E_{n \mid \alpha=+0}=-\left.\frac{\partial \phi}{\partial z}\right|_{z=+0}=-\left.\frac{\partial \phi(\alpha)}{\partial(R \sinh \alpha \cos \beta)}\right|_{\alpha=+0}=\frac{2}{\pi} V \frac{1}{R \cos \beta}=\frac{2}{\pi} V \frac{1}{\left(R^{2}-r^{2}\right)^{1 / 2}} \tag{2.66}
\end{equation*}
$$

and we see that the charge is distributed along the disk very nonuniformly:

$$
\begin{equation*}
\sigma=\frac{4}{\pi} \varepsilon_{0} V \frac{1}{\left(R^{2}-r^{2}\right)^{1 / 2}}, \tag{2.67}
\end{equation*}
$$

with a singularity at the disk edge. Below we will see that such singularities are very typical for sharp edges of conductors. ${ }^{24}$ Fortunately, in our current case the divergence is integrable, giving a finite disk charge:

$$
\begin{equation*}
Q=\int_{\substack{\text { disk } \\ \text { surface }}} \sigma d^{2} r=\int_{0}^{R} \sigma(r) 2 \pi r d r=\frac{4}{\pi} \varepsilon_{0} V 2 \pi \int_{0}^{R} \frac{r d r}{\left(R^{2}-r^{2}\right)^{1 / 2}}=4 \varepsilon_{0} V R \int_{0}^{1} \frac{d \xi}{\sqrt{1-\xi}}=8 \varepsilon_{0} R V \tag{2.68}
\end{equation*}
$$

Thus, for disk's self-capacitance we get a very simple result,

$$
\begin{equation*}
C=8 \varepsilon_{0} R=\frac{2}{\pi} 4 \pi \varepsilon_{0} R, \tag{2.69}
\end{equation*}
$$

a factor of $2 / \pi \approx 0.64$ lower than that for the conducting sphere of the same equal radius, but still complying with the general estimate (18).

Can we always find a "good" system of orthogonal coordinates? Unfortunately, the answer is no, even for highly symmetric geometries. This is why the practical value of this approach is limited, and other methods of boundary problem solution are clearly needed. Before moving to them, however, let us note that in the case of 2D problems (i.e. cylindrical geometries), the orthogonal coordinate method gets help from the following conformal mapping approach.

Let us consider the pair of Cartesian coordinates $\{x, y\}$ of the cross-section plane as a complex variable $\boldsymbol{z}=x+i y,{ }^{25}$ where $i$ is the imaginary unity $\left(i^{2}=-1\right)$, and let $\boldsymbol{u}(z)=u+i v$ be an analytic complex

[^184]function of $\boldsymbol{z} .{ }^{26}$ For our current purposes, the most important property of an analytic function is that its real and imaginary parts obey the following Cauchy-Riemann relations: ${ }^{27}$
\[

$$
\begin{equation*}
\frac{\partial u}{\partial x}=\frac{\partial v}{\partial y}, \quad \frac{\partial v}{\partial x}=-\frac{\partial u}{\partial y} \tag{2.70}
\end{equation*}
$$

\]

For example, for the function

$$
\begin{equation*}
\boldsymbol{u}=z^{2}=(x+i y)^{2}=\left(x^{2}-y^{2}\right)+2 i x y \tag{2.71}
\end{equation*}
$$

whose real and imaginary parts are

$$
\begin{equation*}
u \equiv \operatorname{Re} \boldsymbol{u}=x^{2}-y^{2}, \quad v \equiv \operatorname{Im} \boldsymbol{u}=2 x y \tag{2.72}
\end{equation*}
$$

we immediately see that $\partial u / \partial x=2 x=\partial v / \partial y$, and $\partial v / \partial x=2 y=-\partial u / \partial y$, in accordance with Eq. (70).
Let us differentiate the first of Eqs. (70) over $x$ again, then change the order of differentiation, and after that use the latter of those equations:

$$
\begin{equation*}
\frac{\partial^{2} u}{\partial x^{2}}=\frac{\partial}{\partial x} \frac{\partial u}{\partial x}=\frac{\partial}{\partial x} \frac{\partial v}{\partial y}=\frac{\partial}{\partial y} \frac{\partial v}{\partial x}=-\frac{\partial}{\partial y} \frac{\partial u}{\partial y}=-\frac{\partial^{2} u}{\partial y^{2}} \tag{2.73}
\end{equation*}
$$

and similarly for $v$. This means that the sum of second-order partial derivatives of each of real functions $u(x, y)$ and $v(x, y)$ is zero, i.e. that both functions obey the 2 D Laplace equation. This mathematical fact opens a nice way of solving problems of electrostatics for (relatively simple) 2D geometries. Imagine that for a particular boundary problem we have found a function $u(z)$ for which either $u(x, y)$ or $v(x, y)$ is constant on all electrode surfaces. Then all lines of constant $u$ (or $v$ ) present equipotential surfaces, i.e. the problem of the potential distribution has been essentially solved.

As a simple example, consider a practically important problem: the quadrupole electrostatic lens- a system of four cylindrical ${ }^{28}$ electrodes with hyperbolic cross-sections, whose boundaries obey the following relations:

$$
x^{2}-y^{2}=\left\{\begin{array}{l}
+a^{2}, \quad \text { for the left and right electrodes, }  \tag{2.74}\\
-a^{2},
\end{array} \text { for the top and bottom electrodes }, ~ \$\right.
$$

voltage-biased as shown in Fig. 7a. Comparing these relations with Eqs. (72), we see that each electrode surface corresponds to a constant value of $u= \pm a^{2}$. Moreover, potentials of both surfaces with $u=+a^{2}$ are equal to $+V / 2$, while those with $u=-a^{2}$ are equal to $-V / 2$. Hence we may conjecture that the electrostatic potential at each point is a function of $u$ alone; moreover, a simple linear function,

$$
\begin{equation*}
\phi=c_{1} u+c_{2}=c_{1}\left(x^{2}-y^{2}\right)+c_{2}, \tag{2.75}
\end{equation*}
$$

[^185]is a valid (and hence the unique) solution of our boundary problem. Indeed, it does satisfy the Laplace equation, while its constants $c_{1,2}$ may be selected in a way to satisfy all the boundary conditions shown in Fig. 7a:
\[

$$
\begin{equation*}
\phi=\frac{V}{2} \frac{x^{2}-y^{2}}{a^{2}} . \tag{2.76}
\end{equation*}
$$

\]

so that the boundary problem has been solved.

Fig. 2.7. (a) Quadrupole electrostatic lens geometry and (b) its analysis using conformal mapping.

According to Eq. (76), all equipotential surfaces are hyperbolic cylinders, similar to those of the electrode surfaces. What remains is to find the electric field at an arbitrary point inside the system:

$$
\begin{equation*}
E_{x}=-\frac{\partial \phi}{\partial x}=-V \frac{x}{a^{2}}, \quad E_{y}=-\frac{\partial \phi}{\partial y}=V \frac{y}{a^{2}} . \tag{2.77}
\end{equation*}
$$

These formulas show that if charged particles (e.g., electrons in an electron optics system) are launched to fly ballistically through the lens, along axis $z$, they experience a force pushing them toward the symmetry axis and proportional to particle's deviation from the axis (and thus equivalent in action to an optical lens with positive refraction power) in one direction, and a force pushing them out (negative refractive power) in the perpendicular direction. One can show that letting charged particles fly through several such lenses, with alternating voltage polarities, in series, enables beam focusing. ${ }^{29}$

Hence, we have reduced the 2D Laplace boundary problem to that of finding the proper analytic function $\boldsymbol{u}(z)$. This task may be also understood as that of finding a conformal map, i.e. a correspondence between components of any point pair, $\{x, y\}$ and $\{u, v\}$, residing, respectively, on the initial Cartesian plane $z$ and the plane $\boldsymbol{\mu}$ of the new variables. For example, Eq. (71) maps the real electrode configuration onto the plane capacitor with infinite area (Fig. 7b), and the simplicity of Eq. $(75)$ is due to the fact that for the latter system the equipotential surfaces are just parallel planes.

For more complex geometries, the suitable analytic function $\boldsymbol{\omega}(\boldsymbol{z})$ may be hard to find. However, for conductors with piece-linear cross-section boundaries, substantial help may be obtained from the following Schwarz-Christoffel integral

[^186]\[

$$
\begin{equation*}
\boldsymbol{u}(\boldsymbol{z})=\text { const } \times \int \frac{d \boldsymbol{z}}{\left(\boldsymbol{z}-x_{1}\right)^{k_{1}}\left(\boldsymbol{z}-x_{2}\right)^{k_{2}} \ldots\left(\boldsymbol{z}-x_{N-1}\right)^{k_{N-1}}} . \tag{2.78}
\end{equation*}
$$

\]

that provides the conformal mapping of the interior of an arbitrary $N$-sided polygon on plane $\boldsymbol{\mu}=u+i v$, and the upper-half $(y>0)$ of plane $\boldsymbol{z}=x+i y$. Here $x_{j}(j=1,2, N-1)$ are the points of axis $y=0$ (i.e., of the boundary of the mapped region on plane $z$ ) to which the corresponding polygon vertices are mapped, while $k_{j}$ are the exterior angles at the polygon vertices, measured in the units of $\pi$, with $-1 \leq k_{j} \leq+1-$ see Fig. $8 .{ }^{30}$ Of points $x_{j}$, two may be selected arbitrarily (because their effects may be compensated by the multiplicative constant in Eq. (78), and the constant of integration), while all the others have to be adjusted to provide the correct mapping.

Fig. 2.8. Schwartz-Christoffel mapping of polygon's interior on the upper half-plane.

In the general case, the complex integral (78) may be hard to tackle. However, in some important cases, in particular those with right angles ( $k_{j}= \pm 1 / 2$ ) and/or with some points $\boldsymbol{\omega}_{j}$ at infinity, the integrals may be readily worked out, giving explicit analytical expressions for the mapping functions $\boldsymbol{\omega}(\boldsymbol{z})$. For example, let us consider a semi-infinite strip, defined by restrictions $-1 \leq u \leq+1$ and $0 \leq v$, on plane $\boldsymbol{\omega}-$ see the left panel of Fig. 9.

Fig. 2.9. Semi-infinite strip mapped onto the upper half-plane.

[^187]The strip may be considered as a polygon, with one vertex at the infinitely distant vertical point $\boldsymbol{\omega}_{3}=0+i \infty$. Let us map it on the upper half of plane $\boldsymbol{z}$, shown on the right panel of Fig. 9, with vertex $\boldsymbol{\omega}_{1}=-1+i 0$ mapped onto point $x_{1}=-1, y_{1}=0$, and vertex $\boldsymbol{\omega}_{2}=+1+i 0$ mapped onto point $x_{2}=+1, y_{2}=$ 0 . Since in this case both external angles are equal to $+\pi / 2$, and hence $k_{1}=k_{2}=+1 / 2$, Eq. (78) is reduced to

$$
\begin{equation*}
\boldsymbol{u}(\boldsymbol{z})=\text { const } \times \int \frac{d \boldsymbol{z}}{(\boldsymbol{z}+1)^{1 / 2}(z-1)^{1 / 2}}=\operatorname{const} \times \int \frac{d \boldsymbol{z}}{\left(z^{2}-1\right)^{1 / 2}}=\operatorname{const} \times i \int \frac{d z}{\left(1-z^{2}\right)^{1 / 2}} . \tag{2.79}
\end{equation*}
$$

This complex integral may be taken, just as for real $\boldsymbol{z}$, by the substitution $\boldsymbol{z}=\sin \xi$, giving

$$
\begin{equation*}
w(\boldsymbol{z})=\text { const }^{\prime} \times \int^{\sin ^{-1} \boldsymbol{z}} d \xi=c_{1} \sin ^{-1} z+c_{2} \tag{2.80}
\end{equation*}
$$

Determining constants $c_{1,2}$ from the required mapping, i.e. from the equations $\boldsymbol{\mu}(-1+i 0)=-1+i 0$ and $\boldsymbol{u}(+1+i 0)=+1+i 0$ (see Fig. 9), we finally get

$$
\begin{equation*}
\boldsymbol{\omega}(\boldsymbol{z})=\frac{2}{\pi} \sin ^{-1} z, \quad \text { i.e. } \boldsymbol{z}=\sin \frac{\pi \boldsymbol{u}}{2} . \tag{2.81a}
\end{equation*}
$$

Using the well-known expression for the sine of a complex argument, ${ }^{31}$ we may rewrite this elegant result in either of the two following forms for the real and imaginary components of $z$ and $\boldsymbol{w}$ :

$$
\begin{gather*}
u=\frac{2}{\pi} \sin ^{-1} \frac{2 x}{\left[(x+1)^{2}+y^{2}\right]^{1 / 2}+\left[(x-1)^{2}+y^{2}\right]^{1 / 2}}, \quad v=\frac{2}{\pi} \cosh ^{-1} \frac{\left[(x+1)^{2}+y^{2}\right]^{1 / 2}+\left[(x-1)^{2}+y^{2}\right]^{1 / 2}}{2} \\
x=\sin \frac{\pi u}{2} \cosh \frac{\pi v}{2}, \quad y=\cos \frac{\pi u}{2} \sinh \frac{\pi v}{2} \tag{2.81b}
\end{gather*}
$$

It is amazing how perfectly does the last formula manage to keep $y \equiv 0$ at different borders of our $\boldsymbol{\omega}$ region (Fig. 9): at its side borders ( $u= \pm 1,0 \leq v<\infty$ ), this is performed by the first multiplier, while at the bottom border $(-1 \leq u \leq+1, v=0)$, the equality is insured by the second operand.

This mapping may be used to solve several electrostatics problems with the geometry shown in Fig. 9; probably the most surprising of them is the following one. A straight gap of width $2 t$ is cut in a thin conducting plane, and voltage $V$ is applied between the resulting half-planes - see the bold lines in Fig. 10. Selecting a Cartesian coordinate system with axis $z$ along the cut, axis $y$ perpendicular to the plane, and the origin in the middle of the cut, we can write the boundary conditions of this Laplace problem as

$$
\phi=\left\{\begin{array}{l}
+V / 2, \quad \text { at } x>t, y=0  \tag{2.82}\\
-V / 2,
\end{array} \quad \text { at } x<-t, y=0 . ~ \$\right.
$$

(Due to problem's symmetry, we may expect that in the middle of the gap, i.e. at $-t<x<+t$ and $y=0$, the electric field is parallel to the plane and hence $\partial \phi / \partial y=0$.) The comparison of Figs. 9 and 10 shows that if we normalize our coordinates to $t$, Eq. (81) provides the conformal mapping of our system on plane $z$ to the field in a plane capacitor on plane $\boldsymbol{\omega}$, with voltage $V$ between two planes $u= \pm 1$. Since we

[^188]already know that in that case $\phi=(V / 2) u$, we may immediately use the first of Eqs. (81b) to write the final solution of the problem (in the dimensional coordinates): ${ }^{32}$
\[

$$
\begin{equation*}
\phi=\frac{V}{2} u=\frac{V}{\pi} \sin ^{-1} \frac{2 x}{\left[(x+t)^{2}+y^{2}\right]^{1 / 2}+\left[(x-t)^{2}+y^{2}\right]^{1 / 2}} . \tag{2.83}
\end{equation*}
$$

\]

Fig. 2.10. Equipotential surfaces of the electric field between two thin conducting semi-planes (or rather their cross-sections by the perpendicular plane $z=$ const).

Thin lines in Fig. 10 show the corresponding equipotential surfaces; ${ }^{33}$ it is evident that the electric field concentrates at the gap edges, just as it did at the edge of the thin disk (Fig. 6). Let me leave the remaining calculation of the surface charge distribution and the mutual capacitance between the half-planes (per unit length) for reader's exercise.

### 2.5. Variable separation

The general approach of the methods discussed in the last two sections was to satisfy the Laplace equation by a function of a single variable that also satisfies the boundary conditions. Unfortunately, in many cases this cannot be done (at least, using practicably simple functions). In this case, a very powerful method, called variable separation, may work, frequently producing "semi-analytical" results in the form of series (infinite sums) of either elementary or well-studied special functions. The main idea of the method is to present the solution of the general boundary problem (35) as the sum of partial solutions,

$$
\begin{equation*}
\phi=\sum_{k} c_{k} \phi_{k}, \tag{2.84}
\end{equation*}
$$

where each function $\phi_{k}$ satisfies the Laplace equation, and then select the set of coefficients $c_{k}$ to satisfy the boundary conditions. More specifically, in the variable separation method the partial solutions $\phi_{k}$ are looked for in the form of a product of functions, each depending of just one spatial coordinate.

[^189](i) Cartesian coordinates. Let us discuss this approach on the classical example of a rectangular box with conducting walls (Fig. 11), with the same potential (that I will take for zero) at all the walls, but a different potential $V$ fixed at the top lid. Moreover, in order to demonstrate the power of the variable separation method, let us carry out all the calculations for a more general case when the top lead potential is an arbitrary 2D function $V(x, y) .{ }^{34}$

Fig. 2.11. Standard playground for the variable separation method discussion: a rectangular box with five conducting, grounded walls and a fixed potential distribution $V(x, y)$ on the top lid.

For this geometry, it is natural to use Cartesian coordinates $\{x, y, z\}$ and hence present each of the partial solutions in Eq. (84) as a product

$$
\begin{equation*}
\phi_{k}=X(x) Y(y) Z(z) . \tag{2.85}
\end{equation*}
$$

Plugging it into the Laplace equation expressed in the Cartesian coordinates,

$$
\begin{equation*}
\frac{\partial^{2} \phi_{k}}{\partial x^{2}}+\frac{\partial^{2} \phi_{k}}{\partial y^{2}}+\frac{\partial^{2} \phi_{k}}{\partial z^{2}}=0, \tag{2.86}
\end{equation*}
$$

and dividing the result by product $X Y Z$, we get

$$
\begin{equation*}
\frac{1}{X} \frac{d^{2} X}{d x^{2}}+\frac{1}{Y} \frac{d^{2} Y}{d y^{2}}+\frac{1}{Z} \frac{d^{2} Z}{d z^{2}}=0 \tag{2.87}
\end{equation*}
$$

Here comes the punch line of the variable separation method: since the first term of this sum may depend only on $x$, the second one only of $y$, etc., Eq. (87) may be satisfied everywhere in the volume only if each of these terms equals a constant. In a minute we will see that for our current problem (Fig. 11), these constant $x$ - and $y$-terms have to be negative; hence let us denote these variable separation constants as $\left(-\alpha^{2}\right)$ and $\left(-\beta^{2}\right)$, respectively. Now Eq. (87) shows that the constant $z$-term has to be positive; if we denote it as $\gamma^{2}$, we get the following relation:

$$
\begin{equation*}
\alpha^{2}+\beta^{2}=\gamma^{2} . \tag{2.88}
\end{equation*}
$$

Now the variables are separated in the sense that for functions $X(x), Y(y)$, and $Z(z)$ we have got separate ordinary differential equations,

[^190]\[

$$
\begin{equation*}
\frac{d^{2} X}{d x^{2}}+\alpha^{2} X=0, \quad \frac{d^{2} Y}{d y^{2}}+\beta^{2} Y=0, \quad \frac{d^{2} Z}{d z^{2}}-\gamma^{2} Z=0, \tag{2.89}
\end{equation*}
$$

\]

which are related only by Eq. (88) for their parameters. Let us start from the equation for function $X(x)$. Its general solution is the sum of functions $\sin \alpha x$ and $\cos \alpha x$, multiplied by arbitrary coefficients. Let us select these coefficients to satisfy our boundary conditions. First, since $\phi \propto X$ should vanish at the back vertical wall of the box (i.e., with the choice of coordinate origin shown in Fig. 11, at $x=0$ for any $y$ and $z$ ), the coefficient at $\cos \alpha x$ should be zero. The remaining coefficient (at $\sin \alpha x$ ) may be included into the general factor $c_{k}$ in Eq. (84), so that we may take $X$ in the form

$$
\begin{equation*}
X=\sin \alpha x . \tag{2.90}
\end{equation*}
$$

This solution satisfies the boundary condition at the opposite wall $(x=a)$ only if its argument $\alpha a$ is a multiple of $\pi$, i.e. if $\alpha$ is equal to any of the following numbers (commonly called eigenvalues): ${ }^{35}$

$$
\begin{equation*}
\alpha_{n}=\frac{\pi}{a} n, \quad n=1,2, \ldots \tag{2.91}
\end{equation*}
$$

(Terms with negative values of $n$ would not be linearly-independent from those with positive $n$, and may be dropped from the sum (84). Value $n=0$ is formally possible, but would give $X=0$, i.e. $\phi_{k}=0$, at any $x$, i.e. no contribution to sum (84), so it may be dropped as well.) Now we see that we indeed had to take $\alpha$ real, (i.e. $\alpha^{2}$ positive); otherwise, instead of the oscillating function (90) we would have a sum of two exponential functions, which cannot equal zero in two independent points of axis $x$.

Since the equation for function $Y(y)$ is similar to that for $X(x)$, and the boundary conditions on the walls perpendicular to axis $y(y=0$ and $y=b)$ are similar to those for $x$-walls, the absolutely similar reasoning gives

$$
\begin{equation*}
Y=\sin \beta y, \quad \beta_{m}=\frac{\pi}{b} m, \quad m=1,2, \ldots \tag{2.92}
\end{equation*}
$$

where the choice of integer $m$ is independent of that of integer $n$. Now we see that according to Eq. (88), the separation constant $\gamma$ depends on two indices, $n$ and $m$, so that the relation may be rewritten as

$$
\begin{equation*}
\gamma_{n m}=\left[\alpha_{n}^{2}+\beta_{m}^{2}\right]^{1 / 2}=\pi\left[\left(\frac{n}{a}\right)^{2}+\left(\frac{m}{b}\right)^{2}\right]^{1 / 2} . \tag{2.93}
\end{equation*}
$$

The corresponding solution of the differential equation for $Z$ may be presented as a sum of two exponents $\exp \left\{ \pm \gamma_{n m} z\right\}$, or alternatively as a linear combination of two hyperbolic functions, $\sinh \gamma_{n m} z$ and $\cosh \gamma_{n m} z$, with arbitrary coefficients. At our choice of coordinate origin, the latter option is preferable, because $\cosh \gamma_{n m} z$ cannot satisfy the zero boundary condition at the bottom lid of the box $(z=0)$. Hence we may take $Z$ in the form

$$
\begin{equation*}
Z=\sinh \gamma_{n m} z \tag{2.94}
\end{equation*}
$$

[^191]that automatically satisfies that condition.
Now it is the right time to combine Eqs. (84) and (85) for our case in a more explicit form, replacing symbol $k$ for the set of two integer indices $n$ and $m$ :
\[

$$
\begin{equation*}
\phi(x, y, z)=\sum_{n, m=1}^{\infty} c_{n m} \sin \frac{\pi n x}{a} \sin \frac{\pi m y}{b} \sinh \gamma_{n m} z, \tag{2.95}
\end{equation*}
$$

\]

where $\gamma_{n m}$ is given by Eq. (93). This solution satisfies our boundary conditions on all walls of the box, besides the top lid, for arbitrary coefficients $c_{n m}$. The only job left for us is to choose these coefficients from the top-lid requirement:

$$
\begin{equation*}
\phi(x, y, c)=V(x, y)=\sum_{n, m=1}^{\infty} c_{n m} \sin \frac{\pi n x}{a} \sin \frac{\pi m y}{b} \sinh \gamma_{n m} c . \tag{2.96}
\end{equation*}
$$

It seems like a bad luck to have just one equation for the infinite set of coefficients $c_{n m}$. However, the decisive help come from the fact that the functions of $x$ and $y$ that participate in Eq. (96), form full, orthogonal sets of 1D functions. The last term means that the integrals of the products of the functions with different integer indices over the region of interest equal zero. Indeed, direct integration gives

$$
\int_{0}^{a} \sin \frac{\pi n x}{a} \sin \frac{\pi n^{\prime} x}{a} d x= \begin{cases}a / 2, & \text { for } n=n^{\prime},  \tag{2.97}\\ 0, & \text { for } n \neq n^{\prime},\end{cases}
$$

and similarly for $y$ (with evident replacements $a \rightarrow b, n \rightarrow m$ ). Hence, the fruitful way to proceed is to multiply both sides of Eq. (96) by the product of the basis functions, with arbitrary indices $n$ ' and $m^{\prime}$, and integrate the result over $x$ and $y$ :

$$
\begin{equation*}
\int_{0}^{a} d x \int_{0}^{b} d y V(x, y) \sin \frac{\pi n^{\prime} x}{a} \sin \frac{\pi m^{\prime} y}{b}=\sum_{n, m=1}^{\infty} c_{n m} \sinh \gamma_{n m} c \int_{0}^{a} \sin \frac{\pi n x}{a} \sin \frac{\pi n^{\prime} x}{a} d x \times \int_{0}^{b} \sin \frac{\pi m y}{b} \sin \frac{\pi m^{\prime} y}{b} d y \tag{2.98}
\end{equation*}
$$

Due to Eq. (97), all terms in the right-hand part of the last equation, besides those with $n=n$ ' and $m=$ $m^{\prime}$, vanish, and (replacing $n$ ' with $n$, and $m^{\prime}$ with $m$ ) we finally get

$$
\begin{equation*}
c_{n m}=\frac{4}{a b \sinh \gamma_{n m}} \int_{0}^{a} d x \int_{0}^{b} d y V(x, y) \sin \frac{\pi n x}{a} \sin \frac{\pi m y}{b} . \tag{2.99}
\end{equation*}
$$

Relations (93), (95) and (99) present the complete solution of the posed boundary problem; we can see both good and bad news here. The first bit of bad news is that in the general case we still need to work out (formally, the infinite number of) integrals (99). In some cases, it is possible to do this analytically. For example, in our initial problem of constant potential on the top lid, $V(x, y)=\mathrm{const} \equiv V_{0}$, both 1D integrations are elementary; for example

$$
\int_{0}^{a} \sin \frac{\pi n x}{a} d x=\frac{2 a}{\pi n} \times\left\{\begin{array}{lc}
1, & \text { for } n \text { odd }  \tag{2.100}\\
0, & \text { for } n \text { even }
\end{array}\right.
$$

and similarly for the integral over $y$, so that

$$
c_{n m}=\frac{16 V_{0}}{\pi^{2} n m \sinh \gamma_{n m} c} \times\left\{\begin{array}{lr}
1, & \text { if both } n \text { and } m \text { are odd }  \tag{2.101}\\
0, & \text { otherwise }
\end{array}\right.
$$

The second bad news is that even at such a happy occasion, we still have to sum up the series (95), so that our result may only be called analytical with some reservations, because in most cases we need a computer to get the finial numbers or plots.

Now the first good news. Computers are very efficient for both operations (95) and (99), i.e. summation and integration. (As was discussed in Sec. 1.2, random errors are averaged out at these operations.) As an example, Fig. 12 shows the plots of the electrostatic potential in a cubic box ( $a=b=$ c), with an equipotential top lid ( $V=V_{0}=$ const), obtained by numerical summation of series (95), using the analytical expression (101). The remarkable feature of this calculation is the very fast convergence of the series; for the middle cross-section of the cubic box ( $\mathrm{z} / \mathrm{c}=0.5$ ), already the first term (with $n=m$ $=1$ ) gives accuracy about $6 \%$, while the sum of four leading terms (with $n, m=1,3$ ) reduces the error to just $0.2 \%$. (For a longer box, $c>a, b$, the convergence is even faster - see the discussion below.) Only close to the corners between the top lid and the side walls, where the potential changes very rapidly, several more terms are necessary to get a reasonable accuracy.

Fig. 2.12. Distribution of the electrostatic potential within a cubic box $(a=b=c)$ with constant voltage $V_{0}$ on the top lid (Fig. 11), calculated numerically from Eqs. (93), (95) and (101). The dashed line on the left panel shows the contribution of the main term (with $n=m=1$ ) to the full result.

The second good news is that our "semi-analytical" result allow its ultimate limits to be explored analytically. For example, Eq. (93) shows that for a very flat box ( $c \ll a, b$ ), $\gamma_{n, m} z \leq \gamma_{n, m} c \ll 1$ at least for the lowest terms of series (95), with $n, m \ll c / a, c / b$. In these terms, sinh functions in Eqs. (96) and (99) may be well approximated with their arguments, and their ratio by $z / c$. This means that if we limit the summation to these term, Eq. (95) gives a very simple result

$$
\begin{equation*}
\phi(x, y) \approx \frac{z}{c} V(x, y) \tag{2.102}
\end{equation*}
$$

which means that each segment of the flat box behaves just as a plane capacitor. Only near the vertical walls (or near possible locations where $V(x, y)$ is changed sharply), the higher terms in the series (95) are important, producing deviations from Eq. (102). In the opposite limit ( $a, b \ll c$ ), Eq. (93) shows that, in contrast, $\gamma_{n, m} c \gg 1$ for all $n$ and $m$. Moreover, the ratio $\sinh \gamma_{n, m} z / \sinh \gamma_{n, m} c$ drops sharply if either $n$ or $m$ is increased, if $z$ is not too close to $c$. Hence in this case a very good approximation may be obtained by keeping just the leading term, with $n=m=1$, in Eq. (95), so that the problem of summation disappears. (We saw above that this approximation works reasonably well even for a cubic box.) In particular, for the constant potential of the upper lid, we can use Eq. (101) and the exponential asymptotic for both sinh functions, to get a very simple formula:

$$
\begin{equation*}
\phi=\frac{16}{\pi^{2}} \sin \frac{\pi x}{a} \sin \frac{\pi y}{b} \exp \left\{-\pi \frac{\left(a^{2}+b^{2}\right)^{1 / 2}}{a b}(c-z)\right\} \tag{2.103}
\end{equation*}
$$

The same variable separation method may be used to solve more general problems as well. For example, if all walls of the box shown in Fig. 11 have an arbitrary potential distribution, one can use the linear superposition principle to argue that the electrostatic potential distribution inside the box as the sum of 6 partial solutions of the type of Eq. (95), each with one wall biased by the corresponding voltage, and all other grounded ( $\phi=0$ ).

To summarize, the results given by the variable separation method are closer to what we could call a genuinely analytical solution than to purely numerical solutions - see Sec. 6 below. Now, let us explore the issues that arise when this method is applied in other orthogonal coordinate systems.
(ii) Polar coordinates. If a system of conductors is cylindrical, the potential distribution is independent of the coordinate $z$ along the cylinder axis: $\partial \phi / \partial \mathrm{z}=0$, and the Laplace equation becomes two-dimensional. If conductor's cross-section is rectangular, the variable separation method works best in Cartesian coordinates $\{x, y\}$, and is just a particular case of the 3D solution discussed above. However, if the cross-section is circular, much more compact results may be obtained by using polar coordinates $\{\rho, \varphi\}$. As we already know from the last section, these 2D coordinates are orthogonal, so that the two-dimensional Laplace operator is a simple sum. ${ }^{36}$ Requiring, just as we have done above, each component of sum (84) to satisfy the Laplace equation, we get

$$
\begin{equation*}
\frac{1}{\rho} \frac{\partial}{\partial \rho}\left(\rho \frac{\partial \phi_{k}}{\partial \rho}\right)+\frac{1}{\rho^{2}} \frac{\partial^{2} \phi_{k}}{\partial \varphi^{2}}=0 \tag{2.104}
\end{equation*}
$$

In a full analogy with Eq. (75), let us present each particular solution as a product: $\left.\phi_{k}=\mathbb{X} \rho\right) \mathbb{C} \varphi$ ). Plugging this expression into Eq. (104) and then dividing all its parts by $R \mathcal{F} / \rho^{2}$, we get

$$
\begin{equation*}
\frac{\rho}{R} \frac{d}{d \rho}\left(\rho \frac{d R}{d \rho}\right)+\frac{1}{\neq} \frac{d^{2} \neq}{d \varphi^{2}}=0 . \tag{2.105}
\end{equation*}
$$

Following the same reasoning as for the Cartesian coordinates, we get two separated ordinary differential equations

[^192]\[

$$
\begin{align*}
\rho \frac{d}{d \rho}\left(\rho \frac{d 尺}{d \rho}\right) & =v^{2} R,  \tag{2.106}\\
\frac{d^{2} \neq}{d \varphi^{2}}+v^{2} \neq & =0 \tag{2.107}
\end{align*}
$$
\]

where $v^{2}$ is the variable separation constant.
Let us start their analysis from Eq. (106), plugging into it a probe solution $\mathbb{R}=c \rho^{\alpha}$, where $c$ and $\alpha$ are some constants. Elementary differentiation shows that if $\alpha \neq 0$, the equation is indeed satisfied for any $c$, with just one requirement on constant $\alpha$, namely $\alpha^{2}=v^{2}$. This means that the following linear superposition

$$
\begin{equation*}
R=a_{v} \rho^{+v}+b_{v} \rho^{-v}, \quad \text { for } v \neq 0, \tag{2.108}
\end{equation*}
$$

with constant coefficients $a_{v}$ and $b_{v}$, is also a solution to Eq. (106). Moreover, the general theory of linear ordinary differential equations tells us that the solution of a second-order equation like Eq. (106) may only depend on just two constant factors that scale two linearly-independent functions. Hence, for all values $v^{2} \neq 0$, Eq. (108) presents the general solution of that equation. The case when $v=0$, in which functions $\rho^{+v}$ and $\rho^{-v}$ are just constants and hence are not linearly-independent, is special, but in this case the integration of Eq. (106) is straightforward, ${ }^{37}$ giving

$$
\begin{equation*}
尺=a_{0}+b_{0} \ln \rho, \quad \text { for } v=0 \tag{2.109}
\end{equation*}
$$

In order to specify the separation constant, we should use Eq. (107), whose general solution is

$$
\neq \begin{cases}c_{v} \cos v \varphi+s_{v} \sin v \varphi, & \text { for } v \neq 0,  \tag{2.110}\\ c_{0}+s_{0} \varphi, & \text { for } v=0 .\end{cases}
$$

There are two possible cases here. In many boundary problems solvable in cylindrical coordinates, the free space region, in which the Laplace equation is valid, extends continuously around the origin point $\rho$ $=0$. In this region, the potential has to be continuous and uniquely defined, so that $\nexists$ has to be a $2 \pi$ periodic function of angle $\varphi$. For that, one needs $v(\varphi+2 \pi)$ to be equal to $v(\varphi+2 \pi n)$, with $n$ an integer, immediately giving us a discrete spectrum of possible values of the variable separation constant:

$$
\begin{equation*}
v=n=0, \pm 1, \pm 2, \ldots \tag{2.111}
\end{equation*}
$$

In this case both functions $\mathbb{R}$ and $\neq 7$ may be labeled with the integer index $n$. Taking into account that the terms with negative values of $n$ may be summed up with those with positive $n$, and that $s_{0}$ should equal zero (otherwise the $2 \pi$-periodicity of function 7 would be violated), we see that the general solution to the 2D Laplace equation may be presented as

Variable separation in polar coordinates

$$
\begin{equation*}
\phi(\rho, \varphi)=a_{0}+b_{0} \ln \rho+\sum_{n=1}^{\infty}\left(a_{n} \rho^{n}+\frac{b_{n}}{\rho^{n}}\right)\left(c_{n} \cos n \varphi+s_{n} \sin n \varphi\right) . \tag{2.112}
\end{equation*}
$$

Let us see how all this machinery works on the classical problem of a round cylindrical conductor placed into an electric field that is uniform and perpendicular to cylinder's axis at large
${ }^{37}$ Actually, we have already done it in Sec. 3 - see Eq. (43).
distances - see Fig. 13a. ${ }^{38}$ First of all, let us explore the effect of system's symmetries on coefficients in Eq. (112). Selecting the coordinate system as shown in Fig. 13a, and taking the cylinder's potential for zero, we immediately have $a_{0}=0$. Moreover, due to the mirror symmetry about plane $[x, z]$, the solution has to be an even function of angle $\varphi$, and hence all coefficients $s_{n}$ should also equal zero. Also, at large distances $(\rho \gg R)$ from the cylinder axis its effect on the electric field should vanish, and the potential should approach that of the uniform field $\mathbf{E}=E_{0} \mathbf{n}_{x}$ :

$$
\begin{equation*}
\phi \rightarrow-E_{0} x=-E_{0} \rho \cos \varphi, \quad \text { for } \rho \rightarrow \infty . \tag{2.113}
\end{equation*}
$$

This is only possible if in Eq. (112), $b_{0}=0$, and also all coefficients $a_{n}$ with $n \neq 1$ vanish, while product $a_{1} c_{1}$ should be equal to $\left(-E_{0}\right)$. Thus the solution is reduced to the following form

$$
\begin{equation*}
\phi(\rho, \varphi)=-E_{0} \rho \cos \varphi+\sum_{n=1}^{\infty} \frac{B_{n}}{\rho^{n}} \cos n \varphi, \tag{2.114}
\end{equation*}
$$

in which coefficients $B_{n} \equiv b_{n} c_{n}$ should be found from the boundary condition on the cylinder's surface, i.e. at $\rho=R$ :

$$
\begin{equation*}
\phi(R, \varphi)=0 . \tag{2.115}
\end{equation*}
$$

Fig. 2.13. Conducting cylinder inserted into an initially uniform electric field perpendicular to is axis: (a) the problem's geometry, and (b) the equipotential surfaces given by Eq. (117).

This requirement yields the following equation,

$$
\begin{equation*}
\left(\frac{B_{1}}{R}-E_{0} R\right) \cos \varphi+\sum_{n=2}^{\infty} \frac{B_{n}}{R^{n}} \cos n \varphi=0, \tag{2.116}
\end{equation*}
$$

[^193]which should be satisfied for all $\varphi$. But since functions $\cos n \varphi$ are orthogonal, this equality is only possible if all $B_{n}$ for $n \geq 2$ are equal zero, while $B_{1}=E_{0} R^{2}$. Hence our final answer (which is of course only valid outside of the cylinder, i.e. for $\rho \geq R$ ), is
\[

$$
\begin{equation*}
\phi(\rho, \varphi)=-E_{0}\left(\rho-\frac{R^{2}}{\rho}\right) \cos \varphi=-E_{0}\left(1-\frac{R^{2}}{x^{2}+y^{2}}\right) x . \tag{2.117}
\end{equation*}
$$

\]

This result (Fig. 13b) shows a smooth transition between the uniform field (113) far from the cylinder, to the equipotential surface of the cylinder (with $\phi=0$ ). Such smoothening is very typical for Laplace equation solutions. Indeed, as we know from Chapter 1, these solutions corresponds to the lowest potential energy (1.67), and hence the lowest values of potential gradient modulus, possible at the given boundary conditions.

To complete the problem, let us calculate the distribution of the surface charge density over the cylinder's cross-section, using Eq. (3):

$$
\begin{equation*}
\sigma=\left.\varepsilon_{0} E_{n}\right|_{\text {surface }}=-\left.\varepsilon_{0} \frac{\partial \phi}{\partial \rho}\right|_{\rho=R}=\left.\varepsilon_{0} E_{0} \cos \varphi \frac{\partial}{\partial \rho}\left(\rho-\frac{R^{2}}{\rho}\right)\right|_{\rho_{=R}}=2 \varepsilon_{0} E_{0} \cos \varphi . \tag{2.118}
\end{equation*}
$$

This very simple formula shows that at the field direction shown in Fig. 13a ( $E_{0}>0$ ), the surface charge is positive on the right side of the cylinder and negative on its left side, thus creating a field directed from the right to the left, that compensates the external field inside the conductor, where the net field is zero. Note also that the net electric charge of the cylinder is zero, in the correspondence with the problem symmetry. Another useful by-product of calculation (118) is that the surface electric field equals $2 E_{0} \cos \varphi$, and hence its largest magnitude is twice the field far from the cylinder. Such electric field concentration is very typical for all convex conducting surfaces.

The last observation gets additional confirmation for the second possible topology, when Eq. (110) is used to describe problems with no angular periodicity. A typical example is a cylindrical conductor with a cross-section that features a corner limited by straight lines (Fig. 14). Indeed, at we may argue that at $\rho<R$ (where $R$ is the scale of radial extension of the straight sides of the corner), the Laplace equation may be satisfied by a sum of partial solutions $\mathbb{Z}(\rho)$ 民 $\varphi$ ) if the angular components of the products satisfy the boundary conditions on the corner sides. Taking (just for the simplicity of notation) the conductor's potential to be zero, and one of the corner's sides as axis $x(\varphi=0)$, these boundary conditions are

$$
\begin{equation*}
7(0)=7(\beta)=0, \tag{2.119}
\end{equation*}
$$

where angle $\beta$ may be anywhere between 0 and $2 \pi$ (Fig. 14).

Fig. 2.14. Cylindrical conductor cross-sections with (a) a corner and (b) a wedge.

Comparing this condition with Eq. (110), we see that it requires $c_{v}$ to vanish, and $v$ to take one of the values of the following discrete spectrum:

$$
\begin{equation*}
v_{m}=(\pi / \beta) m, \tag{2.120}
\end{equation*}
$$

with positive integer $m$. Hence the full solution of the Laplace equation takes the form

$$
\begin{equation*}
\phi=\sum_{m=1}^{\infty} a_{m} \rho^{\pi m / \beta} \sin \frac{\pi m \varphi}{\beta}, \quad \text { for } \rho<R, \tag{2.121}
\end{equation*}
$$

where constants $s_{\nu}$ have been incorporated into $a_{m}$. The set of constants $a_{m}$ cannot be simply determined, because it depends on the exact shape of the conductor outside the corner, and the externally applied electric field. However, whatever the set is, in the limit $\rho \rightarrow 0$, solution (121) is almost ${ }^{39}$ always dominated by the term with lowest $v$ (corresponding to $m=1$ ),

$$
\begin{equation*}
\phi \rightarrow a_{1} \rho^{\pi / \beta} \sin \frac{\pi}{\beta} \varphi \tag{2.122}
\end{equation*}
$$

because the higher terms go to zero faster. This potential distribution corresponds to the surface charge density

$$
\begin{equation*}
\sigma=\left.\varepsilon_{0} E_{n}\right|_{\text {surface }}=-\left.\varepsilon_{0} \frac{\partial \phi}{\partial(\rho \varphi)}\right|_{\rho=\text { const, } \varphi \rightarrow+0}=-\varepsilon_{0} \frac{\pi a_{1}}{\beta} \rho^{(\pi / \beta-1)} . \tag{2.123}
\end{equation*}
$$

(It is similar on the opposite face of the angle.)
Equation (123) shows that if we are dealing with a usual, concave corner ( $\beta<\pi$, see Fig. 14a), the charge density (and the surface electric field) tends to zero. On the other case, at a "convex corner" with $\beta>\pi$ (actually, a wedge - see Fig. 14b), both charge and field concentrate, formally diverging at $\rho$ $\rightarrow 0$. (So, do not sit on a roof's ridge during a thunderstorm; rather hide in a ditch!) We already saw qualitatively similar effects at our analyses of the thin round disk and split plane in the past section.
(iii) Cylindrical coordinates. Now, let us discuss whether it is possible to generalize our approach to problems whose geometry is still axially-symmetric, but with a substantial dependence of the potential on the axial coordinate $(\partial \phi / \partial \mathrm{z} \neq 0)$. The classical example of such a problem is shown in Fig. 15. Here the side wall and the bottom lid of a round cylinder are kept at fixed potential (say, $\phi=0$ ), but the potential $V$ fixed at the top lid is different. This problem is qualitatively similar to the rectangular box problem solved above (Fig. 11), and we will also try to solve it for the case of arbitrary voltage distribution over the top lid: $V=V(\rho, \varphi)$.

Fig. 2.15. Round cylinder with conducting walls.

[^194]Following the main idea of the variable separation method，let us require that each partial function $\phi_{k}$ in Eq．（84）satisfies the Laplace equation，now in full cylindrical coordinates $\{\rho, \varphi, z\}: 40$

$$
\begin{equation*}
\frac{1}{\rho} \frac{\partial}{\partial \rho}\left(\rho \frac{\partial \phi_{k}}{\partial \rho}\right)+\frac{1}{\rho^{2}} \frac{\partial^{2} \phi_{k}}{\partial \varphi^{2}}+\frac{\partial^{2} \phi_{k}}{\partial z^{2}}=0 \tag{2.124}
\end{equation*}
$$

Plugging in $\phi_{k}$ in the form $\mathbb{R}(\rho) \mathcal{Z}(\varphi) \mathcal{Z}(z)$ into Eq．（124）and dividing both parts by product $\mathbb{R} \mathcal{Z}$ ，we get

$$
\begin{equation*}
\frac{1}{\rho 尺} \frac{d}{d \rho}\left(\rho \frac{d 尺}{d \rho}\right)+\frac{1}{\rho^{2} \neq} \frac{d^{2} \neq}{d \varphi^{2}}+\frac{1}{Z} \frac{d^{2} \mathcal{Z}}{d z^{2}}=0 . \tag{2.125}
\end{equation*}
$$

Since the first two terms of Eq．（125）can only depend on polar variables $\rho$ and $\varphi$ ，while the third term， only on $z$ ，at least that term should be a constant．Denoting it（just like in the rectangular box problem） by $\gamma^{2}$ ，we get，instead of Eq．（125），a set of two equations：

$$
\begin{gather*}
\frac{d^{2} \mathcal{z}}{d z^{2}}=\gamma^{2} \boldsymbol{z},  \tag{2.126}\\
\frac{1}{\rho 尺} \frac{d}{d \rho}\left(\rho \frac{d 尺}{d \rho}\right)+\gamma^{2}+\frac{1}{\rho^{2} \neq \frac{d^{2} \neq}{d \varphi^{2}}=0 .} \tag{2.127}
\end{gather*}
$$

Now，multiplying all the terms of Eq．（127）by $\rho^{2}$ ，we see that the last term，$\left(d^{2} \neq / d \varphi^{2}\right) / \mathcal{7}$ ，may depend only on $\varphi$ ，and thus should be constant．Calling that constant $\nu^{2}$（as in Sec．（ii）above），we separate Eq． （127）into an angular equation，

$$
\begin{equation*}
\frac{d^{2} \neq}{d \varphi^{2}}+v^{2} \neq 0, \tag{2.128}
\end{equation*}
$$

and a radial equation：

$$
\begin{equation*}
\frac{d^{2} R}{d \rho^{2}}+\frac{1}{\rho} \frac{d R}{d \rho}+\left(\gamma^{2}-\frac{v^{2}}{\rho^{2}}\right) R=0 . \tag{2.129}
\end{equation*}
$$

We see that the ordinary differential equations for functions $\mathcal{Z}(z)$ and $\mathcal{X}(\varphi)$（and hence their solutions）are identical to those discussed earlier in this section．However，Eq．（129）for the radial function $R(\rho)$（called the Bessel equation）is more complex than in the 2D case，and depends on two independent constant parameters，$\gamma$ and $\nu$ ．The latter challenge may be readily overcome if we notice that any change of $\gamma$ may be reduced to re－scaling the radial coordinate $\rho$ ．Indeed，introducing a dimensionless variable $\xi \equiv \gamma \rho,{ }^{41} \mathrm{Eq}$ ．（129）may be reduced to an equation with just one parameter，$v$ ．

$$
\begin{equation*}
\frac{d^{2} R}{d \xi^{2}}+\frac{1}{\xi} \frac{d R}{d \xi}+\left(1-\frac{v^{2}}{\xi^{2}}\right) 尺=0 \tag{2.130}
\end{equation*}
$$

[^195]Moreover, we already know that for angle-periodic problems the spectrum of eigenvalues of Eq. (128) is discrete $v=n$.

Unfortunately, even in this case, Eq. (130) cannot be satisfied by a single "elementary" function, and is the canonical form of an equation defining the Bessel function of the first kind, of order $v$, commonly denoted as $J_{\cup}(\xi)$. Let me review in brief the Bessel function properties most relevant for the boundary problems of physics - and some other problems discussed in these notes. ${ }^{42}$

First of all, the Bessel function of a negative integer order is very simply related to that with the positive order:

$$
\begin{equation*}
J_{-n}(\xi)=(-1)^{n} J_{n}(\xi) \tag{2.131}
\end{equation*}
$$

enabling us to limit our discussion to the functions with $n \geq 0$. Figure 16 shows four functions with a few lowest positive $n$.

Fig. 2.16. Several first-kind Bessel functions $J_{n}(\xi)$ of integer order. Dashed lines show the envelope of asymptotes (135).

As its argument is increased, each function is initially close to a power law: $J_{0}(\xi) \approx 1, J_{1}(\xi) \approx$ $\xi / 2=\xi / 2, J_{2}(\xi) \approx \xi^{2} / 8$, etc. This behavior follows from the Taylor series

$$
\begin{equation*}
J_{n}(\xi)=\left(\frac{\xi}{2}\right)^{n} \sum_{k=0}^{\infty} \frac{(-1)^{k}}{k!(n+k)!}\left(\frac{\xi}{2}\right)^{2 k} \tag{2.132}
\end{equation*}
$$

which that is formally valid for any $\xi$, and may even serve as an alternative definition of function $J_{n}(\xi)$. However, this series is converging fast only at relatively small arguments, $\xi<n$, where its main term is

[^196]\[

$$
\begin{equation*}
\left.J_{n}(\xi)\right|_{\xi \rightarrow 0} \rightarrow \frac{1}{n!}\left(\frac{\xi}{2}\right)^{n} . \tag{2.133}
\end{equation*}
$$

\]

At $\xi \approx n+1.86 n^{1 / 3}$, the Bessel function reaches its maximum ${ }^{43}$

$$
\begin{equation*}
\max _{\xi}\left[J_{n}(\xi)\right] \approx \frac{0.675}{n^{1 / 3}}, \tag{2.134}
\end{equation*}
$$

and then starts to oscillate with a period that gradually approaches $2 \pi$, a phase shift that increases by $\pi / 2$ with each unit increment of $n$, and an amplitude that decreases as $\xi^{1 / 2}$. These features are described by the following asymptotic formula

$$
\begin{equation*}
J_{n}(\xi) \rightarrow\left(\frac{2}{\pi \xi}\right)^{1 / 2} \cos \left(\xi-\frac{\pi}{4}-\frac{n \pi}{2}\right), \quad \text { for } \xi / n \rightarrow \infty \tag{2.135}
\end{equation*}
$$

that starts to give reasonable results very soon above the function peaks - see Fig. 16. ${ }^{44}$
Now we are ready to return to our case study (Fig. 15). Let us select functions $\mathfrak{Z}(z)$ to satisfy the bottom-lid boundary condition $\mathcal{Z}(0)=0$, i.e. proportional to $\sinh \gamma z-\mathrm{cf}$. Eq. (95). Then

$$
\begin{equation*}
\phi=\sum_{n=0}^{\infty} \sum_{\gamma} J_{n}(\gamma \rho)\left(c_{n \gamma} \cos n \varphi+s_{n \gamma} \sin n \varphi\right) \sinh \gamma z . \tag{2.136}
\end{equation*}
$$

Next, we need to satisfy the zero boundary condition at the cylinder's side wall $(\rho=R)$. This may be ensured by taking

$$
\begin{equation*}
J_{n}(\gamma R)=0 . \tag{2.137}
\end{equation*}
$$

Since each function $J_{n}(x)$ has an infinite number of positive zeros (see Fig. 16), which may be numbered by an integer index $m=1,2, \ldots$, Eq. (137) may be satisfied with an infinite number of discrete values of the separation parameter $\gamma$.

$$
\begin{equation*}
\gamma_{n m}=\frac{\xi_{n m}}{R}, \tag{2.138}
\end{equation*}
$$

where $\xi_{n m}$ is the $m$-th zero of function $J_{n}(x)$ - see the top numbers in the cells of Table 1. (Very soon we will see what do we need the bottom numbers for.)

Hence, Eq. (136) may be presented in a more explicit form:

$$
\begin{equation*}
\phi(\rho, \varphi, z)=\sum_{n=0}^{\infty} \sum_{m=1}^{\infty} J_{n}\left(\xi_{n m} \frac{\rho}{R}\right)\left(c_{n m} \cos n \varphi+s_{n m} \sin n \varphi\right) \sinh \left(\xi_{n m} \frac{z}{R}\right) . \tag{2.139}
\end{equation*}
$$

[^197]Here coefficients $c_{n m}$ and $s_{n m}$ have to be selected to satisfy the only remaining boundary condition - that on the top lid:

$$
\begin{equation*}
V(\rho, \varphi)=\phi(\rho, \varphi, L)=\sum_{n=0}^{\infty} \sum_{m=1}^{\infty} J_{n}\left(\xi_{n m} \frac{\rho}{R}\right)\left(c_{n m} \cos n \varphi+s_{n m} \sin n \varphi\right) \sinh \left(\xi_{n m} \frac{L}{R}\right) . \tag{2.140}
\end{equation*}
$$

To use it, let us multiply both parts of Eq. (140) by $J_{n}\left(\xi_{n m} ’ \rho / R\right) \cos n^{\prime} \varphi$, integrate the result over the lid area, and use the following property of the Bessel functions:

$$
\begin{equation*}
\int_{0}^{1} J_{n}\left(\xi_{n m} s\right) J_{n}\left(\xi_{n m^{\prime}} s\right) s d s=\frac{1}{2}\left[J_{n+1}\left(\xi_{n m}\right)\right]^{2} \delta_{m m^{\prime}}, \tag{2.141}
\end{equation*}
$$

where $\delta_{m m}$, is the Kronecker symbol. ${ }^{45}$
Table 2.1. Approximate values of a few first zeros of a few lowest-order Bessel functions $J_{n}(\xi)$ (the top number in each cell), and the values of $d J_{n} / d \xi$ at those points (the bottom number in the cell).

Relation (141) expresses a very specific ("2D") orthogonality of Bessel functions with different indices $m$ - do not confuse them with the function's order $n$, please! ${ }^{46}$ Since it relates two Bessel functions with the same index $n$, it is natural to ask why its right-hand part contains the function with a different index $(n+1)$. Some clue may come from one more very important property of the Bessel functions, the so-called recurrence relations: ${ }^{47}$
${ }^{45}$ Let me hope the reader knows what it is; if not - see MA Eq. (13.1).
${ }^{46}$ The Bessel functions of the same argument but of different orders are also orthogonal, but in a different way:

$$
\int_{0}^{\infty} J_{n}(\xi) J_{n^{\prime}}(\xi) \frac{d \xi}{\xi}=\frac{1}{n+n^{\prime}} \delta_{n n^{\prime}}
$$

${ }^{47}$ These relations provide, in particular, a convenient way for fast numerical computation of all $J_{n}(\xi)$ after $J_{0}(\xi)$ has been computed. (The latter is usually done with an algorithm using Eq. (132) for smaller $\xi$ and an extension of Eq. (135) for larger $\xi$.) Note that most mathematical software packages, including all those listed in MA Sec. 16(iv), include ready subroutines for calculation of functions $J_{n}(\xi)$ and other special functions used in this lecture series. In this sense, the line separated these "special functions" from "elementary functions" is rather blurry.

$$
\begin{align*}
& J_{n-1}(\xi)+J_{n+1}(\xi)=\frac{2 n J_{n}(\xi)}{\xi}  \tag{2.142a}\\
& J_{n-1}(\xi)-J_{n+1}(\xi)=2 \frac{d J_{n}(\xi)}{d \xi} \tag{2.142b}
\end{align*}
$$

that in particular yield the following relation (convenient for working out some Bessel function integrals):

$$
\begin{equation*}
\frac{d}{d \xi}\left(\xi^{n} J_{n}(\xi)\right)=\xi^{n} J_{n-1}(\xi) \tag{2.143}
\end{equation*}
$$

For our current purposes, let us apply the recurrence relations at special points $\xi_{n m}$. At these points, $J_{n}$ vanishes, and the system of two equations (142) may be readily solved to get, in particular,

$$
\begin{equation*}
J_{n+1}\left(\xi_{n m}\right)=-\frac{d J_{n}}{d \xi}\left(\xi_{n m}\right) \tag{2.144}
\end{equation*}
$$

so that the square bracket in the right-hand part of Eq. (141) is just $\left(d J_{n} / d \xi\right)^{2}$ at $\xi=\xi_{n m}$. Thus the values of the Bessel function derivatives at the zero points (given by the lower numbers in the cells of Table 1) are as important for boundary problem solutions as the zeros themselves.

Since the angular functions $\cos n \varphi$ are also orthogonal - both to each other,

$$
\begin{equation*}
\int_{0}^{2 \pi} \cos (n \varphi) \cos \left(n^{\prime} \varphi\right) d \varphi=\pi \delta_{n n^{\prime}} \tag{2.145}
\end{equation*}
$$

and to all functions $\sin n \varphi$, the integration over the lid area kills all terms of both series in right-hand part of Eq. (140), besides just one term proportional to $c_{n^{\prime} m^{\prime}}$, and hence gives an explicit expression for that coefficient. The counterpart coefficients $s_{n^{\prime} m}$ may be found by repeating the same procedure with the replacement of $\cos n^{\prime} \varphi$ by $\sin n^{\prime} \varphi$. This evaluation (left for reader's exercise) completes the solution of our problem for an arbitrary lid potential $V(\rho, \varphi)$.

Still, before leaving the Bessel functions (for a while :-), we need to address two important issues. First, we have seen that in our cylinder problem (Fig. 15), the set of functions $J_{n}\left(\xi_{n m} \rho / R\right)$ with different indices $m$ (that characterize the degree of Bessel function's stretch along axis $\rho$ ) play the role similar to that of functions $\sin (\pi n x / a)$ in the rectangular box problem shown in Fig. 11. In this context, what is the analog of functions $\cos (\pi n x / a)$ - which may be important for some boundary problems? In a more formal language, are there any functions of the same argument $\xi \equiv \xi_{n m} \rho / R$, that would be linearly independent of the Bessel functions of the first kind, while satisfying the same differential equation (130)?

The answer is yes. For the definition of such functions, we first need to generalize our prior formulas for $J_{n}(\xi)$, and in particular Eq. (132), to the case of arbitrary order $v$. The generalization may be performed in the following way:

$$
\begin{equation*}
J_{v}(\xi)=\left(\frac{\xi}{2}\right)^{v} \sum_{k=0}^{\infty} \frac{(-1)^{k}}{k!\Gamma(v+k+1)}\left(\frac{\xi}{2}\right)^{2 k} \tag{2.146}
\end{equation*}
$$

where $\Gamma(s)$ is the so-called gamma function that may be defined, for almost any real $s$, as ${ }^{48}$

$$
\begin{equation*}
\Gamma(s) \equiv \int_{0}^{\infty} \xi^{s-1} e^{-\xi} d \xi \tag{2.147}
\end{equation*}
$$

The simplest, and the most important property of the gamma function is that for integer values of argument it gives the factorial of a number smaller by one:

$$
\begin{equation*}
\Gamma(n+1)=n!\equiv 1 \cdot 2 \cdot \ldots n \tag{2.148}
\end{equation*}
$$

so it is essentially a generalization of the notion of factorial to all real numbers.
The Bessel functions defined by Eq. (146) satisfy (after replacements $n \rightarrow v$ and $n!\rightarrow \Gamma(n+1)$ ), virtually all the relations we have discussed above, including the Bessel equation (130), the asymptotic formula (135), the orthogonality condition (141), and the recurrence relations (142). Moreover, it may be shown that $v \neq n$, functions $J_{V}(\xi)$ and $J_{-1}(\xi)$ are linearly independent and hence their linear combination may be used to present a general solution of the Bessel equation. Unfortunately, as Eq. (131) shows, for $v=n$ this is not true, and a solution independent of $J_{n}(\xi)$ has to be formed in a different way.

The most common way of overcoming this difficulty is first to define, for all $v \neq n$, function

$$
\begin{equation*}
Y_{v}(\xi) \equiv \frac{J_{v}(\xi) \cos v \pi-J_{-v}(\xi)}{\sin v \pi} \tag{2.149}
\end{equation*}
$$

called the Bessel function of second kind, or more often as the Weber functions, ${ }^{49}$ and then to follow the limit $v \rightarrow n$. At this, both the numerator and denominator of the right-hand part of Eq. (149) tend to zero, but their ratio tends to a finite value called $Y_{n}(x)$. It may be shown that these functions are still the solutions of the Bessel equation and are linearly independent of $J_{n}(x)$, though are related just as those functions if the sign of $n$ changes:

$$
\begin{equation*}
Y_{-n}(\xi)=(-1)^{n} Y_{n}(\xi) \tag{2.150}
\end{equation*}
$$

Figure 17 shows a few Weber functions of the lowest integer orders. The plots show that the asymptotic behavior is very much similar to that of $J_{n}(\xi)$,

$$
\begin{equation*}
Y_{n}(\xi) \rightarrow\left(\frac{2}{\pi \xi}\right)^{1 / 2} \sin \left(\xi-\frac{\pi}{4}-\frac{n \pi}{2}\right), \quad \text { for } \xi \rightarrow \infty \tag{2.151}
\end{equation*}
$$

but with the phase shift necessary to make these Bessel functions orthogonal to those of the fist order cf. Eq. (135). However, for small values of argument $\xi$, the Bessel functions of the second kind behave completely differently from those of the first kind:

$$
Y_{n}(\xi) \rightarrow \begin{cases}(2 / \pi)[\ln (\xi / 2)+\gamma], & \text { for } n=0,  \tag{2.152}\\ -\frac{(n-1)!}{\pi}\left(\frac{\xi}{2}\right)^{-n}, & \text { for } n \neq 0,\end{cases}
$$

[^198]where
\[

$$
\begin{equation*}
\gamma \equiv \lim _{n \rightarrow \infty}\left(1+\frac{1}{2}+\frac{1}{3}+\ldots+\frac{1}{n}-\ln n\right) \approx 0.577157 \ldots \tag{2.153}
\end{equation*}
$$

\]

is the so-called Euler constant. Relations (152) and Fig. 17 show that functions $Y_{n}(\xi)$ diverge at $\xi \rightarrow 0$ and hence cannot describe the behavior of any physical variable, in particular the electrostatic potential.

Fig. 2.17. A few Bessel functions of the second kind (a.k.a. the Neumann functions, a.k.a. the Weber functions).

One may wonder: if this is true, when do we need these functions in physics? This does not happen too often, but still does. Figure 18 shows an example of a boundary problem of electrostatics that requires both functions $J_{n}(\xi)$ and $Y_{n}(\xi)$.

Fig. 2.18. Simple boundary problem that cannot be solved using just one kind of Bessel functions.

Two round, coaxial conducting cylinders are kept at the same (say, zero) potential, but at least one of two horizontal lids has a different potential. The problem is almost completely similar to that discussed above (Fig. 15), but now we need to find the potential distribution in the free space between the cylinders, $R_{1}<\rho<R_{2}$. If we use the same variable separation as in the simpler counterpart problem,
we need the radial functions $\mathbb{R}(\rho)$ to satisfy two zero boundary conditions：at $\rho=R_{1}$ and $\rho=R_{2}$ ．With the Bessel functions of just first kind，$J_{n}(\gamma \rho)$ ，it is impossible to do，because the two boundaries would impose two independent（and generally incompatible）conditions，$J_{n}\left(\gamma R_{1}\right)=0$ ，and $J_{n}\left(\gamma R_{2}\right)=0$ ，for one ＂compression parameter＂$\gamma$ ．The existence of the Bessel functions of the second kind immediately saves the day，because if a solution is presented as a linear combination，${ }^{50}$

$$
\begin{equation*}
c_{J} J_{n}(\gamma \rho)+c_{Y} Y_{n}(\gamma \rho), \tag{2.154}
\end{equation*}
$$

two zero boundary conditions give two equations for $\gamma$ and ratio $c \equiv c_{Y} / c_{J}$ ．（Due to the oscillating character of both Bessel functions，these conditions would be typically satisfied by an infinite set of discrete pairs $\{\gamma, c\}$ ．）Note，however，that generally none of these pairs would correspond to zeros of either $J_{n}$ nor $Y_{n}$ ，so that having an analog of Table 1 for the latter function would not help much．Hence， even the simple problems of this kind（like the one shown in Fig．18）typically require numerical solutions of algebraic（transcendental）equations．

One more issue we need to address，before moving on to the spherical coordinates，are the so－ called modified Bessel functions：of the first kind，$I_{\downarrow}(\xi)$ ，and of the second kind，$K_{V}(\xi)$ ．They are two linearly－independent solutions of the modified Bessel equation，

$$
\begin{equation*}
\frac{d^{2} 尺}{d \xi^{2}}+\frac{1}{\xi} \frac{d 尺}{d \xi}-\left(1+\frac{v^{2}}{\xi^{2}}\right) 尺=0 \tag{2.155}
\end{equation*}
$$

Modified Bessel equation
that differs from Eq．（130）＂only＂by the sign of one of its terms．Figure 19 shows a simple problem that leads to this equation：a round conducting cylinder is sliced，perpendicular to its axis，to rings of equal height $h$ ，which are kept at equal but sign－alternating potentials．

Fig．2．19．Typical boundary problem whose solution may be conveniently described in terms of the modified Bessel functions．

If the gaps between the sections are narrow，$t \ll h$ ，we may use the variable separation method for the solution to this problem，but now we evidently need periodic（rather than exponential）solutions

[^199]along axis $z$, i.e. linear combinations of $\sin k z$ and $\cos k z$ with various real values of constant $k$. Separating the variables, we arrive at a differential equation similar to Eq. (129), but with the negative sign before the separation constant:
\[

$$
\begin{equation*}
\frac{d^{2} R}{d \rho^{2}}+\frac{1}{\rho} \frac{d R}{d \rho}-\left(k^{2}+\frac{v^{2}}{\rho^{2}}\right) R=0 . \tag{2.156}
\end{equation*}
$$

\]

Radial coordinate normalization, $\xi \equiv k \rho$, immediately leads us to Eq. (155), and hence (for $v=n$ ) to the modified Bessel functions $I_{n}(\xi)$ and $K_{n}(\xi)$.

Figure 20 shows the behavior of a few such functions, of a few lowest orders. One can see that at $\xi \rightarrow 0$ it is virtually similar to that of the "usual" Bessel functions - cf. Eqs. (132) and (152), with $K_{n}(\xi)$ multiplied (due to purely historical reasons) by an additional coefficient, $\pi / 2$ :

$$
I_{n}(\xi) \rightarrow \frac{1}{n!}\left(\frac{\xi}{2}\right)^{n}, \quad K_{n}(\xi) \rightarrow \begin{cases}-\left[\ln \left(\frac{\xi}{2}\right)+\gamma\right], & \text { for } n=0  \tag{2.157}\\ \frac{(n-1)!}{2}\left(\frac{\xi}{2}\right)^{-n}, & \text { for } n \neq 0\end{cases}
$$

However, the asymptotic behavior of the modified functions is very much different, with $I_{n}(x)$ exponentially growing and $K_{n}(\xi)$ exponentially dropping at $\xi \rightarrow \infty$ :

$$
\begin{equation*}
I_{n}(\xi) \rightarrow\left(\frac{1}{2 \pi \xi}\right)^{1 / 2} e^{\xi}, \quad K_{n}(\xi) \rightarrow\left(\frac{\pi}{2 \xi}\right)^{1 / 2} e^{-\xi} \tag{2.158}
\end{equation*}
$$

Fig. 2.20. Modified Bessel functions of the first kind (left panel) and the second kind (right panel).

To complete our brief survey of the Bessel functions, let me note that all the functions we have discussed so far may be considered as particular cases of Bessel functions of the complex argument, say $J_{n}(\boldsymbol{z})$ and $Y_{n}(\boldsymbol{z})$, or, alternatively, $H_{n}^{(1,2)}(\boldsymbol{z})=J_{n}(\boldsymbol{z}) \pm i Y_{n}(\boldsymbol{z}) .{ }^{51}$ The "usual" Bessel functions $J_{n}(\xi)$ and

[^200]$Y_{n}(\xi)$ may be considered as a set of values of these generalized functions on the real axis $(\boldsymbol{z}=\xi)$, while the modified functions as their particular case at $\boldsymbol{z}=i \xi$ :
\[

$$
\begin{equation*}
I_{\nu}(\xi)=i^{-v} J_{v}(i \xi), \quad K_{v}(\xi)=\frac{\pi}{2} i^{v+1} H_{v}^{(1)}(i \xi) \tag{2.159}
\end{equation*}
$$

\]

Moreover, this generalization of the Bessel functions to the whole complex plane $z$ enables the use of their values along other directions on that plane, for example under angles $\pi / 4 \pm \pi / 2$. As a result, one arrives at the so-called Kelvin functions

$$
\begin{align*}
& \operatorname{ber}_{v} \xi+i \operatorname{bei}_{\nu} \xi \equiv J_{v}\left(\xi e^{-i \pi / 4}\right) \\
& \operatorname{ker}_{v} \xi+i \operatorname{kei}_{v} \xi \equiv i \frac{\pi}{2} H_{v}^{(1)}\left(\xi e^{-i 3 \pi / 4}\right) \tag{2.160}
\end{align*}
$$

which are also useful for some important problems of mathematical physics and engineering. Unfortunately, we do not have time to discuss these problems in this course. ${ }^{52}$
(iv) Spherical coordinates are very important in physics, because of the (approximate) spherical symmetry of many objects - from electrons and nuclei and atoms to planets and stars. Let us again require each component $\phi_{k}$ of Eq. (84) to satisfy the Laplace equation. Using the well known expression for the Laplace operator in spherical coordinates, ${ }^{53}$ we get

$$
\begin{equation*}
\frac{1}{r^{2}} \frac{\partial}{\partial r}\left(r^{2} \frac{\partial \phi_{k}}{\partial r}\right)+\frac{1}{r^{2} \sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial \phi_{k}}{\partial \theta}\right)+\frac{1}{r^{2} \sin ^{2} \theta} \frac{\partial^{2} \phi_{k}}{\partial \varphi^{2}}=0 \tag{2.161}
\end{equation*}
$$

Let us look for a solution of this equation in the following variable-separated form:

$$
\begin{equation*}
\phi_{k}=\frac{R(r)}{r} \mathcal{P}(\cos \theta) \mathcal{F}(\varphi), \tag{2.162}
\end{equation*}
$$

Separating equations one by one, just like this has been done in cylindrical coordinates, we get the following equations for the functions participating in this solution:

$$
\begin{gather*}
\frac{d^{2} 尺}{d r^{2}}-\frac{l(l+1)}{r^{2}} 尺=0,  \tag{2.163}\\
\frac{d}{d \xi}\left[\left(1-\xi^{2}\right) \frac{d \mathcal{P}}{d \xi}\right]+\left[l(l+1)-\frac{v^{2}}{1-\xi^{2}}\right] \mathcal{P}=0,  \tag{2.164}\\
\frac{d^{2} \ngtr}{d \varphi^{2}}+v^{2} \neq 0, \tag{2.165}
\end{gather*}
$$

where $\xi \equiv \cos \theta$ is a new variable in lieu of $\theta$ (so that $-1 \leq \xi \leq+1$ ), and $v^{2}$ and $l(l+1)$ are the separation constants. (The reason for selection of the latter one in this form will be clear in a minute.) One can see that, in contrast with the cylindrical coordinates, the equation for the radial functions is quite simple.

[^201]Indeed, let us look for its solution in the form $c r^{\alpha}$ - just as we have done with Eq. (106). Plugging this solution into Eq. (163), we immediately get the following condition on parameter $\alpha$ :

$$
\begin{equation*}
\alpha(\alpha-1)=l(l+1) . \tag{2.166}
\end{equation*}
$$

This quadratic equation has two roots, $\alpha=l+1$ and $\alpha=-l$, so that the general solution to Eq. (163) is

$$
\begin{equation*}
\mathrm{R}=a_{l} r^{l+1}+\frac{b_{l}}{r^{l}} . \tag{2.167}
\end{equation*}
$$

Equation (165) is also very simple, and is absolutely similar to the Eq. (107) we had for the cylindrical coordinates. However, Eq. (164) function $\mathcal{P}(\xi)$, where $\xi$ is the cosine of the polar angle $\theta$, is the so-called Legendre differential equation, whose solution cannot be expressed via what is usually called "elementary functions" - though, again, there is no generally accepted line between them and "special functions".

Let us start with axially-symmetric problems for which $\partial \phi / \partial \varphi=0$. This means $\pi \varphi)=$ const, and thus $v=0$, so that Eq. (164) is reduced to so-called Legendre's ordinary differential equation:

$$
\begin{equation*}
\frac{d}{d \xi}\left[\left(1-\xi^{2}\right) \frac{d \mathcal{P}}{d \xi}\right]+l(l+1) \mathcal{P}=0 \tag{2.168}
\end{equation*}
$$

One can readily check that the solutions of this equation for integer values of $l$ are specific (Legendre) polynomials ${ }^{54}$ that may be defined, for example, by the following Rodrigues' formula:

$$
\begin{equation*}
\mathcal{P}_{l}(\xi)=\frac{1}{2^{l} l!} \frac{d^{l}}{d \xi^{l}}\left(\xi^{2}-1\right)^{l}, \quad l=0,1,2, \ldots \tag{2.169}
\end{equation*}
$$

As follows from this formula, the first few Legendre polynomials are pretty simple:

$$
\begin{align*}
& P_{0}(\xi)=1 \\
& P_{1}(\xi)=\xi \\
& P_{2}(\xi)=\frac{1}{2}\left(3 \xi^{2}-1\right)  \tag{2.170}\\
& P_{3}(\xi)=\frac{1}{2}\left(5 \xi^{3}-3 \xi\right) \\
& P_{4}(\xi)=\frac{1}{8}\left(35 \xi^{4}-30 \xi^{2}+3\right), \ldots
\end{align*}
$$

though such explicit expressions become more and more bulky as $l$ is increased. As Fig. 21 shows, all these functions, that are defined on the $[-1,+1]$ segment, start at one point, $\mathcal{P}_{l}(+1)=+1$, and end up either at the same point or in the opposite point: $\mathcal{P}_{( }(-1)=(-1)^{l}$. On the way between these two end points, the $l$-th polynomial crosses the horizontal axis $l$ times. It is straightforward to use Eq. (169) for proving that these polynomials form a full, orthogonal set of functions, with the following normalization rule:

[^202]\[

$$
\begin{equation*}
\int_{-1}^{+1} \mathcal{P}_{l}(\xi) \mathcal{P}_{l^{\prime}}(\xi) d \xi=\frac{2}{2 l+1} \delta_{l l^{\prime}} \tag{2.171}
\end{equation*}
$$

\]

so that any function $f(\xi)$, defined on the segment $[-1,+1]$, may be presented as a unique series over the polynomials. ${ }^{55}$

Fig. 2.21. A few lowest Legendre polynomials $P_{l}(\xi)$.

Thus, taking into account the additional division by $r$ in Eq. (162), the general solution of any axially-symmetric Laplace problem may be presented as

$$
\begin{equation*}
\phi(r, \theta)=\sum_{l=0}^{\infty}\left(a_{l} r^{l}+\frac{b_{l}}{r^{l+1}}\right) \mathcal{P}_{l}(\cos \theta) . \tag{2.172}
\end{equation*}
$$

Please note a strong similarity between this solution and Eq. (112) for the 2D Laplace problem in polar coordinates. However, besides the difference in angular functions, there is also a difference (by one) in the power of the second radial function, and this difference immediately shows up in core problems.

Indeed, let us solve a problem similar to that shown in Fig. 13: find the electric field around a conducting sphere of radius $R$, placed into an initially uniform external field $\mathbf{E}_{0}$ (whose direction we will take for axis $z$ ) - see Fig. 22a. If we select $\left.\phi\right|_{z=0}=0$, then $a_{0}=b_{0}=0$. Now, just as has been argued for the cylindrical case, at $r \gg R$ the potential should approach that for the uniform field:

$$
\begin{equation*}
\phi \rightarrow-E_{0} z=-E_{0} r \cos \theta \tag{2.173}
\end{equation*}
$$

and this again means that in Eq. (172), only one of coefficients $a_{l}$ survives: $a_{l}=-E_{0} \delta_{l 1}$. Now, and from the boundary condition on the surface, $\phi(R, \theta)=0$, we get:

$$
\begin{equation*}
0=\left(-E_{0} R+\frac{b_{1}}{R^{2}}\right) \cos \theta+\sum_{l \geq 2} \frac{b_{l}}{R^{l+1}} \mathcal{P}_{l}(\cos \theta) . \tag{2.174}
\end{equation*}
$$

This expression may be viewed as the expansion of function $f(\xi) \equiv 0$ into a series of orthogonal functions $P_{l}(\xi)$. Since such expansions are unique, and Eq. (174) is satisfied if

[^203]\[

$$
\begin{equation*}
b_{l}=E_{0} R^{3} \delta_{l, 1}, \tag{2.175}
\end{equation*}
$$

\]

this is indeed the only possibility to satisfy the boundary condition, so that, finally,

$$
\begin{equation*}
\phi=-E_{0}\left(r-\frac{R^{3}}{r^{2}}\right) \cos \theta . \tag{2.176}
\end{equation*}
$$

(a)
(b)

Fig. 2.22. Conducting sphere in a uniform electric field: (a) problem' geometry, and (b) the equipotential surface pattern given by Eq. (176). The pattern is qualitatively similar but quantitatively different from that for the conducting cylinder in a perpendicular field -cf. Fig. 13.

This distribution, shown in Fig. 22b, is very much similar to Eq. (117) for the cylindrical case, but with a different power of radius in the second term. This leads to a quantitatively different distribution of the surface electric field:

$$
\begin{equation*}
E_{n}=-\left.\frac{\partial \phi}{\partial r}\right|_{r=R}=3 E_{0} \cos \theta \tag{2.177}
\end{equation*}
$$

so that its maximal value is a factor of 3 (rather than 2) larger than the external field.
Now let us discuss the Laplace equation solution in the general case (no axial symmetry), but only for most important systems in which the free space surrounds the origin from all sides. In this case the solutions to Eq. (165) have to be $2 \pi$-periodic, and hence $v=n=0, \pm 1, \pm 2, \ldots$ Mathematics says that the Legendre equation (164) with integer $v=n$ and a fixed integer $l$ has a solution only for a limited range of $n:{ }^{56}$

$$
\begin{equation*}
-l \leq n \leq+l . \tag{2.178}
\end{equation*}
$$

These solutions are called the associated Legendre functions. For $n \geq 0$, they may be defined via the Legendre polynomials using the following formula:

[^204]\[

$$
\begin{equation*}
\mathcal{P}_{l}^{n}(\xi)=(-1)^{n}\left(1-\xi^{2}\right)^{n / 2} \frac{d^{n}}{d \xi^{n}} \mathcal{P}_{l}(\xi) . \tag{2.179}
\end{equation*}
$$

\]

On the segment $\xi \in[-1,+1]$, each set of the associated Legendre functions with a fixed index $n$ and nonnegative $l$ form a full, orthogonal set, with the normalization relation,

$$
\begin{equation*}
\int_{-1}^{+1} P_{l}^{n}(\xi) P_{l^{\prime}}^{n}(\xi) d \xi=\frac{2}{2 l+1} \frac{(l+n)!}{(l-n)!} \delta_{l l^{\prime}} \tag{2.180}
\end{equation*}
$$

that is evidently a generalization of Eq. (171).
Since these relations may seem a bit intimidating, let me write down explicit expressions for a few $P_{l}^{n}(\cos \theta)$ with the lowest values of $l$ and $n \geq 0$ :

$$
\begin{align*}
& l=0: \quad P_{0}^{0}(\cos \theta)=1 ;  \tag{2.181}\\
& l=1:\left\{\begin{array}{l}
P_{1}^{0}(\cos \theta)=\cos \theta, \\
P_{1}^{1}(\cos \theta)=-\sin \theta
\end{array}\right.  \tag{2.182}\\
& l=2:\left\{\begin{array}{l}
P_{2}^{0}(\cos \theta)=\left(3 \cos ^{2} \theta-1\right) / 2, \\
P_{2}^{1}(\cos \theta)=-2 \sin \theta \cos \theta, \\
P_{2}^{2}(\cos \theta)=-3 \cos ^{2} \theta .
\end{array}\right. \tag{2.183}
\end{align*}
$$

The reader should agree there is not much intimidation is these functions - which are most important for applications.

Now the general solution (162) to the Laplace equation in the spherical coordinates may be spelled out as

$$
\begin{equation*}
\phi(r, \theta, \varphi)=\sum_{l=0}^{\infty}\left(a_{l} r^{l}+\frac{b_{l}}{r^{l+1}}\right) \sum_{n=0}^{l} \mathcal{P}_{l}^{n}(\cos \theta) \mathcal{\not}_{n}(\varphi), \quad \not_{n}(\varphi)=c_{n} \cos n \varphi+s_{n} \sin n \varphi \tag{2.184}
\end{equation*}
$$

Since the difference between angles $\theta$ and $\varphi$ is somewhat artificial, physicists prefer to think not about functions $P$ and $\mathcal{F}$ in separation, but directly about their products that participate in this solution. Figure 23 shows a few such angular functions ${ }^{57}$ by plotting their modulus along the radius, and using bi-color to show the function sign. While the lowest function $(l=0, n=0)$ is just a constant, two "dipole" functions $(l=1)$ differ from each other by their spatial orientation. Functions with higher $l($ say, $l=2)$ differ more substantially, with the following general trend: for each value of $l$, the function with $n=0$ is

[^205]Variable
separation in spherical coordinates (general case)
axially-symmetric ${ }^{58}$ and has $l$ zeros on its way from $\theta=0$ to $\theta=\pi$, while the functions with $n=l$ do not have zeros inside that interval, while oscillating most strongly as functions of $\varphi$.

As an exception, in order to save time, I will skip an example of application of the associated Legendre functions, because several such examples are given in the quantum mechanics part of these series. (Note that in this field, index $n$ is traditionally called $m$ - the magnetic quantum number.)

### 2.6. Charge images

So far, we have discussed various methods of solution of the Laplace boundary problem (35). Let us now move on to the discussion of its generalization, the Poisson equation (1.41), that we need when besides the conductors, we also have "free" charges with a known spatial distribution $\rho(\mathbf{r})$. (This will also allow us, better equipped, to revisit the Laplace problem again in the next section.)

Let us start with a somewhat limited, but sometimes very useful charge image (or "image charge") method. Consider a very simple problem: a single point charge near a conducting half-space see Fig. 24. Let us prove that its solution, above conductor's surface ( $z \geq 0$ ), may be presented as:

$$
\begin{equation*}
\phi(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}}\left(\frac{q}{r_{1}}-\frac{q}{r_{2}}\right)=\frac{q}{4 \pi \varepsilon_{0}}\left(\frac{1}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|}-\frac{1}{\left|\mathbf{r}-\mathbf{r}^{\prime \prime}\right|}\right), \tag{2.185}
\end{equation*}
$$

[^206]or in a more explicit (coordinate) form:
\[

$$
\begin{equation*}
\phi(\mathbf{r})=\frac{q}{4 \pi \varepsilon_{0}}\left(\frac{1}{\left[\rho^{2}+(z-d)^{2}\right]^{1 / 2}}-\frac{1}{\left[\rho^{2}+(z+d)^{2}\right]^{1 / 2}}\right) \tag{2.186}
\end{equation*}
$$

\]

where $\rho$ is the distance of the observation point from the vertical line on which the charge is located. Indeed, this solution evidently satisfies both the boundary condition of zero potential at the surface of the conductor $(z=0)$, and the Poisson equation (1.41), with the single $\delta$-functional source at point $\mathbf{r}^{\prime}=$ $\{0,0, d\}$ in its right-hand part, because its another singularity, at point $\mathbf{r}^{\prime \prime}=\{0,0,-d\}$, is outside the region of validity of this solution $(z \geq 0)$.

Fig. 2.24. The simplest problem readily solvable by the charge image method. Point colors in this section are used, here and in the balance of this section, to denote charges of the original (red) and opposite (blue) sign.

Physically, the solution may be interpreted as the sum of the fields of the actual charge $(+q)$ at point $\mathbf{r}$ ', and an equal but opposite charge $(-q)$ at the "mirror image" point $\mathbf{r}$ " (Fig. 24). This is the basic idea of the charge image method. Before moving to more complex problems, let us discuss the situation shown in Fig. 24 in a little bit more detail. First, we can use Eqs. (3) and (186) to calculate the surface charge density:

$$
\begin{equation*}
\sigma=-\left.\varepsilon_{0} \frac{\partial \phi}{\partial z}\right|_{z=0}=-\frac{q}{4 \pi} \frac{\partial}{\partial z}\left(\frac{1}{\left[\rho^{2}+(z-d)^{2}\right]^{1 / 2}}-\frac{1}{\left[\rho^{2}+(z+d)^{2}\right]^{1 / 2}}\right)_{z=0}=-\frac{q}{4 \pi} \frac{2 d}{\left(\rho^{2}+d^{2}\right)^{3 / 2}} . \tag{2.187}
\end{equation*}
$$

The total surface charge is

$$
\begin{equation*}
Q=\int_{A} \sigma d^{2} r=2 \pi \int_{0}^{\infty} \sigma(\rho) \rho d \rho=-\frac{q}{2} \int_{0}^{\infty} \frac{d}{\left(\rho^{2}+d^{2}\right)^{3 / 2}} 2 \rho d \rho \tag{2.188}
\end{equation*}
$$

This integral may be easily taken using the substitution $\xi \equiv \rho^{2} / d^{2}$ (giving $d \xi=2 \rho d \rho / d^{2}$ ):

$$
\begin{equation*}
Q=-\frac{q}{2} \int_{0}^{\infty} \frac{d \xi}{(\xi+1)^{3 / 2}}=-q \tag{2.189}
\end{equation*}
$$

This result is very natural, because the conductor "wants" to bring as much surface charge from its interior to the surface as necessary to fully compensate the initial charge $(+q)$ and hence to kill the
electric field at large distances as efficiently as possible, hence reducing the total electrostatic energy (1.67) to the lowest possible value.

For a deeper understanding of this polarization charge of the surface, let us take our calculations to the extreme - to $q$ equal to one elementary change $e$, and place a particle with this charge (for example, a proton) at a macroscopic distance - say 1 m - from conductor's surface. Then, according to Eq. (189), the total polarization charge of the surface equals to that of an electron, and according to Eq. (187), its spatial extent is of the order of $d^{2}=1 \mathrm{~m}^{2}$. This means that if we consider a much smaller part of the surface, $\Delta A \ll d^{2}$, its polarization charge magnitude $\Delta Q=\sigma \Delta A$ is much less than one electron! For example, Eq. (187) shows that the polarization charge of quite a macroscopic area $\Delta A=1 \mathrm{~cm}^{2}$ right under the initial charge $(\rho=0)$ is $e \Delta A / 2 \pi d^{2} \approx 1.6 \times 10^{-5} e$. Can this be true, or our theory is somehow limited to the charges much larger than $e$ ?

Surprisingly enough, the answer to this question has become clear (at least to some physicists :-) only as late as in the mid-1980s when several experiments demonstrated, and theorists accepted, some rather grudgingly that the usual polarization charge formulas are valid for elementary charges $q$ as well, i.e., such the polarization charge $\Delta Q$ of a macroscopic surface area can indeed be less than $e$. The underlying reason for this paradox is the nature of the polarization charge of the conductor surface: as should be clear from our discussion in Sec. 1, it is due not to new charged particles brought into the conductor (such charge would be in fact quantized in the units of $e$ ), but to a small shift of the free charges of a conductor by a very small distance from their equilibrium positions that they had in the absence of the external field induced by charge $q$. This shift is not quantized, at least on the scale relevant for our issue, and neither is $\Delta Q$. This understanding has opened a way toward the invention and experimental demonstration of several new devices including so-called single-electron transistors, ${ }^{59}$ which may be, in particular, used to measure polarization charges as small as $\sim 10^{-6} \mathrm{e}$.

To complete the discussion of our initial problem (Fig. 24), let us find the potential energy $U$ of the charge-to-surface interaction. For that we may use the value of the electrostatic potential (185) in the point of the charge itself ( $\mathbf{r}=\mathbf{r}$ '), of course ignoring the infinite potential created by the charge itself, so that the remaining potential is that of the image charge

$$
\begin{equation*}
\phi_{\text {image }}\left(\mathbf{r}^{\prime}\right)=-\frac{1}{4 \pi \varepsilon_{0}} \frac{q}{2 d} . \tag{2.190}
\end{equation*}
$$

Looking at the definition of the electrostatic potential, given by Eq. (1.31), it may be tempting to immediately write $U=q \phi_{\text {image }}=-\left(1 / 4 \pi \varepsilon_{0}\right)\left(q^{2} / 2 d\right)$ [WRONG!], but this would not be correct. The reason is that potential $\phi_{\text {image }}$ is not independent of $q$, but is actually induced by this charge. This is why the correct approach is to use Eq. (1.63), with just one term:

$$
\begin{equation*}
U=\frac{1}{2} q \phi_{\text {image }}=-\frac{1}{4 \pi \varepsilon_{0}} \frac{q^{2}}{4 d}, \tag{2.191}
\end{equation*}
$$

twice lower in magnitude than the wrong result cited above. In order to double-check this result, and also get a better feeling of the factor $1 / 2$ that distinguishes it from the wrong guess, we can recalculate

[^207]energy $U$ as the integral of the force exerted on the charge by the conductor (i.e., in our formalism, by the image charge):
\[

$$
\begin{equation*}
U=-\int_{\infty}^{d} F(z) d z=\frac{1}{4 \pi \varepsilon_{0}} \int_{\infty}^{d} \frac{q^{2}}{(2 z)^{2}} d z=-\frac{1}{4 \pi \varepsilon_{0}} \frac{q^{2}}{4 d} . \tag{2.192}
\end{equation*}
$$

\]

This calculation clearly accounts for the gradual build-up of force $F$, as the real charge is brought from afar (where we have opted for $U=0$ ) toward the surface.

This result, used for electrons, particles with charge $q=-e$, has several important applications. For example, let us plot energy $U$ for an electron near a metallic surface, as a function of $d$. For that, we may use Eq. (192) until our macroscopic approximation (2) becomes invalid, and $U$ transitions to some negative constant value ( $-\psi$ ) inside the conductor - see Fig. 25a.

Fig. 2.25. (a) Origin of the workfunction and (b) the field emission of electrons (schematically).

The positive constant $\psi$ is called workfunction, because it describes how much work should be done on an electron to remove it from the conductor. As was discussed in Sec. 1, in good metals the electric field screening happens at interatomic distances $a_{0} \approx 10^{-10} \mathrm{~m}$. Plugging $d=a$ and $q=-e$ into Eq. (191), we get $\approx 6 \times 10^{-19} \mathrm{~J} \approx 3.5 \mathrm{eV}$. This crude estimate is in a surprisingly good agreement with the experimental values of the workfunction, ranging between 4 and 5 eV for most metals. ${ }^{60}$

Next, let us consider the effect of an additional external electric field $\mathbf{E}_{0}$ applied perpendicular to a metallic surface, on this potential profile. Assuming the field to be uniform, we can add its potential $e E_{0} d$ at distance $d$ from the surface, to that created by the image charge. (As we know from Eq. (1.53), since field $\mathbf{E}_{0}$ is independent of the electron position, its recalculation to the potential energy does not require the coefficient $1 / 2$.) As the result, the potential energy of an electron near the surface becomes

$$
\begin{equation*}
U(d)=-e E_{0} d-\frac{1}{4 \pi \varepsilon_{0}} \frac{e^{2}}{4 d}, \quad \text { for } d>a_{0} \tag{2.193}
\end{equation*}
$$

with a similar crossover to $U=-\psi$ inside the conductor - see Fig. 25b. One can see that at the appropriate sign, and sufficient magnitude of the applied field, it lowers the potential barrier that prevented electron from leaving the conductor. At $E_{0} \sim \psi / a_{0}$ this suppression becomes so strong that electrons just below the Fermi surface start quantum-mechanical tunneling through the remaining thin

[^208]barrier. This is the field emission effect, which is used in vacuum electronics to provide efficient cathodes that do not require heating to high temperatures. ${ }^{61}$

Returning to the basic electrostatics, let us consider some other geometries where the method of images may be effectively applied. First, let us consider a right corner (Fig. 26a). Reflecting the initial charge in the vertical plane we get the image charge shown in the top left corner of the panel, that makes the boundary condition $\phi=$ const satisfied on the vertical surface of the corner. However, in order the same to be true on the horizontal surface, we have to reflect both the initial charge and the image charge in the horizontal plane, flipping their signs. The final configuration of 4 charges, shown in Fig. 26a, satisfies all the boundary conditions. The resulting potential distribution may be readily written as the evident generalization of Eq. (185). From there, the electric field and electric charge distributions, and the potential energy and forces acting on the charge may be calculated exactly as above.

Fig. 2.26. Charge images for ( $\mathrm{a}, \mathrm{b}$ ) internal corners with angles $\pi$ and $\pi / 2$, (c) plane capacitor, and (d) rectangular box, and (d) equipotential surfaces for the last system.

[^209]Next, consider a corner with angle $\pi / 4$ (Fig. 26b). Here we need to repeat the reflection operation not 2 but 4 times before we arrive at the final pattern of 8 positive and negative charges. (Any attempt to continue this process would lead to an overlap with the already existing charges.) This reasoning can be readily extended to any 2 D corner with angle $\beta=\pi / n$, with any integer $n$, that requires $2 n$ charges (including the initial one) to satisfy all the boundary conditions.

Some configurations require an infinite number of images that are, however, tractable. The most important of them is a system of two parallel conducting surfaces, i.e. a plane capacitor of infinite area (Fig. 26c). Here the repeated reflection leads to an infinite system of charges $\pm q$ at points

$$
\begin{equation*}
x_{j}^{ \pm}= \pm d+2 D j \tag{2.194}
\end{equation*}
$$

where $0<d<D$ is the position of the initial charge and $j$ an arbitrary integer. However, the resulting infinite sum for the potential of the real charge $q$, created by the field of its images,

$$
\begin{equation*}
\phi(d)=\frac{1}{4 \pi \varepsilon_{0}}\left[-\frac{q}{2 d}+\sum_{j \neq 0} \sum_{ \pm} \frac{ \pm q}{\left|d-x_{j}^{ \pm}\right|}\right]=-\frac{q}{4 \pi \varepsilon_{0}}\left[\frac{1}{2 d}+\frac{d^{2}}{D^{3}} \sum_{j=1}^{\infty} \frac{1}{j\left[j^{2}-(d / D)^{2}\right]}\right] \tag{2.195}
\end{equation*}
$$

is converging (in its last form) very fast. For example, the exact value, $\phi(D / 2)=-2 \ln 2\left(q / 4 \pi \varepsilon_{0} D\right)$, differs by less than $5 \%$ from the approximation using just the first term of the sum.

The same method may be applied to 2D (cylindrical) and 3D rectangular boxes that require, respectively, a 2D or 3D infinite lattices of images; for example in a 3D box with sides $a, b$, and $c$, charges $\pm q$ are located at points (Fig. 26d)

$$
\begin{equation*}
\mathbf{r}_{j k l}^{ \pm}= \pm \mathbf{r}^{\prime}+2 j a+2 k b+2 l c, \tag{2.196}
\end{equation*}
$$

where $\mathbf{r}$ ' is the location of the initial (real) charge, and $j, k$, and $l$ are arbitrary integers. Figure 26e shows the results of summation of the potentials of such charge set, including the real one, in a 2 D box (within the plane of the real charge). One can see that the equipotential surfaces, concentric near the charge, are naturally leaning along the conducting walls of the box, which should be equipotential.

Even more surprisingly, the image charge method works very efficiently not only for the rectilinear geometries, but also for spherical ones. Indeed, let us consider a point charge $q$ at some distance $d$ from the center of a conducting, grounded sphere of radius $R$ (Fig. 27a), and try to satisfy the boundary condition $\phi=0$ for the electrostatic potential on sphere's surface using an imaginary charge $q$ ' located at some point located beyond the surface, i.e. inside the sphere.

(b)

Fig. 2.27. Method of charge images for a conducting sphere: (a) the idea, and (b) the resulting potential distribution for particular case $d=2 R$.

From problem's symmetry, it is clear that the point should be at the line passing through the real charge and the sphere's center, at some distance $d^{\prime}$ from the center. Then the total potential created by the two charges at an arbitrary point with $r \geq R$ (Fig. 27a) is

$$
\begin{equation*}
\phi(r, \theta)=\frac{1}{4 \pi \varepsilon_{0}}\left[\frac{q}{\left(r^{2}+d^{2}-2 r d \cos \theta\right)^{1 / 2}}+\frac{q^{\prime}}{\left(r^{2}+d^{\prime 2}-2 r d^{\prime} \cos \theta\right)^{1 / 2}}\right] \tag{2.197}
\end{equation*}
$$

It is easy to see that we can make the two fractions to be equal and opposite at all points on the sphere's surface (i.e. for any $\theta$ at $r=R$ ), if we take ${ }^{62}$

$$
\begin{equation*}
d^{\prime}=\frac{R^{2}}{d}, \quad q^{\prime}=-\frac{R}{d} q \tag{2.198}
\end{equation*}
$$

Since the solution to any Poisson boundary problem is unique, Eqs. (197) and (198) give us such solution for this problem. Figure 27b shows a typical equipotential pattern calculated using Eqs. (197) and (198). It is surprising how formulas that simple may describe such a nontrivial field distribution.

Now let us calculate the total charge $Q$ induced by charge $q$ on conducting sphere's surface. We could do this, as we have done for the conducting plane, by the brute force integration of the surface charge density $\sigma=-\varepsilon_{0} \partial \phi /\left.\partial r\right|_{r=R}$. It is more elegant, however, to use the following Gauss law argument. Expression (197) is valid (at $r \geq R$ ) regardless whether we are dealing with our real problem (charge $q$ and the conducting sphere) or with the equivalent charge configuration (point charges $q$ and $q^{\prime}$, with no sphere at all). Hence, according to Eq. (1.16), the Gaussian integral over a surface with radius $r=R+0$, and the total charge inside the sphere should be also the same. Hence we immediately get

$$
\begin{equation*}
Q=q^{\prime}=-\frac{R}{d} q \tag{2.199}
\end{equation*}
$$

The similar argumentation may be used to find the charge-to-sphere interaction force:

$$
\begin{equation*}
F=q E_{\mathrm{image}}(d)=q \frac{q^{\prime}}{4 \pi \varepsilon_{0}\left(d-d^{\prime}\right)^{2}}=-\frac{q^{2}}{4 \pi \varepsilon_{0}} \frac{R}{d} \frac{1}{\left(d-R^{2} / d\right)^{2}}=-\frac{q^{2}}{4 \pi \varepsilon_{0}} \frac{R d}{\left(d^{2}-R^{2}\right)^{2}} . \tag{2.200}
\end{equation*}
$$

(Note that this expression is legitimate only at $d>R$.) At large distances, $d / R \gg 1$, this attractive force decreases as $1 / d^{3}$. This unusual dependence arises because, as Eq. (198) specifies, the induced charge of the sphere, responsible for the force, is not constant but decreases as $Q \propto 1 / d$.

All the previous formulas referred to a sphere that is grounded to keep its potential equal to zero. But what if we keep the sphere galvanically insulated, so that its net charge is fixed, e.g., equals zero? Instead of solving the problem from the scratch, let us use (again!) the linear superposition principle. For that, we may add to the previous problem an additional charge, equal to $(-Q)$, to the sphere, and argue that this addition gives an additional potential that does not depend of the potential induced by charge $q$. For the interaction force, such addition yields

[^210]\[

$$
\begin{equation*}
F=\frac{q q^{\prime}}{4 \pi \varepsilon_{0}\left(d-d^{\prime}\right)^{2}}+\frac{q Q}{4 \pi \varepsilon_{0} d^{2}}=-\frac{q^{2}}{4 \pi \varepsilon_{0}}\left[\frac{R d}{\left(d^{2}-R^{2}\right)^{2}}-\frac{R}{d^{3}}\right] . \tag{2.201}
\end{equation*}
$$

\]

At large distances, the two terms proportional to $1 / d^{3}$ cancel each other, giving $F \propto 1 / d^{5}$. Such a rapid force decay is due to the fact that the field of the uncharged sphere is equivalent to that of two (equal and opposite) induced charges $+Q$ and $-Q$, and the distance between them ( $d^{\prime}=R^{2} / d$ ) tends to zero at $d$ $\rightarrow \infty$. The potential energy of such interaction behaves as $U \propto 1 / d^{6}$ at $d \rightarrow \infty$; in the next chapter we will see that this is the general law of the induced dipole interaction.

### 2.7. Green's functions

I have spent so much time/space discussing the potential distributions created by a single point charge in various conductor geometries, because, for any geometry, the generalization of these results to the arbitrary distribution $\rho(\mathbf{r})$ of free charges is straightforward. Namely, if a single charge $q$, located at point $\mathbf{r}$ ', created electrostatic potential

$$
\begin{equation*}
\phi(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} q G\left(\mathbf{r}, \mathbf{r}^{\prime}\right) \tag{2.202}
\end{equation*}
$$

then, due to the linear superposition principle, an arbitrary charge distribution creates potential

$$
\begin{equation*}
\phi(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} \sum_{j} q_{j} G\left(\mathbf{r}, \mathbf{r}_{j}\right)=\frac{1}{4 \pi \varepsilon_{0}} \int \rho\left(\mathbf{r}^{\prime}\right) G\left(\mathbf{r}, \mathbf{r}^{\prime}\right) d^{3} r^{\prime} \tag{2.203}
\end{equation*}
$$

Spatial Green's
function

Kernel $G(\mathbf{r}, \mathbf{r}$ ') is called the (spatial) Green's function - the notion very popular in all fields of physics. ${ }^{63}$ Evidently, as Eq. (1.35) shows, in the unlimited free space

$$
\begin{equation*}
G\left(\mathbf{r}, \mathbf{r}^{\prime}\right)=\frac{1}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} \tag{2.204}
\end{equation*}
$$

i.e. the Green's function depends only on one scalar argument - the distance between the field observation point $\mathbf{r}$ and the field-source (charge) point $\mathbf{r}$ '. However, as soon as there are conductors around, the situation changes. In this course we will only deal with Green's functions that are defined in the space between conductors, and that vanish as soon as the radius-vector $\mathbf{r}$ points to the surface of any conductor: ${ }^{64}$

$$
\begin{equation*}
\left.G\left(\mathbf{r}, \mathbf{r}^{\prime}\right)\right|_{\mathbf{r} \in A}=0 . \tag{2.205}
\end{equation*}
$$

With this definition, it is straightforward to deduce the Green's functions for the solutions of the last section's problems in which conductors were grounded ( $\phi=0$ ). For example, for a semi-space $z \geq 0$ limited by a conducting plane (Fig. 24), Eq. (185) yields

$$
\begin{equation*}
G=\frac{1}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|}-\frac{1}{\left|\mathbf{r}-\mathbf{r}^{\prime \prime}\right|}, \quad \text { with } \rho^{\prime \prime}=\rho^{\prime} \text { and } z^{\prime \prime}=-z^{\prime} \tag{2.206}
\end{equation*}
$$

[^211]We see that in the presence of conductors (and, as we will see later, any other polarizable media), the Green's function may depend not only on the difference $\mathbf{r}-\mathbf{r}$ ', but in a specific way from each of these two arguments.

So far, this looked just like re-naming our old results. The really non-trivial result of the Green's function application to electrostatics is that, somewhat counter-intuitively, the knowledge of the Green's function for a system with grounded conductors (Fig. 28a) allows one to calculate the field created by voltage-biased conductors (Fig. 28b), with the same geometry.
(a)

(b)

Fig. 2.28. Green's function method allows the solution of a simpler boundary problem (a) to be used to find the solution of a more complex problem (b), for the same conductor geometry.

In order to show that, let us use the so-called Green's theorem of the vector calculus. ${ }^{65}$ The theorem states that for any two scalar, differentiable functions $f(\mathbf{r})$ and $g(\mathbf{r})$, and any volume $V$,

$$
\begin{equation*}
\int_{V}\left(f \nabla^{2} g-g \nabla^{2} f\right) d^{3} r=\oint_{S}(f \nabla g-g \nabla f)_{n} d^{2} r, \tag{2.207}
\end{equation*}
$$

where $S$ is the surface limiting the volume. Applying the theorem to the electrostatic potential $\phi(\mathbf{r})$ and the Green's function $G$ (also considered as a function of $\mathbf{r}$ ), let us use the Poisson equation (1.41) to replace $\nabla^{2} \phi$ with $\left(-\rho / \varepsilon_{0}\right)$, and notice that $G$, considered as a function of $\mathbf{r}$, obeys the Poisson equation with the $\delta$-functional source:

$$
\begin{equation*}
\nabla^{2} G\left(\mathbf{r}, \mathbf{r}^{\prime}\right)=-4 \pi \delta\left(\mathbf{r}-\mathbf{r}^{\prime}\right) \tag{2.208}
\end{equation*}
$$

(Indeed, according to its definition (202), this function may be formally considered as the field of a point charge $q=4 \pi \varepsilon_{0}$.) Now swapping the notation of radius-vectors, $\mathbf{r} \leftrightarrow \mathbf{r}$ ', and using the Green's function symmetry, $G\left(\mathbf{r}, \mathbf{r}^{\prime}\right)=G\left(\mathbf{r}^{\prime}, \mathbf{r}\right),{ }^{66}$ we get

$$
\begin{equation*}
-4 \pi \phi(\mathbf{r})-\int_{V}\left(-\frac{\rho\left(\mathbf{r}^{\prime}\right)}{\varepsilon_{0}}\right) G\left(\mathbf{r}, \mathbf{r}^{\prime}\right) d^{3} r^{\prime}=\oint_{S}\left[\phi\left(\mathbf{r}^{\prime}\right) \frac{\partial G\left(\mathbf{r}, \mathbf{r}^{\prime}\right)}{\partial n^{\prime}}-G\left(\mathbf{r}, \mathbf{r}^{\prime}\right) \frac{\partial \phi\left(\mathbf{r}^{\prime}\right)}{\partial n^{\prime}}\right] d^{2} r^{\prime} \tag{2.209}
\end{equation*}
$$

Let us apply this relation to volume $V$ of free space between the conductors, and the boundary $A$ slightly outside of their surface. In this case, by its definition, the Green's function $G\left(\mathbf{r}, \mathbf{r}^{\prime}\right)$ vanishes at the conductor surface ( $\mathbf{r} \in S$ ) - see Eq. (205). Now changing the sign of $\partial n^{\prime}$ (so that it would be the outer normal for conductors, rather than free space volume $V$ ), dividing all terms by $4 \pi$, and partitioning

[^212]the total surface $A$ into the parts (numbered by index $j$ ) corresponding to different conductors (possibly, kept at different potentials $\phi_{k}$ ), we finally arrive at the famous result: ${ }^{67}$
\[

$$
\begin{equation*}
\phi(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} \int_{V} \rho\left(\mathbf{r}^{\prime}\right) G\left(\mathbf{r}, \mathbf{r}^{\prime}\right) d^{3} r^{\prime}+\frac{1}{4 \pi} \sum_{k} \phi_{k} \oint_{S_{k}} \frac{\partial G\left(\mathbf{r}, \mathbf{r}^{\prime}\right)}{\partial n^{\prime}} d^{2} r^{\prime} \tag{2.210}
\end{equation*}
$$

\]

Potential via Green's function

While the first term in the right-hand part of this relation is a direct and evident expression of the superposition principle, given by Eq. (203), the second term is highly non-trivial: it describes the effect of conductors with nonvanishing potentials $\phi_{k}$ (Fig. 28b) using the Green's function calculated for the similar system with grounded conductors, i.e. with all $\phi_{k}=0$ (Fig. 28a). Let me emphasize that since our volume $V$ excludes conductors, the first term in the right-hand part of Eq. (210) includes only the "freestanding" charges of the system (in Fig. 28, marked $q_{1}, q_{2}$, etc.), but not the surface charges of the conductors - which are taken into account, implicitly, by the second term.

In order to illustrate what a powerful tool Eq. (210) is, let us use to calculate the electrostatic field in two systems. In the first of them, a circular disk, separated with a very thin cut from a conducting plane, is biased with potential $\phi=V$, while the rest of the plane is grounded - see Fig. 29.

Fig. 2.29. Voltage-biased conducting circle inside a grounded conducting plane.

If the width of the gap between the circle and rest of the plane is negligible, we may apply Eq. (210) with $\rho\left(\mathbf{r}^{\prime}\right)=0$, and the Green's function for the uncut plane - see Eq. (206). ${ }^{68}$ In the cylindrical coordinates, the function may be rewritten as

$$
\begin{equation*}
G\left(\mathbf{r}, \mathbf{r}^{\prime}\right)=\frac{1}{\left(\rho^{2}+\rho^{\prime 2}-2 \rho \rho^{\prime} \cos \left(\varphi-\varphi^{\prime}\right)+\left(z-z^{\prime}\right)^{2}\right)^{1 / 2}}-\frac{1}{\left(\rho^{2}+\rho^{\prime 2}-2 \rho \rho^{\prime} \cos \left(\varphi-\varphi^{\prime}\right)+\left(z+z^{\prime}\right)^{2}\right)^{1 / 2}} . \tag{2.211}
\end{equation*}
$$

(The sum of the first three terms under the square roots of Eq. (211) is just the squared distance between the horizontal projections $\rho$ and $\rho$ ' of vectors $\mathbf{r}$ and $\mathbf{r}$ ' (or $\mathbf{r}$ "), correspondingly, while the last terms are the squares of their vertical spacings.)

Now we can readily calculate the necessary derivative:

[^213]\[

$$
\begin{equation*}
\left.\frac{\partial G}{\partial n^{\prime}}\right|_{S}=\left.\frac{\partial G}{\partial z^{\prime}}\right|_{z^{\prime}=+0}=\frac{2 z}{\left(\rho^{2}+\rho^{\prime 2}-2 \rho \rho^{\prime} \cos \left(\varphi-\varphi^{\prime}\right)+z^{2}\right)^{3 / 2}} . \tag{2.212}
\end{equation*}
$$

\]

Due the axial symmetry of the system, we can take $\varphi$ for zero. With this, Eqs. (210) and (212) yield

$$
\begin{equation*}
\phi=\frac{V}{4 \pi} \oint_{S} \frac{\partial G\left(\mathbf{r}, \mathbf{r}^{\prime}\right)}{\partial n^{\prime}} d^{2} r^{\prime}=\frac{V z}{2 \pi} \int_{0}^{2 \pi} d \varphi^{\prime} \int_{0}^{R} \frac{\rho^{\prime} d \rho^{\prime}}{\left(\rho^{2}+\rho^{\prime 2}-2 \rho \rho^{\prime} \cos \varphi^{\prime}+z^{2}\right)^{3 / 2}} . \tag{2.213}
\end{equation*}
$$

This integral is not too pleasing, but may be readily worked out for points on the symmetry axis $(\rho=0)$ :

$$
\begin{equation*}
\phi=V z \int_{0}^{R} \frac{\rho^{\prime} d \rho^{\prime}}{\left(\rho^{\prime 2}+z^{2}\right)^{3 / 2}}=\frac{V^{R^{2} / z^{2}}}{2} \int_{0}^{\frac{d \xi}{(\xi+1)^{3 / 2}}=V\left[1-\frac{z}{\left(R^{2}+z^{2}\right)^{1 / 2}}\right] . . . . . . .} \tag{2.214}
\end{equation*}
$$

This expression shows that if $z \rightarrow 0$, the potential tends to $V$ (as it should), while at $z \gg R$,

$$
\begin{equation*}
\phi \rightarrow V \frac{R^{2}}{2 z^{2}} . \tag{2.215}
\end{equation*}
$$

This asymptotic behavior is typical for electric dipoles - see the next chapter.
Now, let us use the same Eq. (210) to solve the (in :-)famous problem of the cut sphere (Fig. 30). Again, if the gap between the two conducting semi-spheres is very thin $(t \ll R)$, we may use the Green's function for the grounded (and uncut) sphere. For a particular case $\mathbf{r}^{\prime}=d \mathbf{n}_{z}$, this function is given by Eqs. (197)-(198); generalizing the former relation for an arbitrary direction of vector $\mathbf{r}$ ', we get

$$
\begin{equation*}
G=\frac{1}{\left(r^{2}+r^{\prime 2}-2 r r^{\prime} \cos \gamma\right)^{1 / 2}}-\frac{R / r^{\prime}}{\left(r^{2}+\left(R^{2} / r^{\prime}\right)^{2}-2 r\left(R^{2} / r^{\prime}\right) \cos \gamma\right)^{1 / 2}}, \quad \text { for } r, r^{\prime} \geq R . \tag{2.216}
\end{equation*}
$$

where $\gamma$ is the angle between vectors $\mathbf{r}$ and $\mathbf{r}^{\prime}$, and hence $\mathbf{r}$ " (Fig. 30).

Fig. 2.30. A system of two, oppositely biased semispheres.

Now, finding the Green's function's derivative,

$$
\begin{equation*}
\left.\frac{\partial G}{\partial r^{\prime}}\right|_{r^{\prime}=R+0}=-\frac{\left(r^{2}-R^{2}\right)}{R\left[r^{2}+R^{2}-2 R r \cos \gamma\right]^{3 / 2}}, \tag{2.217}
\end{equation*}
$$

and plugging it into Eq. (210), we see that the integration is easy only for the field on the symmetry axis $\left(\mathbf{r}=r \mathbf{n}_{z}, \gamma=\theta\right)$, giving

$$
\begin{equation*}
\phi=\frac{V}{2}\left[1-\frac{z^{2}-R^{2}}{z\left(z^{2}+R^{2}\right)^{1 / 2}}\right] . \tag{2.218}
\end{equation*}
$$

For $z \rightarrow R, \phi \rightarrow V / 2$ (just checking :-), while for $z \gg R$,

$$
\begin{equation*}
\phi \rightarrow V \frac{3 R^{2}}{4 z^{2}} \tag{2.219}
\end{equation*}
$$

so this is also an electric dipole field - see the next chapter.

### 2.8. Numerical methods

Despite the richness of analytical methods, for many boundary problems (especially in geometries without high degree of symmetry), numerical methods is the only way to the solution. Despite the current abundance of software codes and packages offering their automatic numerical solution, ${ }^{69}$ it is important to an educated physicist to understand "what is under their hood", at least because most universal programs exhibit mediocre performance in comparison with custom codes written for particular problems, and sometimes do not converge at all, especially for fast-changing (say, exponential) functions.

The simplest of the numerical methods of solution of partial differential equations is the finitedifference method ${ }^{70}$ in which the sought function of $N$ scalar arguments $f\left(r_{1}, r_{2}, \ldots r_{N}\right)$ is represented by its values in discrete points of a rectangular grid (also called mesh) of the corresponding dimensionality (Fig. 31).

Fig. 2.31. General idea of the finite-difference method in (a) one, (b) two, and (c) three dimensions.

Each partial second derivative of the function is approximated by the formula that readily follows from the linear approximations for the function $f$ and then its partial derivatives - see Fig. 31a:

$$
\begin{equation*}
\frac{\partial^{2} f}{\partial r_{j}^{2}}=\frac{\partial}{\partial r_{j}}\left(\frac{\partial f}{\partial r_{j}}\right) \approx \frac{1}{h}\left(\left.\frac{\partial f}{\partial r_{j}}\right|_{r_{j}+h / 2}-\left.\frac{\partial f}{\partial r_{j}}\right|_{r_{j}-h / 2}\right) \approx \frac{1}{h}\left[\frac{f_{\rightarrow}-f}{h}-\frac{f-f_{\leftarrow}}{h}\right]=\frac{f_{\rightarrow}+f_{\leftarrow}-2 f}{h^{2}} \tag{2.220}
\end{equation*}
$$

[^214]where $f_{\rightarrow} \equiv f\left(r_{j}+h\right)$ and where $f_{\leftarrow} \equiv f\left(r_{j}-h\right)$. (The relative error of this approximation is of the order of $h^{4} \partial^{4} f / \partial r_{j}^{4}$.) As a result, a 2D Laplace operator may be presented as
\[

$$
\begin{equation*}
\frac{\partial^{2} f}{\partial x^{2}}+\frac{\partial^{2} f}{\partial y^{2}}=\frac{f_{\rightarrow}+f_{\leftarrow}-2 f}{h^{2}}+\frac{f_{\uparrow}+f_{\downarrow}-2 f}{h^{2}}=\frac{f_{\rightarrow}+f_{\leftarrow}+f_{\uparrow}+f_{\downarrow}-4 f}{h^{2}}, \tag{2.221}
\end{equation*}
$$

\]

while the 3D operator as

$$
\begin{equation*}
\frac{\partial^{2} f}{\partial x^{2}}+\frac{\partial^{2} f}{\partial y^{2}}+\frac{\partial^{2} f}{\partial z^{2}}=\frac{f_{\rightarrow}+f_{\leftarrow}+f_{\uparrow}+f_{\downarrow}+f_{\otimes}+f_{\times}-6 f}{h^{2}} . \tag{2.222}
\end{equation*}
$$

(The notation used in these formulas should be clear from Figs. 31b and 31c, respectively.)
Let us apply this scheme to find the electrostatic potential distribution inside of a cylindrical box with conducting walls and square cross-section, using an extremely coarse mesh with step $h=a / 2$ (Fig. 32). In this case our function, the electrostatic potential, equals zero on the side walls and the bottom, and equals to $V_{0}$ at the top lid, so that, according to Eq. (221), the Laplace equation may be approximated as

$$
\begin{equation*}
\frac{0+0+V_{0}+0-4 \phi}{(a / 2)^{2}}=0 \tag{2.223}
\end{equation*}
$$

The resulting value for the potential in the center of the box is $\phi=V_{0} / 4$. Surprisingly, this is the exact value! This may be proved by solving this problem by the variable separation method, just as this has been done for the similar 3D problem in Sec. 4 above. The result is

$$
\phi(x, y)=\sum_{n=1}^{\infty} c_{n} \sin \frac{\pi n x}{a} \sinh \frac{\pi n y}{a}, \quad c_{n}=\frac{4 V_{0}}{\pi n \sinh (\pi n)} \times\left\{\begin{array}{l}
1, \text { if } n \text { is odd }  \tag{2.224}\\
0, \text { otherwise } .
\end{array}\right.
$$

so that at the central point $(x=y=a / 2)$,

$$
\begin{equation*}
\phi=\frac{4 V_{0}}{\pi} \sum_{j=0}^{\infty} \frac{\sin [\pi(2 j+1) / 2] \sinh [\pi(2 j+1) / 2]}{(2 j+1) \sinh [\pi(2 j+1)]}=\frac{2 V_{0}}{\pi} \sum_{j=0}^{\infty} \frac{(-1)^{j}}{(2 j+1) \cosh [\pi(2 j+1) / 2]} . \tag{2.225}
\end{equation*}
$$

The last series equals exactly to $\pi / 8$, so that $\phi=V_{0} / 4$.

Fig. 2.32. Numerical solution of the internal 2D boundary problem for a conducting, cylindrical box with square crosssection, using a very coarse mesh (with $h=a / 2$ ).

For a similar 3D problem (a cubic box) we can use Eq. (222) to get

$$
\begin{equation*}
\frac{0+0+V_{0}+0+0+0-6 \phi}{(a / 2)^{2}}=0 \tag{2.226}
\end{equation*}
$$

so that $\phi=V_{0} / 6$. Unbelievably enough, this result is also exact! (This follows from our variable separation result expressed by Eqs. (95) and (99).)

Though such exact results should be considered as a happy coincidence rather than the norm, they still show that numerical methods, with a relatively crude mesh, may be more computationally efficient than the "analytical" approaches, like the variable separation method with its infinite-sum results that, in most cases, require computers anyway - at least for the result's comprehension and analysis.

A more powerful (but also much more complex for implementation) approach is the finiteelement method in which the discrete point mesh, typically with triangular cells, is (automatically) generated in accordance with the system geometry. Such mesh generators provide higher point concentration near sharp convex parts of conductor surfaces, where the field concentrates and hence the potential changes faster, and thus ensure better accuracy-to-performance trade-off than the finitedifference methods on a uniform grid. The price to pay for this improvement is the algorithm complexity that makes manual adjustments much harder. Unfortunately I do not have time for going into the details of that method, and have to refer the reader to the special literature on this subject. ${ }^{71}$

### 2.9. Exercise problems

2.1. Calculate the force (per unit area) exerted on a conducting surface by an electric field. Compare the result with the definition of the electric field, given by Eq. (1.5).
2.2. A thin plane film, carrying a uniform electric charge density $\sigma$, is placed inside a plane capacitor whose plates are connected by a wire - see Fig. on the right. Neglecting the edge effects, calculate the surface charges of the plates, and the net force acting on the film (per unit area).

2.3. Following the discussion of two weakly coupled spheres in Sec. 2, find an approximate expression for the mutual capacitance (per unit length) between two very thin, parallel wires, both with a round cross-section, but each with its own diameter. Compare the result with that for two small spheres, and interpret the difference.
2.4. Use the Gauss law to calculate the mutual capacitance of the following 2 -electrode systems, with the cross-section shown in Fig. 5 (reproduced on the right):
(i) a conducting sphere inside a concentric spherical cavity in another conductor, and
(ii) a conducting cylinder inside a coaxial cavity in another conductor.

[^215](In this case, we speak about the capacitance per unit length).
Compare the results with those obtained in Sec. 2.2, using the Laplace equation solution.
2.5. Calculate the electrostatic potential distribution around two barely separated conductors in the form of coaxial, round cones (see Fig. on the right), with voltage $V$ between them. Compare the result with that of a similar 2D problem, with the cones replaced by plane-face wedges. Can you calculate the mutual capacitance between the conductors in any of these systems? If not, can you estimate it?

2.6. A system of two thin conducting plates is located over a ground plane as shown in Fig. on the right, where $A$ ' and $A$ '" are plate part areas, while $d^{\prime}$ and $d^{\prime \prime}$ are distances between them. Neglecting the fringe effects, calculate:
(i) the effective capacitance of each plate, and
(ii) their mutual capacitance.

(ापापापापापापापापापा
2.7. Using the results for a single thin round disk, obtained in Sec. 4, consider a system of two such disks at a small distance $d \ll R$ from each other see Fig. on the right. In particular, calculate:

(i) the reciprocal capacitance matrix of the system,
(ii) the mutual capacitance between the disks,
(iii) the partial capacitance, and
(iv) the effective capacitance of one disk,
(all in the first non-vanishing approximations in $d / R \ll 1$ ). Compare the results (ii)-(iv) and interpret their similarities and differences.
2.8. ${ }^{*}$ Calculate the mutual capacitance (per unit length) between two cylindrical conductors forming a system with the cross-section shown in Fig. on the right, in the limit $t \ll w \ll R$.

Hint: You may like to use elliptical (not "ellipsoidal"!) coordinates $\{\alpha, \beta\}$ defined by the following equation:

$$
\begin{equation*}
x+i y=c \cosh (\alpha+i \beta) \tag{*}
\end{equation*}
$$

with the appropriate choice of constant $c$. In these orthogonal 2D coordinates, the Laplace operator is very simple: ${ }^{72}$

$$
\nabla^{2}=\frac{1}{c^{2}\left(\cosh ^{2} \alpha-\cos ^{2} \beta\right)}\left(\frac{\partial^{2}}{\partial \alpha^{2}}+\frac{\partial^{2}}{\partial \beta^{2}}\right)
$$

[^216]2.9. Formulate 2D electrostatic problems that can be solved using each of the following analytic functions of the complex variable $z \equiv x+i y$ :
(i) $\boldsymbol{w}=\ln \boldsymbol{z}$,
(ii) $\boldsymbol{\omega}=\boldsymbol{z}^{1 / 2}$,
and solve these problems.
2.10. On each wall of a cylindrical volume with a rectangular cross-section $a \times b$, with no electric charges inside it, the electric field is uniform, normal to the wall plane, and opposite to that on opposite side - see Fig. on the right. Calculate the distribution of the electric potential inside the volume, provided that the field magnitude on the vertical walls equals $E$.

2.11. Complete the solution of the problem shown in Fig. 10, by calculating the distribution of the surface charge of the semi-planes. Can you calculate the mutual capacitance between the plates (per unit length)? If not, can you estimate it?
2.12.* A straight, long, thin, round-cylindrical metallic pipe has been cut, along its axis, into two equal parts - see Fig. on the right.
(i) Use the conformal mapping method to calculate the distribution of the electrostatic potential, created by voltage $V$ applied between the two parts, both outside and inside the pipe, and of the surface charge.
(ii) Calculate the mutual capacitance between pipe's halves (per unit length), taking into account a small width $2 t \ll R$ of the cut.

Hints: In Task (i), you may like to use the following complex function:

$$
\boldsymbol{u}=\ln \left(\frac{R+z}{R-z}\right)
$$

while in Task (ii), it is advisable to use the solution of the previous problem.
2.13. Solve Task (i) of the previous problem using the variable separation method, and compare the results.
2.14. Use the variable separation method to calculate the potential distribution above the plane surface of a conductor, with a strip of width $w$ separated by very thin cuts, and biased with voltage $V-$ see Fig. below.

2.15. In the Fig. of the previous problem, the cut-out and voltage-biased part of the conducting plane is now not a strip, but a square with side $w$. Calculate the potential distribution above conductor's surface.
2.16. Complete the cylinder problem started in Sec. 5 (see Fig. 15), for the cases when voltage on the top lid is fixed as follows:
(i) $V=V_{0} J_{1}\left(\xi_{11} \rho / R\right) \sin \varphi$, where $\xi_{11} \approx 3.832$ is the first root of function $J_{1}(x)$, and
(ii) $V=V_{0}=$ const.

For both cases, calculate the electric field in the centers of the lower and upper lids. (For assignment (ii), an answer including series and/or integrals is satisfactory.)
2.17. Each electrode of a large plane capacitor is cut into long strips of equal width $l$, with very narrow gaps between them. These strips are kept at the alternating potentials as shown in Fig. on the right. Use the variable separation method to calculate the electrostatic potential distribution. Explore the limit $l \ll d$.

2.18. Solve the problem shown in Fig. 19. In particular:
(i) calculate and sketch the distribution of the electrostatic potential inside the system for various values of ratio $R / h$, and
(ii) simplify the results for the limit $R / h \rightarrow 0$.
2.19. Use the variable separation method to find the potential distribution inside and outside of a thin spherical shell of radius $R$, with fixed potential $\phi(R, \theta, \varphi)=V_{0} \sin \theta \cos \varphi$.
2.20. A thin spherical shell carries charge with areal density $\sigma=\sigma_{0} \cos \theta$. Calculate the spatial distribution of the electrostatic potential and field.
2.21. Use the variable separation method to calculate the potential distribution both inside and outside of a thin spherical shell of radius $R$, separated with a very thin cut, along plane $\mathrm{z}=0$, into two halves, with voltage $V$ applied between them - see Fig. on the right. Analyze the solution; in particular, compare the field at axis $z$, for $z>R$, with Eq. (2.218), obtained by the Green's function method.

Hint: You may like to use the following integral of a Legendre polynomial with odd index $l=1,3,5 \ldots=2 n-1:^{73}$

[^217]$$
I_{n} \equiv \int_{0}^{1} P_{2 n-1}(\xi) d \xi=\frac{1}{n!} \cdot\left(\frac{1}{2}\right) \cdot\left(-\frac{3}{2}\right) \cdot\left(-\frac{5}{2}\right) \cdots\left(\frac{3}{2}-n\right) \equiv(-1)^{n-1} \frac{(2 n-3)!!}{2 n(2 n-2)!!} .
$$
2.22. A small conductor (in this context, usually called the single-electron box or single-electron island) is placed between two conducting electrodes, with voltage $V$ applied between them. The gap between one of the electrodes and the box is so narrow that electrons may tunnel quantum-mechanically through this gap ("weak tunnel junction") - see Fig. on the right. Neglecting thermal fluctuations, calculate the equilibrium charge of the island as a function of $V$.

Hint: To solve this problem, you do not need to know much about quantum-mechanical tunneling through weak junctions, ${ }^{74}$ besides that such
 tunneling of an electron, and its subsequent energy relaxation inside the conductor, may be considered as a single inelastic (energy-dissipating) event. In the absence of thermal agitation, such event takes place when (and only when) it decreases the potential energy of the system.
2.23. Calculate the total surface charges induced in the plates of a very broad plane capacitor of thickness $D$ by a point charge $q$ separated from one of the electrodes by distance $d$.
2.24. Prove the statement, made in Sec. 6, that the 2D boundary problem shown in Fig. on the right can be solved using a finite number of image charges if angle $\beta$ equals $\pi / n$, where $n=1,2, \ldots$

2.25. Use the image charge method to calculate the energy of electrostatic interaction between a point charge placed in the center of a spherical cavity that was carved inside a grounded conductor, and the conductor's walls. Looking at the result, could it be obtained in a simpler way (or ways)?
2.26. Use the method of images to find the Green's function of the system shown in Fig. on the right, where the bulge on the conducting plane has the shape of a semi-sphere of radius $R$.
2.27.* Use the fact of spherical inversion, expressed by Eq. (198), to develop an iterative method for more and more precise calculation of the mutual capacitance between two similar metallic spheres of radius $R$, with centers separated by distance $d>2 R$.

[^218]2.28.* A metallic sphere of radius $R_{1}$, carrying electric charge $Q$, is placed inside a spherical cavity of radius $R_{2}>R_{1}$, cut inside another metal. Calculate the force exerted on the sphere if is center is displaced by a small distance $\delta \ll R_{1}, R_{2}-R_{1}$ from that of the cavity - see Fig. on the right.

2.29. Within the simple model of electric field screening in conductors, discussed in Sec. 2.1, analyze the partial screening of the electric field of a point charge $q$ by a plane, uniform conducting film of thickness $t \ll \lambda$, where $\lambda$ is (depending on charge carrier statistics) either the Debye or the ThomasFermi screening length - see, respectively, Eqs. (2.8) or (2.10). Assume that the distance $d$ between the charge and plane is much larger than $t$.
2.30. Suggest a convenient definition of 2D Green's function for electrostatic problems, and calculate it for:
(i) the unlimited free space, and
(ii) the free space above a conducting plane.

Use the latter result to re-solve Problem 14.
2.31. Find the 2D Green's function for the free space
(i) outside a round conducting cylinder,
(ii) inside a round cylindrical hole in a conductor.
2.32. Solve Task (i) of Problem 12 (see also Problem 13), using the Green's function method.

Hints: You may like to use the 2D Green's function derived in the solution of Problem 2.27(ii), and the following table integral: ${ }^{75}$

$$
\int \frac{d \xi}{a+b \cos \xi}=\frac{2}{\left(a^{2}-b^{2}\right)^{1 / 2}} \tan ^{-1}\left[\frac{(a-b)}{\left(a^{2}-b^{2}\right)^{1 / 2}} \tan \frac{\xi}{2}\right], \quad \text { if } a^{2}-b^{2}>0 .
$$

2.33. Solve the same 2D boundary problem that was discussed in Sec. 6 (Fig. 32) using:
(i) the finite difference method, with a finer square mesh, $h=a / 3$, and
(ii) the variable separation method.

Compare the results (at the mesh points only) and comment.

[^219]

## Chapter 3. Polarization of Dielectrics

In the last chapter, we have discussed the electric polarization of conductors. In contrast to those materials, in dielectrics the charge motion is limited to the interior of an atom or a molecule, so that the electric polarization of these materials by external field takes a different form. This issue is the main subject of this chapter. In preparation to the analysis of dielectrics, we have to start with a more general discussion of the electric field of a spatially-restricted system of charges.

### 3.1. Electric dipole

Let us consider a localized system of charges, of a linear size scale $a$, and calculate a simple but approximate expression for the electrostatic field induced by the system at a distant point $\mathbf{r}$. For that, let us select a reference frame with the origin either somewhere inside the system, or at a distance of the order of $a$ from it (Fig. 1).

Fig. 3.1. Deriving the approximate expression (5) for the electrostatic field of a localized system of charges at a distant point $(r \gg r \prime \sim a)$.

Then positions of all charges of the system satisfy the following condition

$$
\begin{equation*}
r^{\prime} \ll r . \tag{3.1}
\end{equation*}
$$

Using this condition, we can expand the general expression (1.38) for the electrostatic potential $\phi(\mathbf{r})$ of the system into the Taylor series in small parameter $\mathbf{r}^{\prime} \equiv\left\{r^{\prime}{ }_{1}, r^{\prime}{ }_{2}, r^{\prime}{ }_{3}\right\}$. For any spatial function of the type $f\left(\mathbf{r}-\mathbf{r}^{\prime}\right)$, the expansion may be presented as ${ }^{1}$

$$
\begin{equation*}
f\left(\mathbf{r}-\mathbf{r}^{\prime}\right) \approx f(\mathbf{r})-\sum_{j=1}^{3} r_{j}^{\prime} \frac{\partial f}{\partial r_{j}}(\mathbf{r})+\frac{1}{2!} \sum_{j, j^{\prime}=1}^{3} r_{j}^{\prime} r_{j^{\prime}}^{\prime} \frac{\partial^{2} f}{\partial r_{j} \partial r_{j^{\prime}}}(\mathbf{r})-\ldots \tag{3.2}
\end{equation*}
$$

The two leading terms of this expansion, sufficient for our current purposes, may be rewritten in the vector form: ${ }^{2}$

$$
\begin{equation*}
f\left(\mathbf{r}-\mathbf{r}^{\prime}\right) \approx f(\mathbf{r})-\mathbf{r}^{\prime} \cdot \nabla f(\mathbf{r})+\ldots \tag{3.3}
\end{equation*}
$$

Let us apply this approximate formula to the free-space Green's function (2.204), which weighs the charge density contributions in Eq. (1.38). The gradient of such a spherically-symmetric function $f(r)=$ $1 / r$ is just $\mathbf{n}_{r} d f / d r$, so that

[^220]\[

$$
\begin{equation*}
\frac{1}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} \approx \frac{1}{r}-\mathbf{r}^{\prime} \cdot \mathbf{n}_{r} \frac{d}{d r}\left(\frac{1}{r}\right)=\frac{1}{r}+\mathbf{r}^{\prime} \cdot \frac{\mathbf{r}}{r^{3}} . \tag{3.4}
\end{equation*}
$$

\]

Plugging this dipole expansion into Eq. (1.38), we get

$$
\begin{equation*}
\phi(\mathbf{r}) \approx \frac{1}{4 \pi \varepsilon_{0}}\left[\frac{1}{r} \int \rho\left(\mathbf{r}^{\prime}\right) d^{3} r^{\prime}+\frac{\mathbf{r}}{r^{3}} \cdot \int \rho\left(\mathbf{r}^{\prime}\right) \mathbf{r}^{\prime} d^{3} r^{\prime}\right]=\frac{1}{4 \pi \varepsilon_{0}}\left(\frac{Q}{r}+\frac{\mathbf{r} \cdot \mathbf{p}}{r^{3}}\right), \tag{3.5}
\end{equation*}
$$

where $Q$ is the net charge of the system, while the vector

$$
\begin{equation*}
\mathbf{p} \equiv \int \rho\left(\mathbf{r}^{\prime}\right) \mathbf{r}^{\prime} d^{3} r^{\prime} \tag{3.6}
\end{equation*}
$$

with magnitude $p$ of the order of $Q a$, is called its (electric) dipole moment. ${ }^{3}$
If $Q \neq 0$, the second term in the right-hand part of Eq. (5) is just a small correction to the first one, and in many cases may be ignored. (Remember, Eq. (5) is only valid in the limit $r / a \rightarrow \infty$ ). However, the net charge of many systems is exactly zero. The most important example is a neutral atom or a neutral molecule, in which the negative charge of electrons exactly compensates the positive charge of protons in nuclei. For such neural systems, the second (dipole-moment) term, $\phi_{d}$, in Eq. (5) is the leading one. Due to its importance, let us rewrite this expression in two other, equivalent forms:

$$
\begin{equation*}
\phi_{d} \equiv \frac{1}{4 \pi \varepsilon_{0}} \frac{\mathbf{r} \cdot \mathbf{p}}{r^{3}}=\frac{1}{4 \pi \varepsilon_{0}} \frac{p \cos \theta}{r^{2}}=\frac{1}{4 \pi \varepsilon_{0}} \frac{p z}{\left[x^{2}+y^{2}+z^{2}\right]^{3 / 2}}, \tag{3.7}
\end{equation*}
$$

Electric dipole's potential
that are more convenient for some applications. Here $\theta$ is the angle between vectors $\mathbf{p}$ and $\mathbf{r}$, and in the last (Cartesian) presentation, axis $z$ is directed along vector $\mathbf{p}$. Figure 2a shows equipotential surfaces of the dipole field (or rather their cross-sections by a plane in which vector $\mathbf{p}$ resides).

Fig. 3.2. Dipole field: (a) equipotential surfaces and (b) electric field lines, for vertical vector $\mathbf{p}$.

[^221]The simplest example of the dipole (that gave such systems their name) is a system of two equal but opposite point charges, $+q$ and $-q$, with radius-vectors, respectively, $\mathbf{r}_{+}$and $\mathbf{r}_{\text {.: }}$

$$
\begin{equation*}
\rho(\mathbf{r})=(+q) \delta\left(\mathbf{r}-\mathbf{r}_{+}\right)+(-q) \delta\left(\mathbf{r}-\mathbf{r}_{-}\right) . \tag{3.8}
\end{equation*}
$$

For this system, Eq. (6) yields

$$
\begin{equation*}
\mathbf{p}=(+q) \mathbf{r}_{+}+(-q) \mathbf{r}_{-}=q\left(\mathbf{r}_{+}-\mathbf{r}_{-}\right)=q \mathbf{a}, \tag{3.9}
\end{equation*}
$$

where $\mathbf{a}$ is the vector connecting points $\mathbf{r}_{-}$and $\mathbf{r}_{+}$. Note that in this case (and for all systems with $Q=0$ ), the dipole moment does not depend on the reference frame origin choice.

A less trivial example is a conducting sphere of radius $R$ in a uniform external electric field $\mathbf{E}_{0}$. As a reminder, we have solved this problem in Sec. 2.5(iv) and obtained Eq. (2.176) as a result. The first term in the parentheses of that relation describes the external field (2.173), so that the field of the sphere itself (meaning the field of its surface charge induced by $\mathbf{E}_{0}$ ) is given by the second term:

$$
\begin{equation*}
\phi_{s}=\frac{E_{0} R^{3}}{r^{2}} \cos \theta \tag{3.10}
\end{equation*}
$$

Comparing this expression with the second form of Eq. (7), we see that the sphere has an induced dipole moment

$$
\begin{equation*}
\mathbf{p}=4 \pi \varepsilon_{0} \mathbf{E}_{0} R^{3} \tag{3.11}
\end{equation*}
$$

This is an interesting example of a purely dipole field - in all points outside the sphere $(r>R)$, the field has no higher moments. ${ }^{4}$

Returning to the general properties of the dipole field, let us calculate its characteristics. First of all, we may use Eq. (7) to calculate the electric field of a dipole:

$$
\begin{equation*}
\mathbf{E}_{d}=-\nabla \phi_{d}=-\frac{1}{4 \pi \varepsilon_{0}} \nabla\left(\frac{\mathbf{r} \cdot \mathbf{p}}{r^{3}}\right)=-\frac{1}{4 \pi \varepsilon_{0}} \nabla\left(\frac{p \cos \theta}{r^{2}}\right) \tag{3.12}
\end{equation*}
$$

The differentiation is easiest in spherical coordinates, using the following well-known expression for the gradient of a scalar function in these coordinates ${ }^{5}$ and taking axis $z$ parallel to vector $\mathbf{p}$. From the last form of Eq. (12) we immediately get

$$
\begin{equation*}
\mathbf{E}_{d}=\frac{p}{4 \pi \varepsilon_{0} r^{3}}\left(2 \mathbf{n}_{r} \cos \theta+\mathbf{n}_{\theta} \sin \theta\right)=\frac{1}{4 \pi \varepsilon_{0}} \frac{3 \mathbf{r}(\mathbf{r} \cdot \mathbf{p})-\mathbf{p} r^{2}}{r^{5}} \tag{3.13}
\end{equation*}
$$

Figure $2 b$ shows the electric field lines given by Eqs. (13).
Next, let us calculate the potential energy of interaction between a fixed dipole and a external electric field, using Eq. (1.54). Assuming that the external field does not change much at distances of the order of $a$ (Fig. 1), we may expand the external potential $\phi_{\text {ext }}(\mathbf{r})$ into the Taylor series, just as Eq. (3) prescribes, and keep only its two leading terms:

[^222]\[

$$
\begin{equation*}
U=\int \rho(\mathbf{r}) \phi_{\mathrm{ext}}(\mathbf{r}) d^{3} r \approx \int \rho(\mathbf{r})\left[\phi_{\mathrm{ext}}(0)+\mathbf{r} \cdot \nabla \phi_{\mathrm{ext}}(0)\right] d^{3} r=Q \phi_{\mathrm{ext}}(0)-\mathbf{p} \cdot \mathbf{E}_{\mathrm{ext}} . \tag{3.14}
\end{equation*}
$$

\]

The first term is the potential energy the system would have if it were a point charge. If the net charge $Q$ is zero, that term disappears, and the leading contribution is due to the dipole moment:

$$
\begin{equation*}
U=-\mathbf{p} \cdot \mathbf{E}_{\mathrm{ext}} . \tag{3.15}
\end{equation*}
$$

Note, however, that Eq. (15) is only valid for a fixed dipole, with $\mathbf{p}$ independent of $\mathbf{E}_{\text {ext }}$. In the opposite limit, when the dipole is induced by the field, i.e. $\mathbf{p} \propto \mathbf{E}_{\text {ext }}$ (see Eq. (11) as an example), we can repeat the discussion that accompanied Fig. 1.6 to show that Eq. (15) acquires an additional factor $1 / 2$.

In particular, combining Eqs. (13) and Eq. (15), we may get the following important formula for interaction of two independent dipoles

$$
\begin{equation*}
U=\frac{1}{4 \pi \varepsilon_{0}} \frac{\mathbf{p}_{1} \cdot \mathbf{p}_{2} r^{2}-3\left(\mathbf{r} \cdot \mathbf{p}_{1}\right)\left(\mathbf{r} \cdot \mathbf{p}_{2}\right)}{r^{5}}=\frac{1}{4 \pi \varepsilon_{0}} \frac{p_{1 x} p_{2 x}+p_{1 y} p_{2 y}-2 p_{1 z} p_{2 z}}{r^{3}}, \tag{3.16}
\end{equation*}
$$

where $\mathbf{r}$ is the vector connecting the dipoles, and axis $z$ is directed along this vector. If each moment is due to the polarization of the dipole by the electric field of its counterpart: $\mathbf{p}_{1,2} \propto \mathbf{E}_{2,1} \propto 1 / r^{3}$, this expression (which is valid for this case with the additional factor $1 / 2$ ) the potential is always negative and proportional to $1 / r^{6}$. Such potential describes, in particular, the long-range, attractive part (the so-called London dispersion force) of the interaction between electrically neutral atoms and molecules. ${ }^{6}$

According to Eq. (15), in order to reach the minimum of $U$, the electric field "tries" to align the dipole direction along its own. The quantitative expression of this effect is the torque $\tau$ exerted by the field. The simplest way to calculate it is to sum up all the elementary torques $d \tau=\mathbf{r} \times d \mathbf{F}_{\text {ext }}=$ $\mathbf{r} \times \mathbf{E}_{\text {ext }}(\mathbf{r}) \rho(\mathbf{r}) d^{3} r$ exerted on all elementary charges of the system:

$$
\begin{equation*}
\boldsymbol{\tau}=\int \mathbf{r} \times \mathbf{E}_{\mathrm{ext}}(\mathbf{r}) \rho(\mathbf{r}) d^{3} r \approx \mathbf{p} \times \mathbf{E}_{\mathrm{ext}}(0), \tag{3.17}
\end{equation*}
$$

where at the last transition we have again neglected the spatial dependence of the external field.
The spatial dependence of $\mathbf{E}_{\text {ext }}$ cannot, however, be ignored at the calculation of the total force exerted by the field on the dipole (with $Q=0$ ). Indeed, Eq. (15) shows that if the field is constant, the dipole energy is the same at all spatial points, and hence the net force is zero. However, if the field has a finite gradient, a total force does appear:

$$
\begin{equation*}
\mathbf{F}=-\nabla U=\nabla\left(\mathbf{p} \cdot \mathbf{E}_{\mathrm{ext}}\right), \tag{3.18}
\end{equation*}
$$

where the derivative has to be taken at the dipole's position (in our notation, at $\mathbf{r}=0$ ). If the dipole that is being moved in a field retains its magnitude and orientation, then the last formula is equivalent to ${ }^{7}$

$$
\begin{equation*}
\mathbf{F}=(\mathbf{p} \cdot \nabla) \mathbf{E}_{\mathrm{ext}} . \tag{3.19}
\end{equation*}
$$

Alternatively, the last expression may be obtained similarly to Eq. (14):

$$
\begin{equation*}
\mathbf{F}=\int \rho(\mathbf{r}) \mathbf{E}_{\mathrm{ext}}(\mathbf{r}) d^{3} r \approx \int \rho(\mathbf{r})\left[\mathbf{E}_{\mathrm{ext}}(0)+(\mathbf{r} \cdot \nabla) \mathbf{E}_{\mathrm{ext}}\right] d^{3} r=Q \mathbf{E}_{\mathrm{ext}}(0)+(\mathbf{p} \cdot \nabla) \mathbf{E}_{\mathrm{ext}} \tag{3.20}
\end{equation*}
$$

[^223]Finally, let me add a note on the so-called coarse-grain model of the dipole. The dipole approximation explored above is asymptotically correct at large distances, $r \gg a$. However, for some applications (including the forthcoming discussion in Sec. 5 of molecular field effects) it is important to have an expression that would be approximately valid everywhere in space, though maybe without exact details at $r \sim a$, and also give the correct result for the space-average of the electric field,

$$
\begin{equation*}
\overline{\mathbf{E}} \equiv \frac{1}{V} \int_{V} \mathbf{E} d^{3} r \tag{3.21}
\end{equation*}
$$

where $V$ is a regularly-shaped volume much larger than $a^{3}$, for example a sphere of radius $R \gg a$, with the dipole at its center. For the field $\mathbf{E}_{d}$ given by Eq. (13), such average is zero. Indeed, let us consider Cartesian components of that vector in the coordinate system with axis $z$ directed along vector $\mathbf{p}$. Due to the axial symmetry of the field, the averages of components $E_{x}$ and $E_{y}$ evidently vanish. Let us use Eq. (13) to spell out the "vertical" component of the field (parallel to the dipole moment vector):

$$
\begin{equation*}
E_{z} \equiv \mathbf{E}_{d} \cdot \frac{\mathbf{p}}{p}=\frac{1}{4 \pi \varepsilon_{0} r^{3}}\left(2 \mathbf{n}_{r} \cdot \mathbf{p} \cos \theta-\mathbf{n}_{\theta} \cdot \mathbf{p} \sin \theta\right)=\frac{p}{4 \pi \varepsilon_{0} r^{3}}\left(2 \cos ^{2} \theta-\sin ^{2} \theta\right) . \tag{3.22}
\end{equation*}
$$

Integrating this expression over the whole solid angle $\Omega=4 \pi$, at fixed $r$, using a convenient variable substitution $\cos \theta \equiv \xi$, we get

$$
\begin{equation*}
\oint_{4 \pi} E_{z} d \Omega=2 \pi \int_{0}^{\pi} E_{z} \sin \theta d \theta=\frac{p}{2 \varepsilon_{0} r^{3}} \int_{0}^{\pi}\left(2 \cos ^{2} \theta-\sin ^{2} \theta\right) \sin \theta d \theta=\frac{p}{2 \varepsilon_{0} r^{3}} \int_{-1}^{+1}\left(3 \xi^{3}-\xi\right) d \xi=0 \tag{3.23}
\end{equation*}
$$

On the other hand, the exact electric field of an arbitrary charge distribution, having the total dipole moment $\mathbf{p}$, satisfies the following condition,

$$
\begin{equation*}
\int_{V} \mathbf{E}(\mathbf{r}) d^{3} r=-\frac{\mathbf{p}}{3 \varepsilon_{0}} \tag{3.24}
\end{equation*}
$$

where the integration is over any sphere containing all the charges. A proof of this formula for the general case requires a somewhat cumbersome, though straightforward integration, ${ }^{8}$ but later in the course we will see that it is correct for several particular cases. The origin of the difference between Eqs. (23) and (24) is illustrated in Fig. 3 on the example of a dipole created by two equal but opposite charges - see Eqs. (8)-(9). The zero average of the dipole field (13) does not take into account the contribution of the field in the region between the charges (where Eq. (13) is not valid), which is directed mostly against the dipole vector (9).

Thus in order to be used as a reasonable coarse-grain model, Eq. (13) should be modified as follows:

$$
\begin{equation*}
\mathbf{E}_{c g}=\frac{1}{4 \pi \varepsilon_{0}}\left[\frac{3 \mathbf{r}(\mathbf{r} \cdot \mathbf{p})-\mathbf{p} r^{2}}{r^{5}}-\frac{4 \pi}{3} \mathbf{p} \delta(\mathbf{r})\right] . \tag{3.25}
\end{equation*}
$$

Evidently, such modification does not change the field at large distances $r \gg a$, i.e. in the region where the expansion (3) and hence Eq. (13) are valid.

[^224]

Fig. 3.3. Illustrating the origin of Eq. (24). (The field lines are very approximate.)

### 3.2. Dipole media

Let us generalize equation (7) to the case of several (possibly, many) dipoles $\mathbf{p}_{j}$ located at arbitrary points $\mathbf{r}_{j}$. Using the linear superposition principle, we get

$$
\begin{equation*}
\phi(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} \sum_{j} \mathbf{p}_{j} \cdot \frac{\mathbf{r}-\mathbf{r}_{j}}{\left|\mathbf{r}-\mathbf{r}_{j}\right|^{3}} . \tag{3.26}
\end{equation*}
$$

If our system (medium) contains many similar dipoles, distributed in space with density $n(\mathbf{r})$, we may use the same standard argumentation that has led us from Eq. (1.5) to Eq. (1.8), to rewrite the last sum as an integral

$$
\begin{equation*}
\phi(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} \int \mathbf{P}\left(\mathbf{r}^{\prime}\right) \cdot \frac{\mathbf{r}-\mathbf{r}^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{3}} d^{3} r^{\prime}, \tag{3.27}
\end{equation*}
$$

where vector $\mathbf{P}(\mathbf{r}) \equiv n(\mathbf{r}) \mathbf{p}$, called electric polarization has the physical meaning of the net dipole moment per unit volume. Note again that since Eq. (26) does not describe that field at distances comparable to the dipole size, and hence Eq. (27), and all the following formulas of this section, describes the so-called macroscopic electric field, i.e. the dipole field averaged over the microscopic (dipole-size) distances.

Now comes a very impressive mathematical trick. Just as has been done in the previous section (just with the appropriate sign change), Eq. (27) may be rewritten in the equivalent form

$$
\begin{equation*}
\phi(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} \int \mathbf{P}\left(\mathbf{r}^{\prime}\right) \cdot \nabla^{\prime} \frac{1}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} d^{3} r^{\prime} \tag{3.28}
\end{equation*}
$$

where $\nabla$ ' means the del operator (in this particular case, the gradient) acting in the "source space" of vectors $\mathbf{r}$ '. The right-hand part of Eq. (28), applied to any volume $V$ limited by surface $S$, may be integrated by parts in the following way: ${ }^{9}$

$$
\begin{equation*}
\phi(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} \oint_{S} P_{n}\left(\mathbf{r}^{\prime}\right) \frac{1}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} d^{2} r^{\prime}-\frac{1}{4 \pi \varepsilon_{0}} \int_{V} \frac{\nabla^{\prime} \cdot \mathbf{P}\left(\mathbf{r}^{\prime}\right)}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} d^{3} r^{\prime} . \tag{3.29}
\end{equation*}
$$

[^225]If the surface does not carry an infinitely dense ( $\delta$-functional) sheet of additional dipoles, or it is just very far, the first term in the right-hand part is negligible. Now comparing the second term with the basic equation (1.38) for the electric potential, we see that this term may be interpreted as the field of certain effective electric charges with density

Effective
charge density

$$
\begin{equation*}
\rho_{\mathrm{ef}}=-\nabla \cdot \mathbf{P} \tag{3.30}
\end{equation*}
$$

Figure 4 illustrates the physics of this relation for a cartoon model of a multi-dipole system: a layer of uniformly-distributed two-point-charge units oriented perpendicular to the layer surface. (In this case $\nabla \cdot \mathbf{P}=d P / d x$.) One can see that $\rho_{\text {ef }}$, defined by Eq. (30), may be interpreted as the density of uncompensated surface charges of polarized elementary dipoles.

Fig. 3.4. Spatial distributions of the polarization and effective charges in a layer of similar elementary dipoles (schematically).

Next, from Sec. 1.2, we already know that Eq. (1.38) is equivalent to the inhomogeneous Maxwell equation (1.27) for the electric field. This is why Eq. (30) implies that if, besides the compensated charges of the dipoles, the system also has certain stand-alone charges (not a part of the dipoles!) distributed in space with density $\rho(\mathbf{r})$, the average electric field obeys, instead of Eq. (1.27), the following generalized equation

$$
\begin{equation*}
\nabla \cdot \mathbf{E}=\frac{1}{\varepsilon_{0}}\left(\rho+\rho_{\mathrm{ef}}\right)=\frac{1}{\varepsilon_{0}}(\rho-\nabla \cdot \mathbf{P}) . \tag{3.31}
\end{equation*}
$$

It is evidently tempting (and very convenient for applications!) to carry over the dipole-related term of this equation over to the left-hand part of Eq. (31), and rewrite the resulting equality as the so-called macroscopic Maxwell equation

$$
\begin{equation*}
\nabla \cdot \mathbf{D}=\rho \tag{3.32}
\end{equation*}
$$

where a new vector, called the electric displacement, is defined as ${ }^{10}$

[^226]\[

$$
\begin{equation*}
\mathbf{D} \equiv \varepsilon_{0} \mathbf{E}+\mathbf{P} \tag{3.33}
\end{equation*}
$$

\]

The comparison of Eqs. (32) and (1.27) shows that $\mathbf{D}$ may be interpreted as the "would-be" electric field that would be created by stand-alone charges in the absence of the dipole medium polarization. In contrast, $\mathbf{E}$ is the actual electric field - though, as was mentioned above, space-averaged over a volume much larger that of an elementary dipole. ${ }^{11}$

To complete the general analysis of the multi-dipole systems, let us rewrite the macroscopic Maxwell equation (32) in the integral form. Applying the divergence theorem to an arbitrary volume $V$ limited by surface $S$, we get the following macroscopic Gauss law:

$$
\begin{equation*}
\oint_{S} D_{n} d^{2} r=\int_{V} \rho d^{3} r \equiv Q \tag{3.34}
\end{equation*}
$$

where $Q$ is the total stand-alone charge inside volume $V$.
Let me emphasize again that the key Eq. (27), and hence all the following equations of this section, only to the macroscopic field, i.e. the electric field averaged over its rapid variations at the atomic space scale. Such macroscopic description is valid as soon as we are not concerned with the inter-atomic field variations - for whose description the classical physics is inadequate in any case.

### 3.3. Linear dielectrics

The general equations derived above are broadly used to describe any dielectrics - materials with bound electric charges (and hence with no dc electric conduction). The polarization properties of these materials may be described by the dependence between vectors $\mathbf{P}$ and $\mathbf{E}$. In the most materials, in the absence of external electric field, the elementary dipoles $\mathbf{p}$ either equal zero or have a random orientation in space, so that the net dipole moment of each macroscopic volume (still containing many such dipoles) equals zero: $\mathbf{P}=0$.

Moreover, if the field changes are sufficiently slow, most materials may be characterized by a unique dependence of $\mathbf{P}$ on $\mathbf{E}$. Then using the Taylor expansion of function $\mathbf{P}(\mathbf{E})$, we may argue that in relatively low electric fields the function should be well approximated by a linear dependence between these two vectors. In an isotropic media, the coefficient of proportionality should be just a scalar. ${ }^{12}$ In SI units, this constant is defined by the following relation:

$$
\begin{equation*}
\mathbf{P}=\chi_{e} \varepsilon_{0} \mathbf{E} \tag{3.35}
\end{equation*}
$$

Electric susceptibility definition
with the dimensionless constant $\chi_{e}$ called the electric susceptibility. However, it is much more common to use, instead of $\chi_{e}$, another parameter,

$$
\begin{equation*}
\varepsilon_{r} \equiv 1+\chi_{e}, \tag{3.36}
\end{equation*}
$$

[^227]which is sometimes called the relative electric permittivity, but much more often, the dielectric constant. ${ }^{13}$ This parameter is very convenient, because combining Eqs. (35) and (36),
\[

$$
\begin{equation*}
\mathbf{P}=\left(\varepsilon_{r}-1\right) \varepsilon_{0} \mathbf{E} . \tag{3.37}
\end{equation*}
$$

\]

and then plugging the resulting relation into the general Eq. (33), we get simply ${ }^{14}$

Electric permittivity

$$
\begin{equation*}
\mathbf{D}=\varepsilon \mathbf{E}, \quad \text { with } \varepsilon \equiv \varepsilon_{0} \varepsilon_{r}=\varepsilon_{0}\left(1+\chi_{e}\right) \tag{3.38}
\end{equation*}
$$

where $\varepsilon$ is called the electric permittivity of the material. Table 1 gives values of the dielectric constant for several representative materials.

Table 3.1. Dielectric constants of a few representative (and/or practically important) dielectrics

| Material | $\varepsilon_{r}$ |
| :---: | :---: |
| Air (at ambient conditions) | 1.00054 |
| Teflon (polytetrafluoroethylene, $\mathrm{C}_{n} \mathrm{~F}_{2 n}$ ) | 2.1 |
| Silicon dioxide (amorphous) | 3.9 |
| Glasses (of various compositions) | $3.7-10$ |
| Castor oil | 4.5 |
| Silicon | 11.7 |
| Water (at $100^{\circ} \mathrm{C}$ ) | 55.3 |
| Water (at $20^{\circ} \mathrm{C}$ ) | 80.1 |
| Barium titanate $\left(\mathrm{BaTiO}_{3}\right.$ at $20^{\circ} \mathrm{C}$ ) | $\sim 1,600$ |

In order to get some feeling of the physics behind these values, let us consider a very common model of a media whose elementary dipoles do not interact, so that in the relation $\mathbf{P}=n \mathbf{p}$ the elementary dipole moments $\mathbf{p}$ may be calculated independently of each other. This means that in a linear dielectric, in which Eq. (35) holds, each induced dipole moment $\mathbf{p}$ has to be proportional to the applied field $\mathbf{E}$ as well. Let us write this dependence in the following traditional form,

Molecular polarizability

$$
\begin{equation*}
\mathbf{p}=4 \pi \varepsilon_{0} \alpha_{\mathrm{mol}} \mathbf{E} \tag{3.39}
\end{equation*}
$$

where $\alpha_{\text {mol }}$ is called the molecular (or, sometimes, "atomic") polarizability, so that

$$
\begin{equation*}
\mathbf{P} \equiv n \mathbf{p}=4 \pi \varepsilon_{0} \alpha_{\mathrm{mol}} n \mathbf{E} . \tag{3.40}
\end{equation*}
$$

Comparing this relation with Eq. (35), we get $\chi_{e}=4 \pi \alpha_{\text {mol }} n$, so that Eq. (36) yields ${ }^{15}$

[^228]\[

$$
\begin{equation*}
\varepsilon_{r}=1+4 \pi \alpha_{\mathrm{mol}} n \tag{3.41}
\end{equation*}
$$

\]

Now let us consider the following toy model of a dielectric: ${ }^{16}$ a set of similar conducting spheres of radius $R$, spread apart with small density $n \ll 1 / R^{3}$. At such low density of the spheres, their electrostatic interaction is negligible, and we can use Eq. (11) for the induced dipole moment of a single sphere. Then the polarizability definition (39) yields $\alpha_{\text {mol }}=R^{3}$, so that $\chi_{e}=4 \pi n R^{3}$, and

$$
\begin{equation*}
\varepsilon_{r}=1+4 \pi R^{3} n \tag{3.42}
\end{equation*}
$$

Let us use this result for a crude estimate of the dielectric constant of air at the so-called ambient conditions, meaning the normal atmospheric pressure, and temperature $T=300 \mathrm{~K}$. At these conditions the molecular density $n$ may be, with a few-percent accuracy, found from the equation of state of an ideal gas: ${ }^{17} n \approx P / k_{\mathrm{B}} T \approx\left(1.013 \times 10^{5}\right) /\left(1.38 \times 10^{-23} \times 300\right) \approx 2.5 \times 10^{25} \mathrm{~m}^{-3}$. The main component of air, molecular nitrogen $\mathrm{N}_{2}$, has a van-der-Waals radius ${ }^{18}$ of $155 \mathrm{pm}=1.55 \times 10^{-10} \mathrm{~m}$. Using it for $R$, from our crude model we get $\varepsilon_{r} \approx 1.001$. Comparing this number with the first line of Table 1 , we see that our crude model gives surprisingly reasonable results: in order to get the exact experimental value, it is sufficient to decrease $R$ by just $\sim 25 \%$.

This result may encourage us to try using Eq. (42) for larger density $n$, i.e., beyond the range of its quantitative applicability. For example, as a crude model for solid and liquids let us assume that spheres form a simple cubic lattice with period $a=2 R$ (i.e., the neighboring spheres almost touch). With this $n=1 / a^{3}=1 / 8 R^{3}$, Eq. (33) yields $\varepsilon_{r}=1+4 \pi / 8 \approx 2.5$. Due to the crude nature of this estimate, we may conclude that it provides a reasonable explanation for the values of $\varepsilon_{r}$, listed in first few lines of Table 1. Still, it is clear that such model cannot even approximately describe dielectric properties of either water or barium titanate (and similar materials), as well as their strong temperature dependence. Such high values may be explained by the molecular field effect: each elementary dipole is polarized not only by the external field (as in our current toy model), but by the field of neighboring dipoles as well.

Before analyzing this effect (in the next section), let us review how are the most important results of electrostatics modified by a uniform linear dielectric medium that obeys Eq. (38) with a spaceindependent dielectric constant $\varepsilon_{r}$. The simplest problem of this kind is a set of free charges of density $\rho(\mathbf{r})$, inserted into the medium. For this case, we can combine Eqs. (32) and (38) to write

$$
\begin{equation*}
\nabla \cdot \mathbf{E}=\frac{\rho}{\varepsilon}, \quad \text { i.e. } \nabla^{2} \phi=-\frac{\rho}{\varepsilon} \tag{3.43}
\end{equation*}
$$

For charges in vacuum, we had similar equations (1.27) and (1.41), but with a different constant, $\varepsilon_{0}=$ $\varepsilon / \varepsilon_{r}$. Hence all the results discussed in Chapter 1 are valid, with both $\mathbf{E}$ and $\phi$ reduced by the factor of $\varepsilon_{r}$. Thus, the most straightforward result of the induced polarization of a dielectric media is the electric field reduction. This is a very important effect, especially taken into account the very high values of $\varepsilon_{r}$ in such dielectrics as water - see Table 1 . Indeed, this is the reduction of the attraction between positive

[^229]and negative ions (called, respectively, cations and anions) in water that enables their substantial dissociation and hence almost all biochemical reactions, which are the basis of biological cell functions and hence of the life itself.

Now, what if the electric field in a uniform dielectric is induced by charges located on conductors - with potentials rather than charge density fixed? Then, with the substitution of the electrostatic potential definition $\mathbf{E} \equiv-\nabla \phi$, Eq. (43) in the space between the conductors is reduced to the Laplace equation, and the boundary problem remains exactly the same as formulated in Chapter 2 - see Eqs. (2.35). Hence the potential distribution $\phi(\mathbf{r})$ is related to the conductor potential in exactly the same way as in vacuum (see, e.g., any problem discussed in Chapter 2), without any effect of the medium polarization. However, in order to find, from that distribution, the density $\sigma$ of charges on conductor surfaces, we need to use the macroscopic Gauss law (34). Applying this equation to a pillbox-shaped volume on the conductor surface, we get the following relation,

$$
\begin{equation*}
\sigma=D_{n}=\varepsilon E_{n}=-\varepsilon \frac{\partial \phi}{\partial n}, \tag{3.44}
\end{equation*}
$$

which differs from Eq. (2.3) only by the replacement $\varepsilon_{0} \rightarrow \varepsilon=\varepsilon_{r} \varepsilon_{0}$. Hence the charge density, calculated for the vacuum case, should be increased by the factor of $\varepsilon_{r}-$ that's it. In particular, this means that all the capacitances that had been calculated in vacuum, should be increased by that factor. For example, for planar capacitor filled with linear dielectric $\varepsilon_{r}$, we get the well-known formula

$$
\begin{equation*}
C_{m}=\frac{\varepsilon_{r} \varepsilon_{0} A}{d}=\frac{\varepsilon A}{d} \tag{3.45}
\end{equation*}
$$

(As a reminder, this increase of $C_{m}$ by $\varepsilon_{r}$ has been already used in Sec. 2.2 for capacitance estimates.)
Now let us discuss more complex situations in which the dielectric medium is not uniform, for example when it contains a boundary separating two regions filled by different uniform dielectrics. (The analysis is clearly applicable to a dielectric/vacuum boundary as well, with one of the dielectric constants set to 1.) For that, let us apply the macroscopic Gauss law (34) to a pillbox formed at the interface between two dielectrics, with no surface charges - see the solid lines in Fig. 5.

Fig. 3.5. Deriving boundary conditions on the interface between two dielectrics: a Gauss pillbox and a circulation contour. $\mathbf{n}$ and $\tau$ are the unit vectors which are, respectively, normal and tangential to the interface.

This immediately gives $\left(D_{n}\right)_{1}=\left(D_{n}\right)_{2}$, so that Eq. (38) yields

Boundary condition for $E_{n}$

$$
\begin{equation*}
\left(\varepsilon E_{n}\right)_{1}=\left(\varepsilon E_{n}\right)_{2}, \quad \text { i.e. } \varepsilon_{1} \frac{\partial \phi_{1}}{\partial n}=\varepsilon_{2} \frac{\partial \phi_{2}}{\partial n} \tag{3.46}
\end{equation*}
$$

Now, what about the tangential component $\left(E_{\tau}\right)$ of the electric field? In dielectrics, static electric field is still potential, hence we can still use Eq. (1.28). Integrating this equation along to a narrow contour stretched along the interface (see the dashed line in Fig. 5), we get

$$
\begin{equation*}
\left(E_{\tau}\right)_{1}=\left(E_{\tau}\right)_{2}, \quad \text { i.e. } \frac{\partial \phi_{1}}{\partial \tau}=\frac{\partial \phi_{2}}{\partial \tau} . \tag{3.47}
\end{equation*}
$$

Note that this condition is compatible with (and may be derived follows from) the continuity of the electrostatic potential itself, $\phi_{1}=\phi_{2}$, at each point of the interface. That relation may be derived from the electric field definition as the gradient of $\phi$-see Eq. (1.33). Indeed, if the potential leaped at the border, the electric field would be infinite.

Let us apply the boundary conditions (46)-(47), for example, to two thin ( $t \ll d$ ) vacuum slits cut in a uniform dielectric with an initially uniform ${ }^{19}$ electric field $\mathbf{E}_{0}$ (Fig. 6). In both cases, a slit with $t$ $\rightarrow 0$ cannot modify the field distribution outside it substantially.

Fig. 3.6. Fields inside narrow slits cut in a linear dielectric.

For slit (a), normal to the applied field, we may apply Eq. (46) to the "major" (broad) interfaces, shown horizontal in Fig. 6, we see that $D$ should be continuous. But according to Eq. (33), this means that inside the gap (i. e. in the vacuum, with $\mathbf{P}=0$ ) the electric field equals $\mathbf{D} / \varepsilon_{0}$. This field, and hence D, may be measured, showing that the electric displacement is not a purely mathematical construct. Superficially, this result violates the boundary condition (47) on the vertical ("minor") interfaces of the slit. Note, however, that the electric field within the gap is $\varepsilon_{r}$ times higher than in the dielectric outside it. Hence the slit deforms the equipotential surfaces around it to concentrate the field inside itself. The curving of the surfaces near the minor interfaces takes care of the fulfillment of Eq. (47) at the minor interfaces.

On the contrary, for slit (b) parallel to the applied field, we may apply Eq. (47) to the major (now, vertical) interfaces of the slit, to see that it is electric field $\mathbf{E}$ that is continuous now, while the electric displacement $\mathbf{D}=\varepsilon_{0} \mathbf{E}$ inside the gap is a factor of $\varepsilon_{r}$ lower than its value in the dielectric. (Any perturbation of the field uniformity, caused by the compliance with Eq. (46) at the minor interfaces, is settled at distances $\sim t$ from these interfaces.)

[^230]For problems with piecewise-constant $\varepsilon$ but more complex geometries we may need to apply the methods studied in Chapter 2. As in vacuum, in the simplest cases we can select such a set of orthogonal coordinates that the electrostatic potential depends on just one of them. Consider, for example, two types of plane capacitor filling with two different dielectrics - see Fig. 7.

In case (a), voltage $V$ between the electrodes is the same for each part of the capacitor, and at least far from the dielectric interface, the electric field is vertical, uniform, and similar ( $E=V / d$ ). Hence the boundary condition (47) is satisfied even if such a distribution is valid near the surface as well, i.e. at any point of the system. The only effect of different values of $\varepsilon$ in the two parts is that the electric displacement $D=\varepsilon E$ and hence electrodes' surface charge density $\sigma=D$ are different in the two parts. Thus we can calculate the electrode charges $Q_{1,2}$ of the two parts independently, in each case using Eq. (44), and then add up the results to get the total capacitance

$$
\begin{equation*}
C_{m}=\frac{Q_{1}+Q_{2}}{V}=\frac{1}{d}\left(\varepsilon_{1} A_{1}+\varepsilon_{2} A_{2}\right) . \tag{3.48}
\end{equation*}
$$

Note that this formula may be interpreted as the total capacitance of two separate capacitors connected (by conducting wires) in parallel. This is natural, because we may cut the system along the dielectric interface, without any effect on the fields in either part, and then connect the corresponding electrodes by external wires, again without any effect on the system - besides very close to capacitor's edges.

(b)

Fig. 3.7. Plane capacitors filled with two different dielectrics.

Case (b) may be analyzed by applying Eq. (34) to a Gaussian pillbox with the lower lid inside the (for example) bottom electrode, and the top lid in any of the layers. From this we see that $D$ anywhere inside the system should be equal to the surface charge density $\sigma$ of the lower electrode, i.e. constant. Hence, in the top dielectric layer the electric field is constant: $E_{1}=D_{1} / \varepsilon_{1}=\sigma / \varepsilon_{1}$, while in bottom layer, similarly, $E_{2}=D_{2} / \varepsilon_{2}=\sigma / \varepsilon_{2}$. Integrating $E$ across the whole capacitor, we get

$$
\begin{equation*}
V=\int_{0}^{d_{1}+d_{2}} E(z) d z=E_{1} d_{1}+E_{2} d_{2}=\left(\frac{d_{1}}{\varepsilon_{1}}+\frac{d_{2}}{\varepsilon_{2}}\right) \sigma, \tag{3.49}
\end{equation*}
$$

so that the mutual capacitance per unit area

$$
\begin{equation*}
\frac{C_{m}}{A} \equiv \frac{\sigma}{V}=\left[\frac{d_{1}}{\varepsilon_{1}}+\frac{d_{2}}{\varepsilon_{2}}\right]^{-1} \tag{3.50}
\end{equation*}
$$

Note that this result is equivalent to the total capacitance of an in-series connection of two plane capacitors based on each of the layers. This is natural, because we could insert an uncharged thin conducting sheet (rather than a cut as in the previous case) at the layer interface, which is an
equipotential surface, without changing the field distribution in the system. Then we could thicken the conducting sheet as much as we like (turning it into a wire), also without changing the fields and hence the capacitance.

In order to warm up for more complex problems, let us see how the last problem could be solved using the Laplace equation approach. Due to the symmetry of the system, the electrostatic potential in each layer may only depend on one (in Fig. 7b, vertical) coordinate $z$, so that the Laplace equation in each uniform part of the system is reduced to $d^{2} \phi / d^{2} z=0$. Hence in each layer the electrostatic potential changes linearly, though possibly with different coefficients: $\phi_{1}=c_{11} Z+c_{12}$, and $\phi_{2}=c_{21} Z+c_{22}$. Selecting the electrode potentials as $\phi(0)=0$ and $\phi\left(d_{1}+d_{2}\right)=V$, from those boundary conditions we get $c_{12}=0, c_{21}\left(d_{1}+d_{2}\right)+c_{22}=V$, so that we need two more equations to find all four coefficients $c_{j j}$. These additional equations come from the conditions of continuity of the potential ( $c_{11} d_{1}+c_{12}=c_{21} d_{1}+c_{22}$ ) and displacement $\left(\varepsilon_{1} c_{11}=\varepsilon_{2} c_{21}\right)$ at the interface $z=d_{1}$. Solving these equations, we can readily find the electric field and displacement in both layers, then the surface charge densities

$$
\begin{equation*}
\sigma(0)=\left.D\right|_{z=0}=-\left.\varepsilon_{1} \frac{d \phi_{1}}{d z}\right|_{z=0}, \quad \sigma\left(d_{1}+d_{2}\right)=\left.D\right|_{z=d_{1}+d_{2}}=-\left.\varepsilon_{2} \frac{d \phi_{2}}{d z}\right|_{z=d_{1}+d_{2}} \tag{3.51}
\end{equation*}
$$

(which in this case are equal and opposite) and finally the capacitance per unit area, with (of course) the same result (50).

Let us apply the same approach to a more complex problem, shown in Fig. 8a: a dielectric sphere placed into a uniform external electric field $\mathbf{E}_{0}$.

Fig. 3.8. Dielectric sphere in an initially uniform electric field: (a) the problem, and (b) the equipotential surfaces, as given by Eq. (55), for $\varepsilon_{r}=3$.

In this case the Laplace equation is not one-dimensional, and hence invites the variable separation method discussed in Sec. 2.5. From that discussion we already know, in particular, the general solution (2.172) of the Laplace equation outside of the sphere. To satisfy the uniform-field condition at $r \rightarrow \infty$, it reduces to

$$
\begin{equation*}
\phi_{r \geq R}=-E_{0} r \cos \theta+\sum_{l=1}^{\infty} \frac{b_{l}}{r^{l+1}} \mathcal{P}_{l}(\cos \theta) . \tag{3.52}
\end{equation*}
$$

Inside the sphere we can only use the radial functions that are finite at $r \rightarrow 0$ :

$$
\begin{equation*}
\phi_{r \leq R}=\sum_{l=1}^{\infty} a_{l} r^{l} \mathcal{P}_{l}(\cos \theta) . \tag{3.53}
\end{equation*}
$$

Now, writing the boundary conditions (46) and (47) at $r=R$, we see that for all coefficients $a_{l}$ and $b_{l}$ with $l \geq 2$ we (just like for the conducting sphere in vacuum) get homogeneous equations that have only trivial solutions. Hence, all these terms may be dropped, while for the only surviving angular harmonic, proportional to $\mathcal{P}_{1}(\cos \theta)=\cos \theta$, Eqs. (46)-(47) yield two equations:

$$
\begin{equation*}
-E_{0}-\frac{2 b_{1}}{R^{3}}=\varepsilon_{r} a_{1}, \quad-E_{0} R+\frac{b_{1}}{R^{2}}=a_{1} R . \tag{3.54}
\end{equation*}
$$

Solving this simple system for $a_{1}$ and $b_{1}$, we get the final solution of the problem:

$$
\begin{equation*}
\phi_{r \geq R}=E_{0}\left(-r+\frac{\varepsilon_{r}-1}{\varepsilon_{r}+2} \frac{R^{3}}{r^{2}}\right) \cos \theta, \quad \phi_{r \leq R}=-E_{0} \frac{3}{\varepsilon_{r}+2} r \cos \theta . \tag{3.55}
\end{equation*}
$$

Figure 8 b shows the equipotential surfaces given by this solution, for a particular value off the dielectric constant $\varepsilon_{r}$. Note that, just like for a conducting sphere, at $r \geq R$ the dielectric sphere produces (on the top of the uniform external field) a purely dipole field, with $\mathbf{p}=4 \pi R^{3} \varepsilon_{0} \mathbf{E}_{0}\left(\varepsilon_{r}-1\right) /\left(\varepsilon_{r}+2\right)$ - an evident generalization of Eq. (11), to which our result tends at $\varepsilon_{r} \rightarrow \infty$. By the way, this property is common: from the point of view of their electrostatic (but not transport!) properties, conductors may be adequately described as dielectrics with $\varepsilon_{r} \rightarrow \infty$.

Another remarkable feature of Eqs. (55) is that the electric field inside the sphere is uniform ${ }^{20}$ with $R$-independent values

$$
\begin{equation*}
\mathbf{E}=\frac{3}{\varepsilon_{r}+2} \mathbf{E}_{0}, \quad \mathbf{D} \equiv \varepsilon_{r} \varepsilon_{0} \mathbf{E}=\varepsilon_{0} \frac{3 \varepsilon_{r}}{\varepsilon_{r}+2} \mathbf{E}_{0}, \quad \mathbf{P} \equiv \mathbf{D}-\varepsilon_{0} \mathbf{E}=3 \varepsilon_{0} \frac{\varepsilon_{r}-1}{\varepsilon_{r}+2} \mathbf{E}_{0} . \tag{3.56}
\end{equation*}
$$

In the limit $\varepsilon_{r} \rightarrow 1$ (the "vacuum sphere", i.e. no sphere at all), the electric field inside the sphere naturally tends to the external one, and its polarization disappears. In the opposite limit and $\varepsilon_{r} \rightarrow \infty$ the electric field inside the sphere vanishes, and the field outside the sphere approaches that we have found for the conducting sphere - see Eq. (2.176).

To complete the discussion of this example, note a very curious result: the field $\mathbf{E}_{\text {self }}$, created by the dielectric sphere inside itself, is related to its polarization vector by a simple equation independent of either the dielectric constant or sphere's size:

$$
\begin{equation*}
\mathbf{E}_{\text {self }} \equiv \mathbf{E}-\mathbf{E}_{0}=-\frac{\varepsilon_{r}-1}{\varepsilon_{r}+2} \mathbf{E}_{0}=-\frac{1}{3 \varepsilon_{0}} \mathbf{P}, \tag{3.57}
\end{equation*}
$$

where factor 3 stems sphere's dimensionality. (For a round cylinder in a normal external field, the similar relation is valid, but with factor 2.) This equality is just the particular manifestation of the general relation (24). Indeed, if summed over all $N=n V$ similar dipoles $\mathbf{p}$, distributed inside the sphere with constant density $\mathbf{n}$ (so that the polarization vector $\mathbf{P}=n \mathbf{p}$ is constant), Eq. (24) yields

[^231]\[

$$
\begin{equation*}
\int_{V} \mathbf{E}_{\text {self }}(\mathbf{r}) d^{3} r=-\frac{\mathbf{P}}{3 \varepsilon_{0}} V, \tag{3.58}
\end{equation*}
$$

\]

so that after division by $V$, and taking into account the field uniformity in our particular case, it coincides with Eq. (57). ${ }^{21}$ We will use these results in the following section to discuss the molecular field effect.

Before doing that, let me briefly revisit the method of charge images that was discussed in Sec. 2.6, to find its new features pertaining to dielectrics. As the simplest example, consider a point charge near a dielectric half-space - see Fig. 9 (cf. Fig. 2.24).

Fig. 3.9. Charge images for a dielectric half-space.

The Laplace equations in the upper half-space $z>0$ (besides the charge point $\rho=0, z=d$ ) may still be satisfied using a single image charge $q$ ' at point $\rho=0, z=-d$, but now $q$ ' may differ from ( $-q$ ). In addition, in contrast to the conducting plane case, we should also find the field inside the dielectric ( $z$ $\leq 0$ ). This field cannot be contributed by the image charge, because it would provide a potential divergence at its location. Thus, in that half-space we should try to use the real point source only, but maybe with a re-normalized charge $q$ " rather than the genuine charge $q$ - see Fig. 9. As a result, we may look for the potential distribution in the form

$$
\phi(\rho, z)=\frac{1}{4 \pi \varepsilon_{0}} \times \begin{cases}{\left[\frac{q}{\left(\rho^{2}+(z-d)^{2}\right)^{1 / 2}}+\frac{q^{\prime}}{\left(\rho^{2}+(z+d)^{2}\right)^{1 / 2}}\right],} & \text { for } z \geq 0  \tag{3.59}\\ \frac{q^{\prime \prime}}{\left(\rho^{2}+(z-d)^{2}\right)^{1 / 2}}, & \text { for } z \leq 0\end{cases}
$$

at this stage with unknown $q^{\prime}$ and $q$ ". Plugging this solution into the boundary conditions (46) and (47) at $z=0$ (with $\partial / \partial n=\partial / \partial z$ ), we see that they are indeed satisfied (so that Eqs. (59) express the unique solution of the boundary problem) if the effective charges $q$ ' and $q$ '' obey the following relations:

[^232]\[

$$
\begin{equation*}
q-q^{\prime}=\varepsilon_{r} q^{\prime \prime}, \quad q+q^{\prime}=q^{\prime \prime} . \tag{3.60}
\end{equation*}
$$

\]

Solving this simple system of linear equations, we get

$$
\begin{equation*}
q^{\prime}=-\frac{\varepsilon_{r}-1}{\varepsilon_{r}+1} q, \quad q^{\prime \prime}=\frac{2}{\varepsilon_{r}+1} q . \tag{3.61}
\end{equation*}
$$

If $\varepsilon_{r} \rightarrow 1$, then $q^{\prime} \rightarrow 0$, and $q^{\prime \prime} \rightarrow q$ - both facts very natural, because in this limit (no polarization!) we have to recover the unperturbed field of the initial point charge in both semi-spaces. In the opposite limit $\varepsilon_{r} \rightarrow \infty$ (which, according to our discussion of the last problem, should correspond to a conducting plane), $q^{\prime} \rightarrow q$ (repeating the result we have discussed in very much detail in Sec. 2.6) and $q \prime \rightarrow 0$. According to the second of Eqs. (3.59), the last result means the field in the dielectric tends to zero in this limit, as it should.

Finally, following the logic of Chapter 2, at this point it would be appropriate to discuss the Green's function method. However, due to the time/space restrictions, I will skip this discussion, especially because the all the method's philosophy remains absolutely the same as for the vacuum case, so that the generalization to the case of dielectrics is straightforward.

### 3.4. Molecular field effects

In 1850, O.-F. Mossotti and (probably, independently, but almost 30 years later!) R. Clausius made an interesting experimental observation known now, rather unfairly, as the Clausius-Mossotti relation: if density $n$ of molecules in a chemical compound may be changed without changing its molecular structure, then the following ratio,

$$
\begin{equation*}
\frac{\varepsilon_{r}-1}{\varepsilon_{r}+2} \tag{3.62}
\end{equation*}
$$

is approximately proportional to $n$. For $\varepsilon_{r} \rightarrow 1$, i.e., $n \rightarrow 0$, there is no surprise here: according to Eq. (41), for independent molecular dipoles $\varepsilon_{r}-1=4 \pi \alpha_{\text {mol }} n \propto \propto n$. However, at larger density $n$, the effective field $\mathbf{E}_{\text {ef }}$, acting on each dipole, includes not only the external field $\mathbf{E}_{0}$, but also a substantial "molecular field" $\mathbf{E}_{\text {mol }}$ of the surrounding dipoles:

$$
\begin{equation*}
\mathbf{E}_{\mathrm{ef}}=\mathbf{E}_{0}+\mathbf{E}_{\mathrm{mol}}(0), \tag{3.63}
\end{equation*}
$$

where the position of the particular dipole we are discussing is taken for $\mathbf{r}=0$. Let us calculate $\mathbf{E}_{\text {mol }}(0)$, using a very simple model: a regular cubic lattice of identical dipoles (Fig. 10). In a Cartesian coordinate system with axes directed along the lattice vectors, coordinates of the dipoles are

$$
\begin{equation*}
x_{j k l}=a j, \quad y_{j k l}=a k, \quad z_{j k l}=a l, \tag{3.64}
\end{equation*}
$$

where $j, k$, and $l$ are the integers numbering the dipoles. Now we may use the last form of Eq. (13), and the linear superposition principle, to calculate one of the Cartesian components (say, along axis $x$ ) of the molecular field induced by all other dipoles of the lattice:

$$
\begin{equation*}
\left(E_{\mathrm{mol}}\right)_{x}(0)=\frac{1}{4 \pi \varepsilon_{0} a^{3}} \sum_{j, k, l=-\infty}^{+\infty} \frac{3 j\left(j p_{x}+k p_{y}+l p_{z}\right)-p_{x}\left(j^{2}+k^{2}+l^{2}\right)}{\left(j^{2}+k^{2}+l^{2}\right)^{5 / 2}} \tag{3.65}
\end{equation*}
$$

with excluded term $j=k=l=0$ is excluded. The sums of all cross-terms, proportional to $j k$ and $j l$, vanish due to system symmetry, so that Eq. (65) reduces to

$$
\begin{equation*}
\left(E_{\mathrm{mol}}\right)_{x}(0)=\frac{1}{4 \pi \varepsilon_{0} a^{3}} \sum_{j, k, l=-\infty}^{+\infty} \frac{\left[3 j^{2}-\left(j^{2}+k^{2}+l^{2}\right)\right]}{\left(j^{2}+k^{2}+l^{2}\right)^{5 / 2}} p_{x} \tag{3.66}
\end{equation*}
$$

Since all the sums participating in this expression are equal,

$$
\begin{equation*}
\sum_{j, k, l=-\infty}^{+\infty} \frac{j^{2}}{\left(j^{2}+k^{2}+l^{2}\right)^{5 / 2}}=\sum_{j, k, l=-\infty}^{+\infty} \frac{k^{2}}{\left(j^{2}+k^{2}+l^{2}\right)^{5 / 2}}=\sum_{j, k, l=-\infty}^{+\infty} \frac{l^{2}}{\left(j^{2}+k^{2}+l^{2}\right)^{5 / 2}}, \tag{3.67}
\end{equation*}
$$

we get $\left(E_{\text {mol }}\right)_{x}(0)=0$. Due to the system symmetry, the same result is valid for all other components of the dipole field. Hence, $\mathbf{E}_{\text {mol }}(0)=0$, and (due to the equivalence of all the dipoles of the system), the molecular field vanishes at the location of each dipole, so that Eq. (3.63) is reduced to $\mathbf{E}_{\text {ef }}=\mathbf{E}_{0}$.

Fig. 3.10. Cubic lattice of similar dipoles.

In order to relate the external field $\mathbf{E}_{0}$ and the average dipole ${ }^{22}$ field $\mathbf{E}$ in the medium, we may use Eq. (56) for a uniform, macroscopic sphere ${ }^{23}$ with a radius much larger then the inter-dipole distance $a$, so that our assumption of infinite limits of the rapidly converging sum (65) is not substantially affected:

$$
\begin{equation*}
\mathbf{E}=\frac{3}{\varepsilon_{r}+2} \mathbf{E}_{0}=\frac{3}{\varepsilon_{r}+2} \mathbf{E}_{\mathrm{ef}} \tag{3.68}
\end{equation*}
$$

Now we may plug this relation into the general formula (37) for linear dielectrics:

$$
\begin{equation*}
\mathbf{P}=\left(\varepsilon_{r}-1\right) \varepsilon_{0} \mathbf{E}=\frac{3\left(\varepsilon_{r}-1\right)}{\varepsilon_{r}+2} \varepsilon_{0} \mathbf{E}_{\mathrm{ef}} . \tag{3.69}
\end{equation*}
$$

This "macroscopic" relation has to give the same result as the "microscopic" Eq. (40) - with the replacement $\mathbf{E} \rightarrow \mathbf{E}_{\text {ef }}$ which reflects the fact that in the general case each dipole is polarized by the effective field (63) rather than the average field $\mathbf{E}$ :

$$
\begin{equation*}
\mathbf{P}=4 \pi \varepsilon_{0} \alpha_{\mathrm{mol}} n \mathbf{E}_{\mathrm{ef}} \tag{3.70}
\end{equation*}
$$

[^233]The comparison yields the so-called Lorentz-Lorenz formula, ${ }^{24}$

Lorentz-
Lorenz
formula

$$
\begin{equation*}
\frac{4 \pi \alpha_{\mathrm{mol}}}{3} n=\frac{\varepsilon_{r}-1}{\varepsilon_{r}+2} \tag{3.71}
\end{equation*}
$$

that complies with the Clausius-Mossotti observation, provided that the molecular polarizability $\alpha_{\text {mol }}$ is independent of density. (This is a good approximation at least for weak "molecular" bonding.)

It is somewhat surprising how many dielectric materials obey Eq. (71) rather well, because of its approximate nature. Indeed, its derivation is based on the assumption of a specific crystal lattice and, more importantly, that the molecules are localized exactly in the crystal lattice nodes, and the field of each molecule may be expressed by the dipole approximation. In reality, atom's electrons, which participate in the dipole moment formation, are spread in space due to quantum-mechanical uncertainty on a scale that may be comparable with distances between the molecules.

Solving Eq. (71) for the dielectric constant, we get

$$
\begin{equation*}
\varepsilon_{r}=\frac{1+8 \pi \alpha_{\mathrm{mol}} n / 3}{1-4 \pi \alpha_{\mathrm{mol}} n / 3} . \tag{3.72}
\end{equation*}
$$

If the dipole density is low, $\alpha_{\text {mol }} n \ll 1$, we get our old result (41) corresponding to independent dipoles, and hence to $\mathbf{E}_{\text {ef }}=\mathbf{E}$. However, at high dipole density and/or polarizability, the effective field acting on the each dipole,

$$
\begin{equation*}
\mathbf{E}_{\mathrm{ef}}=\frac{\varepsilon_{r}+2}{3} \mathbf{E}=\frac{\mathbf{E}}{1-4 \pi \alpha_{\mathrm{mol}} n / 3}, \tag{3.73}
\end{equation*}
$$

may be substantially larger than the average field $\mathbf{E}$, due to the molecular field contribution. Note $\varepsilon_{r}$, the $\mathbf{E}_{\mathrm{ef}} / \mathbf{E}$ ratio, and hence the electric susceptibility

$$
\begin{equation*}
\chi_{e} \equiv \frac{\mathbf{P}}{\varepsilon_{0} \mathbf{E}}=\varepsilon_{r}-1=\frac{4 \pi \alpha_{\mathrm{mol}} n}{1-4 \pi \alpha_{\mathrm{mol}} n / 3}, \tag{3.74}
\end{equation*}
$$

all diverge when the density-polarizability product approaches the critical value $\alpha_{\mathrm{mol}} n=3 / 4 \pi$.
This is essentially a rudimentary ${ }^{25}$ description of the transition from linear dielectrics to the socalled ferroelectrics with self-sustained (spontaneous) polarization even in the absence of external

[^234]electric field. These materials are typically recognized by the hysteretic behavior of their polarization as a function of applied electric field - see, for example, Fig. 11.

Ferroelectric materials are being actively explored as the active materials for nonvolatile random-access memories (dubbed either FRAM or FeRAM). ${ }^{26}$ In cells of this memory, binary information is stored in the form of one of two possible directions of spontaneous polarization at $\mathbf{E}=0-$ see, e.g., Fig.11, and is read out by the effect of the average electric field on a nearby semiconductor field-effect transistor. Unfortunately, most materials suitable for fabrication of ferroelectric thin films are rather complex and incompatible with standard processes of microelectronics. In addition, the time of spontaneous depolarization of ferroelectric thin films is typically well below than 10 years - the industrial standard for data retention in nonvolatile memories, and this time may be decreased even more by "fatigue" from repeated polarization recycling. Due to these reasons, industrial production of FRAM is currently just a tiny, few-percent fraction of the nonvolatile memory market (which is currently dominated by floating-gate memories - see Sec. 4.2).

Fig. 3.11. Ferroelectric hysteretic loops: (a) for various material types (schematically), and (b) for several amplitudes of the applied ac electric field. (Panel b, showing recent (2013) experimental results by S.-W. Jung et al. for an inkjet-printed layer of organic semiconductor PC12TV12T, is adapted from http://etrij.etri.re.kr/etrij/journal/article/article.do?volume=35\&issue=4\&page=734.)

Other polarization effects can also be met, possible, e.g., antiferroelectricity or helielectricity. Unfortunately, we will not have time for a discussion of these exotic phenomena in this course; ${ }^{27}$ the main reason I am mentioning them is to emphasize again that the "material relation" $\mathbf{P}=\mathbf{P}(\mathbf{E})$ is by no means exact or fundamental, though most material, in practicable fields, behave as linear dielectrics.

[^235]
### 3.5. Energy of electric field in a dielectric

In Chapter 1, we have obtained two key results for the electrostatic energy: Eq. (1.54) for a charge interaction with an independent ("external") field, and a similarly structured formula (1.62), but with an additional factor $1 / 2$, for the field is produced by the charges under consideration. Both relations could be merged and rewritten in a "local" form involving energy density $u$ - see Eq. (1.67). These equations are of course always valid for dielectrics as well if the charge density includes all charges (including those bound into dipoles), but it is convenient to recast them unto a form depending on density $\rho(\mathbf{r})$ of only "stand-alone" charges.

If a field is created only by stand-alone charges under consideration, and is proportional to $\rho(\mathbf{r})$ (requiring that we deal with a linear dielectric!), we can repeat all the argumentation of the beginning of Sec. 1.3, and again arrive at Eq. (1.62), provided that $\phi$ is calculated correctly, i.e., with a due account of the dielectric. Now we can recast this result in terms of fields - essentially as this was done in Eqs. (1.64)-(1.66), but now making a clear difference between the electric field $\mathbf{E}$ (that still equals $-\nabla \phi$ ) and the electric displacement field $\mathbf{D}$ that obeys the macroscopic Maxwell equation (32). Plugging $\rho(\mathbf{r})$, expressed from that equation, into Eq. (1.62), we get

$$
\begin{equation*}
U=\frac{1}{2} \int(\nabla \cdot \mathbf{D}) \phi d^{3} r . \tag{3.75}
\end{equation*}
$$

Using the fact ${ }^{28}$ that for any differentiable functions $\phi$ and $\mathbf{D}$,

$$
\begin{equation*}
(\nabla \cdot \mathbf{D}) \phi=\nabla \cdot(\phi \mathbf{D})-(\nabla \phi) \cdot \mathbf{D} \tag{3.76}
\end{equation*}
$$

we may rewrite Eq. (75) as

$$
\begin{equation*}
U=\frac{1}{2} \int \nabla \cdot(\phi \mathbf{D}) d^{3} r-\frac{1}{2} \int(\nabla \phi) \cdot \mathbf{D} d^{3} r . \tag{3.77}
\end{equation*}
$$

The divergence theorem, applied to first term, reduces it to a surface integral of $\phi D_{n}$. (As a reminder, in Eq. (1.65) the integral was of $\phi(\nabla \phi)_{n} \propto \phi E_{n}$.) If the surface of the volume we consider is sufficiently far, this surface integral vanishes. On the other hand, the gradient in the second term of Eq. (77) is just (minus) field $\mathbf{E}$, so that it gives

$$
\begin{equation*}
U=\frac{1}{2} \int \mathbf{E} \cdot \mathbf{D} d^{3} r=\frac{1}{2} \int E(\mathbf{r}) \cdot \varepsilon(\mathbf{r}) E(\mathbf{r}) d^{3} r=\frac{\varepsilon_{0}}{2} \int \varepsilon_{r}(\mathbf{r}) E^{2}(\mathbf{r}) d^{3} r . \tag{3.78}
\end{equation*}
$$

This expression is a natural generalization of Eq. (1.67) and shows that we can, like we did in vacuum, present the electrostatic energy in a local form ${ }^{29}$

Field energy in a linear dielectric

$$
\begin{equation*}
U=\int u(\mathbf{r}) d^{3} r, \quad u=\frac{1}{2} \mathbf{E} \cdot \mathbf{D}=\frac{\varepsilon}{2} E^{2}=\frac{D^{2}}{2 \varepsilon} \tag{3.79}
\end{equation*}
$$

Again, this expression is not valid for nonlinear dielectrics, because our starting point, Eq. (1.62), is only valid if $\phi$ is proportional to $\rho$. In order to make our calculation more general, we should

[^236]intercept our calculations in Sec. 1.3 at an earlier stage, at which we have not yet used this proportionality. For example, Eq. (1.54) may be rewritten, in the continuous limit, as
\[

$$
\begin{equation*}
\delta U=\int \phi(\mathbf{r}) \delta \rho(\mathbf{r}) d^{3} r \tag{3.80}
\end{equation*}
$$

\]

where symbol $\delta$ means a small variation of the function - e.g., its change in time, sufficiently slow to ignore the relativistic and magnetic-field effects. Applying such variation to Eq. (32), and plugging the resulting $\delta \rho=\nabla \cdot \delta \mathbf{D}$ into Eq. (80), we get

$$
\begin{equation*}
\delta U=\int(\nabla \cdot \delta \mathbf{D}) \phi d^{3} r . \tag{3.81}
\end{equation*}
$$

(Note that in contrast to Eq. (75), this expression does not have factor $1 / 2$.) Now repeating the same calculations as in the linear case, for the energy density variation we get a remarkably simple (and general!) expression,

$$
\begin{equation*}
\delta u=\mathbf{E} \cdot \delta \mathbf{D} . \tag{3.82}
\end{equation*}
$$

This is as far as we can go for the general dependence $\mathbf{D}(\mathbf{E})$. If the dependence is linear and isotropic, as in Eq. (38), then $\delta \mathbf{D}=\varepsilon \delta \mathbf{E}$ and

$$
\begin{equation*}
\delta u=\varepsilon \mathbf{E} \cdot \delta \mathbf{E} \tag{3.83}
\end{equation*}
$$

Integration of this expression over variations, from zero field to a certain final distribution $\mathbf{E}(\mathbf{r})$, brings us back to Eq. (79).

Another important role of Eq. (82) is that it shows that Cartesian coordinates of $\mathbf{E}$ may be interpreted as generalized forces, and those of $\mathbf{D}$ as generalized coordinates (per unit volume). ${ }^{30}$ This allows one to form the proper Gibbs potential energy ${ }^{31}$ of a system inside some volume $V$, placed in an external electric field $\mathbf{E}_{\text {ext }}$ :

$$
\begin{equation*}
g=\int_{V} g(\mathbf{r}) d^{3} r, \quad g(\mathbf{r})=u(\mathbf{r})-\mathbf{E}_{\mathrm{ext}} \cdot \mathbf{D} . \tag{3.84}
\end{equation*}
$$

As an analytical mechanics reminder, if a generalized external force (in our case, $\mathbf{E}_{\text {ext }}$ ) is fixed, the stable equilibrium of the system corresponds to the minimum of $g$, rather than of the potential energy $U$ as such - in our case, that of the field:

$$
\begin{equation*}
U=\int_{V} u(\mathbf{r}) d^{3} r, \quad u(\mathbf{r})=\int \mathbf{E} \cdot \delta \mathbf{D} . \tag{3.85}
\end{equation*}
$$

In order to illustrate this important point, let us return to the simple case of a system with linear dielectric(s), in which $\delta \mathbf{D} \propto \delta \mathbf{E} \propto \delta \mathbf{E}_{\text {ext }}$, so that Eq. (85) may be explicitly integrated over the external field variation, to reproduce the second of Eqs. (79):

[^237]General energy variation

$$
\begin{equation*}
u(\mathbf{r})=\frac{1}{2} \mathbf{E} \cdot \mathbf{D} . \tag{3.86}
\end{equation*}
$$

In this case, Eq. (84) yields

$$
\begin{equation*}
g(\mathbf{r})=\frac{1}{2} \mathbf{E} \cdot \mathbf{D}-\mathbf{E}_{\mathrm{ext}} \cdot \mathbf{D}=\frac{\varepsilon}{2} E^{2}-\varepsilon \mathbf{E} \cdot \mathbf{E}_{\mathrm{ext}} \equiv \frac{\varepsilon}{2}\left(\mathbf{E}-\mathbf{E}_{\mathrm{ext}}\right)^{2}+\mathrm{const} \tag{3.87}
\end{equation*}
$$

where the constant may depend on the external field, but not on the resulting field distribution. As a sanity check, let us apply this result to a volume $V$ well inside a long dielectric cylinder placed into a uniform external field $\mathbf{E}_{\text {ext }}$ parallel to cylinder's axis. (Such orientation is important to ignore the geometric effects discussed in Sec. 3 - see, e.g., Fig. 6 and its discussion.) Then $\mathbf{E}$ has to be uniform in the dominating part of the cylinder, so that Eq. (84) may be explicitly integrated over the volume, giving

$$
\begin{equation*}
g=\frac{\varepsilon}{2}\left(\mathbf{E}-\mathbf{E}_{\mathrm{ext}}\right)^{2} V+\text { const } . \tag{3.88}
\end{equation*}
$$

The minimum of this function is achieved at the evidently correct result $\mathbf{E}=\mathbf{E}_{\text {ext }}$ - in contrast to the unphysical result $\mathbf{E}=0$ (meaning electric field's expulsion from the volume) that we would get minimizing $U$.

### 3.6. Exercise problems

3.1.* Prove the following extension of Eq. (5):

$$
\phi(\mathbf{r}) \approx \frac{1}{4 \pi \varepsilon_{0}}\left(\frac{1}{r} Q+\frac{1}{r^{3}} \sum_{j=1}^{3} r_{j} p_{j}+\frac{1}{2 r^{5}} \sum_{j, j^{\prime}=1}^{3} r_{j} r_{j^{\prime}} Q_{i j j^{\prime}}\right),
$$

where $Q$ is a scalar - the total charge of the system, $p_{j}$ are the Cartesian components of a vector system's dipole moment (6), and $\mathscr{Q}_{j j}$, are Cartesian components of a tensor - system's quadrupole moment:

$$
Q=\int \rho\left(\mathbf{r}^{\prime}\right) d^{3} r^{\prime}, \quad p_{j}=\int \rho\left(\mathbf{r}^{\prime}\right) r_{j}^{\prime} d^{3} r^{\prime}, \quad Q_{j j j^{\prime}}=\int \rho\left(\mathbf{r}^{\prime}\right)\left(3 r_{j}^{\prime} r_{j^{\prime}}^{\prime}-r^{\prime 2} \delta_{i j^{\prime}}\right) d^{3} r^{\prime}
$$

3.2. A plane, thin ring of radius $R$ is charged with a constant linear density $\lambda$. Calculate the exact electrostatic potential distribution along the symmetry axis of the ring, and prove that at large distances, $r \gg R$, it is indeed described by the multipole expansion spelled out in Problem 1.
3.3. Without carrying out an exact calculation, can you predict the spatial dependence of the interaction between various electric multipoles, including point charges (in this context, frequently called monopoles), dipoles, and quadrupoles? Based on these predictions, what is the functional dependence of the interaction between dumbbell-shaped diatomic molecules such as $\mathrm{H}_{2}, \mathrm{~N}_{2}, \mathrm{O}_{2}$, etc., on the distance between them, if the distance is much larger than the molecular size?
3.4. In suitable reference frames, calculate the dipole and quadrupole moments of the following systems (see Figs. below):
(i) 4 point charges of the same magnitude, but alternating signs, placed in the corners of a square;
(ii) a similar system, but with a pair charge sign alternation; and
(iii) a point charge in the center of a thin ring carrying a similar but opposite charge, uniformly distributed along its circumference.

(ii)

(iii)

3.5. Two similar electric dipoles, of fixed magnitude $p$, located at fixed distance $r$ from each other, are free to rotate, changing their directions. What stable equilibrium position(s) may they take as a result of their electrostatic interaction?
3.6. An electric dipole is located above an infinite conducting plane (see Fig. on the right). Calculate:
(i) the distribution of the induced charge in the conductor,
(ii) the dipole-to-plane interaction energy, and
(ii) the force and the torque acting on the dipole.

3.7. Use two different approaches to calculate the energy of interaction between a grounded conductor and an electric dipole $\mathbf{p}$, placed in the center of a spherical cavity of radius $R$, carved in the conductor.
3.8. A plane separating two parts of otherwise free space is densely and uniformly (with constant areal density $n$ ) filled with dipoles, with their dipole moments $\mathbf{p}$ oriented in a direction normal to the plane.
(i) Calculate the boundary conditions for the electrostatic potential on both sides of the plane.
(ii) Use the result of Task (i) to calculate the potential distribution created in space by a spherical surface, with radius $R$, densely and uniformly filled with radially-oriented dipoles.
(iii) What condition that should be imposed on the dipole density $n$ for your results to be qualitatively valid?
3.9. A plane capacitor, with zero voltage between its conducting plates (as may be fixed, e.g., with an external wire - see Fig. on the right), is partly filled with a material

with spontaneous, constant polarization $\mathbf{P}_{0} .{ }^{32}$ Find the distributions of the electric field, electric displacement, and the surface charge density of each plate.
3.10. A sphere of radius $R$ is made of a material with a uniform, fixed polarization $\mathbf{P}_{0}$.
(i) Calculate the electric field everywhere in space - both inside and outside the sphere.
(ii) Explore the limit $R \rightarrow 0$, keeping $P_{0} R^{3}=$ const, and compare the result with Eq. (25).
3.11. Discuss the physics of Eq. (3.85) of the lecture notes, in particular the physical nature of the potential energy $U$ in a dipole medium. Apply your conclusion to a material with fixed (fieldindependent) polarization $\mathbf{P}_{0}$, and calculate the electric field energy of the uniformly polarized sphere considered in the previous problem.
3.12. Experimental plots in Fig. on the right show that the polarization of $\mathrm{EuMn}_{2} \mathrm{O}_{5}$, a typical ferroelectric/paraelectric material, becomes almost linear at 50 K . Use the plot to calculate (with an accuracy better than $10 \%$ ) its dielectric constant $\varepsilon_{r}$ at this temperature.

3.13. In two separate experiments, a thin, plane sheet of a linear dielectric with $\varepsilon_{r}=$ const is placed into a uniform external electric field $\mathbf{E}_{0}$ :
(i) with sheet's surface parallel to the electric field, and
(ii) the surface perpendicular to the field.

For each case, find the electric field $\mathbf{E}$, the electric displacement $\mathbf{D}$, and the polarization vector $\mathbf{P}$ inside the dielectric (far from sheet's edges).
3.14. A point charge $q$ is located at distance $r \gg R$ from the center of a uniform sphere of radius $R$, made of a uniform linear dielectric. In the first nonvanishing approximation in small parameter $R / r$, calculate the interaction force, and the energy of interaction between the sphere and the charge.
3.15. A fixed dipole $\mathbf{p}$ is placed in the center of a spherical cavity of radius $R$, cut inside a uniform, linear dielectric. Calculate the electric field distribution everywhere in the system (both for $r<$ $R$ and $r>R$ ).

Hint: You may start with the assumption that the field at $r>R$ has a distribution typical for a dipole (but be ready for surprises :-).

[^238]3.16. A spherical capacitor (see Fig. on the right) is filled with a linear dielectric whose permittivity $\varepsilon$ depends on spherical angles $\theta$ and $\varphi$, but not on the distance $r$ from system's center. Give an explicit expression for its capacitance $C$.

3.17. For each of the two capacitors shown in Fig. 3.7 of the lecture notes, calculate the electric forces (per unit area) on the boundaries of two uniform dielectrics, in terms of the electric fields.
3.18. A uniform electric field $\mathbf{E}_{0}$ has been created (by external sources) inside a uniform linear dielectric. Find the change of the electric field, created by cutting out a cavity in the shape of a round cylinder of radius $R$, with the axis perpendicular to the external field - see Fig. on the right.

3.19. Small linear-dielectric particles of spherical shape are dispersed in free space with low concentration $n \ll 1 / R^{3}$, where $R$ is particle's radius. Calculate the average dielectric constant of such a medium. Compare the result with the apparent, but incomplete answer
$$
\overline{\varepsilon_{r}}-1=\left(\varepsilon_{r}-1\right) n V,
$$
(where $\varepsilon_{r}$ is the dielectric constant of particle's material and $V=(4 \pi / 3) R^{3}$ is its volume), and explain the origin of the difference.
3.20.* Calculate the spatial distribution of the electric potential induced by a point charge $q$ is placed at distance $d$ from a very wide parallel plate, of thickness $D$, made of a linear dielectric - see Fig. on the right.

## Chapter 4. DC Currents

In this chapter I discuss the laws governing the distribution of constant ("dc") currents inside conducing media, with a focus on the linear ("Ohmic") conductivity. In most cases, the partial differential equation governing the distribution may be reduced to the same Laplace and Poisson equations whose solution methods have been discussed in detail in Chapter 2. Due to this fact, this chapter is rather short.

### 4.1. Continuity equation and the Kirchhoff laws

Until this point, our discussion of conductors has been limited to the cases when they are separated with insulators (meaning either vacuum or dielectric media) preventing any continuous motion of charges from one conductor to another, even if there is a voltage difference (and hence electric field) between them - see Fig. 1a.

Fig. 4.1. Two oppositely charged conductors: (a) at the electrostatic situation, (b) at charge relaxation through an additional narrow conductor ("wire"), and (c) a system sustaining dc current in the wire.

Now let us connect two conductors galvanically, say with a wire - a thin, elongated conductor (Fig. 1b). Then the electric field causes the motion of charges in the wire - from a conductor with a higher electrostatic potential toward that with a lower potential, until the potentials equilibrate. Such process is called charge relaxation. The main equation governing this process may be obtained from the experimental fact (already mentioned in Sec. 1.1) that electric charges cannot appear or disappear (though opposite charges may recombine with the conservation of the net charge.) As a result the change of charge $Q$ in one conductor may change only due to the current $I$ through the wire: ${ }^{1}$

$$
\begin{equation*}
\frac{d Q}{d t}=-I . \tag{4.1}
\end{equation*}
$$

[^239]Let us express this law in a differential form, introducing the notion of current density vector $\mathbf{j}(\mathbf{r})$. This vector may be defined via the following relation for current $d I$ crossing an elementary area $d A$ (Fig. 2)

$$
\begin{equation*}
d I=j d A \cos \theta=(j \cos \theta) d A=j_{n} d A, \tag{4.2}
\end{equation*}
$$

where $\theta$ is the angle between the normal to the surface and the carrier motion direction (which is taken for the direction of vector $\mathbf{j}$ ).

Fig. 4.2. Current density vector.

With that definition, Eq. (1) may be re-written as

$$
\begin{equation*}
\frac{d}{d t} \int_{V} \rho d^{3} r=-\oint_{S} j_{n} d^{2} r \tag{4.3}
\end{equation*}
$$

where $V$ is an arbitrary stationary volume limited by the closed surface $S$. Applying to this volume the same divergence theorem as was repeatedly used in previous chapters, we get

$$
\begin{equation*}
\int_{V}\left[\frac{\partial \rho}{\partial t}+\nabla \cdot \mathbf{j}\right] d^{3} r=0 \tag{4.4}
\end{equation*}
$$

Since volume $V$ if arbitrary, this equation may be true only if

$$
\begin{equation*}
\frac{\partial \rho}{\partial t}+\nabla \cdot \mathbf{j}=0 \tag{4.5}
\end{equation*}
$$

Continuity equation

This is the fundamental continuity equation - which is true even for the time-dependent phenomena. ${ }^{2}$
The charge relaxation is of course a dynamic, time-dependent process. However, electric currents may also exist in stationary situations, when a current source, for example a battery, replenishes the conductor charges and hence sustains currents at a certain time-independent level - see Fig. 1c. (As we will see below, in most cases this process requires a persistent replenishment of the electrostatic energy from either a source or storage of energy of a different kind - say, the chemical energy of the battery.) Let us discuss the laws governing the distribution of such dc currents. In this case $(\partial / \partial t=0)$, Eq. (5) reduces to a very simple equation

$$
\begin{equation*}
\nabla \cdot \mathbf{j}=0 \tag{4.6}
\end{equation*}
$$

This equation acquires an even a simpler form in the particular but important case of electric circuits (Fig. 3), the systems may be presented as an electric connection of components of two types:

[^240](i) small-size (lumped) circuit elements (also called "two-terminal devices"), meaning a passive resistor, a current source, etc. - generally, any black box with two wires sticking out of it, and
(ii) perfectly conducting wires, with negligible voltage drop along them, that are galvanically connected at certain points, called nodes (or "junctions").

Fig. 4.3. Typical system obeying the Kirchhoff laws.

In the standard circuit theory, the electric charges of the nodes are considered negligible, and we may integrate Eq. (6) over the closed surface drawn around any node to get

$$
\begin{equation*}
\sum_{j} I_{j}=0, \tag{4.7a}
\end{equation*}
$$

where the summation is over all the wires (numbered with index $j$ ) connected in the node. On the other hand, according to its definition (2.25), voltage drop $V_{k}$ across each circuit element may be presented as the difference of potentials of the adjacent nodes, $V_{k}=\phi_{k}-\phi_{k-1}$. Summing such differences around any closed loop of the circuit (Fig. 3), we get all terms cancelled, so that

$$
\begin{equation*}
\sum_{k} V_{k}=0 . \tag{4.7b}
\end{equation*}
$$

These relations are called, respectively, the $1^{\text {st }}$ and $2^{\text {nd }}$ Kirchhoff laws - or sometimes the node rule and the loop rule. They may seem elementary, and the genuine power of the Kirchhoff approach is in the fact a set of Eqs. (7), covering every node and every circuit element of the system, gives a system of equations sufficient for the calculation of all currents and voltages in it - provided that the relation between current and voltage in known for each circuit element.

It is almost evident that in the absence of current sources, the system of equations (7) has only a trivial solution: $I_{j}=0, V_{k}=0$ - with the exotic exception of superconductivity, to be discussed in Sec. 6.3. The current sources, that allow non-vanishing current flows, may be described by their electromotive forces (e.m.f.) $v_{k}$, having the dimensionality of voltage, which have to be taken into account in the corresponding terms $V_{k}$ of sum (7b). Let me hope that the reader has some experience of using Eqs. (7) for the analysis of simple circuits - say consisting of several resistors and dc batteries so I may save time on a discussion of these simple problems.

### 4.2. The Ohm law

As was mentioned above, the relations spelled out in Sec. 1 are sufficient for forming a closed system of equations for finding currents and electric field in a system only if they are complemented
with material equations relating scalars $I$ and $V$ in each circuit element, i.e. vectors $\mathbf{j}$ and $\mathbf{E}$ in each point of the medium of such an element. The simplest, and most frequently met relation of this kind is the famous Ohm law whose differential form is

$$
\begin{equation*}
\mathbf{j}=\sigma \mathbf{E} \tag{4.8}
\end{equation*}
$$

where $\sigma$ is a constant called conductivity. ${ }^{3}$ Though this is not a fundamental relation, and is approximate for any conducting media, we can argue that if:
(i) there is no current at $\mathbf{E}=0$ (mind superconductors!),
(ii) the medium is isotropic or almost isotropic (a notable exception: some organic conductors),
(iii) the mean free path $l$ of current carriers is much smaller than the characteristic scale $a$ of the spatial variations of $\mathbf{j}$ and $\mathbf{E}$,
then the Ohm law may be viewed as a result of the Taylor expansion of the local relation $\mathbf{j}(\mathbf{E})$ in relatively small fields, and thus is very common.

Table 1 gives the experimental values of dc conductivity for some practically important (or just representative) materials. The reader can see that the range of its values is very broad, covering more that 30 orders of magnitude, even without going to such extremes as very pure metallic crystals at very low temperatures, where $\sigma$ may reach $\sim 10^{12} \mathrm{~S} / \mathrm{m}$.

Table 4.1. Ohmic conductivities for some representative (or practically important) materials at $20^{\circ} \mathrm{C}$.

| Material | $\sigma(\mathrm{S} / \mathrm{m})$ |
| :---: | :---: |
| Teflon $\left(\left[\mathrm{C}_{2} \mathrm{~F}_{4}\right]_{n}\right)$ | $10^{-22}-10^{-24}$ |
| Silicon dioxide | $10^{-16}-10^{-19}$ |
| Various glasses | $10^{-10}-10^{-14}$ |
| Deionized water | $\sim 10^{-6}$ |
| Sea water | 5 |
| Silicon $n$-doped to $10^{16} \mathrm{~cm}^{-3}$ | $2.5 \times 10^{2}$ |
| Silicon $n$-doped to $10^{19} \mathrm{~cm}^{-3}$ | $1.6 \times 10^{4}$ |
| Silicon $p$-doped to $10^{19} \mathrm{~cm}^{-3}$ | $1.1 \times 10^{4}$ |
| Nichrome (alloy $80 \% \mathrm{Ni}+20 \% \mathrm{Cr})$ | $0.9 \times 10^{6}$ |
| Aluminum | $3.8 \times 10^{7}$ |
| Copper | $6.0 \times 10^{7}$ |
| Zinc crystal along $a$-axis | $1.65 \times 10^{7}$ |
| Zinc crystal along $c$-axis | $1.72 \times 10^{7}$ |

[^241]In order to get some feeling what do these values mean, let us consider a very simple system (Fig. 4): a plane capacitor of area $A \gg d^{2}$, filled with a material that has not only a dielectric constant $\varepsilon_{r}$, but also some Ohmic conductivity $\sigma$, with much more conductive plate electrodes.

Fig. 4.4. "Leaky" plane capacitor.

Assuming that these properties are compatible with each other, ${ }^{4}$, we may assume that the distribution of electric potential (not too close to the capacitor edges) still obeys Eq. (2.39), so that the electric field is vertical and uniform, with $E=V / d$. Then, according to Eq. (6) the current density is also uniform, $j=\sigma E=\sigma V / d$. From here, the total current between the plates is

$$
\begin{equation*}
I=j A=\sigma E A=\sigma \frac{V}{d} A . \tag{4.9}
\end{equation*}
$$

On the other hand, from Eqs. (2.26) and (3.45), the instant value of plate charge is $Q=C_{m} V=$ $\left(\varepsilon_{r} \varepsilon_{0} A / d\right) V$. Plugging these relations into Eq. (1), we see that the speed of charge (and voltage) relaxation does not depend on the geometric parameters $A$ and $d$ :

$$
\begin{equation*}
\frac{d V}{d t}=-\frac{V}{\tau_{r}}, \quad \tau_{r} \equiv \frac{\varepsilon_{r} \varepsilon_{0}}{\sigma}, \tag{4.10}
\end{equation*}
$$

where parameter $\tau_{r}$ has the sense of the relaxation time constant. As we know (see Table 3.1), for most practical materials the dielectric constant is within one order of magnitude from 10 , so that the numerator of Eq. (10) is of the order of $10^{-10}$. As a result, according to Table 1, the charge relaxation time ranges from $\sim 10^{14} \mathrm{~s}$ (more than a million years!) for best insulators like teflon, to $\sim 10^{-18} \mathrm{~s}$ for the least resistive metals.

What is the physics behind these values of $\sigma$ and why, for some materials, Table 1 gives them with such a large uncertainty? If charge carriers move as classical particles (e.g., in plasmas or nondegenerate semiconductors), a reasonable description of conductivity is given by the famous Drude formula. ${ }^{5}$ In his picture, due to weak electric field, the charge carriers are accelerated in its direction (possibly on the top of their random motion in all directions, i.e. with a vanishing average velocity vector):

$$
\begin{equation*}
\frac{d \mathbf{v}}{d t}=\frac{q}{m} \mathbf{E}, \tag{4.11}
\end{equation*}
$$

and as a result their velocity acquires an the average value

$$
\begin{equation*}
\langle\mathbf{v}\rangle=\frac{d \mathbf{v}}{d t} \tau=\frac{q}{m} \mathbf{E} \tau \tag{4.12}
\end{equation*}
$$

[^242]where the phenomenological parameter $\tau=l / v$ (not to be confused with $\tau_{r}$ !) may be understood as the effective average time between carrier scattering events. From here, the current density:
\[

$$
\begin{equation*}
\mathbf{j}=q n\langle\mathbf{v}\rangle=\frac{q^{2} n \tau}{m} \mathbf{E}, \quad \text { i.e. } \sigma=\frac{q^{2} n \tau}{m} \tag{4.13a}
\end{equation*}
$$

\]

(Notice the independence of $\sigma$ of the carrier charge sign.) Another form of the same result, more popular in the physics of semiconductors, is

$$
\begin{equation*}
\sigma=q^{2} n \mu, \quad \text { with } \mu=\frac{\tau}{m} \tag{4.13b}
\end{equation*}
$$

where parameter $\mu$, defined by relation $\langle\mathbf{v}\rangle \equiv \mu \mathbf{E}$, is called the charge carrier mobility.
Most good conductors (e.g., metals) are essentially degenerate Fermi gases (or liquids), in which the average thermal energy of a particle, $k_{\mathrm{B}} T$ is much lower that the Fermi energy $\varepsilon_{\mathrm{F}}$. In this case, a quantum theory is needed for the calculation of $\sigma$. Such theory was developed by the quantum physics’ godfather A. Sommerfeld in 1927 (and is sometimes called the Drude-Sommerfeld model). I have no time to discuss it in this course, ${ }^{6}$ and here I will only notice that for an ideal, isotropic Fermi gas the result is reduced to Eq. (13), with a certain effective value of $\tau$, so it may be used for estimates of $\sigma$, with due respect to the quantum theory of scattering. In a typical metal, $n$ is very high ( $\sim 10^{23} \mathrm{~cm}^{-3}$ ) and is fixed by the atomic structure, so that the sample quality may only affect $\sigma$ via the scattering time $\tau$.

At room temperature, the scattering of electrons by thermally-excited lattice vibrations (phonons) dominates, so that $\tau$ and $\sigma$ are high but finite, and do not change much from one sample to another. (Hence, the more accurate values given for metals in Table 1.) On the other hand, at $T \rightarrow 0$, a perfect crystal should not exhibit scattering at all, and conductivity should be infinite. In practice, this is never true (for example, due to electron scattering from imperfect boundaries of finite-size samples), and the effective conductivity $\sigma$ is infinite (or practically infinite, at least above the measurable value $\sim 10^{20} \mathrm{~S} / \mathrm{m}$ ) only in superconductors. ${ }^{7}$

On the other hand, the conductivity of quasi-insulators (including deionized water) and semiconductors depends mostly of the carrier density $n$ that is much lower than in metals. From the point of view of quantum mechanics, this happens because the ground-state eigenenergies of charge carriers are localized within an atom (or molecule), and separated from excited states, with spaceextended wavefunctions, by a large energy gap (called bandgap). For example, in $\mathrm{SiO}_{2}$ the bandgap approaches 9 eV , equivalent to $\sim 4,000 \mathrm{~K}$. This is why, even at room temperatures the density of thermally-excited free charge carriers in good insulators is negligible. In these materials, $n$ is determined by impurities and vacancies, and may depend on a particular chemical synthesis or other fabrication technology, rather than on fundamental properties of the material. (On the contrary, the carrier mobility $\mu$ in these materials is almost technology-independent.)

The practical importance of the technology may be illustrated on the following example. In cells of the so-called floating-gate memories, in particular the flash memories, which currently dominate the nonvolatile digital memory technology, data bits are stored as small electric charges ( $Q \sim 10^{-16} \mathrm{C}$ ) of

[^243]highly doped silicon islands (so-called floating gates) separated from the rest of the integrated circuit with a $\sim 10-n m$-thick layer of silicon dioxide, $\mathrm{SiO}_{2}$. Such layers are fabricated by high-temperature oxidation of virtually perfect silicon crystals. The conductivity of the resulting high-quality (though amorphous) material is so low, $\sigma \sim 10^{-19} \mathrm{~S} / \mathrm{m}$, that the relaxation time $\tau_{r}$, defined by Eq. (10), is well above 10 years - the industrial standard for data retention in non-volatile memories. In order to appreciate how good this technology is, the cited value should be compared with the typical conductivity $\sigma \sim 10^{-16} \mathrm{~S} / \mathrm{m}$ of the usual, bulk $\mathrm{SiO}_{2}$ ceramics. ${ }^{8}$

### 4.3. Boundary problems

For an Ohmic conducting media, we may combine Eqs. (6) and (8) the following differential equation

$$
\begin{equation*}
\nabla \cdot(\sigma \nabla \phi)=0 \tag{4.14}
\end{equation*}
$$

For a uniform conductor ( $\sigma=$ const), Eq. (14) is reduced to the Laplace equation for the electrostatic potential $\phi$. As we already know from Chapters 2 and 3, its solution depends on the boundary conditions. These conditions depend on the interface type.
(i) Conductor-conductor interface. Applying the continuity equation (6) to a Gauss-type pillbox at the interface of two different conductors (Fig. 5), we get

$$
\begin{equation*}
\left(j_{n}\right)_{1}=\left(j_{n}\right)_{2}, \tag{4.15}
\end{equation*}
$$

so that if the Ohm law is valid inside each medium, then

$$
\begin{equation*}
\sigma_{1} \frac{\partial \phi_{1}}{\partial n}=\sigma_{2} \frac{\partial \phi_{2}}{\partial n} . \tag{4.16}
\end{equation*}
$$

Fig. 4.5. DC current "refraction" at the interface between two different conductors.

Also, since the electric field should be finite, its potential $\phi$ has to be continuous across the interface - the condition that may also be written as

[^244]\[

$$
\begin{equation*}
\frac{\partial \phi_{1}}{\partial \tau}=\frac{\partial \phi_{2}}{\partial \tau} \tag{4.17}
\end{equation*}
$$

\]

Both these conditions (and hence the solutions of the boundary problems using them) are similar to those for the interface between two dielectrics - cf. Eqs. (3.46)-(3.47).

Note that using the Ohm law, Eq. (17) may be rewritten as

$$
\begin{equation*}
\frac{1}{\sigma_{1}}\left(j_{\tau}\right)_{1}=\frac{1}{\sigma_{2}}\left(j_{\tau}\right)_{2} \tag{4.18}
\end{equation*}
$$

Comparing it with Eq. (15) we see that, generally, the current density magnitude changes at the interface: $j_{1} \neq j_{2}$. It is also curious that if $\sigma_{1} \neq \sigma_{2}$, the current line slope changes at the interface (Fig. 4), qualitatively to the refraction of light rays in optics - see Chapter 7.
(ii) Conductor-electrode interface. The definition of an electrode, or a "perfect conductor", is a medium with $\sigma \rightarrow \infty$. Then, at fixed current density at the interface, the electric field in the electrode tends to zero, and hence it may be described by equation

$$
\begin{equation*}
\phi=\phi_{j}=\text { const }, \tag{4.19}
\end{equation*}
$$

where constants $\phi_{j}$ may be different for different electrodes (numbered with index $j$ ). Note that with such boundary conditions the Laplace boundary problem becomes exactly the same as in electrostatics see Eq. (2.35) - and hence we can use all the methods (and some solutions :-) of Chapter 2 for finding dc current distribution.
(iii) Conductor-insulator interface. For the description of an insulator, we can use $\sigma=0$, so that Eq. (16) yields the following boundary condition,

$$
\begin{equation*}
\frac{\partial \phi}{\partial n}=0 \tag{4.20}
\end{equation*}
$$

for the potential derivative inside the conductor. From the Ohm law we see that this is just the very natural requirement for the dc current not to flow into an insulator.

Now, note that this condition makes the Laplace problem inside the conductor completely welldefined, and independent on the potential distribution in the adjacent insulator. On the contrary, due to the continuity of the electrostatic potential at the border, its distribution in the insulator has to follow that inside the conductor. Let us discuss this conceptual issue on the following (apparently, trivial) example: dc current in a long wire with a constant cross-section area $A$. The reader certainly knows the answer:

$$
\begin{equation*}
I=\frac{V}{R}, \quad \text { where } R \equiv \frac{V}{I}=\frac{l}{\sigma A}, \tag{4.21}
\end{equation*}
$$

where $l$ is the wire length, and constant $R$ is called the resistance. ${ }^{9}$ However, let us get this result formally from our theoretical framework. For the ideal geometry shown in Fig. 6a, this is easy to do. Here the potential evidently has a linear 1D distribution

[^245]\[

$$
\begin{equation*}
\phi=\text { const }-\frac{x}{l} V \text {, } \tag{4.22}
\end{equation*}
$$

\]

both in the conductor and the surrounding free space, with both boundary conditions (16) and (17) satisfied at the conductor-insulator interfaces, and condition (20) satisfied at the conductor-electrode interfaces. As a result, the electric field is constant and has only one component $E_{x}=V / l$, so that inside the conductor

$$
j_{x}=\sigma E_{x}, \quad I=j_{x} A,
$$

giving us the well-known Eq. (21).
(a)

(b)

Fig. 4.6. (a) Trivial and (b) not-so-trivial problems of the field distribution at dc current flow. (For the latter case, schematically.)

However, what about the geometry shown in Fig. 6b? In this case the field distribution in the insulator is dramatically different, but according to boundary problem defined by Eqs. (14) and (20), inside the conductor the solution is exactly the same as it was in the former case. Now, the Laplace equation in the surrounding insulator has to be solved with the boundary values of the electrostatic potential, "dictated" by the distribution of the current (and hence potential) in the conductor.

Let us solve a problem in that this conduction hierarchy may be followed analytically to the very end. Consider an empty spherical cavity cut in a conductor with an initially uniform current flow with constant density $\mathbf{j}_{0}=\mathbf{n}_{z} j_{0}$ (Fig. 7a). Following the conduction hierarchy, we have to solve the boundary problem in the conducting part of the system, i.e. outside the sphere ( $r \geq R$ ), first. Since the problem is evidently axially-symmetric, we already know the general solution of the Laplace equation - see Eq. (2.172). Moreover, we know that in order to match the uniform field at $r \rightarrow \infty$, all coefficients $a_{l}$ but one ( $a_{1}=-E_{0}=-j_{0} / \sigma$ ) have to be zero, and that the boundary conditions at $r=R$ will give zero solutions for all coefficients $b_{l}$ but one ( $b_{1}$ ), so that

$$
\begin{equation*}
\phi=-\frac{j_{0}}{\sigma} r \cos \theta+\frac{b_{1}}{r^{2}} \cos \theta, \quad \text { for } r \geq R . \tag{4.24}
\end{equation*}
$$

In order to find coefficient $b_{1}$, we have to use the boundary condition (20) at $r=R$ :

$$
\begin{equation*}
\left.\frac{\partial \phi}{\partial r}\right|_{r=R}=\left(-\frac{j_{0}}{\sigma}-\frac{2 b_{1}}{R^{3}}\right) \cos \theta=0 . \tag{4.25}
\end{equation*}
$$

This gives $b_{1}=-j_{0} R^{3} / 2 \sigma$, so that, finally,

$$
\begin{equation*}
\phi(r, \theta)=-\frac{j_{0}}{\sigma}\left(r+\frac{R^{3}}{2 r^{2}}\right) \cos \theta \tag{4.26}
\end{equation*}
$$

(Note that this potential distribution corresponds to the dipole moment $\mathbf{p}=-\mathbf{E}_{0} R^{3} / 2$. It is easy to check that if the empty sphere was cut in a dielectric, the potential distribution outside the cavity would be similar, with $\mathbf{p}=-\mathbf{E}_{0} R^{3}\left(\varepsilon_{r}-1\right) /\left(\varepsilon_{r}+2\right)$. In the limit $\varepsilon_{r} \rightarrow \infty$, these two results coincide, despite the rather different type of the problem: in the dielectric case, there is no current at all.)

Fig. 4.7. Spherical cavity in a uniform conductor: (a) the problem's geometry, and (b) the equipotential surfaces, as given by Eq. (26) and (28).

Now, as the second step in the conductivity hierarchy, we may find the electrostatic potential distribution $\phi(r, \theta)$ in the insulator, in this particular case inside the cavity ( $r \leq R$ ). It should also satisfy the Laplace equation with the boundary conditions at $r=R$, "dictated" by distribution (26):

$$
\begin{equation*}
\phi(R, \theta)=-\frac{3}{2} \frac{j_{0}}{\sigma} R \cos \theta \tag{4.27}
\end{equation*}
$$

We could again solve this problem by the formal variable separation (keeping in the general solution (2.172) only the term proportional to $b_{1}$, that does not diverge at $r \rightarrow 0$ ), but if we notice that boundary condition (27) depends on just one Cartesian coordinate, $z=R \cos \theta$, the solution may be just guessed:

$$
\begin{equation*}
\phi(r, \theta)=-\frac{3}{2} \frac{j_{0}}{\sigma} z=-\frac{3}{2} \frac{j_{0}}{\sigma} r \cos \theta, \quad \text { at } r \leq R . \tag{4.28}
\end{equation*}
$$

It evidently satisfies the Laplace equation and the boundary condition (27), and corresponds to a constant vertical electric field equal to $3 j_{0} / 2 \sigma$ - see Fig. 6b.

The conductivity hierarchy says that static electrical fields and charges outside conductors (e.g., electric wires) do not affect currents flowing in the wires, and it is physically clear why. For example, if
a charge in vacuum is slowly moved close to a wire, it (in accordance with the linear superposition principle) will only induce an additional surface charge (see Chapter 2) that screens the external charge's field, without participating in (or disturbing) the current flow inside the conductor.

Besides the conceptual discussion, the two examples given above may be considered as a demonstration of the application of the first two methods described in Chapter 2 (the orthogonal coordinates (Fig. 5) and variable separation (Fig. 6)) to dc current distribution problems. Continuing this review of the methods we know, let us discuss the analog of the method of charge images. Let us consider the spherically-symmetric potential distribution of the electrostatic potential, similar to that given by Eq. (1.35):

$$
\begin{equation*}
\phi=\frac{c}{r} . \tag{4.29}
\end{equation*}
$$

As we know from Chapter 1, this is a particular solution of the 3D Laplace equation at all points but $r=$ 0 , and hence is a legitimate solution in a current-carrying conductor as well. In vacuum, this distribution would correspond to a point charge $q=4 \pi \varepsilon_{0} c$; but what about the conductor? Calculating the corresponding electric field and current density,

$$
\begin{equation*}
\mathbf{E}=-\nabla \phi=\frac{c}{r^{3}} \mathbf{r}, \quad \mathbf{j}=\sigma \mathbf{E}=\sigma \frac{c}{r^{3}} \mathbf{r}, \tag{4.30}
\end{equation*}
$$

we see that the total current flowing from the point in the origin through a sphere of an arbitrary radius $r$ does not depend on the radius:

$$
\begin{equation*}
I=A j=4 \pi r^{2} j=4 \pi \sigma c \tag{4.31}
\end{equation*}
$$

Plugging the resulting c into Eq. (29), we get

$$
\begin{equation*}
\phi=\frac{I}{4 \pi \sigma r} . \tag{4.32}
\end{equation*}
$$

Hence the Coulomb-type distribution of the electric potential in a conductor is possible (at least at some distance from the singular point $r=0$ ), and describes dc current $I$ flowing out of a small-size electrode - or into such a point, if coefficient $c$ is negative. Such current injection may be readily implemented experimentally; think for example about an insulated wire with a small bare end, inserted into a poorly conducting soil - an important method in geophysical research. ${ }^{10}$

Now let the injection point $\mathbf{r}$ ' be close to a plane interface between the conductor and an insulator (Fig. 8). In this case, besides the Laplace equation, we should satisfy the boundary condition,

$$
\begin{equation*}
j_{n}=\sigma E_{n}=-\sigma \frac{\partial \phi}{\partial n}=0 . \tag{4.33}
\end{equation*}
$$

It is clear that this can be done by replacing the insulator for a conductor with an additional current injection point, at the mirror image point $\mathbf{r}$ ". Note, however, that in contrast to the charge images, the sign of the imaginary current has to be similar, not opposite, to the initial one, so that the total electrostatic potential inside the conducting semi-space is

[^246]\[

$$
\begin{equation*}
\phi(\mathbf{r})=\frac{I}{4 \pi \sigma}\left(\frac{1}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|}+\frac{1}{\left|\mathbf{r}-\mathbf{r}^{\prime \prime}\right|}\right) \tag{4.34}
\end{equation*}
$$

\]

(Note that the image current's sign would be opposite if we discussed an interface between a conductor with a moderate conductivity and a perfect conductor ("electrode") whose potential should be virtually constant.)

Fig. 4.8. Method of images at dc conduction.

This result may be readily used, for example, to calculate the current density at the conductor's surface, as a function of distance $\rho$ from point 0 (the surface point closest to the current injection) - see Fig. 8. At the surface, Eq. (34) yields

$$
\begin{equation*}
\phi=\frac{I}{2 \pi \sigma} \frac{1}{\left(\rho^{2}+d^{2}\right)^{1 / 2}}, \tag{4.35}
\end{equation*}
$$

so that the current density is independent of $\sigma$.

$$
\begin{equation*}
j_{\rho}=\sigma E_{\rho}=-\sigma \frac{\partial \phi}{\partial \rho}=\frac{I}{2 \pi} \frac{\rho}{\left(\rho^{2}+d^{2}\right)^{3 / 2}} \tag{4.36}
\end{equation*}
$$

Deviations from Eqs. (35) and (36), which are valid for a uniform medium, may be used to find and characterize conductance inhomogeneities, say, those due to mineral deposits in the Earth crust. ${ }^{11}$

### 4.4. Dissipation power

Let me conclude this brief chapter with an ultra-short discussion of energy dissipation in conductors. In contrast to the electrostatics situations in insulators (vacuum or dielectrics), at dc conduction the electrostatic energy $U$ is "dissipated" (i.e. transferred to heat) at a certain rate $\mathcal{P} \equiv-$ $d U / d t$, called dissipation power. ${ }^{12}$ This rate may evaluated by calculating the power of electric field's work on a single moving charge:

[^247]\[

$$
\begin{equation*}
\mathcal{P}_{1}=\mathbf{F} \cdot \mathbf{v}=q \mathbf{E} \cdot \mathbf{v} . \tag{4.37}
\end{equation*}
$$

\]

After the summation over all charges, Eq. (37) gives us the dissipation power. If the charge density $n$ is uniform, multiplying by it both parts of this equation, and taking into account that $q n \mathbf{v}=\mathbf{j}$, for the power dissipated in a unit volume we get the Joule law

General Joule law

$$
\begin{equation*}
\mathfrak{p} \equiv \frac{\mathcal{P}}{V}=\frac{\mathcal{P}_{1} N}{V}=\mathcal{P}_{1} n=q \mathbf{E} \cdot \mathbf{v} n=\mathbf{E} \cdot \mathbf{j} . \tag{4.38}
\end{equation*}
$$

In the particular case of the Ohmic conductivity, this expression may be also rewritten in two other forms:

Joule law for Ohmic conductivity

$$
\begin{equation*}
p=\sigma E^{2}=\frac{j^{2}}{\sigma} \tag{4.39}
\end{equation*}
$$

At dc conduction, the energy is permanently replenished by a flow of power from the current source(s).
With our electrostatics background, it is straightforward (and hence left for reader's exercise) to prove that the dc current distribution in a uniform Ohmic conductor, at a fixed voltage applied at its borders, corresponds to the minimum of the total dissipation power

$$
\begin{equation*}
\mathcal{P}=\sigma \int_{V} E^{2} d^{3} r . \tag{4.40}
\end{equation*}
$$

### 4.5. Exercise problems

4.1. Find the resistance between two large conductors separated with a very thin, plane, insulating partition, with a circular hole of radius $R$ in it - see Fig. on the right.

Hint: You may like to use the degenerate ellipsoidal coordinates that had been used in Sec. 2.4 to find the self-capacitance of a round disk in vacuum.
4.2. Calculate the effective (average) conductivity $\sigma_{\mathrm{ef}}$ of a medium with many empty spherical cavities of radius $R$, carved at random points in a uniform Ohmic conductor (see Fig. on the right), in the limit of low density $n \ll R^{-3}$ of the spheres.

Hint: Try to use the analogy with a dipole media (Sec. 3.2).

4.3. In two separate experiments, a narrow gap, of irregular width, between two close metallic electrodes is filled with some material - in the first case, with a uniform linear insulator with an electric permittivity $\varepsilon$, and in the second case, with a uniform conducting material with an Ohmic conductivity $\sigma$. Neglecting the fringe effects, calculate the relation between the mutual capacitance $C$ between the electrodes (in the first case) and the dc resistance $R$ between them (in the second case).
4.4. Calculate the voltage drop $V$ across a uniform, wide resistive slab of thickness $t$, at distance $l$ from the points of injection/ejection of dc current $I$ that is passed across the slab - see Fig. on the right.

Hint: Try to use the dc current analog of the charge image method.

4.6. Calculate the distribution of dc current density in a thin, round, uniform resistive disk, if the current is inserted into a point at its rim, and picked up at the center.
4.7.* The simplest model of a vacuum diode consists of two plane, parallel metallic electrodes of area $A$, separated by a gap of thickness $d \ll A^{1 / 2}$ : a "cathode" which emits electrons to vacuum, and an "anode" which absorbs the electrons arriving at its surface. Calculate the dc $I-V$ curve of the diode, i.e. the stationary relation between current $I$ flowing between the electrodes and voltage $V$ applied between them, using the following simplifying assumptions:
(i) due to the effect of the negative space charge of the emitted electrons, current $I$ is much smaller than the emission ability of the cathode,
(ii) the initial velocity of the emitted electrons is negligible, and
(iii) the direct Coulomb interaction of electrons (besides the space charge effect) is negligible.
4.8.* Calculate the space-charge-limited current in a system with the same geometry, and using the same assumptions as in the previous problem, besides assuming now that the emitted charge carriers move not ballistically, but in accordance with the Ohm law, with the conductivity given by Eq. (4.13): $\sigma$ $=q^{2} \mu \pi$, with constant mobility $\mu$.

Hint: In order to get a realistic result, assume that the medium in which the carriers move ${ }^{13}$ has a certain dielectric constant $\varepsilon_{r}$.
4.9. Prove that the distribution of dc currents in a uniform Ohmic conductor, at fixed voltage applied at its boundaries, corresponds to the minimum of the total power dissipation ("Joule heat").

[^248]
## Chapter 5. Magnetism

Despite the fact that we are now starting to discuss a completely new type of electromagnetic interactions, its coverage (for the stationary case) will take just one chapter, because we will be able to recycle many ideas and methods of electrostatics, though with a twist or two.

### 5.1. Magnetic interaction of currents

DC currents in conductors usually leave them electroneutral, $\rho(\mathbf{r})=0$, with a very good precision, because any virtual misbalance of positive and negative charge density results in extremely strong Coulomb forces that restore their balance by an additional shift of free carriers. ${ }^{1}$ This is why let us start the discussion of magnetic interactions from the simplest case of two spatially-separated, current-carrying, electroneutral conductors (Fig. 1).

Fig. 5.1. Magnetic interaction of two currents.

According to the Coulomb law, there should be no force between them. However, several experiments carried out in the early $1820 \mathrm{~s}^{2}$ proved that such non-Coulomb forces do exist, and are the manifestation of another, magnetic interactions between the currents. In the contemporary used in this course, their results may be summarized with one formula, in SI units expressed as: ${ }^{3}$

$$
\begin{equation*}
\mathbf{F}=-\frac{\mu_{0}}{4 \pi} \int_{V} d^{3} r \int_{V^{\prime}} d^{3} r^{\prime}\left(\mathbf{j}(\mathbf{r}) \cdot \mathbf{j}^{\prime}\left(\mathbf{r}^{\prime}\right)\right) \frac{\mathbf{r}-\mathbf{r}^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{3}} . \tag{5.1}
\end{equation*}
$$

Here coefficient $\mu_{0} / 4 \pi$ (where $\mu_{0}$ is called either the magnetic constant or the free space permeability), by definition, equals exactly $10^{-7}$ SI units, thus relating the electric current (and hence electric charge) definition to that of force - see below.

Note that the Coulomb law (1.1), with the account of the linear superposition principle, may be presented in a very similar form:

[^249]\[

$$
\begin{equation*}
\mathbf{F}=\frac{1}{4 \pi \varepsilon_{0}} \int_{V} d^{3} r \int_{V^{\prime}} d^{3} r^{\prime} \rho(\mathbf{r}) \rho^{\prime}\left(\mathbf{r}^{\prime}\right) \frac{\mathbf{r}-\mathbf{r}^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{3}} . \tag{5.2}
\end{equation*}
$$

\]

Besides the different coefficient and sign, the "only" difference of Eq. (1) from Eq. (2) is the scalar product of current densities, evidently necessary because of the vector character of the current density. We will see that this difference will bring certain complications in applying the electrostatics approaches, discussed in the previous chapters, to magnetostatics.

Before going to their discussion, let us have one more glance at the coefficients in Eqs. (1) and (2). To compare them, let us consider two objects with uncompensated charge distributions $\rho(\mathbf{r})$ and $\rho^{\prime}(\mathbf{r})$, each moving parallel to each other as a whole certain velocities $\mathbf{v}$ and $\mathbf{v}^{\prime}$, as measured in an inertial "lab" frame. In this case, $\mathbf{j}(\mathbf{r})=\rho(\mathbf{r}) \mathbf{v}, \mathbf{j}(\mathbf{r}) \cdot \mathbf{j}{ }^{\prime}(\mathbf{r})=\rho(\mathbf{r}) \rho^{\prime}(\mathbf{r}) v v^{\prime}$, and the integrals in Eqs. (1) and (2) become functionally similar, and differ only by the factor

$$
\begin{equation*}
\frac{F_{\text {magnetic }}}{F_{\text {electric }}}=-\frac{\mu_{0} v v^{\prime}}{4 \pi} / \frac{1}{4 \pi \varepsilon_{0}}=-\frac{v v^{\prime}}{c^{2}} . \tag{5.3}
\end{equation*}
$$

(This expression hold in any consistent system of units.) We immediately see that magnetism is an essentially relativistic phenomenon, very weak in comparison with the electrostatic interaction at the human scale velocities, $v \ll c$, and may dominate only if the latter interaction vanishes - as it does in electroneutral systems. ${ }^{4}$

Also, Eq. (3) points at an interesting paradox. Consider two electron beams moving parallel to each other, with the same velocity $v$ with respect to a lab reference frame. Then, according to Eq. (3), the net force of their total (electric and magnetic) interaction is proportional to $\left(1-v^{2} / c^{2}\right)$, and tends to zero in the limit $v \rightarrow c$. However, in the reference frame moving together with electrons, they are not moving at all, i.e. $v=0$. Hence, from the point of view of such a moving observer, the electron beams should interact only electrostatically, with a repulsive force independent of velocity $v$. Historically, this had been one of several paradoxes that led to the development of the special relativity; its resolution will be discussed in Chapter 9, devoted to this theory.

Returning to Eq. (1), in some simple cases, the double integration in it may be carried out analytically. First of all, let us simplify this expression for the case of two thin, long conductors (wires) separated by a distance much larger than their thickness. In this case we may integrate the products $\mathbf{j} d^{3} r$ and $\mathbf{j}^{\prime} d^{3} r^{\prime}$ over wires' cross-sections first, neglecting the corresponding change of ( $\mathbf{r}-\mathbf{r}^{\prime}$ ). Since the integrals of the current density over the cross-sections of the wire are just the currents $I$ and $I^{\prime}$ in the wires, and cannot change along their lengths (correspondingly, $l$ and $l$ '), they may be taken out of the remaining integrals, reducing Eq. (1) to

$$
\begin{equation*}
\mathbf{F}=-\frac{\mu_{0} I I^{\prime}}{4 \pi} \oint_{l} \oint_{l^{\prime}}\left(d \mathbf{r} \cdot d \mathbf{r}^{\prime}\right) \frac{\mathbf{r}-\mathbf{r}^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{3}} \tag{5.4}
\end{equation*}
$$

[^250]As the simplest example, consider two straight, parallel wires (Fig. 2), separated by distance $d$, with length $l \gg \rho$. In this case, due to symmetry, the vector of magnetic interaction force has to:
(i) lay in the same plane as the currents, and
(ii) be perpendicular to the wires - see Fig. 2.

Hence we can limit our calculations to just one component of the force. Using the fact that with the coordinate choice shown in Fig. 2, $d \mathbf{r} \cdot d \mathbf{r}^{\prime}=d x d x$ ', we get

$$
\begin{equation*}
F=-\frac{\mu_{0} I I^{\prime}}{4 \pi} \int_{-\infty}^{+\infty} d x \int_{-\infty}^{+\infty} d x^{\prime} \frac{\sin \theta}{d^{2}+\left(x-x^{\prime}\right)^{2}}=-\frac{\mu_{0} I I^{\prime}}{4 \pi} \int_{-\infty}^{+\infty} d x \int_{-\infty}^{+\infty} d x^{\prime} \frac{d}{\left[d^{2}+\left(x-x^{\prime}\right)^{2}\right]^{3 / 2}} \tag{5.5}
\end{equation*}
$$

Introducing, instead of $x^{\prime}$, a new, dimensionless variable $\xi \equiv\left(x-x^{\prime}\right) / \rho$, we may reduce the internal integral to a table integral which we have already met in this course:

$$
\begin{equation*}
F=-\frac{\mu_{0} I I^{\prime}}{4 \pi d} \int_{-\infty}^{+\infty} d x \int_{-\infty}^{+\infty} \frac{d \xi}{\left(1+\xi^{2}\right)^{3 / 2}}=-\frac{\mu_{0} I I^{\prime}}{2 \pi d} \int_{-\infty}^{+\infty} d x . \tag{5.6}
\end{equation*}
$$

The integral over $x$ is formally diverging, but this means merely that the interaction force per unit length of the wires is constant:

$$
\begin{equation*}
\frac{F}{l}=-\frac{\mu_{0} I I^{\prime}}{2 \pi d} . \tag{5.7}
\end{equation*}
$$

Note that the force drops rather slowly (only as $1 / d$ ) as the distance $d$ between the wires is increased, and is attractive (rather than repulsive as in the Coulomb law) if the currents are of the same sign.

Fig. 5.2. Magnetic force between two straight parallel currents. a current

This is an important result, ${ }^{5}$ but again, the problems solvable so simply are few and far between, and it is intuitively clear that we would strongly benefit from the same approach as in electrostatics, i.e., from breaking Eq. (1) into a product of two factors via the introduction of a suitable field. Such decomposition may done as follows:

[^251]where vector $\mathbf{B}$ is called the magnetic field (in our particular case, induced by current $\mathbf{j}$ '): ${ }^{6}$
\[

$$
\begin{equation*}
\mathbf{B}(\mathbf{r}) \equiv \frac{\mu_{0}}{4 \pi} \int_{V^{\prime}} \mathbf{j}^{\prime}\left(\mathbf{r}^{\prime}\right) \times \frac{\mathbf{r}-\mathbf{r}^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{3}} d^{3} r^{\prime} \tag{5.9}
\end{equation*}
$$

\]

BiotSavart law

The last equation is called the Biot-Savart law, while F expressed by Eq. (8) is sometimes called the Lorentz force. ${ }^{7}$ However, more frequently the later term is reserved for the full force,

$$
\begin{equation*}
\mathbf{F}=q(\mathbf{E}+\mathbf{v} \times \mathbf{B}) \tag{5.10}
\end{equation*}
$$

exerted by electric and magnetic fields field on a point charge $q$, moving with velocity $\mathbf{v}$. (The equivalence of Eq. (8) and the magnetic part of Eq. (10) follows from the summation of all forces acting on $n$ particles in a unit volume, moving with the same velocity $\mathbf{v}$, so that $\mathbf{j}=q n \mathbf{v}$.)

Now we have to prove that the new formulation (8)-(9) is equivalent to Eq. (1). At the first glance, this seems unlikely. Indeed, first of all, Eqs. (8) and (9) involve vector products, while Eq. (1) is based on a scalar product. More profoundly, in contrast to Eq. (1), Eqs. (8) and (9) do not satisfy the $3^{\text {rd }}$ Newton's law, applied to elementary current components $\mathbf{j} d^{3} r$ and $\mathbf{j}^{\prime} d^{3} r^{\prime}$, if these vectors are not parallel to each other. Indeed, consider the situation shown in Fig. 3. Here vector $\mathbf{j}$ ' is perpendicular to vector ( $\mathbf{r}$ $-\mathbf{r}$ '), and hence, according to Eq. (9), produces a nonvanishing contribution $d \mathbf{B}$ ' to the magnetic field, directed (in Fig. 3) perpendicular to the plane of drawing, i.e. is perpendicular to vector $\mathbf{j}$. Hence, according to Eq. (8), this field provides a nonvanishing contribution to $\mathbf{F}$. On the other hand, if we calculate the reciprocal force $\mathbf{F}$ ' by swapping indices in Eqs. (8) and (9), the latter equation immediately shows that $d \mathbf{B}\left(\mathbf{r}^{\prime}\right) \propto \mathbf{j} \times\left(\mathbf{r}-\mathbf{r}^{\prime}\right)=0$, because the two operand vectors are parallel (Fig. 3). Hence, the current component $\mathbf{j}^{\prime} d^{3} \mathbf{r}^{\prime}$ does exert a force on its counterpart, while $\mathbf{j} d^{3} \mathbf{r}$ does not.

Fig. 5.3. Apparent violation of the $3^{\text {rd }}$
Newton law in magnetism.

Despite this apparent problem, let us still go ahead and plug Eq. (9) into Eq. (8):

$$
\begin{equation*}
\mathbf{F}=\frac{\mu_{0}}{4 \pi} \int_{V} d^{3} r \int_{V^{\prime}} d^{3} r^{\prime} \mathbf{j}(\mathbf{r}) \times\left(\mathbf{j}^{\prime}\left(\mathbf{r}^{\prime}\right) \times \frac{\mathbf{r}-\mathbf{r}^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{3}}\right) \tag{5.11}
\end{equation*}
$$

[^252]This double vector product may transformed into two scalar products, using the vector algebraic identity called the bac minus cab rule, $\mathbf{a} \times(\mathbf{b} \times \mathbf{c})=\mathbf{b}(\mathbf{a} \cdot \mathbf{c})-\mathbf{c}(\mathbf{a} \cdot \mathbf{b}) .{ }^{8}$ Applying this relation, with $\mathbf{a}=\mathbf{j}, \mathbf{b}=\mathbf{j}$, and $\mathbf{c}$ $=\mathbf{R} \equiv \mathbf{r}-\mathbf{r}^{\prime}$, to Eq. (11), we get

$$
\begin{equation*}
\mathbf{F}=\frac{\mu_{0}}{4 \pi} \int_{V^{\prime}} d^{3} r^{\prime} \mathbf{j}^{\prime}\left(\mathbf{r}^{\prime}\right)\left(\int_{V} d^{3} r \frac{\mathbf{j}(\mathbf{r}) \cdot \mathbf{R}}{R^{3}}\right)-\frac{\mu_{0}}{4 \pi} \int_{V} d^{3} r \int_{V^{\prime}} d^{3} r^{\prime} \mathbf{j}(\mathbf{r}) \cdot \mathbf{j}^{\prime}\left(\mathbf{r}^{\prime}\right) \frac{\mathbf{R}}{R^{3}} \tag{5.12}
\end{equation*}
$$

The second term in the right-hand part of this equation coincides with the right-hand part of Eq. (1), while the first term equals zero, because its the internal integral vanishes. Indeed, we may break volumes $V$ and $V^{\prime}$ into narrow current tubes, the stretched sub-volumes whose walls are not crossed by current lines $\left(j_{n}=0\right)$. As a result, the (infinitesimal) current in each tube, $d I=j d A=j d^{2} r$, is the same along its length, and, just as in a thin wire, $\mathbf{j} d^{2} r$ may be replaced with $d I d \mathbf{r}$. Because of this, each tube's contribution to the internal integral in the first term of Eq. (12) may be presented as

$$
\begin{equation*}
d I \oint_{l} d \mathbf{r} \cdot \frac{\mathbf{R}}{R^{3}}=-d I \oint_{l} d \mathbf{r} \cdot \nabla \frac{1}{R}=-d I \oint_{l} d r \frac{\partial}{\partial r} \frac{1}{R}, \tag{5.13}
\end{equation*}
$$

where operator $\nabla$ acts in the $\mathbf{r}$ space, and the integral is taken along tube's length $l$. Due to the current continuity, each loop should follow a closed contour, and an integral of a full differential of some scalar function (in our case, $1 / r_{12}$ ) along it equals zero.

So we have recovered Eq. (1). Returning for a minute to the paradox illustrated with Fig. 3, we may conclude that the apparent violation of the $3^{\text {rd }}$ Newton law was the artifact of our interpretation of Eqs. (8) and (9) as sums of independent elementary components. In reality, due to the dc current continuity expressed by Eq. (4.6), these components are not independent. For the whole currents, Eqs. (8)-(9) do obey the $3^{\text {rd }}$ law - as follows from their already proved equivalence to Eq. (1).

Thus we have been able to break the magnetic interaction into the two effects: the creation of the magnetic field $\mathbf{B}$ by one current (in our notation, $\mathbf{j}$ '), and the effect of this field on the other current ( $\mathbf{j}$ ). Now comes an additional experimental fact: other elementary components $\mathbf{j} d^{3} r$ ' of current $\mathbf{j}$ also contribute to the magnetic field (9) acting on component $\mathbf{j} d^{3} r$. ${ }^{9}$ This fact allows us to drop prime after $\mathbf{j}$ in Eq. (9), and rewrite Eqs. (8) and (9) as

$$
\begin{gather*}
\mathbf{B}(\mathbf{r})=\frac{\mu_{0}}{4 \pi} \int_{V^{\prime}} \mathbf{j}\left(\mathbf{r}^{\prime}\right) \times \frac{\mathbf{r}-\mathbf{r}^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{3}} d^{3} r^{\prime},  \tag{5.14}\\
\mathbf{F}=\int_{V} \mathbf{j}(\mathbf{r}) \times \mathbf{B}(\mathbf{r}) d^{3} r, \tag{5.15}
\end{gather*}
$$

Again, the field observation point $\mathbf{r}$ and the field source point $\mathbf{r}$ ' have to be clearly distinguished. We immediately see that these expressions are similar to, but still different from the corresponding relations of the electrostatics, namely Eq. (1.8),

[^253]\[

$$
\begin{equation*}
\mathbf{E}(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} \oint_{V^{\prime}} \rho\left(\mathbf{r}^{\prime}\right) \frac{\mathbf{r}-\mathbf{r}^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{\prime}} d^{3} r^{\prime}, \tag{5.16}
\end{equation*}
$$

\]

and the distributed version of Eq. (1.6):

$$
\begin{equation*}
\mathbf{F}=\oint_{V} \rho(\mathbf{r}) \mathbf{E}(\mathbf{r}) d^{3} r \tag{5.17}
\end{equation*}
$$

(Note that the sign difference has disappeared, at the cost of the replacement of scalar-by-vector multiplications in electrostatics with cross-products of vectors in magnetostatics.)

For the frequent case of a field of a thin wire of length l', Eq. (14) may be re-written as

$$
\begin{equation*}
\mathbf{B}(\mathbf{r})=\frac{\mu_{0} I}{4 \pi} \oint_{l^{\prime}} d \mathbf{r}^{\prime} \times \frac{\mathbf{r}-\mathbf{r}^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{3}} . \tag{5.18}
\end{equation*}
$$

Let us see how does the last formula work for the simplest case of a straight wire (Fig. 4a). The magnetic field contribution $d \mathbf{B}$ due to any small fragment $d \mathbf{r}$ ' of the wire's length is directed along the same line (perpendicular to both the wire and the perpendicular $d$ dropped from the observation point to the wire line), and its magnitude is

$$
\begin{equation*}
d B=\frac{\mu_{0} I}{4 \pi} \frac{d x^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{2}} \sin \theta=\frac{\mu_{0} I}{4 \pi} \frac{d x^{\prime}}{\left(d^{2}+x^{2}\right)} \frac{d}{\left(d^{2}+x^{2}\right)^{1 / 2}} . \tag{5.19}
\end{equation*}
$$

Summing up all such contributions, we get

$$
\begin{equation*}
B=\frac{\mu_{0} I \rho}{4 \pi} \int_{-\infty}^{\infty} \frac{d x}{\left(x^{2}+d^{2}\right)^{3 / 2}}=\frac{\mu_{0} I}{2 \pi d} . \tag{5.20}
\end{equation*}
$$

Fig. 5.4. Magnetic fields of: (a) a straight current, and (b) a current loop.
This is a simple but very important result. (Note that it is only valid for very long ( $l \gg d$ ), straight wires.) It is especially crucial to note the "vortex" character of the field: its lines go around the wire, forming round rings with the centers on the current line. This is in the sharp contrast to the electrostatic field lines that can only begin and end on electric charges and never form closed loops (otherwise the Coulomb force $q \mathbf{E}$ would not be conservative). In the magnetic case, the vortex field may be reconciled with the potential character of magnetic forces, which is evident from Eq. (1), due to the vector products in Eqs. (14)-(15).

Now we may use Eq. (15), or rather its thin-wire version

$$
\begin{equation*}
\mathbf{F}=I \oint_{l} d \mathbf{r} \times \mathbf{B}(\mathbf{r}), \tag{5.21}
\end{equation*}
$$

to apply Eq. (20) to the two-wire problem (Fig. 2). Since for the second wire vectors $\mathrm{d} \mathbf{r}$ and $\mathbf{B}$ are perpendicular to each other, we immediately arrive at our previous result (7).

The next important application of the Biot-Savart law (14) is the magnetic field at the axis of a circular current loop (Fig. 4b). Due to the problem symmetry, the net field $\mathbf{B}$ has to be directed along the axis, but each of its components $\mathrm{d} \mathbf{B}$ is tilted by angle $\theta=\tan ^{-1}(z / R)$ to this axis, so that its axial component

$$
\begin{equation*}
d B_{z}=d B \cos \theta=\frac{\mu_{0} I}{4 \pi} \frac{d r^{\prime}}{R^{2}+z^{2}} \frac{R}{\left(R^{2}+z^{2}\right)^{1 / 2}} \tag{5.22}
\end{equation*}
$$

Since the denominator of this expression remains the same for all wire components $d r$, in this case the integration is trivial $\left(\int d r^{\prime}=2 \pi R\right)$, giving finally

$$
\begin{equation*}
B=\frac{\mu_{0} I}{2} \frac{R^{2}}{\left(R^{2}+z^{2}\right)^{3 / 2}} . \tag{5.23}
\end{equation*}
$$

Note that the magnetic field in the loop's center (i.e., for $z=0$ ),

$$
\begin{equation*}
B=\frac{\mu_{0} I}{2 R} \tag{5.24}
\end{equation*}
$$

is $\pi$ times higher than that due to a similar current in a straight wire, at distance $d=R$ from it. This increase it readily understandable, since all elementary components of the loop are at the same distance $R$ from the observation point, while in the case of a straight wire, all its point but one are separated from the observation point by a distance larger than $d$.

Another notable fact is that at large distances $\left(z^{2} \gg R^{2}\right)$, field (23) is proportional to $z^{-3}$ :

$$
\begin{equation*}
B \approx \frac{\mu_{0} I}{2} \frac{R^{2}}{|z|^{3}}=\frac{\mu_{0}}{4 \pi} \frac{2 m}{|z|^{3}} \tag{5.25}
\end{equation*}
$$

just like the electric field of a dipole (along its direction), with the replacement of the electric dipole moment magnitude $p$ with $m=I A$, where $A=\pi R^{2}$ is the loop area. This is the best example of a magnetic dipole, with dipole moment $m$ - the notions to be discussed in more detail in Sec. 5 below.

### 5.2. Vector-potential and the Ampère law

The reader can see that the calculations of the magnetic field using Eq. (14) or (18) are still cumbersome even for the very simple systems we have examined. As we saw in Chapter 1, similar calculations in electrostatics, at least for several important systems of high symmetry, could be substantially simplified using the Gauss law (1.16). A similar relation exists in magnetostatics as well, but has a different form, due to the vortex character of the magnetic field. To derive it, let us notice that in an analogy with the scalar case, the vector product under integral (14) may be transformed as

$$
\begin{equation*}
\frac{j\left(\mathbf{r}^{\prime}\right) \times\left(\mathbf{r}-\mathbf{r}^{\prime}\right)}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{3}}=\nabla \times \frac{\mathbf{j}\left(\mathbf{r}^{\prime}\right)}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{\prime}}, \tag{5.26}
\end{equation*}
$$

where operator $\nabla$ acts in the $\mathbf{r}$ space. (This equality may be really verified by its Cartesian components, noticing that the current density is a function of $\mathbf{r}^{\prime}$ and hence its components are independent of $\mathbf{r}$.) Plugging Eq. (26) into Eq. (14), and moving operator $\nabla$ out of the integral over $\mathbf{r}$ ', we see that the magnetic field may be presented as the curl of another vector field: ${ }^{10}$

$$
\begin{equation*}
\mathbf{B}(\mathbf{r})=\nabla \times \mathbf{A}(\mathbf{r}), \tag{5.27}
\end{equation*}
$$

namely the so-called vector-potential:

$$
\begin{equation*}
\mathbf{A}(\mathbf{r}) \equiv \frac{\mu_{0}}{4 \pi} \int_{V^{\prime}} \frac{\mathbf{j}\left(\mathbf{r}^{\prime}\right)}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} d^{3} r^{\prime} \tag{5.28}
\end{equation*}
$$

Please note a wonderful analogy between Eqs. (27)-(28) and, respectively, Eqs. (1.33) and (1.38). This analogy implies that vector-potential A plays, for the magnetic field, essentially the same role as the scalar potential $\phi$ plays for the electric field (hence the name "potential"), with due respect to the vortex character of $\mathbf{A}$. I will discuss this notion in detail below.

Now let us see what equations we may get for the spatial derivatives of the magnetic field. First, vector algebra says that the divergence of any curl is zero. ${ }^{11}$ In application to Eq. (27), this means that

$$
\begin{equation*}
\nabla \cdot \mathbf{B}=0 . \tag{5.29}
\end{equation*}
$$

Comparing this equation with Eq. (1.27), we see that Eq. (29) may be interpreted as the absence of a magnetic analog of an electric charge on which magnetic field lines could originate or end. Numerous searches for such hypothetical magnetic charges, called magnetic monopoles, using very sensitive and sophisticated experimental setups, have never given a convincing evidence of their existence in Nature.

Proceeding to the alternative, vector derivative of the magnetic field (i.e., its curl), and using Eq. (28), we get

$$
\begin{equation*}
\nabla \times \mathbf{B}(\mathbf{r})=\frac{\mu_{0}}{4 \pi} \nabla \times\left(\nabla \times \int_{V^{\prime}} \frac{\mathbf{j}\left(\mathbf{r}^{\prime}\right)}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} d^{3} r^{\prime}\right) \tag{5.30}
\end{equation*}
$$

This expression may be simplified by using the following general vector identity: ${ }^{12}$

$$
\begin{equation*}
\nabla \times(\nabla \times \mathbf{c})=\nabla(\nabla \cdot \mathbf{c})-\nabla^{2} \mathbf{c} \tag{5.31}
\end{equation*}
$$

applied to vector $\mathbf{c}(\mathbf{r})=\mathbf{j}\left(\mathbf{r}^{\prime}\right) /\left|\mathbf{r}-\mathbf{r}^{\prime}\right|$ :

$$
\begin{equation*}
\nabla \times \mathbf{B}=\frac{\mu_{0}}{4 \pi} \nabla \int_{V^{\prime}} \mathbf{j}\left(\mathbf{r}^{\prime}\right) \cdot \nabla \frac{1}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} d^{3} r^{\prime}-\frac{\mu_{0}}{4 \pi} \int_{V^{\prime}} \mathbf{j}\left(\mathbf{r}^{\prime}\right) \nabla^{2} \frac{1}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} d^{3} r^{\prime} \tag{5.32}
\end{equation*}
$$

As was already discussed during our study of electrostatics,

[^254]\[

$$
\begin{equation*}
\nabla^{2} \frac{1}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|}=-4 \pi \delta\left(\mathbf{r}-\mathbf{r}^{\prime}\right) \tag{5.33}
\end{equation*}
$$

\]

so that the last term of Eq. (32) is just $\mu_{0} \mathbf{j}(\mathbf{r})$. On the other hand, inside the first integral we can replace $\nabla$ with ( $-\nabla^{\prime}$ ), where prime means differentiation in the space of radius-vector $\mathbf{r}^{\prime}$. Integrating that term by parts, we get

$$
\begin{equation*}
\nabla \times \mathbf{B}=-\frac{\mu_{0}}{4 \pi} \nabla \oint_{S^{\prime}} j_{n}\left(\mathbf{r}^{\prime}\right) \frac{1}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} d^{2} r^{\prime}+\nabla \int_{V^{\prime}} \frac{\nabla^{\prime} \cdot \mathbf{j}\left(\mathbf{r}^{\prime}\right)}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} d^{3} r^{\prime}+\mu_{0} \mathbf{j}(\mathbf{r}) . \tag{5.34}
\end{equation*}
$$

Applying this equation to the volume $V^{\prime}$ limited by a surface $S^{\prime}$ sufficiently distant from the field concentration (or with no current crossing it), we may neglect the first term in the right-hand part of Eq. (34), while the second term always equals zero in statics, due to the dc charge continuity - see Eq. (4.6). As a result, we arrive at a very simple differential equation ${ }^{13}$

$$
\begin{equation*}
\nabla \times \mathbf{B}=\mu_{0} \mathbf{j} . \tag{5.35}
\end{equation*}
$$

This is (the dc form of) the inhomogeneous Maxwell equation, which in magnetostatics plays the role similar to the Poisson equation (1.27) in electrostatics. Let me display, for the first time in this course, this fundamental system of equations (at this stage, for statics only), and give the reader a minute to stare at their beautiful symmetry - that has inspired so much of the $20^{\text {th }}$ century physics:

Static Maxwell equations

$$
\begin{array}{ll}
\nabla \times \mathbf{E}=0, & \nabla \times \mathbf{B}=\mu_{0} \mathbf{j}, \\
\nabla \cdot \mathbf{E}=\frac{\rho}{\varepsilon_{0}}, & \nabla \cdot \mathbf{B}=0 . \tag{5.36}
\end{array}
$$

Their only asymmetry, two zeros in the right hand parts (for the magnetic field's divergence and electric field's curl), is due to the absence in Nature of, respectively, the magnetic monopoles and their currents. I will discuss these equations in more detail in Sec. 6.7, after the equations for field curls have been generalized to their full (time-dependent) versions.

Returning now to a more mundane but important task of calculating magnetic field induced by simple current configurations, we can benefit from an integral form of Eq. (35). For that, let us integrate this equation over an arbitrary surface $S$ limited by a closed contour $C$, applying to it the Stokes theorem. ${ }^{14}$ The resulting expression,

$$
\begin{equation*}
\oint_{C} \mathbf{B} \cdot d \mathbf{r}=\mu_{0} \oint_{S} j_{n} d^{2} r \equiv \mu_{0} I \tag{5.37}
\end{equation*}
$$

where $I$ is the net electric current crossing surface $S$, is called the Ampère law.
As the first example of its application, let us return to a current in a straight wire (Fig. 4a). With the Ampère law in our arsenal, we can readily pursue an even more ambitious goal - calculate the magnetic field both outside and inside of a wire of arbitrary radius $R$, with an arbitrary (albeit axiallysymmetric) current distribution $j(\rho)$ - see Fig. 5. Selecting two contours $C$ in the form of rings of some

[^255]radius $\rho$ in the plane perpendicular to the wire axis $z$, we have $\mathbf{B} \cdot d \mathbf{r}=B \rho(d \varphi)$, these $\varphi$ is the azimuthal angle, so that the Ampère law (37) yields:
\[

2 \pi \rho B=\mu_{0} \times $$
\begin{cases}2 \pi \int_{0}^{\rho} j\left(\rho^{\prime}\right) \rho^{\prime} d \rho^{\prime}, & \text { for } \rho \leq R  \tag{5.38}\\ 2 \pi \int_{0}^{R} j\left(\rho^{\prime}\right) \rho^{\prime} d \rho^{\prime} \equiv I, & \text { for } \rho \geq R\end{cases}
$$
\]

Thus we have not only recovered our previous result (20), with the notation replacement $d \rightarrow \rho$, in a much simpler way, but could also find the magnetic field distribution inside the wire. (In the most common case when the wire conductivity $\sigma$ is constant, and hence the current is uniformly distributed along its cross-section, $j(\rho)=$ const, the first of Eqs. (38) immediately yields $B \propto \rho$ for $\rho \leq R$ ).

Fig. 5.5. The simplest application of the Ampère law: dc current in a straight wire.

Another important example is a straight, long solenoid (Fig. 6a), with dense winding: $n^{2} A \gg 1$, where $n$ is the number of wire turns per unit length and $A$ is the area of solenoid's cross-section - not necessarily circular.

(a)
(b)

Fig. 5.6. Magnetic field of (a) straight and (b) toroidal solenoids.

From the symmetry of this problem, the longitudinal (in Fig. 6a, vertical) component $B_{z}$ of the magnetic field may only depend on the horizontal position $\rho$ of the observation point. First taking a plane Ampère contour $C_{1}$, with both long sides outside the solenoid, we get $B_{z}\left(\rho_{2}\right)-B_{z}\left(\rho_{1}\right)=0$, because the total current piercing the contour equals zero. This is only possible if $B_{z}=0$ at any $\rho$ outside of the
(infinitely long!) solenoid. ${ }^{15}$ With this result on hand, from contour $C_{2}$ we get the following relation for the only (z-) component of the internal field:

$$
\begin{equation*}
B l=\mu_{0} N I \tag{5.39}
\end{equation*}
$$

where $N$ is the number of wire turns passing through the contour of length $l$. This means that regardless of the exact position internal side of the contour, the result is the same:

$$
\begin{equation*}
B=\mu_{0} \frac{N}{l} I=\mu_{0} n I . \tag{5.40}
\end{equation*}
$$

Thus, the field inside an infinitely long solenoid is uniform; in this sense, a long solenoid is a magnetic analog of a wide plane capacitor.

As should be clear from its derivation, the obtained result, especially that the field outside of the solenoid equals zero, is conditional on the solenoid length being very large in comparison with its lateral size. (From Eq. (25), we may predict that for a solenoid of a finite length $l$, the external field is only a factor of $\sim A / l^{2}$ lower than the internal one.) Much better suppression of this external ("fringe") field may be obtained using the toroidal solenoid (Fig. 6b). The application of Ampère law to this geometry shows that, in the limit of dense winding ( $N \gg 1$ ), there is no fringe field at all - for any relation between two radii of the thorus, while inside the solenoid, and distance $\rho$ from the center,

$$
\begin{equation*}
B=\frac{\mu_{0} N I}{2 \pi \rho} . \tag{5.41}
\end{equation*}
$$

We see that a possible drawback of this system for practical applications is that internal field depends on $\rho$, i.e. is not quite uniform; however, if the thorus is thin, this problem is minor.

How should we solve the problems of magnetostatics for systems whose low symmetry does not allow getting easy results from the Ampère law? (The examples are of course too numerous to list; for example, we cannot use this approach even to reproduce Eq. (23) for a round current loop.) From the deep analogy with electrostatics, we may expect that in this case we could recover the field from the solution of a certain partial boundary problem for the field's potential, in this case the vector-potential A defined by Eq. (28). However, despite the similarity of this formula and Eq. (1.38) for $\phi$, that was emphasized above, there are two additional issues we should tackle in the magnetic case.

First, finding vector-potential distribution means determining three scalar functions (say, $A_{x}, A_{y}$, and $A_{z}$ ), rather than one $(\phi)$. Second, generally the differential equation satisfied by $\mathbf{A}$ is more complex than the Poisson equation for $\phi$. Indeed, plugging Eq. (27) into Eq. (35), we get

$$
\begin{equation*}
\nabla \times(\nabla \times \mathbf{A})=\mu_{0} \mathbf{j} . \tag{5.42}
\end{equation*}
$$

If we wrote the left-hand part of this equation in (say, Cartesian) components, we would see that they are much more interwoven than in the Laplace operator, and hence much less convenient for using the orthogonal coordinate approach or the variable separation method. In order to remedy the situation, let us apply to Eq. (42) the now-familiar identity (31). The result is

[^256]\[

$$
\begin{equation*}
\nabla(\nabla \cdot \mathbf{A})-\nabla^{2} \mathbf{A}=\mu_{0} \mathbf{j} . \tag{5.43}
\end{equation*}
$$

\]

We see that if we could kill the first term in the left-hand part, for example if $\nabla \cdot \mathbf{A}=0$, the second term would give us a set of independent Poisson equations for each Cartesian component of vector $\mathbf{A}$.

In this context, let us discuss what discretion do we have in the potentials' choice. In electrostatics, we might add to any function $\phi^{\prime}$, that satisfies Eq. (1.33), not only an arbitrary constant, but also an arbitrary function of time, without affecting the electric field:

$$
\begin{equation*}
-\nabla\left[\phi^{\prime}+f(t)\right]=-\nabla \phi^{\prime}=\mathbf{E} . \tag{5.44}
\end{equation*}
$$

Similarly, using the fact that curl of the gradient of any scalar function equals zero, ${ }^{16}$ we may add to any function $\mathbf{A}^{\prime}$, that satisfies Eq. (27) for a given field $\mathbf{B}$, not only a constant, but even a gradient of an arbitrary function $\chi(\mathbf{r}, t)$, because

$$
\begin{equation*}
\nabla \times\left(\mathbf{A}^{\prime}+\nabla \chi\right)=\nabla \times \mathbf{A}^{\prime}+\nabla \times(\nabla \chi)=\nabla \times \mathbf{A}^{\prime}=\mathbf{B} . \tag{5.45}
\end{equation*}
$$

Such additions, keeping the actual (observable) fields intact, are called gauge transformations. ${ }^{17}$ Let us see what such a transformation does to $\nabla \cdot \mathbf{A}^{\prime}$ ':

$$
\begin{equation*}
\nabla \cdot\left(\mathbf{A}^{\prime}+\nabla \chi\right)=\nabla \cdot \mathbf{A}^{\prime}+\nabla^{2} \chi \tag{5.46}
\end{equation*}
$$

Hence we can always choose a function $\chi$ in such a way that the right-hand part of this relation, and hence the divergence of the transformed vector-potential, $\mathbf{A} \equiv \mathbf{A}^{\prime}+\nabla \chi$, would vanish at all points. In this case, Eq. (43) is reduced to the vector Poisson equation

$$
\begin{equation*}
\nabla^{2} \mathbf{A}=-\mu_{0} \mathbf{j} \tag{5.47}
\end{equation*}
$$

As we know from the electrostatics (please compare Eqs. (1.38) and (1.41)), the vector-potential defined by Eq. (28) does satisfy this equation. So, the so-called Coulomb gauge condition,

$$
\begin{equation*}
\nabla \cdot \mathbf{A}=0 \tag{5.48}
\end{equation*}
$$

reduces the set of the functions $\mathbf{A}(\mathbf{r})$ that satisfy Eq. (27) to the actual vector-potential (28). However, this condition still leaves some liberty in the vector-potential selection. In order to demonstrate that, and also to get a better feeling of vector-potential's distribution in space, let us calculate it for two important particular cases.

First, let us revisit the straight wire problem (Fig. 5). As Eq. (28) shows, in this case vector A has just one component (along the axis $z$ ). Moreover, due to the problem's axial symmetry, its magnitude may only depend on the distance from the axis: $\mathbf{A}=\mathbf{n}_{z} A(\rho)$. Hence, the gradient of $\mathbf{A}$ is directed across axis $z$, so that Eq. (48) is satisfied even for this vector, i.e. the Poisson equation (47) is satisfied even for the original vector $\mathbf{A}$. For our symmetry $(\partial / \partial \varphi=\partial / \partial z=0)$, the Laplace operator, written in cylindrical coordinates, has just one term, ${ }^{18}$ reducing Eq. (47) to

$$
\begin{equation*}
\frac{1}{\rho} \frac{d}{d \rho}\left(\rho \frac{d A}{d \rho}\right)=-\mu_{0} j(\rho) \tag{5.49}
\end{equation*}
$$

[^257]Multiplying both parts of this equation by $\rho$ and integrating them over the coordinate once, we get

$$
\begin{equation*}
\rho \frac{d A}{d \rho}=-\mu_{0} \int_{0}^{\rho} j\left(\rho^{\prime}\right) \rho^{\prime} d \rho^{\prime}+\text { const } \tag{5.50}
\end{equation*}
$$

Since in the cylindrical coordinates, for our symmetry, ${ }^{19} B=-d A / d \rho$, Eq. (50) is nothing else than our old result (38) for the magnetic field. ${ }^{20}$ However, let us continue the integration, at least for the region outside the wire, where the function $A(\rho)$ depends only on the full current $I$ rather than on the current distribution inside the wire. Dividing both parts of Eq. (50) by $\rho$, and integrating them over that coordinate again, we get

$$
\begin{equation*}
A(\rho)=-\frac{\mu_{0} I}{2 \pi} \ln \rho+\text { const, where } I=2 \pi \int_{0}^{R} j(\rho) \rho d \rho . \tag{5.51}
\end{equation*}
$$

As a reminder, we had the similar logarithmic behavior for the electrostatic potential outside a uniformly charged straight line. This is natural, because the Poisson equations for both cases are similar.

Now let us find the vector-potential for the long solenoid (Fig. 6a), with its uniform magnetic field. Since Eq. (28) prescribes vector $\mathbf{A}$ to follow the direction of the current, we can start with looking for it in the form $\mathbf{A}=\mathbf{n}_{\varphi} A(\rho)$. (This is especially natural if the solenoid's cross-section is circular.) With this orientation of $\mathbf{A}$, the same general expression for the curl operator in cylindrical coordinates yields $\nabla \times \mathbf{A}=\mathbf{n}_{z}(1 / \rho) d(\rho A) / d \rho$. According to the definition (27) of $\mathbf{A}$, this expression should be equal to $\mathbf{B}$, in our case equal to $\mathbf{n}_{z} B$, with constant $B$ - see Eq. (40). Integrating this equality, and selecting such integration constant so that $A(0)$ is finite, we get

$$
\begin{equation*}
A(\rho)=\frac{B \rho}{2} . \tag{5.52}
\end{equation*}
$$

Plugging this result into the general expression for the Laplace operator in the cylindrical coordinates, ${ }^{21}$ we see that the Poisson equation (47) with $\mathbf{j}=0$ (i.e. the Laplace equation), is satisfied again - which is natural since for this distribution, $\nabla \cdot \mathbf{A}=0$. However, Eq. (52) is not the unique (or even the simplest) solution of the problem. Indeed, using the well-known expression for the curl operator in Cartesian coordinates, ${ }^{22}$ it is straightforward to check that either function $\mathbf{A}^{\prime}=\mathbf{n}_{y} B x$, or function $\mathbf{A}^{\prime \prime}=-\mathbf{n}_{\mathrm{x}} B y$, or any of their weighed sums, for example $\mathbf{A}^{\prime \prime \prime}=\left(\mathbf{A}^{\prime}+\mathbf{A}^{\prime \prime}\right) / 2=B\left(-\mathbf{n}_{\mathrm{x}} y+\mathbf{n}_{y} x\right) / 2$, also give the same magnetic field, and also evidently satisfy the Laplace equation. If such solutions do not look very natural due to their anisotropy in the $[x, y]$ plane, please consider the fact that they represent the uniform magnetic field regardless of its source (e.g., of the shape of long solenoid's crosssection). Such choices of vector-potential may be very convenient for some problems, for example for the analysis of the 2 D motion of a charged quantum particle in the perpendicular magnetic field, giving the famous Landau energy levels. ${ }^{23}$

[^258]
### 5.3. Magnetic energy, flux, and inductance

Considering currents flowing in a system as generalized coordinates, magnetic forces (1) between them are their unique functions, and in this sense the magnetic interaction energy $U$ may be considered a potential energy of the system. The apparent (but deceptive) way to guess the energy is to use the analogy between Eq. (1) and its electrostatic analog, Eq. (2). As we know from Chapter 1, if these densities describe the distribution of the same charge, i.e. if $\rho^{\prime}(\mathbf{r})=\rho(\mathbf{r})$, then the self-interaction of its elementary components correspond to the potential energy expressed by Eq. (1.61):

$$
\begin{equation*}
U=\frac{1}{4 \pi \varepsilon_{0}} \frac{1}{2} \int d^{3} r \int d^{3} r^{\prime} \frac{\rho(\mathbf{r}) \rho\left(\mathbf{r}^{\prime}\right)}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} \tag{5.53}
\end{equation*}
$$

Using the analogy, for the magnetic interaction between elementary components of the same current, with density $\mathbf{j}(\mathbf{r})=\mathbf{j}$ ' $(\mathbf{r})$, we could guess that

$$
\begin{equation*}
U=\frac{\mu_{0}}{4 \pi} \frac{1}{2} \int d^{3} r \int d^{3} r^{\prime} \frac{\mathbf{j}(\mathbf{r}) \cdot \mathbf{j}\left(\mathbf{r}^{\prime}\right)}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|}, \tag{5.53}
\end{equation*}
$$

while for independent currents the coefficient $1 / 2$ should be removed. Now let me confess that this is a wrong way to get this correct result. Indeed, the sign in Eq. (1) is opposite to that in Eq. (2), so that following this argumentation we would get Eq. (53) with the minus sign. The reason of this paradox is fundamental: fixing electric charges does not require external interference (work), while the maintenance of currents generally does. Strictly speaking, a derivation of Eq. (53) required additional experimental fact, the Faraday induction law. However, I would like to defer its discussion until the beginning of the next chapter, and for now ask the reader to believe me that the sign in Eq. (53) is correct.

Due to the importance of this relation, let us rewrite it in several other forms, beneficial for different applications. First of all, just as in electrostatics, Eq. (54) may be recast into a potential-based form. Indeed, using definition (28) of the vector-potential $\mathbf{A}(\mathbf{r})$, Eq. (54) becomes ${ }^{24}$

$$
\begin{equation*}
U=\frac{1}{2} \int \mathbf{j}(\mathbf{r}) \cdot \mathbf{A}(\mathbf{r}) d^{3} r . \tag{5.55}
\end{equation*}
$$

This formula, that is a clear magnetic analog of Eq. (1.62) of electrostatics, is very popular among theoretical physicists, because it is very handy for the field theory manipulations. However, for many calculations it is more convenient to have a direct expression of energy via the magnetic field. Again, this may be done very similarly to what we have done in Sec. 1.3 for electrostatics, i.e. plugging into Eq. (55) the current density expressed from Eq. (35) to transform it as ${ }^{25}$

$$
\begin{equation*}
U=\frac{1}{2} \int \mathbf{j} \cdot \mathbf{A} d^{3} r=\frac{1}{2 \mu_{0}} \int \mathbf{A} \cdot(\nabla \times \mathbf{B}) d^{3} r=\frac{1}{2 \mu_{0}} \int \mathbf{B} \cdot(\nabla \times \mathbf{A}) d^{3} r-\frac{1}{2 \mu_{0}} \int \nabla \cdot(\mathbf{A} \times \mathbf{B}) d^{3} r . \tag{5.56}
\end{equation*}
$$

Now using the divergence theorem, the second integral may be transformed into a surface integral of product $(\mathbf{A} \times \mathbf{B})_{n}$. Equations (27)-(28) show that if the current distribution $\mathbf{j}(\mathbf{r})$ is localized, this product drops with distance $r$ faster than $1 / r^{2}$, so that if the integration volume is large enough, the surface

[^259]integral is negligible. In the remaining first integral, we may use Eq. (27) to recast $\nabla \times \mathbf{A}$ into the magnetic field. As a result, we get a very simple and fundamental formula.
\[

$$
\begin{equation*}
U=\frac{1}{2 \mu_{0}} \int B^{2} d^{3} r . \tag{5.57a}
\end{equation*}
$$

\]

Just as with the electric field, this expression may be interpreted as a volume integral of the magnetic energy density $u$ :

Magnetic field energy

$$
\begin{equation*}
U=\int u(\mathbf{r}) d^{3} r, \quad \text { with } u(\mathbf{r}) \equiv \frac{1}{2 \mu_{0}} \mathbf{B}^{2}(\mathbf{r}), \tag{5.57b}
\end{equation*}
$$

clearly similar to Eq. (1.67). ${ }^{26}$ Again, the conceptual choice between the spatial localization of magnetic energy - either at the location of electric currents only, as implied by Eqs. (54) and (55), or in all regions where the magnetic field exists, as apparent from Eq. (57b), cannot be done within the framework of magnetostatics, and only electrodynamics gives the decisive preference for the latter choice.

For the practically important case of currents flowing in several thin wires, Eq. (54) may be first integrated over the cross-section of each wire, just as was done at the derivation of Eq. (4). Again, since the integral of the current density over $k^{\text {th }}$ wire's cross-section is just the current $I_{k}$ in the wire, and cannot change along its length, it may be taken from the remaining integrals, giving

$$
\begin{equation*}
U=\frac{\mu_{0}}{4 \pi} \frac{1}{2} \sum_{k, k^{\prime}} I_{k} I_{k^{\prime}} \oint_{l_{k}} \oint_{l_{k^{\prime}}} \frac{d \mathbf{r}_{k} \cdot d \mathbf{r}_{k^{\prime}}}{\left|\mathbf{r}_{k}-\mathbf{r}_{k^{\prime}}\right|}, \tag{5.58}
\end{equation*}
$$

where $l$ is the full length of the wire loop. Note that Eq. (58) is valid if currents $I_{k}$ are independent of each other, because the double sum counts each current pair twice, compensating coefficient $1 / 2$ in front of the sum. It is useful to decompose this relation as

Mutual inductance coefficients

$$
\begin{equation*}
U=\frac{1}{2} \sum_{k, k^{\prime}} I_{k} I_{k^{\prime}} L_{k k^{\prime}} \tag{5.59}
\end{equation*}
$$

$$
\begin{equation*}
L_{k k^{\prime}} \equiv \frac{\mu_{0}}{4 \pi} \oint_{l_{k}} \oint_{l_{k^{\prime}}} \frac{d \mathbf{r}_{k} \cdot d \mathbf{r}_{k^{\prime}}}{\left|\mathbf{r}_{k}-\mathbf{r}_{k^{\prime}}\right|} \tag{5.60}
\end{equation*}
$$

Coefficient $L_{k k^{\prime}}$ in the quadratic form (59), with $k \neq k^{\prime}$, is called the mutual inductance between current loops $k$ and $k$, while the diagonal coefficient $L_{k} \equiv L_{k k}$ is called the self-inductance (or just inductance) of $k^{\text {th }}$ loop. ${ }^{27}$ From the symmetry of Eq. (60) with respect to the index swap, $k \leftrightarrow k^{\prime}$, it evident that the matrix of coefficients $L_{k k}$, is symmetric: ${ }^{28}$

[^260]\[

$$
\begin{equation*}
L_{k k^{\prime}}=L_{k^{\prime} k}, \tag{5.61}
\end{equation*}
$$

\]

so that for the practically important case of two interacting currents $I_{1}$ and $I_{2}$, Eq. (59) reads

$$
\begin{equation*}
U=\frac{1}{2} L_{1} I_{1}^{2}+M I_{1} I_{2}+\frac{1}{2} L_{2} I_{2}^{2}, \tag{5.62}
\end{equation*}
$$

where $M \equiv L_{12}=L_{21}$ is the mutual inductance coefficient.
These formulas clearly show the importance of self- and mutual inductances, so I will demonstrate their calculation for at least a few basic geometries. Before doing that, however, let me recast Eq. (58) into one more form that may facilitate such calculations. Namely, let us notice that for the magnetic field induced by current $I_{k}$ in a thin wire, Eq. (28) is reduced to

$$
\begin{equation*}
\mathbf{A}_{k}(\mathbf{r})=\frac{\mu_{0}}{4 \pi} I_{k} \int_{l^{\prime}} \frac{d \mathbf{r}_{k}}{\left|\mathbf{r}-\mathbf{r}_{k}\right|} \tag{5.63}
\end{equation*}
$$

so that Eq. (58) may be rewritten as

$$
\begin{equation*}
U=\frac{1}{2} \sum_{k, k^{\prime}} I_{k} \oint_{l_{k}} \mathbf{A}_{k^{\prime}}\left(\mathbf{r}_{k}\right) \cdot d \mathbf{r}_{k^{\prime}} . \tag{5.64}
\end{equation*}
$$

But according to the same Stokes theorem that was used earlier in this chapter to derive the Ampère law, and Eq. (27), such integral is nothing more than the magnetic field flux (more frequently called just the magnetic flux) through a surface $S$ limited by the contour $l: 29$

$$
\begin{equation*}
\oint_{l} \mathbf{A}(\mathbf{r}) \cdot d \mathbf{r}=\int_{S}(\nabla \times A)_{n} d^{2} r=\int_{S} B_{n} d^{2} r \equiv \Phi . \tag{5.65}
\end{equation*}
$$

$$
\begin{equation*}
U=\frac{1}{2} \sum_{k, k^{\prime}} I_{k} \Phi_{k k^{\prime}} \tag{5.66}
\end{equation*}
$$

where $\Phi_{k k^{\prime}}$ is the flux of the field induced by $k^{\prime}$-th current through the loop of the $k$-th current. Comparing this expression with Eq. (59), we see that

$$
\begin{equation*}
\Phi_{k k^{\prime}} \equiv \int_{S_{k}}\left(\mathbf{B}_{k^{\prime}}\right)_{n} d^{2} r=L_{k k^{\prime}} I_{k^{\prime}}, \tag{5.67}
\end{equation*}
$$

This expression not only gives us one more means for calculating coefficients $L_{k k^{\prime}}$, but also shows their physical sense: the mutual inductance characterizes how much field (colloquially, "how many field lines") induced by current $I_{k^{\prime}}$ penetrate the loop of current $I_{k}$, and vice versa. Since due to the linear superposition principle, the total flux piercing $k$-th loop may be presented as

$$
\begin{equation*}
\Phi_{k} \equiv \sum_{k^{\prime}} \Phi_{k k^{\prime}}=\sum_{k^{\prime}} L_{k k^{\prime}} I_{k^{\prime}} . \tag{5.68}
\end{equation*}
$$

[^261]For example, for the system of two currents this expression is reduced to a clear analog of Eqs. (2.19):

$$
\begin{align*}
& \Phi_{1}=L_{1} I_{1}+M I_{2},  \tag{5.69}\\
& \Phi_{2}=M I_{1}+L_{2} I_{2} .
\end{align*}
$$

For the even simpler case of a single current,
$\Phi$ and $U$ of a
single current

$$
\begin{equation*}
\Phi=L I \tag{5.70}
\end{equation*}
$$

so that the magnetic energy of the current may be presented in several equivalent forms:

$$
\begin{equation*}
U=\frac{L}{2} I^{2}=\frac{1}{2} I \Phi=\frac{1}{2 L} \Phi^{2} \tag{5.71}
\end{equation*}
$$

These relations, similar to Eqs. (2.14)-(2.15) of electrostatics, show that the self-inductance $L$ of a current loop may be considered as a measure of system's magnetic energy at fixed current.

Now we are well equipped for the calculation of inductances, having three options. The first one is to use Eq. (60) directly. ${ }^{30}$ The second one is to calculate the magnetic field energy from Eq. (57) as the function of currents $I_{k}$ in the system, and then use Eq. (59) to find all coefficients $L_{k k^{\prime}}$. For example, for a system with just one current, Eq. (71) yields

$$
\begin{equation*}
L=\frac{U}{I^{2} / 2} . \tag{5.72}
\end{equation*}
$$

Finally, if the system consists of thin wires, so that the loop areas $S_{k}$ and hence fluxes $\Phi_{k k^{\prime}}$ are well defined, we may calculate them from Eq. (65), and then use Eq. (67) to find the inductances.

Actually, the first two options may have advantages over the third one even for such system of thin wires for whom the notion of magnetic flux is not quite clear. As an important example, let us find inductance of a long solenoid - see Fig. 6a. We have already calculated the magnetic field inside it - see Eq. (40) - so that, due to the field uniformity, the magnetic flux piercing each wire turn is just

$$
\begin{equation*}
\Phi_{1}=B A=\mu_{0} n I A \tag{5.73}
\end{equation*}
$$

where $A$ is the area of solenoid's cross-section - for example $\pi R^{2}$ for a round solenoid, though Eq. (40) is more general. Comparing Eqs. (73) and (67), one might wrongly conclude that $L=\Phi_{1} / I=\mu_{0} n A$ [WRONG!], i.e. that the solenoid's inductance is independent on its length. Actually, the magnetic flux $\Phi_{1}$ pierces each wire turn, so that the total flux through the whole current loop, consisting of $N$ turns, is

$$
\begin{equation*}
\Phi=N \Phi_{1}=\mu_{0} n^{2} l A I, \tag{5.74}
\end{equation*}
$$

and the correct expression for solenoid's inductance is

$$
\begin{equation*}
L=\frac{\Phi}{I}=\mu_{0} n^{2} l A \tag{5.75}
\end{equation*}
$$

i.e. the inductance per unit length is constant: $L / l=\mu_{0} n^{2} A$. Since this reasoning may seem a bit flimsy, it is prudent to verify it by using Eq. (72) to calculate the full magnetic energy inside the solenoid (neglecting minor fringe and external field contributions):

[^262]\[

$$
\begin{equation*}
U=\frac{1}{2 \mu_{0}} B^{2} A l=\frac{1}{2 \mu_{0}}\left(\mu_{0} n I\right)^{2} A l=\mu_{0} n^{2} l A \frac{I^{2}}{2} . \tag{5.76}
\end{equation*}
$$

\]

Plugging this result into Eq. (72) immediately confirms result (75).
The use of the first two options for inductance calculation becomes inevitable for continuously distributed currents. As an example, let us calculate self-inductance $L$ of a long coaxial cable with the cross-section shown in the Fig. 7. ${ }^{31}$

Fig. 5.7. Cross-section of a coaxial cable.

Let us assume that the current is uniformly distributed over the cross-sections of both conductors. (As we know from the previous chapter, such distribution indeed takes place if both the internal and external conductors are made of a uniform resistive material.) First, we should calculate the radial distribution of the magnetic field (that of course has only one, azimuthal component, because of the axial symmetry of the problem). This distribution may be immediately found from the application of the Ampère law to circles of radii $\rho$ within four different ranges:

$$
2 \pi \rho B=\left.\mu_{0} I\right|_{\text {piercing the circle area }}=\mu_{0} I \times\left\{\begin{array}{cc}
\frac{\rho^{2}}{a^{2}}, & \text { for } \rho<a  \tag{5.77}\\
1, & \text { for } a<\rho<b, \\
\frac{c^{2}-\rho^{2}}{c^{2}-b^{2}}, & \text { for } b<\rho<c \\
0, & \text { for } c<\rho
\end{array}\right.
$$

Now, an elementary integration yields the magnetic energy per unit length of the cable:

$$
\begin{align*}
\frac{U}{l} & =\frac{1}{2 \mu_{0}} \int B^{2} d^{2} r=\frac{\pi}{\mu_{0}} \int_{0}^{\infty} B^{2} \rho d \rho=\frac{\mu_{0} I^{2}}{4 \pi}\left[\int_{0}^{a}\left(\frac{\rho}{a^{2}}\right)^{2} \rho d \rho+\int_{a}^{b}\left(\frac{1}{\rho}\right)^{2} \rho d \rho+\int_{b}^{c}\left(\frac{c^{2}-\rho^{2}}{\rho\left(c^{2}-b^{2}\right)}\right)^{2} \rho d \rho\right]  \tag{5.78}\\
& =\frac{\mu_{0}}{2 \pi}\left[\ln \frac{b}{a}+\frac{c^{2}}{c^{2}-b^{2}}\left(\frac{c^{2}}{c^{2}-b^{2}} \ln \frac{c}{b}-\frac{1}{2}\right)\right] \frac{I^{2}}{2}
\end{align*}
$$

From here, and Eq. (72), we get the final answer:

$$
\begin{equation*}
\frac{L}{l}=\frac{\mu_{0}}{2 \pi}\left[\ln \frac{b}{a}+\frac{c^{2}}{c^{2}-b^{2}}\left(\frac{c^{2}}{c^{2}-b^{2}} \ln \frac{c}{b}-\frac{1}{2}\right)\right] . \tag{5.79}
\end{equation*}
$$

[^263]Note that for the particular case of a thin outer conductor, $c-b \ll b$, this expression reduces to

$$
\begin{equation*}
\frac{L}{l} \approx \frac{\mu_{0}}{2 \pi}\left(\ln \frac{b}{a}+\frac{1}{4}\right), \tag{5.80}
\end{equation*}
$$

where the first term in the parentheses may be traced back to the contribution of the magnetic field energy in the free space between the conductors. This distinction is important for some applications, because in superconductor cables, as well as resistive-metal cables as high frequencies (to be discussed in the next chapter), the field does not penetrate the conductor bulk, so that Eq. (80) is valid without the last term, $1 / 4$, in the parentheses, which is due to the magnetic field energy inside the wire.

As the last example, let us calculate the mutual inductance between a long straight wire and a round wire loop adjacent to it (Fig. 8), neglecting the thickness of both wires.

Fig. 5.8. Study case for the mutual inductance calculation.

Here there is no problem with using the last formalism, based on the magnetic flux calculation. Indeed, in the Cartesian coordinates shown in Fig. 8, Eq. (20) reads $B_{1}=\mu_{0} I_{1} / 2 \pi y$, giving the following magnetic flux through the round wire loop:

$$
\begin{equation*}
\Phi_{21}=\frac{\mu_{0} I_{1}}{2 \pi} \int_{-R}^{+R} d x \int_{R-\left(R^{2}-x^{2}\right)^{1 / 2}}^{R+\left(R^{2}-x^{2}\right)^{1 / 2}} d y \frac{1}{y}=\frac{\mu_{0} I_{1}}{\pi} \int_{0}^{R} \ln \frac{R+\left(R^{2}-x^{2}\right)^{1 / 2}}{R-\left(R^{2}-x^{2}\right)^{1 / 2}} d x=\frac{\mu_{0} I_{1} R}{\pi} \int_{0}^{1} \ln \frac{1+\left(1-\xi^{2}\right)^{1 / 2}}{1+\left(1-\xi^{2}\right)^{1 / 2}} d \xi \tag{5.81}
\end{equation*}
$$

This is a table integral equal to $\pi,{ }^{32}$ so that $\Phi_{21}=\mu_{0} I_{1} R$, and the final answer for the mutual inductance $M=L_{12}=L_{21}=\Phi_{21} / I_{1}$ is finite (and very simple):

$$
\begin{equation*}
M=\mu_{0} R, \tag{5.82}
\end{equation*}
$$

despite magnetic field's divergence at the lowest point of the loop $(y=0)$. Note that in contrast with the finite mutual inductance of this system, self-inductances of both wires are formally infinite in the thinwire limit - see, e.g., Eq. (80), that in the limit $b / a \gg 1$ describes a thin straight wire. However, since this divergence is very weak (logarithmic), it is quenched by any deviation from this perfect geometry. For example, a good estimate of the inductance of a wire of a large but finite length $l$ may be obtained from Eq. (81) via the replacement of $b$ with $l$ :

$$
\begin{equation*}
L \sim \frac{\mu_{0}}{2 \pi} l \ln \frac{l}{a} . \tag{5.83}
\end{equation*}
$$

[^264](Note, however, that the exact result depends on where from/to the current flows beyond that segment. ) A close estimate, with $l$ replaced with $2 \pi R$, and $b$ replaced with $R$, is valid for the self-inductance of the round loop. A more exact calculation of this inductance, which would be asymptotically correct in the limit $a \ll R$, is a very useful exercise, which is highly recommended to the reader. ${ }^{33}$

### 5.4. Magnetic dipole moment, and magnetic dipole media

The most natural way of description of magnetic media parallels that described in Chapter 3 for dielectrics, and is based on properties of magnetic dipoles. To introduce this notion quantitatively, let us consider, just as in Sec. 3.1, a spatially-localized system with current distribution $\mathbf{j}(\mathbf{r})$, whose magnetic field is measured at relatively large distances $r \gg r^{\prime}$ (Fig. 9).

Applying the truncated Taylor expansion (3.4) to definition (28) of the vector potential, we get

$$
\begin{equation*}
\mathbf{A}(\mathbf{r}) \approx \frac{\mu_{0}}{4 \pi}\left[\frac{1}{r} \int_{V} \mathbf{j}\left(\mathbf{r}^{\prime}\right) d^{3} r^{\prime}+\frac{1}{r^{3}} \int_{V}\left(\mathbf{r} \cdot \mathbf{r}^{\prime}\right) \mathbf{j}\left(\mathbf{r}^{\prime}\right) d^{3} r^{\prime}\right] . \tag{5.84}
\end{equation*}
$$

Due to the vector character of this potential, we have to depart slightly from the approach of Sec. 3.1 and use the following vector algebra identity: ${ }^{34}$

$$
\begin{equation*}
\int_{V}[f(\mathbf{j} \cdot \nabla g)+g(\mathbf{j} \cdot \nabla f)] d^{3} r=0 \tag{5.85}
\end{equation*}
$$

that is valid for any pair of smooth (differentiable) scalar functions $f(\mathbf{r})$ and $g(\mathbf{r})$, and any vector function $\mathbf{j}(\mathbf{r})$ that, as the de current density, satisfies the continuity condition $\nabla \cdot \mathbf{j}=0$ and whose normal component vanishes on its surface.

First, let us use Eq. (85) with $f \equiv 1$ and $g$ equal to any component of the radius-vector $\mathbf{r}: g=r_{i}(i$ $=1,2,3)$. Then it yields

$$
\begin{equation*}
\int_{V}\left(\mathbf{j} \cdot \mathbf{n}_{i}\right) d^{3} r=\int_{V} j_{i} d^{3} r=0, \tag{5.86}
\end{equation*}
$$

so that for the vector as the whole

[^265]\[

$$
\begin{equation*}
\int_{V} \mathbf{j}(\mathbf{r}) d^{3} r=0 \tag{5.87}
\end{equation*}
$$

\]

showing that the first term in the right-hand part of Eq. (84) equals zero. Next, let us use Eq. (85) with $f$ $=r_{i}, g=r_{i^{\prime}}\left(i, i^{\prime}=1,2,3\right)$; then it yields

$$
\begin{equation*}
\int_{V}\left(r_{i} j_{i^{\prime}}+r_{i^{\prime}} j_{i}\right) d^{3} r=0, \tag{5.88}
\end{equation*}
$$

so that the $i^{\text {th }}$ Cartesian component of the second integral in Eq. (84) may be transformed as

$$
\begin{align*}
\int_{V}\left(\mathbf{r} \cdot \mathbf{r}^{\prime}\right) j_{i} d^{3} r^{\prime} & =\int_{V} \sum_{i^{\prime}=1}^{3} r_{i^{\prime}} r_{i^{\prime}}^{\prime} j_{i} d^{3} r^{\prime}=\frac{1}{2} \sum_{i^{\prime}=1}^{3} r_{i^{\prime}} \int_{V}\left(r_{i^{\prime}}^{\prime} j_{i}+r_{i^{\prime}}^{\prime} j_{i}\right) d^{3} r^{\prime} \\
& =\frac{1}{2} \sum_{i^{\prime}=1}^{3} r_{i^{\prime}} \int_{V}\left(r_{i^{\prime}}^{\prime} j_{i}-r_{i^{\prime}}^{\prime} j_{i^{\prime}}\right) d^{3} r^{\prime}=-\frac{1}{2}\left[\mathbf{r} \times \int_{V}\left(\mathbf{r}^{\prime} \times \mathbf{j}\right) d^{3} r^{\prime}\right]_{i} . \tag{5.89}
\end{align*}
$$

As a result, Eq. (85) may be rewritten as

$$
\begin{equation*}
\mathbf{A}(\mathbf{r})=\frac{\mu_{0}}{4 \pi} \frac{\mathbf{m} \times \mathbf{r}}{r^{3}}, \tag{5.90}
\end{equation*}
$$

Magnetic dipole and its potential
where vector $\mathbf{m}$, defined as ${ }^{35}$

$$
\begin{equation*}
\mathbf{m} \equiv \frac{1}{2} \int_{V} \mathbf{r} \times \mathbf{j}(\mathbf{r}) d^{3} r, \tag{5.91}
\end{equation*}
$$

is called the magnetic dipole moment of our system - that itself, within approximation (90), is called the magnetic dipole.

Note a close analogy between $\mathbf{m}$ and the angular momentum of a non-relativistic particle with mass $m_{k}$ :

$$
\begin{equation*}
\mathbf{L}_{k} \equiv \mathbf{r}_{k} \times \mathbf{p}_{k}=\mathbf{r}_{k} \times m_{k} \mathbf{v}_{k}, \tag{5.92}
\end{equation*}
$$

where $\mathbf{p}_{k}=m_{k} \mathbf{v}_{k}$ is its mechanical momentum. Indeed, for a continuum of such particles with the same electric charge $q$, with the spatial density $n, \mathbf{j}=q n \mathbf{v}$, and Eq. (91) yields

$$
\begin{equation*}
\mathbf{m}=\int_{V} \frac{1}{2} \mathbf{r} \times \mathbf{j} d^{3} r=\int_{V} \frac{n q}{2} \mathbf{r} \times \mathbf{v} d^{3} r \tag{5.93}
\end{equation*}
$$

while the total angular momentum of such continuous system of particles of the same mass $\left(m_{k}=m_{0}\right)$ is

$$
\mathbf{L}=\int_{V} n m_{0} \mathbf{r} \times \mathbf{v} d^{3} r
$$

so that we get a very straightforward relation
m vs. L

$$
\begin{equation*}
\mathbf{m}=\frac{q}{2 m_{0}} \mathbf{L} \tag{5.95}
\end{equation*}
$$

[^266]For the orbital motion, this classical relation survives in quantum mechanics for operators and hence for eigenvalues, in whom the angular momentum is quantized in the units of the Planck's constant $\hbar$, so that for an electron, the orbital magnetic moment is always a multiple of the so-called Bohr magneton

$$
\begin{equation*}
\mu_{\mathrm{B}} \equiv \frac{e \hbar}{2 m_{e}} \tag{5.96}
\end{equation*}
$$

where $m_{e}$ is the free electron mass. ${ }^{36}$ However, for particles with spin, such a universal relation between vectors $\mathbf{m}$ and $\mathbf{L}$ is no longer valid. For example, electron's spin $s=1 / 2$ gives contribution $\hbar / 2$ to the mechanical momentum, but its contribution to the magnetic moment it still very close to $\mu_{\mathrm{B}} .{ }^{37}$

The next important example of a magnetic dipole is a planar wire loop limiting area $A$ (of an arbitrary shape), carrying current $I$, for which $\mathbf{m}$ has a surprisingly simple form,

$$
\begin{equation*}
\mathbf{m}=I \mathbf{A}, \tag{5.97}
\end{equation*}
$$

where the modulus of vector A equals area $A$, and its direction is perpendicular to loop's plane. This formula may be readily proved by noticing that if we select the coordinate origin on the plane of the loop (Fig. 10), then the elementary component of the magnitude of integral (91),

$$
\begin{equation*}
d m=\frac{1}{2}\left|\oint_{C} \mathbf{r} \times I d \mathbf{r}\right|=I \oint_{C}\left|\frac{1}{2} \mathbf{r} \times d \mathbf{r}\right|=I \oint_{C} \frac{1}{2} r^{2} d \varphi, \tag{5.98}
\end{equation*}
$$

is just the elementary area $d A=(1 / 2) r d(r \varphi) \equiv r^{2} d \varphi / 2$.

Fig. 5.10. Calculating the magnetic dipole moment of a planar current loop.

The combination of Eqs. (96) and (97) allows a useful estimate of the scale of atomic currents, by finding what current $I$ should flow in a circular loop of atomic size scale (the Bohr radius) $r_{\mathrm{B}} \approx$ $0.5 \times 10^{-10} \mathrm{~m}$, i.e. of area $A \approx 10^{-20} \mathrm{~m}^{2}$, to produce a magnetic moment equal to $\mu_{\mathrm{B}} .{ }^{38}$ The result is surprisingly macroscopic: $I \sim 1 \mathrm{~mA}$ (quite comparable to the currents driving your earbuds :-). Though this estimate should not be taken too literally, due to the quantum-mechanical spread of electron's wavefunctions, it is very useful for getting a feeling how significant the atomic magnetism is and hence why ferromagnets may provide such a strong field.

[^267]After these illustrations, let us return to Eq. (90). Plugging it into the general formula (27), we may calculate the magnetic field of a magnetic dipole:

Magnetic dipole in external field

$$
\begin{equation*}
\mathbf{B}(\mathbf{r})=\frac{\mu_{0}}{4 \pi} \frac{3 \mathbf{r}(\mathbf{r} \cdot \mathbf{m})-\mathbf{m} r^{2}}{r^{5}} \tag{5.99}
\end{equation*}
$$

The structure of this formula exactly duplicates that of Eq. (3.15) for the electric dipole field. Because of this similarity, the energy of a dipole in an external field, and hence the torque and force exerted on it by the field, are also absolutely similar to the expressions for an electric dipole - see Eqs. (3.15)-(3.18):

$$
\begin{equation*}
U=-\mathbf{m} \cdot \mathbf{B}_{\mathrm{ext}}, \tag{5.100}
\end{equation*}
$$

and as a result,

$$
\begin{gather*}
\boldsymbol{\tau}=\mathbf{m} \times \mathbf{B}_{\mathrm{ext}},  \tag{5.101}\\
\mathbf{F}=\nabla\left(\mathbf{m} \cdot \mathbf{B}_{\mathrm{ext}}\right) . \tag{5.102}
\end{gather*}
$$

Now let us consider a system of many magnetic dipoles (e.g., atoms or molecules), distributed in space with density $n$. Then we can use Eq. (90) (generalized in the evident way for an arbitrary position, $\mathbf{r}$ ', of a dipole), and the linear superposition principle, to calculate the "macroscopic" component of the vector-potential A - in other words, dipole's potential averaged over short-scale variations on the interdipole distances:

$$
\begin{equation*}
\mathbf{A}(\mathbf{r})=\frac{\mu_{0}}{4 \pi} \int \frac{\mathbf{M}\left(\mathbf{r}^{\prime}\right) \times\left(\mathbf{r}-\mathbf{r}^{\prime}\right)}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|^{3}} d^{3} r^{\prime} \tag{5.103}
\end{equation*}
$$

where $\mathbf{M} \equiv n \mathbf{m}$ is the macroscopic (average) magnetization, i.e. the magnetic moment per unit volume. Transforming this integral absolutely similarly to how Eq. (3.27) had been transformed into Eq. (3.29), we get:

$$
\begin{equation*}
\mathbf{A}(\mathbf{r})=\frac{\mu_{0}}{4 \pi} \int \frac{\nabla^{\prime} \times \mathbf{M}\left(\mathbf{r}^{\prime}\right)}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} d^{3} r^{\prime} \tag{5.104}
\end{equation*}
$$

Comparing this result with Eq. (28), we see that $\nabla \times \mathbf{M}$ is equivalent, in its effect, to the density $\mathbf{j}_{\text {ef }}$ of a certain effective "magnetization current". Just as the electric-polarization "charge" $\rho_{\text {ef }}$ discussed in Sec. 3.2 (see Fig. 3.3), $\mathbf{j}_{\text {ef }}=\nabla \times \mathbf{M}$ may be interpreted the uncompensated part of vortex currents representing single magnetic dipoles (Fig. 11).

Fig. 5.11. Cartoon illustrating the physical nature of the "magnetization current" $\mathbf{j}_{\text {ef }}=\nabla \times \mathbf{M}$.

Now, using Eq. (28) to add the possible contribution from "stand-alone" currents j, not included into the currents of microscopic dipoles, we get the general equation for the vector-potential of the macroscopic field:

$$
\begin{equation*}
\mathbf{A}(\mathbf{r})=\frac{\mu_{0}}{4 \pi} \int \frac{\left[\mathbf{j}\left(\mathbf{r}^{\prime}\right)+\nabla^{\prime} \times \mathbf{M}\left(\mathbf{r}^{\prime}\right)\right]}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} d^{3} r^{\prime} . \tag{5.105}
\end{equation*}
$$

Repeating the calculations that have led us from Eq. (28) to the Maxwell equation (35), with the account of the magnetization current term, for the macroscopic magnetic field $\mathbf{B}$ we get ${ }^{39}$

$$
\begin{equation*}
\nabla \times \mathbf{B}=\mu_{0}(\mathbf{j}+\nabla \times \mathbf{M}) \tag{5.106}
\end{equation*}
$$

Following the same philosophy as in Sec. 3.2, we may recast this equation as

$$
\begin{equation*}
\nabla \times \mathbf{H}=\mathbf{j} \tag{5.107}
\end{equation*}
$$

where a new field defined as

$$
\begin{equation*}
\mathbf{H} \equiv \frac{\mathbf{B}}{\mu_{0}}-\mathbf{M}, \tag{5.108}
\end{equation*}
$$

by historic reasons (and very unfortunately) is also called the magnetic field. ${ }^{40}$ It is crucial to remember that the physical sense of field $\mathbf{H}$ is very much different from field $\mathbf{B}$. In order to understand the difference better, let us use Eq. (107) to complete a macroscopic analog of system (36), called the macroscopic Maxwell equations (again, so far for the stationary case $\partial / \partial t=0$ ):

$$
\begin{array}{ll}
\nabla \times \mathbf{E}=0, & \nabla \times \mathbf{H}=\mathbf{j}  \tag{5.109}\\
\nabla \cdot \mathbf{D}=\rho, & \nabla \cdot \mathbf{B}=0 .
\end{array}
$$

One can clearly see that the roles of vector fields $\mathbf{D}$ and $\mathbf{H}$ are very similar: they could be called "wouldbe" fields - which would be induced by stand-alone charges and currents, if the media had not modified them by its dielectric and/or magnetic polarization.

[^268]Despite this similarity, let me note an important difference of signs in the relation (3.33) between $\mathbf{E}, \mathbf{D}$, and $\mathbf{P}$, on one hand, and relation (108) between $\mathbf{B}, \mathbf{H}$, and $\mathbf{M}$, on the other hand. It is not just the matter of definition. Indeed, due to the similarity of Eqs. (3.15), and (100), including similar signs, the electric and magnetic fields both try to orient the corresponding dipole moments along the field. Hence, in the media that allow such orientation (and as we will see momentarily, for magnetic media it is not always the case), the induced polarizations $\mathbf{P}$ and $\mathbf{M}$ are directed along, respectively, vectors $\mathbf{E}$ and $\mathbf{B}$. According to Eq. (3.33), if the would-be field $\mathbf{D}$ is fixed - say, by a fixed stand-alone charge distribution $\rho(\mathbf{r})$ - such polarization reduces the genuine average electric field $\mathbf{E}=(\mathbf{D}-\mathbf{P}) / \varepsilon_{0}$. On the other hand, Eq. (108) shows that in a magnetic media with a fixed would-be field $\mathbf{H}$, magnetic polarization with $\mathbf{M} \Uparrow \mathbf{B}$ enhances the average magnetic field $\mathbf{B}=\mu_{0}(\mathbf{H}+\mathbf{M})$. This difference may be traced back to the sign difference in the initial relations (1.1) and (5.1), i.e. to the basic fact that charges of the same sign repulse, while currents of the same direction attract each other.

In order to form a complete system of differential equations, the macroscopic Maxwell equations (109) have to be complemented with "constitutive relations" $\mathbf{D} \leftrightarrow \mathbf{E}, \mathbf{j} \leftrightarrow \mathbf{E}$, and $\mathbf{B} \leftrightarrow \mathbf{H}$. In previous two chapters we already discussed, in brief, two of them; let us proceed to the last one.

### 5.5. Magnetic materials

A major difference between the dielectric and magnetic material equations $\mathbf{D}(\mathbf{E})$ and $\mathbf{B}(\mathbf{H})$ is that while a typical dielectric media reduces the external electric field, magnetic media may either reduce or enhance it. In order to quantify this fact, let us consider the so-called linear magnetics in which $\mathbf{M}$ (and hence $\mathbf{H}$ ) are proportional to $\mathbf{B}$. Just as in dielectrics, in material without spontaneous magnetization, such linearity at relatively low fields follows from the Taylor expansion of function $\mathbf{M}(\mathbf{B})$. For isotropic materials, this proportionality is characterized by a scalar - either the magnetic permeability $\mu$, defined by the following relation:

Magnetic permeability

$$
\begin{equation*}
\mathbf{B} \equiv \mu \mathbf{H} \tag{5.110}
\end{equation*}
$$

or the magnetic susceptibility ${ }^{41}$ defined as

Magnetic
susceptibility susceptibility

$$
\begin{equation*}
\mathbf{M}=\chi_{m} \mathbf{H} \tag{5.111}
\end{equation*}
$$

Plugging these relations into Eq. (108), we see that these two parameters are not independent, but are related as

$$
\begin{equation*}
\mu=\left(1+\chi_{m}\right) \mu_{0} . \tag{5.112}
\end{equation*}
$$

Note that despite the superficial similarity between Eqs. (110)-(111) and relations (3.35)-(3.38) for linear dielectrics:

[^269]\[

$$
\begin{equation*}
\mathbf{D}=\varepsilon \mathbf{E}, \quad \mathbf{P}=\chi_{e} \varepsilon_{0} \mathbf{E}, \quad \varepsilon=\left(1+\chi_{e}\right) \varepsilon_{0}, \tag{5.113}
\end{equation*}
$$

\]

there is an important conceptual difference between them. Namely, while vector $\mathbf{E}$ in the right-hand parts of Eqs. (113) is the real (average) electric field, vector $\mathbf{H}$ in the right-hand part of Eqs. (110)-(111) represents a "would-be" magnetic field, in all aspects similar to vector $\mathbf{D}$ rather than $\mathbf{E}$. For relatively dense media, whose polarization may affect the genuine fields substantially, this difference between parameters $\varepsilon$ and $\mu$ may make their properties (e.g., the Kramers-Kronig relations, to be discussed in Sec. 7.3) rather different.

Another difference between parameters $\varepsilon$ and $\mu$ (and hence between $\chi_{e}$ and $\chi_{m}$ ) is evident from Table 1 which lists the values of magnetic susceptibility for several materials. It shows that in contrast to linear dielectrics whose susceptibility $\chi_{e}$ is always positive, i.e. the dielectric constant $\varepsilon_{r}=\chi_{e}+1$ is always larger than 1 (see Table 3.1), linear magnetics may be either paramagnets ( $\chi_{m}>0$, i. e. $\mu>\mu_{0}$ ) or diamagnets ( $\chi_{m}<0, \mu<\mu_{0}$ ).

Table 5.1. Magnetic susceptibility $\left(\chi_{m}\right)_{\mathrm{SI}}$ of a few representative (and/or important) materials ${ }^{(\mathrm{a})}$

| "Mu-metal" (75\% Ni + 15\% Fe + a few \%\% of Cu and Mo) | $\sim 20,000^{(\mathrm{b})}$ |
| :---: | :---: |
| Permalloy ( $80 \% \mathrm{Ni}+20 \% \mathrm{Fe}$ ) | $\sim 8,000^{(\mathrm{b})}$ |
| "Soft" (or "transformer") steel (Fe +a few $\% \%$ of Si) | $\sim 4,000^{\text {(b) }}$ |
| Nickel | $\sim 100$ |
| Aluminum | $+2 \times 10^{-5}$ |
| Diamond | $-2 \times 10^{-5}$ |
| Copper | $-7 \times 10^{-5}$ |
| Water | $-9 \times 10^{-6}$ |
| Bismuth (the strongest non-superconducting diamagnet) | $-1.7 \times 10^{-4}$ |

${ }^{(2)}$ The table does not include bulk superconductors, which in a crude ("macroscopic") approximation may be described as perfect diamagnets (with $\mathbf{B}=0$, i.e. $\chi_{m}=-1$ and $\mu=0$ ), though the actual physics of this phenomenon is more complex - see Sec. 6.3 below.
${ }^{(b)}$ The exact values of $\chi_{m}$ for soft ferromagnetic materials depend not only on their exact composition, but also on their thermal processing ("annealing"). Moreover, due to unintentional vibrations, the extremely high $\chi_{m}$ of such materials may somewhat decay with time, though may be restored to approach the original value by new annealing.

The reason of this difference is that in dielectrics, two different polarization mechanisms (schematically illustrated by Fig. 12) lead to the same sign of the average polarization. The first of them takes place in atoms without their own spontaneous polarization. A crude classical image of such an atom is an isotropic cloud of negatively charged electrons surrounding a positively charged nucleus - see Fig. 12a. The external electric field shifts the positive charge in the direction of $\mathbf{E}$, and negative charges in the opposite direction, thus creating a dipole with aligned vectors $\mathbf{p}$ and $\mathbf{E}$, and hence positive
polarizability $\alpha_{\text {mol }}$ - see Eq. (3.39). As a result, the electric susceptibility is also positive - see Eqs. (3.41) or (3.71).

In the second case (Fig. 12b) of a gas or liquid consisting of polar molecules, each molecule has its own, spontaneous dipole moment $\mathbf{p}_{0}$ even in the absence of external electric field. (A typical example is a water molecule $\mathrm{H}_{2} \mathrm{O}$, with the positive oxygen ion positioned out of the line connecting two positive hydrogen atoms, thus producing a spontaneous dipole with moment's magnitude $p_{0} \approx e \times 0.38 \times 10^{-10} \mathrm{~m}$.) However, in the absence of the applied electric field, the orientation of such dipoles is random, so that the average polarization $\mathbf{P}=n\left\langle\mathbf{p}_{0}\right\rangle$ equals zero. A weak applied field does not change the magnitude of the dipole moments significantly, but creates their preferential orientation along the field (in order to decrease the potential energy $U=-\mathbf{p}_{0} \cdot \mathbf{E}$ ), thus creating a nonvanishing vector average $\left\langle\mathbf{p}_{0}\right\rangle$ directed along E. If the applied field is not two high $\left(p_{0} E \ll k_{\mathrm{B}} T\right)$, the induced polarization $\mathbf{P}=n\left\langle\mathbf{p}_{0}\right\rangle$ is proportional to $\mathbf{E}$, again giving a positive polarizability $\alpha_{\mathrm{mol}}{ }^{42}$

Fig. 5.12. Cartoons of two types of induced electrical polarization: (a) elementary dipole induction and (b) partial ordering of spontaneous elementary dipoles.

Returning to magnetics, the second of the above mechanisms, i.e. the ordering of spontaneous dipoles by the applied field, is responsible for the paramagnetism. Again, now according to Eq. (100), such field tends to align the dipoles along its direction, so that the average direction of spontaneous elementary moments $\mathbf{m}_{0}$, and hence the direction of $\mathbf{M}$, is the same as that of the average field $\mathbf{B}$ (i.e., for a diluted media, of $\mathbf{H} \approx \mathbf{B} / \mu_{0}$ ), resulting in a positive susceptibility $\chi_{m}$. However, in contrast to the electric polarization, there is a mechanism of magnetic polarization, called the orbital (or "Larmor"43) diamagnetism, which gives $\chi_{m}<0$. As its simplest model, let us consider the orbital motion of an atomic electron as classical particle of mass $m_{0}$, with electric charge $q$, about an immobile attractive center - modeling the atomic nucleus. As classical mechanics tells us, the central attractive force does

[^270]not change particle's angular momentum $\mathbf{L} \equiv m_{0} \mathbf{r} \times \mathbf{v}$, but the applied magnetic field $\mathbf{B}$ (that may be taken uniform on the atomic scale) does, due to the torque (101) it applies to magnetic moment (95):
\[

$$
\begin{equation*}
\frac{d \mathbf{L}}{d t}=\boldsymbol{\tau}=\mathbf{m} \times \mathbf{B}=\frac{q}{2 m_{0}} \mathbf{L} \times \mathbf{B} . \tag{5.114}
\end{equation*}
$$

\]

The vector diagram in Fig. 13 shows that in the limit of relatively weak field, when the magnitude of the angular momentum $\mathbf{L}$ may be considered constant, this equation describes the rotation (called the torque-induced precession ${ }^{44}$ ) of vector $\mathbf{L}$ about the direction of vector $\mathbf{B}$, with angular frequency $\boldsymbol{\Omega}=-q \mathbf{B} / 2 m_{0}$, independent on angle $\theta$. Let me leave for the reader to use Eq. (114) for checking that, irrespectively the sign of charge $q$, the resulting additional magnetic moment $\Delta \mathbf{m}$ has a direction opposite to that of vector $\mathbf{B}$, and hence $\chi_{m}$ is negative, leading to the Larmor diamagnetism. ${ }^{45}$

Fig. 5.13. Torque-induced precession of a charged particle in a magnetic field.

An important conceptual question is what exactly prevents the initial magnetic moment $\mathbf{m}$ that, according to Eq. (95), is associated with the angular momentum $\mathbf{L}$ of the electron, from turning along the magnetic field, just as in the second polarization mechanism illustrated by Fig. 12b - thus decreasing the potential energy (100) of the system. The answer is the same as for the usual mechanical top - it "wants" to fall due to the gravity field, but cannot do that due to the mechanical inertia. In classical physics, even a small friction (dissipation) eventually drains top's rotational kinetic energy, and it falls. However, in quantum mechanics the ground-state "motion" of electrons in an atom is not subjected to friction, because they cannot be brought to full rest due to Heisenberg's uncertainty principle. Somewhat counter-intuitively, the magnetic moments due to such fully-quantum effect as spin are much more susceptible to interaction with environment, so that in atoms with uncompensated spins, the magnetic dipole orientation mechanism prevails over the orbital diamagnetism, and the materials incorporating such atoms usually exhibit net paramagnetism - see Table 1.

Due to possible strong interactions between elementary dipoles, magnetism of materials is an extremely rich field of physics, with numerous interesting phenomena and elaborated theories.

[^271]Unfortunately, all this physics is well outside the framework of this course, and I have to refer the interested reader to special literature, ${ }^{46}$ but still need to mention its key notions.

Most importantly, a sufficiently strong dipole-dipole interaction may lead to their spontaneous ordering, even in the absence of the applied field. This ordering may correspond to either parallel alignment of the atomic dipoles (ferromagnetism) or anti-parallel alignment of the adjacent dipoles (antiferromagnetism). Evidently, the external effects of ferromagnetism are stronger, because such phase corresponds to a substantial spontaneous magnetization $\mathbf{M}$. (This value is frequently called the saturation magnetization, $\mathbf{M}_{s}$, while the corresponding magnitude of $\mathbf{B}=\mu_{0} \mathbf{M}$ is called either the saturation magnetic field, or the remanence field, $\mathbf{B}_{R}$ ). The direction of $\mathbf{B}_{R}$ may switched by the application an external magnetic field, with a magnitude above certain value $H_{C}$ called coercivity, ${ }^{47}$ leading to the well-known hysteretic loops on the $[B, H]$ plane - see Fig. 14 for a typical example.

Fig. 5.14. Experimental magnetization curves of specially processed (cold-rolled) transformer steel, i.e. a solid solution of $\sim 10 \% \mathrm{C}$ and $\sim 6 \% \mathrm{Si}$ in Fe. (Adapted from www.thefullwiki.org/Hysteresis.)

In relatively low fields, $H \ll H_{C}$, such materials may be described as hard (or "permanent") ferromagnets; at such approximate treatment, magnetization $\mathbf{M}$ is considered constant. On the other hand, the theory needed for a fair description phenomena at $H \sim H_{C}$ is rather complicated. Indeed, the direction of magnetization of crystals may be affected by the anisotropy of the crystal lattice. Because of that, typical non-crystalline ferromagnetic materials (like steel, permalloy, "mu-metal", etc.) consist of randomly oriented magnetic domains, each with certain spontaneous magnetization direction. The magnetic interaction of the domain with its neighbors and the external field determines the evolution of its magnetization and hence the average magnetic properties of the ferromagnet. In particular, such interaction explains why the hysteresis loop shape is dependent on the cycled field amplitude and cycling history - see Fig. 14. A very important class of multi-domain materials is the so-called soft ferromagnets, whose coercivity is relatively low. At low cycled field amplitude, the soft ferromagnets behave, on the average, as linear magnetics with very high values of $\chi_{m}$ and hence $\mu$ (see the top rows of Table 1, and Fig. 14) that are highly dependent on the material's fabrication technology and its postfabrication thermal and mechanical treatments.

[^272]High values of $\chi_{m}$ are is also pertinent to magnetics in which the molecular dipole interaction is relatively weak, so that their ferromagnetic ordering may be destroyed by thermal fluctuations, if temperature is increased above the so-called Curie temperature $T_{\mathrm{C}}$. At $T>T_{\mathrm{C}}$, such materials behave as paramagnets, with susceptibility obeying the Curie-Weiss law

$$
\begin{equation*}
\chi_{m} \propto \frac{1}{T-T_{\mathrm{C}}} . \tag{5.115}
\end{equation*}
$$

(At vanishing moment interaction, $T_{\mathrm{C}} \rightarrow 0$, and Eq. (115) is reduced to the Curie law $\chi_{m} \propto 1 / T$ typical for weak paramagnets.) The transition between the ferromagnetic and paramagnetic phase at $T=T_{\mathrm{C}}$ is the classical example of continuous phase transitions, similar to that between the paraelectric and ferroelectric phases of a dielectric. In both cases, the "macroscopic" (average) polarization - either $\mathbf{M}$ or $\mathbf{P}$ - plays the role of the so-called order parameter that (in the absence of external fields) appears at $T=$ $T_{\mathrm{C}}$ and increases gradually at the further reduction of temperature. ${ }^{48}$

Before returning to magnetostatics per se, I have to mention the large practical role played by hard ferromagnetic materials (well beyond refrigerator magnets :-). Indeed, despite the decades of the exponential (Moore's-law) progress of semiconductor electronics, most computer data storage systems are still based on the hard disk drives whose active medium is a submicron-thin ferromagnetic layer, with bits stored in the form of the direction of the spontaneous magnetization of small film spots. This technology has reached a fantastic sophistication, ${ }^{49}$ with recording data density approaching $10^{12}$ bits per square inch. Only recently it has started to be seriously challenged by the so-called solid state drives based on the flash semiconductor memories already mentioned in Chapter 3.

### 5.6. Systems with magnetics

Similarly to the electrostatics of linear dielectrics, magnetostatics of linear magnetics is very simple in the particular case when the stand-alone currents are deeply embedded into a medium with a constant permeability $\mu$. Indeed, in this case, boundary conditions on the distant surface of the media do not affect the solution of the boundary problem described by the magnetic equations of the macroscopic Maxwell system (109). Now let us assume that we know the solution $\mathbf{B}_{0}(\mathbf{r})$ of the magnetic pair of the genuine ("microscopic") Maxwell equations (36) in free space, i.e. when the genuine current density $\mathbf{j}$ coincides with that of stand-alone currents. Then the macroscopic equations and the material equation (110) are completely satisfied with the pair of functions

$$
\begin{equation*}
\mathbf{H}(\mathbf{r})=\frac{\mathbf{B}_{0}(\mathbf{r})}{\mu_{0}}, \quad \mathbf{B}(\mathbf{r})=\mu \mathbf{H}(\mathbf{r})=\frac{\mu}{\mu_{0}} \mathbf{B}_{0}(\mathbf{r}) . \tag{5.116}
\end{equation*}
$$

Hence the only effect of a complete filling a system of fixed currents with a uniform, linear magnetic is the increase of the magnetic field $\mathbf{B}$ at all points by the same constant factor $\mu / \mu_{0} \equiv 1+\chi_{m}$. (As a reminder, a similar filling of a system of fixed charges with a uniform, linear dielectric leads to a reduction of the electric field $\mathbf{E}$ by factor $\varepsilon / \varepsilon_{0}=\varepsilon_{\mathrm{r}}=1+\chi_{e}$.)

[^273]However, this simple result is generally invalid in the case of non-uniform (or piece-wise uniform) magnetic samples. Theoretical analyses of magnetic field distribution in such non-uniform systems may be facilitated by two additional tools. First, integrating the macroscopic Maxwell equation (107) along a closed contour $C$ limiting a smooth surface $S$, and using the Stokes theorem, we get the macroscopic version of the Ampère law (37):

$$
\begin{equation*}
\oint_{C} \mathbf{H} \cdot d \mathbf{r}=I \tag{5.117}
\end{equation*}
$$

This is exactly the replica of the "microscopic" equation Eq. (37), with the replacement $\mathbf{B} / \mu_{0} \rightarrow \mathbf{H}$.
Let us apply this relation to a boundary between two regions with constant, but different $\mu$, with no stand-alone currents on the border, similarly how this was done for field $\mathbf{E}$ in Sec. 3.4-see Fig. 3.5. The result is similar as well:

$$
\begin{equation*}
H_{\tau}=\text { const } . \tag{5.118}
\end{equation*}
$$

On the other hand, the integration of the Maxwell equation (29) over a Gaussian pillbox enclosing a border fragment (again similar to that shown in Fig. 3.5) yields the result similar to Eq. (3.46):

$$
\begin{equation*}
B_{n}=\text { const, i.e. } \mu H_{n}=\text { const } . \tag{5.119}
\end{equation*}
$$

Let us use these boundary conditions, first, to see what happens with a thin sheet of magnetic material (or any other strongly elongated sample) placed parallel to a uniform external field $\mathbf{H}_{0}$. Such sample cannot noticeably disturb the field in the free space outside it: $\mathbf{H}_{\text {ext }}=\mathbf{H}_{0}, \mathbf{B}_{\text {ext }}=\mathbf{H}_{\text {ext }} / \mu_{0}=\mathbf{H}_{0} / \mu_{0}$. Now applying Eq. (118) to the dominating, large-area interfaces, we get $\mathbf{H}_{\text {int }}=\mathbf{H}_{0}$, i.e., $\mathbf{B}_{\text {int }}=\left(\mu / \mu_{0}\right) \mathbf{B}_{0} .{ }^{50}$ The fact of constancy of field $\mathbf{H}$ in this geometry explains why this field is used as the horizontal axis in plots like Fig. 14: such measurements are typically carried out by placing an elongated sample of the material into the uniform field - say the one produced by a long solenoid.

Samples of other geometries may create strong perturbations of the external field, extended to distances of the order of the transversal dimensions of the sample. In order to analyze such problems, we may benefit from a simple, partial differential equation for a scalar function, e.g., the Laplace equation, because in Chapter 2 we have learned how to solve it for many simple geometries. In magnetostatics, the introduction of a scalar potential is generally impossible due to the vortex-like magnetic field lines, but if there are no stand-alone currents within the region we are interested in, then the Maxwell equation (32) for field $\mathbf{H}$ is reduced to $\nabla \times \mathbf{H}=0$, and we may introduce the scalar potential of the magnetic field, $\phi_{m}$, using the relation similar to Eq. (1.33):

$$
\begin{equation*}
\mathbf{H}=-\nabla \phi_{m} . \tag{5.120}
\end{equation*}
$$

Combining it with the homogenous Maxwell equation for magnetic field, $\nabla \cdot \mathbf{B}=0$, we arrive at the familiar differential equation,

$$
\begin{equation*}
\nabla \cdot\left(\mu \nabla \phi_{m}\right)=0 \tag{5.121}
\end{equation*}
$$

that, for a uniform media ( $\mu=$ const), is reduced to our beloved Laplace equation. Moreover, Eqs. (118) and (119) give the very familiar boundary conditions: first

[^274]\[

$$
\begin{equation*}
\frac{\partial \phi_{m}}{\partial \tau}=\mathrm{const} \tag{5.122a}
\end{equation*}
$$

\]

which is equivalent to

$$
\begin{equation*}
\phi_{m}=\text { const }, \tag{5.122b}
\end{equation*}
$$

and also

$$
\begin{equation*}
\mu \frac{\partial \phi_{m}}{\partial n}=\text { const } . \tag{5.123}
\end{equation*}
$$

Note that these boundary conditions are similar for (3.46) and (3.47) of electrostatics, with the replacement $\varepsilon \rightarrow \mu .{ }^{51}$

Let us analyze the geometric effects on magnetization, using the (too?) familiar structure: a sphere, made of a linear magnetic material, in a uniform external field. Since the differential equation and boundary conditions are similar to those of the similar electrostatics problem (see Fig. 3.8), we can use the above analogy to recycle the solution we already have got - see Eqs. (3.55)-(3.56). Just as in the electric case, the field outside the sphere, with potential

$$
\begin{equation*}
\left(\phi_{m}\right)_{r>R}=H_{0}\left(-r+\frac{\mu-\mu_{0}}{\mu+2 \mu_{0}} \frac{R^{3}}{r^{2}}\right) \cos \theta \tag{5.125a}
\end{equation*}
$$

is a sum of the uniform external field $\mathbf{H}_{0}$ and the dipole field (99) with the following induced magnetic dipole moment of the sphere: ${ }^{52}$

$$
\begin{equation*}
\mathbf{m}=4 \pi \frac{\mu-\mu_{0}}{\mu+2 \mu_{0}} R^{3} \mathbf{H}_{0} . \tag{5.125b}
\end{equation*}
$$

On the contrary, the internal field is perfectly uniform:

$$
\begin{equation*}
\left(\phi_{m}\right)_{r<R}=-H_{0} \frac{3 \mu_{0}}{\mu+2 \mu_{0}} r \cos \theta, \quad \frac{H_{\mathrm{int}}}{H_{0}}=\frac{3 \mu_{0}}{\mu+2 \mu_{0}}, \quad \frac{B_{\mathrm{int}}}{B_{0}}=\frac{\mu H_{\mathrm{int}}}{\mu_{0} H_{0}}=\frac{3 \mu}{\mu+2 \mu_{0}} . \tag{5.126}
\end{equation*}
$$

Note that though $\mathbf{H}$ inside the sphere is not equal to its value of the external field $\mathbf{H}_{0}$. This example shows that the interpretation of $\mathbf{H}$ as the "would-be" magnetic field generated by external

[^275]currents $\mathbf{j}$ should not be exaggerated into saying that its distribution is independent on the magnetic bodies in the system. ${ }^{53}$

In the limit $\mu \gg \mu_{0}$, Eqs. (126) yield $H_{\text {int }} / H_{0} \ll 1, B_{\text {int }} / H_{0}=3 \mu_{0}$, the factor 3 being specific for the particular geometry of the sphere. If a sample is stretched along the applied field, this limitation of the field concentration is gradually removed, and $B_{\text {int }}$ tends to its maximum value $\mu H_{0} \gg B_{\text {ext }}$, as was discussed above. This effect of "magnetic line concentration" in high $-\mu$ materials is used in such practically important devices as transformers, in which two multi-turn coils are wound on a ring-shaped (e.g., toroidal, see Fig. 6b) core made of a soft ferromagnetic material (such as the transformer steel, see Table 1) with $\mu \gg \mu_{0}$. This minimizes the number of "stray" field lines, and makes the magnetic flux $\Phi$ piercing each wire turn (of either coil) virtually the same - the equality important for secondary voltage induction - see the next chapter.

The second theoretical tool, frequently useful for problem solution, is a macroscopic expression for magnetic field energy $U$. For a system with linear magnetic materials, we may repeat the transformation of Eq. (55), made in Sec. 3, but with due respect to the magnetization, i.e. replacing $\mathbf{j}$ not from Eq. (56), but from Eq. (107). As a result, instead of Eq. (57) we get

energy in a
linear magnetic

General magnetic energy variation

$$
\begin{equation*}
U=\int_{V} u(\mathbf{r}) d^{3} r, \quad \text { with } u=\frac{\mathbf{B} \cdot \mathbf{H}}{2}=\frac{B^{2}}{2 \mu}=\frac{\mu H^{2}}{2}, \tag{5.127}
\end{equation*}
$$

This result is evidently similar to Eq. (3.79) of electrostatics.
For the general case of nonlinear magnetics, calculations similar to those resulting in Eq. (3.82) give the following analog of that relation:
for a linear magnetic yielding Eq. (127). Similarly to the electrostatics of dielectrics, we may argue that according to Eq. (128), in systems with magnetic media, $\mathbf{H}$ plays the role of the generalized force, and $\mathbf{B}$ of the generalized coordinate (per unit volume). ${ }^{54}$ As the result, the Gibbs potential energy, whose minimum corresponds to the stable equilibrium of the system in an external field $\mathbf{H}_{\text {ext }}$, is

$$
\begin{equation*}
g=\int_{V} g(\mathbf{r}) d^{3} r, \quad \text { with } g(\mathbf{r}) \equiv u(\mathbf{r})-\mathbf{H}_{\mathrm{ext}} \cdot \mathbf{B}, \tag{5.129}
\end{equation*}
$$

the expression to be compared with Eq. (3.84). Similarly, for a system with linear magnetics, the latter of these expressions may be integrated over the variations to give

[^276]\[

$$
\begin{equation*}
g(\mathbf{r})=\frac{1}{2 \mu} \mathbf{B} \cdot \mathbf{B}-\mathbf{H}_{\mathrm{ext}} \cdot \mathbf{B}=\frac{1}{2 \mu}\left(\mathbf{B}-\mu \mathbf{H}_{\mathrm{ext}}\right)^{2}+\text { const } \tag{5.130}
\end{equation*}
$$

\]

with similar consequences for the external magnetic field penetration into a system with magnetics. As a sanity check, for a uniform system with negligible fringe fields, such as a long solenoid filled with a uniform, linear magnetic material, Eq. (130) may be readily integrated over the sample volume to give

$$
\begin{equation*}
g(\mathbf{r})=\frac{1}{2 \mu}\left(\mathbf{B}-\mu \mathbf{H}_{\mathrm{ext}}\right)^{2} V+\mathrm{const} \tag{5.131}
\end{equation*}
$$

so that the minimum of the Gibbs potential energy, i.e. the stable equilibrium of the system, corresponds to the result that has already been derived in the beginning of this section: $\mathbf{B}=\mu \mathbf{H}_{\text {ext }}$, i.e. $\mathbf{H}=\mathbf{H}_{\text {ext }}$.

For the important particular case of a long solenoid (Fig. 6a) filled with a linear magnetic material, we hay find field $H$ from Eq. (117), just as we used Eq. (37) in Sec. 2 for finding $B$ for a similar empty solenoid, getting

$$
\begin{equation*}
H=I n, \text { and hence } B=\mu I n . \tag{5.132}
\end{equation*}
$$

Now we may plug this result into Eq. (127) to calculate the magnetic energy stored in the solenoid:

$$
\begin{equation*}
U=u V=\frac{\mu H^{2}}{2} l A=\frac{\mu(n I)^{2} l A}{2} \tag{5.132}
\end{equation*}
$$

and then use Eq. (72) to calculate its self-inductance:

$$
\begin{equation*}
L=\frac{U}{I^{2} / 2}=\mu n^{2} l A \tag{5.133}
\end{equation*}
$$

- as evident generalization of Eq. (75). This result explains why filling of solenoids with soft ferromagnets with $\mu \gg \mu_{0}$ is so popular in the electrical engineering practice, where large self- and mutual inductances are frequently needed in systems with size and/or weight restrictions.

Now, let us use these two tools to discuss a curious (and practically important) approach to systems with ferromagnetic cores. First, let us find the magnetic flux $\Phi$ in a system with a relatively thin, closed magnetic core made of sections of (possibly, different) soft ferromagnets, with the crosssection areas $A_{k}$ much smaller than the squared lengths $l_{k}$ of the sections - see Fig. 15.

Fig. 5.15. Deriving the "magnetic Ohm law" (135).

If all $\mu_{k} \gg \mu_{0}$, virtually all field lines are confined to the interior of the core. Then, applying the macroscopic Ampère law (117) to contour $C$, which follows a magnetic field line inside the core (see the
dashed line in Fig. 15), we get the following approximate expression (exactly valid only in the limit $\left.\mu_{k} / \mu_{0}, l_{k}^{2} / A_{k} \rightarrow \infty\right)$ :

$$
\begin{equation*}
\oint_{C} H_{l} d l \approx \sum_{k} l_{k} H_{k}=\sum_{k} l_{k} \frac{B_{k}}{\mu_{k}}=N I . \tag{5.134}
\end{equation*}
$$

However, since the magnetic field lines stay in the core, the magnetic flux $\Phi_{k} \approx B_{k} A_{k}$ should be the same $(\equiv \Phi)$ for each section, so that $B_{k}=\Phi / A_{k}$. Plugging this condition into Eq. (134), we get

$$
\begin{equation*}
\Phi=\frac{N I}{\sum_{k} R_{k}}, \quad \text { where } R_{k} \equiv \frac{l_{k}}{\mu_{k} A_{k}} \tag{5.135}
\end{equation*}
$$

Note a close analogy of the first of these equations with the Ohm law for several resistors connected in series, with the magnetic flux playing the role of electric current, while the product $N I$, of the voltage applied to the resistor chain. This analogy is fortified by the fact that the second of Eqs. (135) is similar to the expression for resistance $R=l / \sigma A$ of a long uniform conductor, with the magnetic permeability $\mu$ playing the role of the electric conductivity $\sigma$. (In order to sound similar, but still different from resistance $R$, parameter $\mathbb{R}$ is called the reluctance.) This is why Eq. (135) is called the magnetic Ohm law; it is very useful for approximate analyses of systems like ac transformers, magnetic energy storage systems, etc.

The role of the "magnetic e.m.f." NI may be also played by a permanent-magnet section of the core. Indeed, for relatively low fields we may use the Taylor expansion of the nonlinear function $B(H)$ near $H=0$ to write

$$
\begin{equation*}
B \approx \mp \mu_{0} M_{s}+\mu_{d} H,\left.\quad \mu_{d} \equiv \frac{d B}{d H}\right|_{H=0}, \tag{5.136}
\end{equation*}
$$

where $M_{s}$ is the spontaneous magnetization magnitude at $H=0$, the $\mp$ sign corresponds to two possible directions of the magnetization, and parameter $\mu_{d}$ is called the differential (or "dynamic") permeability. Expressing $H$ from this relation, and using it in one of components of the sum (134), we again get a result similar to Eq. (135)

$$
\begin{equation*}
\Phi=\mp \frac{(N I)_{\mathrm{ef}}}{R_{H}+\sum_{k} R_{k}}, \quad \text { with } R_{H} \equiv \frac{l_{H}}{A_{H} \mu_{d}} \tag{5.137}
\end{equation*}
$$

where $l_{H}$ and $A_{H}$ are geometric dimensions of the hard-ferromagnet section, and product $N I$ is replaced with its effective value

$$
\begin{equation*}
(N I)_{\mathrm{ef}}=\mp \frac{\mu_{0}}{\mu_{d}} M_{s} l_{H} . \tag{5.138}
\end{equation*}
$$

This result may be used for a semi-quantitative explanation of the well-known short-range forces acting between permanent magnets (or between them and soft ferromagnets) at their mechanical contact (Fig. 16).

Fig. 5.16. Short-range interaction between magnets.

Indeed, considering the free-space gaps between them as sections of the core (which is approximately correct, because due to the small gap thickness $d$ the magnetic field lines cannot stray far from the contact area), and neglecting the reluctance $\mathbb{P}$ of the bulk material (due to its larger crosssection), we get

$$
\begin{equation*}
|\Phi| \propto\left(\frac{2 d}{\mu_{0}}+\frac{l}{\mu_{d}}\right)^{-1} \tag{5.139}
\end{equation*}
$$

so that, according to Eq. (127), the magnetic energy of the system (disregarding the constant energy of the permanent magnetization) is

$$
\begin{equation*}
U \propto\left(\frac{2 d}{\mu_{0}}+\frac{l}{\mu_{d}}\right) B^{2} \propto\left(\frac{2 d}{\mu_{0}}+\frac{l}{\mu_{d}}\right)^{-1} \propto \frac{1}{d+d_{0}}, \quad d_{0} \equiv \frac{1}{2} \frac{\mu_{0}}{\mu_{d}} l \ll l . \tag{5.140}
\end{equation*}
$$

Hence the magnet attraction force,

$$
\begin{equation*}
F=\left|\frac{\partial U}{\partial d}\right| \propto \frac{1}{\left(d+d_{0}\right)^{2}}, \tag{5.141}
\end{equation*}
$$

behaves almost as the divergence $1 / d^{2}$ truncated at a short distance $d_{0} \ll l$. Due to that truncation, the force is finite at $d=0$; this exactly the force you need to apply to detach two magnets.

Finally, let us discuss in brief a related effect in experiments with thin and long hard ferromagnetic samples - "needles", like those used in magnetic compasses. Using the definition (108) of field $\mathbf{H}$, the Maxwell equation (29) takes the form

$$
\begin{equation*}
\nabla \cdot \mathbf{B} \equiv \mu_{0} \nabla \cdot(\mathbf{H}+\mathbf{M})=0 \tag{5.142}
\end{equation*}
$$

and may be rewritten as

$$
\begin{equation*}
\nabla \cdot \mathbf{H}=-\nabla \cdot \mathbf{M} . \tag{5.143}
\end{equation*}
$$

While this relation is general, it is especially convenient in hard ferromagnets, where $\mathbf{M}$ is virtually fixed by the saturation. Comparing this equation with Eq. (1.27) for the electrostatic field, we see that the right-hand part of Eq. (143) may be considered as a fixed source of a Coulomb-like magnetic field.

For example, let us apply Eq. (143) to a thin, long needle made of a hard ferromagnet (Fig. 17a). Inside the needle, $\mathbf{M}=\mathbf{M}_{s}=$ const, while outside it $\mathbf{M}=0$, so that the right-hand part of Eq. (143) is substantially different from zero only in two small areas at the needle's ends, and on much larger distances we can use the following approximation:

$$
\begin{equation*}
\nabla \cdot \mathbf{H}=-q_{m} \delta\left(\mathbf{r}-\mathbf{r}_{1}\right)+q_{m} \delta\left(\mathbf{r}-\mathbf{r}_{2}\right), \tag{5.155}
\end{equation*}
$$

where $\mathbf{r}_{1,2}$ are ends' positions, and $q_{m} \equiv M_{s} A$, with $A$ being the needle's cross-section area. This equation is completely similar to Eq. (1.27) for the electric field created by two equal and opposite point charges. In particular, if two ends of two needles are hold at an intermediate distance $r$ ( $A^{1 / 2} \ll r \ll l$, where $l$ is the needle length, see Fig. 17b), the ends interact in accordance with the magnetic Coulomb law

$$
\begin{equation*}
F \propto \frac{q_{m}^{2}}{r^{2}}=\frac{M_{s}^{2} A^{2}}{r^{2}} \tag{5.156}
\end{equation*}
$$

Fig. 5.17. (a) "Magnetic charges" at the ends of a thin ferromagnetic needle and (b) the result of its breaking into two parts (schematically).

The "only" (but conceptually, very significant!) difference with electrostatics is that the "magnetic charges" $\pm q_{m}$ cannot be fully separated. For example, if we break a magnetic needle in the middle in at attempt to bring its two ends further apart, two new "charges" appear - see Fig. 17b. There are several solid state systems where more flexible structures, similar to the magnetic needles, may be implemented. First of all, certain ("type-II") superconductors may sustain so-called Abrikosov vortices crudely, flexible tubes with field-suppressed superconductivity inside, each carrying one magnetic flux quantum $\Phi_{0}=\pi \hbar / e \approx 2 \times 10^{-15} \mathrm{~Wb}$ - see Sec. 6.3. Ending on superconductor's surface, these tubes let the magnetic field lines to spread into the surrounding space, essentially forming a magnetic monopole analog (of course, with an equal and opposite "monopole" on another end of the line). Such flux tubes are not only flexible but readily stretchable, resulting in several peculiar effects. ${ }^{55}$ Another, recently found, examples of paired "monopoles" include spin chains in so-called spin ices - crystals with paramagnetic ions arranged into a specific (pyrochlore) lattice - such as dysprosium titanate $\mathrm{Dy}_{2} \mathrm{Ti}_{2} \mathrm{O}_{7} .{ }^{56}$

### 5.7. Exercise problems

5.1. Two straight, parallel, long, plane, thin strips of width $d$, separated by distance $d$, are used to form a current loop - see Fig. on the right. Calculate the magnetic field in the plane located at the middle between the planes of the strips, assuming that current $I$ is uniformly distributed across strip width.

${ }^{55}$ A detailed discussion of the Abrikosov vortices may be found, for example, in Chapter 5 of M. Tinkham, Introduction to Superconductivity, $2^{\text {nd }}$ ed., McGraw-Hill, 1996.
${ }^{56}$ See, e.g., L. Jaubert and P. Holdworth, J. Phys. - Cond. Matt. 23, 164222 (2011) and references therein.
5.2. For the system studied in the previous problem, but now only in the limit $d \ll w$, calculate:
(i) the distribution of the magnetic field (in the simplest possible way),
(ii) the vector-potential of the field,
(iii) the force (per unit length) acting on each strip, and
(iv) the magnetic energy and self-inductance of the system (per unit length).
5.3. Calculate the magnetic field distribution near the center of the system of two similar, plane, round, coaxial wire coils, fed by equal but oppositely directed currents - see Fig. on the right.

5.4. The two-coil-system, similar to that considered in the previous problem, carries equal and similarly directed currents - see Fig. on the right. Calculate what should be the ratio $d / R$ for the second derivative $\partial^{2} B_{z} / \partial z^{2}$ at $z=0$ to vanish. ${ }^{57}$
5.5. Calculate the magnetic field distribution along the axis of a straight solenoid (see Fig. 6a, partly reproduced on the right) with a finite length $l$, and round cross-section of radius $R$. Assume that the solenoid has many wire turns ( $N \gg 1$ ) that are uniformly distributed along its length.

5.6. A thin spherical shell of radius $R$, with charge $Q$ uniformly distributed over its surface, rotates about its axis with angular velocity $\omega$. Calculate the distribution of the magnetic field everywhere in space.
5.7. A sphere of radius $R$, made of an insulating material with a uniform electric charge density $\rho$, rotates about its diameter with angular velocity $\omega$. Calculate the magnetic field distribution inside the sphere and outside it.
5.8. The reader is (hopefully :-) familiar with the classical Hall effect when it takes place in the usual rectangular Hall bar geometry - see the left panel of the Fig. below. However, the effect takes a different form in the so-called Corbino disk - see the right panel below. (Dark shading shows electrodes, with no appreciable resistance.) Analyze the effect in both geometries, assuming that in both cases the conductors are thin, planar, have a constant Ohmic conductivity $\sigma$ and charge carrier density $n$, and that the applied magnetic field $\mathbf{B}$ is uniform and normal to conductors' planes.

[^277]
5.9. ${ }^{*}$ The simplest model of the famous homopolar motor ${ }^{58}$ is a thin, round conducting disk, placed into a uniform magnetic field normal to its plane, and fed by dc current flowing from disk's center to a sliding electrode ("brush") - see Fig. on the right.
(i) Express the torque, rotating the disk, via its radius $R$, magnetic field $\mathbf{B}$, and current $I$.

(ii) If the disk is allowed to rotate about its axis, and the motor is driven by a battery with e.m.f. $V$, calculate its angular velocity $\omega$, neglecting electric circuit's resistance and friction.
(iii) Now assuming that the current circuit (battery + wires + contacts + disk itself) has full resistance $R$, derive and solve the equation for the time evolution of $\omega$, and analyze the solution.
5.10. ${ }^{*}$ Estimate the values of magnetic susceptibility due to
(i) orbital diamagnetism, and
(ii) spin paramagnetism,
for a dilute medium with negligible interaction between molecular dipoles.
Hints: For task (i), you may use the classical model described by Eq. (114) (see Fig. 13), while for task (ii), assume the mechanism of ordering of spontaneous magnetic dipoles $\mathbf{m}_{0}$, similar to the one sketched for electric dipoles in Fig. 12b, with the magnitude of the order of the Bohr magneton $\mu_{\mathrm{B}}-$ see Eq. (96).
5.11.* Use the classical picture of the orbital ("Larmor") diamagnetism, discussed in Sec. 5.5 of the lecture notes, to calculate its (small) correction $\Delta \mathbf{B}(0)$ to the magnetic field $\mathbf{B}$, as felt by the atomic nucleus, modeling atomic electrons by a spherically-symmetric cloud with electric charge density $\rho(r)$. Express the result via the value $\phi(0)$ of the electrostatic potential of electrons' cloud, and use this expression for a crude numerical estimate of the relative correction, $\Delta B(0) / B$, for the hydrogen atom.
5.12. Current $I$ is flows in a thin wire bent into a plane, round loop of radius $R$. Calculate the net magnetic flux through the whole plane in which the loop is located.

[^278]5.13. Calculate the (self-) inductance of a toroidal solenoid (Fig. 6b) with the round cross-section of radius $r \sim R$ (see Fig. on the right), filled with a material of magnetic permeability $\mu$, with many ( $N \gg 1, R / r$ ) wire turns uniformly distributed along the perimeter. Check your results by analyzing the limit $r \ll R$.

Hint : You may like to use the following table integral:59

$$
\int_{0}^{1} \ln \frac{a+\left(1-\xi^{2}\right)^{1 / 2}}{a-\left(1-\xi^{2}\right)^{1 / 2}} d \xi=\pi\left[a-\left(a^{2}-1\right)^{1 / 2}\right], \quad \text { for } a \geq 1
$$

5.14. Prove that:
(i) the self-inductance $L$ of a current loop cannot be negative, and
(ii) each mutual inductance coefficient $L_{k k}$, defined by Eq. (60), cannot be larger than $\left(L_{k k} L_{k^{\prime} k^{\prime}}\right)^{1 / 2}$.
5.15. A round cylindrical shell, made of a soft ferromagnet, is placed into a uniform external field $\mathbf{H}_{0}$ perpendicular to its axis - see Fig. on the right. Find the distribution of the magnetic field everywhere in the system, and discuss its efficiency as a "magnetic shield".
5.16. A straight thin wire, carrying current $I$, passes parallel to the plane boundary between two uniform, linear magnetics - see Fig. on the right. Calculate the magnetic field everywhere in the system, and the force (per unit length) exerted on the wire.

5.17. Calculate the distribution of magnetic field around a sphere made of a hard ferromagnet with a permanent, uniform magnetization $\mathbf{M}=$ const.
5.18.* A limited volume $V$ is filled with a magnetic material with magnetization $\mathbf{M}(\mathbf{r})$.
(i) Use Eq. (5.143) to write explicit expressions for the magnetic field and its potential, induced by the magnetization.
(ii) Recast these expressions in forms convenient when $\mathbf{M}(\mathbf{r})=\mathbf{M}_{0}=$ const inside volume $V$.
5.19. Use the results of the previous problem to calculate the distribution of the magnetic field along the axis of a straight

[^279]permanent magnet of length $2 l$, with round cross-section of radius $R$, and uniform magnetization $\mathbf{M}_{0}$ parallel to the axis - see Fig. on the right.
5.20. A very broad film of thickness $2 t$ is magnetized normally to its plane, with a periodic checkerboard pattern with square side $a$ :
\[

\left.\mathbf{M}\right|_{|z|<t}=\mathbf{n}_{z} M(x, y), \quad with M(x, y)=M_{0} \times $$
\begin{cases}(+1), & \text { if } \cos \frac{\pi x}{a} \cos \frac{\pi y}{a}>0 \\ (-1), & \text { if } \cos \frac{\pi x}{a} \cos \frac{\pi y}{a}<0 .\end{cases}
$$
\]

Calculate the magnetic field distribution in space. ${ }^{60}$
5.21. A flat end of a rod magnet, with cross-section area $A$, with saturated magnetization $\boldsymbol{M}_{s}$ directed along rod's length, is let to stuck to a plane surface of a large sample made of a soft ferromagnetic material with $\mu \gg \mu_{0}$. Calculate the force necessary to detach the rod from the surface, if it is applied strictly perpendicular to the contact surface - see Fig. on the right.

5.22.* Based on the discussion of the quadrupole electrostatic lens in Sec. 2.4 of the lecture notes, suggest permanent-magnet systems which may similarly focus particles moving close to system's axis, and carrying:
(i) an electric charge,
(ii) no net electric charge, but a nonvanishing spontaneous magnetic dipole moment $\mathbf{m}$.
5.23. A circular wire loop, carrying a fixed dc current, has been placed inside a similar but larger loop, carrying a fixed current in the same direction - see Fig. on the right. Use semi-quantitative arguments to analyze the mechanical stability of the coaxial, coplanar position of the inner loop
 with respect to its possible angular, axial, and lateral displacements, if the position of the outer loop is fixed.

[^280]

## Chapter 6. Time-Dependent Electromagnetism

This chapter discusses two major new effects that appear if the electric and magnetic fields are changing in time: the "electromagnetic induction" of electric field by changing magnetic field, and the reciprocal effect of "displacement currents" - the induction of magnetic field by changing electric field. These two phenomena, which make the time-dependent electric and magnetic fields inseparable, contribute to the system of four Maxwell equations, and make it valid for arbitrary electromagnetic processes. On the way, I will pause for a brief review of the electrodynamics of superconductivity, which (besides its own significance), provides a perfect platform for a discussion of the gauge invariance.

### 6.1. Electromagnetic induction

As Eqs. (5.36) and (5.109) show, in static situations $(\partial / \partial t=0)$ the Maxwell equations describing the electric and magnetic fields are independent, and are coupled only implicitly, via the continuity equation (4.5) relating their right-hand parts $\rho$ and $\mathbf{j}$. (In statics this relation imposes a restriction only on vector $\mathbf{j}$.) In dynamics, when the fields change in time, the situation in different.

Historically, the first discovered explicit coupling between the electric and magnetic fields was the effect of electromagnetic induction. ${ }^{1}$ The summary of Faraday's numerous experiments has turned out to be very simple: if the magnetic flux, defined by Eq. (5.65),

$$
\begin{equation*}
\Phi \equiv \int_{S} B_{n} d^{2} r \tag{6.1}
\end{equation*}
$$

through a surface $S$ limited by contour $C$, changes in time by whatever reason (e.g., either due to a change of the magnetic field $\mathbf{B}$, or contour's motion, or its deformation), it induces an additional, vortexlike electric field $\mathbf{E}_{\text {ind }}$, similar in its topology to the magnetic field induced by a current. The exact distribution of $\mathbf{E}_{\text {ind }}$ in space depends on system geometry details and may be rather complex, but its integral along the contour $C$, called the inductive electromotive force (e.m.f.), obeys a very simple Faraday induction law: ${ }^{2}$
 induction

$$
\begin{equation*}
V_{\text {ind }} \equiv \oint_{C} \mathbf{E}_{\text {ind }} \cdot d \mathbf{r}=-\frac{d \Phi}{d t} . \tag{6.2}
\end{equation*}
$$

In is straightforward (and hence left for the reader's exercise :-) to show that the e.m.f. may be measured, for example, either inserting a voltmeter into a conducting loop following contour $C$, or by measuring current $I=V_{\text {ind }} / R$ it induces in a thin wire with Ohmic resistance $R$, whose shape follows that contour. The minus sign in Eq. (2) corresponds to the so-called Lenz rule: the magnetic field of the induced Ohmic current provides a partial compensation of the change of the original $\Phi$ in time.

In order to recast Eq. (2) in a differential form, let us apply, to the above definition of $V_{\text {ind }}$, the same Stokes theorem that was repeatedly used in Chapter 5. ${ }^{3}$ The result is

[^281]\[

$$
\begin{equation*}
V_{\text {ind }}=\int_{S}\left(\nabla \times \mathbf{E}_{\text {ind }}\right)_{n} d^{2} r . \tag{6.3}
\end{equation*}
$$

\]

Now combining Eqs. (1)-(3), for a contour $C$ whose shape does not change in time (so that the integration along it is interchangeable with the time derivative), ${ }^{4}$ we get

$$
\begin{equation*}
\int_{S}\left(\nabla \times \mathbf{E}_{\mathrm{ind}}+\frac{\partial \mathbf{B}}{\partial t}\right)_{n} d^{2} r=0 . \tag{6.4}
\end{equation*}
$$

Since the induced electric field is additional to the field (1.33) created by electric charges, for the net field we should write $\mathbf{E}=\mathbf{E}_{\text {ind }}-\nabla \phi$. However, since curl of any gradient field is zero, ${ }^{5} \nabla \times(\nabla \phi)=0$, Eq. (4) is valid for the net field $\mathbf{E}$. Since this equation should be correct for any closed area $S$, we may conclude that

$$
\begin{equation*}
\nabla \times \mathbf{E}+\frac{\partial \mathbf{B}}{\partial t}=0 \tag{6.5}
\end{equation*}
$$

at any point. This is the final (time-dependent) form of this Maxwell equation. Superficially, it may look that Eq. (5) is less general than Eq. (2); for example that it does not describe any electric field, and hence any e.m.f. in a moving loop, if field $\mathbf{B}$ is constant in time, so that flux (1) does change in time. However, this is not true; in Chapter 9 we will see that in the reference frame moving with the loop such e.m.f. does appear.

Now let us re-formulate Eq. (5) in terms of the vector-potential. Since the induction effect does not alter the fundamental relation $\nabla \cdot \mathbf{B}=0$, we still may present the magnetic field as prescribed by Eq. (5.27), i.e. as $\mathbf{B}=\nabla \times \mathbf{A}$. Plugging this expression into Eq. (6), we get

$$
\begin{equation*}
\nabla \times\left(\mathbf{E}+\frac{\partial \mathbf{A}}{\partial t}\right)=0 \tag{6.6}
\end{equation*}
$$

Hence we can use the argumentation of Sec. 1.3 (there applied to vector $\mathbf{E}$ alone) to present the expression in parentheses as $-\nabla \phi$, so that

$$
\begin{equation*}
\mathbf{E}=-\frac{\partial \mathbf{A}}{\partial t}-\nabla \phi \tag{6.7}
\end{equation*}
$$

Differential form of the
Faraday law

Electric field vs. potentials

It is tempting to interpret the first term of the right-hand part as describing the electromagnetic induction alone, and the second term representing a purely electric field induced by electric charges. However, the separation of these two terms is, to a certain extent, conditional. Indeed, let us consider the gauge transformation already mentioned in Sec. 5.2,

$$
\begin{equation*}
\mathbf{A} \rightarrow \mathbf{A}+\nabla \chi \tag{6.8}
\end{equation*}
$$

[^282]that, as we already know, does not change the magnetic field. According to Eq. (8), in order to keep the full electric field intact (gauge-invariant) as well, the scalar electric potential has to be transformed simultaneously, as
\[

$$
\begin{equation*}
\phi \rightarrow \phi-\frac{\partial \chi}{\partial t} \tag{6.9}
\end{equation*}
$$

\]

leaving the choice of a time-independent addition to $\phi$ restricted only by the Laplace equation - since the full $\phi$ should satisfy the Poisson equation (1.41) with a gauge-invariant right-hand part. We will return to the discussion of gauge invariance in Sec. 3.

Now let us discuss whether Eqs. (2) or (5) describing the electromagnetic induction represent some completely new facts, on top of all the equations of electrostatics and magnetostatics, discussed in previous five chapters. The answer is not. To demonstrate that, let us consider a thin wire loop with current $I$, placed in a magnetic field (Fig. 1). According to Eq. (5.21), the magnetic force exerted by the field upon a small fragment of the wire is

$$
\begin{equation*}
d \mathbf{F}=I(d \mathbf{r} \times \mathbf{B})=-I(\mathbf{B} \times d \mathbf{r}), \tag{6.10}
\end{equation*}
$$

where $\mathrm{d} \mathbf{r}$ is a small vector, tangential to loop's contour and directed along current $I$. Now let the wire be slightly (and slowly) deformed so that this particular fragment is displaced by a small distance $\delta \mathbf{r}$. (Let me hope that Fig. 1 makes the difference between the elementary vectors $d \mathbf{r}$ and $\delta \mathbf{r}$ absolutely clear.)

Fig. 6.1. Thin wire with current in a magnetic field, and its small deformation.

Since the wire's acceleration (if any) is negligibly small, external (non-magnetic) forces should balance force (10), i.e. provide an equal and opposite force. This is why the work of these external forces at the displacement $\delta \mathbf{r}$, i.e. the change of the magnetic field energy $U$, is,

$$
\begin{equation*}
\delta(d U)=-d \mathbf{F} \cdot \delta \mathbf{r}=I \delta \mathbf{r} \cdot(\mathbf{B} \times d \mathbf{r}) \tag{6.11}
\end{equation*}
$$

Let us apply to this mixed product the general operand rotation rule of the vector algebra, ${ }^{6}$ so that vector B comes out of the vector product:

$$
\begin{equation*}
\delta(d U)=I \mathbf{B} \cdot(d \mathbf{r} \times \delta \mathbf{r}) \tag{6.12}
\end{equation*}
$$

But the magnitude of this vector product is nothing more than the area $\delta\left(d^{2} r\right) \equiv \delta(d S)$ swept by the wire's fragment at the deformation (Fig. 1), while its direction is perpendicular to this elementary area $d S$, along the "proper" normal vector $\mathbf{n}=(d \mathbf{r} / d r) \times(\delta \mathbf{r} / \delta r)$. The scalar multiplication of $\mathbf{B}$ by this vector is

[^283]equivalent to taking its normal component. Hence, integrating Eq. (12) over all the wire length, we get the following result for the total variation of the magnetic energy:
\[

$$
\begin{equation*}
\delta U=I \oint_{C} B_{n} \delta\left(d^{2} r\right) . \tag{6.13}
\end{equation*}
$$

\]

If $\mathbf{B}$ does not change at the wire deformation, the variation sign may be moved out from the integral, and Eq. (13) yields ${ }^{7}$

$$
\begin{equation*}
\delta U=I \delta \Phi \tag{6.14}
\end{equation*}
$$

where $\Phi$ is the magnetic flux through the loop.
Now let the work $\delta \mathcal{W}=\delta U$, necessary for this energy change, to come from a generator of voltage $V_{\text {ext }}$, inserted somewhere in the loop. In order for the system to be in quasi-equilibrium, this voltage should counter-balance the electromagnetic induction's e.m.f. $V_{\text {ind }}$. Work of the voltage at transfer of charge $\delta Q=I \delta t$, during elementary deformation's duration $\delta t$, is

$$
\begin{equation*}
\delta w=V_{\text {ext }} \delta Q=-V_{\text {ind }} \delta Q=-V_{\text {ind }} I \delta t . \tag{6.15}
\end{equation*}
$$

Comparing Eqs. (14) and (15), we arrive at the Faraday induction law (2).
Moreover, some authors derive Eq. (2) in this way, implying that there is no new information in the induction law at all. Note, however, that the simple derivation given above has used the assumption of magnetic field's independence on the deformation. A removal of this limitation would require using the Lorentz field transform (which will be only discussed in Chapter 9), and a very careful argumentation to exclude a faulty logic loop, because the transform itself is typically derived from Maxwell equations - including Eq. (5) that we are trying to prove. Personally I am happy that Dr. Faraday did his thorough work so early, placing the electromagnetic induction law on a firm experimental basis.

### 6.2. Quasistatic approximation and skin effect

As we will see later in this chapter, the interplay of the electromagnetic induction with one more time-dependent effect (the so-called displacement currents), enables electromagnetic waves propagating with speed $c=1 /\left(\varepsilon_{0} \mu_{0}\right)^{1 / 2}$ in free space, and with a comparable speed $v=1 /(\varepsilon \mu)^{1 / 2}$ in dielectric and/or magnetic materials. For the phenomena whose spatial scale is much smaller than the wavelength $\lambda=$ $2 \pi v / \omega$, the displacement current effects are negligible, and time-dependent phenomena may be described by using Eq. (6) together with three other macroscopic Maxwell equations in their unmodified form: ${ }^{8}$

$$
\begin{array}{ll}
\nabla \times \mathbf{E}+\frac{\partial \mathbf{B}}{\partial t}=0, & \nabla \times \mathbf{H}=\mathbf{j}  \tag{6.16}\\
\nabla \cdot \mathbf{D}=\rho, & \nabla \cdot \mathbf{B}=0
\end{array}
$$

These equations define the so-called quasistatic approximation of electromagnetism, and are sufficient to describe many important phenomena. Let us use them first of all for an analysis of the so-

[^284]called skin effect, the phenomenon of self-shielding of the alternating (ac) magnetic fields by currents flowing in a conductor.

In order to form a complete system of equations, Eqs. (16) should be augmented by material equations describing the medium. Let us take them, for a conductor, in the simplest (and simultaneously, most common) linear and isotropic form:

$$
\begin{equation*}
\mathbf{j}=\sigma \mathbf{E}, \quad \mathbf{B}=\mu \mathbf{H} \tag{6.17}
\end{equation*}
$$

If the conductor is uniform, i.e. coefficients $\sigma$ and $\mu$ are constant inside it, the whole system of equations (16)-(17) may be reduced to a single equation. Indeed, a sequential substitution of these equations into each other yields:

$$
\begin{align*}
\frac{\partial \mathbf{B}}{\partial t} & =-\nabla \times \mathbf{E}=-\frac{1}{\sigma} \nabla \times \mathbf{j}=-\frac{1}{\sigma} \nabla \times(\nabla \times \mathbf{H})=-\frac{1}{\sigma \mu} \nabla \times(\nabla \times \mathbf{B})=-\frac{1}{\sigma \mu}\left[\nabla(\nabla \cdot \mathbf{B})-\nabla^{2} \mathbf{B}\right]  \tag{6.18}\\
& =\frac{1}{\sigma \mu} \nabla^{2} \mathbf{B} .
\end{align*}
$$

Thus we have arrived, without any further assumptions, at a very simple partial differential equation. Let us use it to analyze the skin effect in the simplest geometry (Fig. 2a) when an external source (which, at this point, does not need to be specified) produces, near a plane surface of a bulk conductor, a spatially-uniform ac magnetic field $\mathbf{H}^{(0)}(t)$ parallel to the surface.

(a)

(b)

Fig. 6.2. (a) Skin effect in the simplest, planar geometry, and (b) two Ampère contours for deriving the "microscopic" (contour $C_{1}$ ) and the "macroscopic" (contour $C_{2}$ ) boundary conditions for $\mathbf{H}$.

Selecting the coordinate system as shown in Fig. 2, we may express this condition as

$$
\begin{equation*}
\left.\mathbf{H}\right|_{x=-0}=H^{(0)}(t) \mathbf{n}_{y} . \tag{6.19}
\end{equation*}
$$

The translational symmetry of our simple problem within the surface plane $[y, z]$ implies that inside the conductor $\partial / \partial y=\partial / \partial z=0$ as well, and $\mathbf{H}=H(x, t) \mathbf{n}_{y}$ even at $x \geq 0$, so that Eq. (18) for conductor's interior is reduced to a differential equation for just one scalar function $H(x, t)=B(x, t) / \mu:{ }^{9}$

$$
\begin{equation*}
\frac{\partial H}{\partial t}=\frac{1}{\sigma \mu} \frac{\partial^{2} H}{\partial x^{2}}, \quad \text { for } x \geq 0 \tag{6.20}
\end{equation*}
$$

[^285]This equation may be further simplified by noticing that due to its linearity, we may use the linear superposition principle for the time dependence of the field, ${ }^{10}$ via expanding it, as well as the external field (19), into the Fourier series,

$$
\begin{array}{ll}
H(x, t)=\sum_{\omega} H_{\omega}(x) e^{-i \omega t}, & \text { for } x . \geq 0,  \tag{6.21}\\
H^{(0)}(t)=\sum_{\omega} H_{\omega}^{(0)} e^{-i \omega t}, & \text { for } x=0,
\end{array}
$$

and arguing that if we know the solution for each frequency component, the whole field may be found through the elementary summation (17) of these solutions. For each single-frequency component, Eq. (21) is immediately reduced to an ordinary differential equation for the complex amplitude $H_{\omega}(x)$ :

$$
\begin{equation*}
-i \omega H_{\omega}=\frac{1}{\sigma \mu} \frac{d^{2}}{d x^{2}} H_{\omega} \tag{6.22}
\end{equation*}
$$

From the theory of linear differential equations we know that Eq. (22) has the following general solution:

$$
\begin{equation*}
H_{\omega}(x)=H_{+} e^{\kappa_{+} x}+H_{-} e^{\kappa_{-} x}, \tag{6.23}
\end{equation*}
$$

where constants $\kappa_{ \pm}$are roots of the characteristic equation that may be obtained by substitution of any of these two exponents into the initial differential equation. For our particular case, the characteristic equation, following from Eq. (22), is

$$
\begin{equation*}
-i \omega=\frac{\kappa^{2}}{\sigma \mu} \tag{6.24}
\end{equation*}
$$

and its roots are complex constants

$$
\begin{equation*}
\kappa_{ \pm}=(-i \mu \omega \sigma)^{1 / 2}= \pm \frac{1-i}{\sqrt{2}}(\mu \omega \sigma)^{1 / 2} \tag{6.25}
\end{equation*}
$$

For our problem, the field cannot grow exponentially at $x \rightarrow+\infty$, so that only one of the coefficients, namely $H$. corresponding to the decaying exponent, with $\operatorname{Re} \kappa<0$ (i.e. $\kappa=\kappa$ ), may be nonvanishing, so that $H_{\omega}(x)=H_{\omega}(0) \exp \left\{\kappa_{X} x\right\}$. In order to find the constant factor $\mathrm{H}_{\omega}(0)$, we can integrate the Maxwell equation $\nabla \times \mathbf{H}=\mathbf{j}$ along a pre-surface contour - say, contour $C_{1}$ shown in Fig. 2b. The right-hand part's integral is negligible, because $\mathbf{j}$ does not contain any "genuinely surface" currents, localized at a depth much smaller than $1 / \operatorname{Re}[-\mathcal{K}]$. As a result, we get the "microscopic" ${ }^{11}$ boundary condition similar to Eq. (5.118) for the stationary magnetic field, $H_{\tau}=$ const at $x=0$, we get

$$
\begin{equation*}
H(0, t)=H^{(0)}(t), \quad \text { i.e. } H_{\omega}(0)=H_{\omega}^{(0)} \tag{6.26}
\end{equation*}
$$

[^286]so that the final solution of the problem may be presented as
\[

$$
\begin{equation*}
H_{\omega}(x)=H_{\omega}^{(0)} \exp \left\{-\frac{x}{\delta_{s}}\right\} \exp \left\{-i\left(\omega t-\frac{x}{\delta_{s}}\right)\right\}, \tag{6.27a}
\end{equation*}
$$

\]

where constant $\delta_{s}$ is called the skin depth:

$$
\begin{equation*}
\delta_{s} \equiv-\frac{1}{\operatorname{Re} \kappa_{-}}=\left(\frac{2}{\mu \sigma \omega}\right)^{1 / 2} \tag{6.27b}
\end{equation*}
$$

This solution describes the skin effect: the penetration of the ac magnetic field of frequency $\omega$ into a conductor only to a depth of the order of $\delta_{s}$. A couple of examples of the skin depth: for copper at room temperature, $\delta_{s} \approx 1 \mathrm{~cm}$ at the ac power distribution frequency of 60 Hz , and is of the order of just $1 \mu \mathrm{~m}$ at a few GHz , i.e. at typical frequencies of cell phone signals and kitchen microwave magnetrons. For a modestly salted water, $\delta_{s}$ is close to 250 m at 1 Hz (with big implications for radio communications with submarines), and is of the order of 1 cm at a few GHz (explaining a nonuniform heating of a soup bowl in a microwave oven).

In order to complete the skin effect discussion, let us consider what happens with the induced ac currents ${ }^{12}$ and the electric field at this effect. When deriving our basic equation (18), we have used, in particular, relations $\mathbf{j}=\nabla \times \mathbf{H}=\mu^{-1} \nabla \times \mathbf{B}$, and $\mathbf{E}=\mathbf{j} / \sigma$. Since a spatial differentiation of an exponent yield a similar exponents, the electric field and current density have the same spatial dependence as the magnetic field, i.e. penetrate inside the conductor by distances of the order of $\delta_{s}(\omega)$, but their vectors are directed perpendicularly to $\mathbf{B}$, while still being parallel to the conductor surface: ${ }^{13}$

$$
\begin{equation*}
\mathbf{j}_{\omega}(x)=\kappa_{-} H_{\omega}(x) \mathbf{n}_{z}, \quad \mathbf{E}_{\omega}(x)=\frac{\kappa_{-}}{\sigma} H_{\omega}(x) \mathbf{n}_{z} . \tag{6.28}
\end{equation*}
$$

By the way, integrating the first of these relations with the help of Eq. (26a), we may find that the linear density $\mathbf{J}$ of the surface currents (measured in $\mathrm{A} / \mathrm{m}$ ), is simply and fundamentally related to the applied magnetic field:

$$
\begin{equation*}
\mathbf{J}_{\omega} \equiv \int_{0}^{\infty} \mathbf{j}_{\omega}(x) d x=H_{\omega}^{(0)} \mathbf{n}_{z} \tag{6.29}
\end{equation*}
$$

Since this relation does not have frequency-dependent factors, we may sum it up for all frequencies and get a universal relation

$$
\begin{equation*}
\mathbf{J}(t)=H^{(0)}(t) \mathbf{n}_{z} \equiv H^{(0)}(t)\left(-\mathbf{n}_{y} \times \mathbf{n}_{x}\right)=\mathbf{H}^{(0)}(t) \times\left(-\mathbf{n}_{x}\right)=\mathbf{H}^{(0)}(t) \times \mathbf{n} \tag{6.30}
\end{equation*}
$$

where $\mathbf{n}=-\mathbf{n}_{X}$ is the outer normal to the surface - see Fig. 2b. This simple relation (whose last form is independent of the reference frame choice) is not occasional. Indeed, Eq. (30) may be readily obtained from the Ampère law (5.37) applied to a contour drawn around a fragment of the surface, but extending under it much deeper than the skin depth - see contour $C_{2}$ in Fig. 2b, regardless of the exact law of the

[^287]field penetration. Relation (30) is frequently called the "macroscopic" boundary condition for the magnetic field near conductor's surface, to distinguish it from the "microscopic" boundary condition (26).

For the skin effect, the fundamental relation between the surface current density and the external magnetic field means that the effect implementation does not require a dedicated ac magnetic field source. For example, it takes place in any wire that carries ac current, and leads to current concentration in a surface sheet of thickness $\sim \delta_{s}$. (Of course the quantitative analysis of this problem in a wire with an arbitrary cross-section may be technically complicated, because it requires to solve Eq. (18) for a 2D geometry; even for the round cross-section, the solution involves the Bessel functions.) In this case, the ac magnetic field outside the conductor, that still obeys Eq. (30), is better understood as the effect, rather than the reason, of the ac current flow.

Finally, the reader should mind the validity limits of these results - besides the universal Eq. (30). First, in order for the quasistatic approximation to be valid, frequency $\omega$ should not be too high, so that the skin depth (27) remains much smaller than the corresponding wavelength,

$$
\begin{equation*}
\lambda=\frac{2 \pi v}{\omega}=\left(\frac{4 \pi^{2}}{\varepsilon \mu \omega^{2}}\right)^{1 / 2} \tag{6.31}
\end{equation*}
$$

which decreases with $\omega$ faster than $\delta_{s}(27 \mathrm{~b})$. Note that the crossover frequency (at which $\delta_{s}=\lambda$ ),

$$
\begin{equation*}
\omega_{r}=\frac{\sigma}{\varepsilon}=\frac{\sigma}{\varepsilon_{r} \varepsilon_{0}} \tag{6.32}
\end{equation*}
$$

is nothing else than the reciprocal charge relaxation time (4.10). As was discussed in Sec. 4.2, for good metals this frequency is extremely high (about $10^{18} \mathrm{~s}^{-1}$ ).

A more practical upper limit on $\omega$ is that the skin depth $\delta_{s}$ should stay much larger than the mean free path $l$ of charge carriers. ${ }^{14}$ Beyond this point, a non-local relation between vectors $\mathbf{j}(\mathbf{r})$ and $\mathbf{E}(\mathbf{r})$ becomes essential. Both theory and experiment show that at $\delta_{s}<l$, the skin effect still persists, but acquires a slightly different frequency dependence, $\delta_{s} \propto \omega^{-1 / 3}$. Such anomalous skin effect has useful applications, for example, for experimental measurements of the Fermi surface in metals. ${ }^{15}$

### 6.3. Electrodynamics of superconductivity and gauge invariance

The effect of superconductivity ${ }^{16}$ takes place when temperature $T$ is reduced below a certain critical temperature $\left(T_{c}\right)$, specific for each material. For most metallic superconductors, $T_{c}$ is of the order of typically a few kelvins, though several exotic compounds (the so-called high-temperature superconductors) with $T_{c}$ above 100 K have been found since 1987 . The most notable property of superconductors is the absence, at $T<T_{c}$, of measurable resistance to not very high dc currents.

[^288]However, electromagnetic properties of superconductors cannot be described by just taking $\sigma=$ $\infty$ in our previous results. Indeed, for this case, Eq. (27b) would give $\delta_{s}=0$, i.e., no ac magnetic field penetration at all, while for the dc field we would have the uncertainty $\sigma \omega=$ ? Experiment shows something substantially different: weak magnetic fields do penetrate into superconductors by a materialspecific London penetration depth $\delta_{\mathrm{L}} \sim 10^{-7}-10^{-6} \mathrm{~m},{ }^{17}$ which is virtually frequency-independent until the skin depth $\delta_{s}$, measured in the same material in its "normal" state, i.e. the absence of superconductivity, becomes less than $\delta_{\mathrm{L}}$. (This crossover happens typically at frequencies $\sim 10^{13} \mathrm{~s}^{-1}$.) The smallness of $\delta_{\mathrm{L}}$ means that the magnetic field is pushed out of macroscopic samples at their transition into the superconducting state.

This Meissner-Ochsenfeld effect, discovered experimentally in 1933, ${ }^{18}$ may be partly understood using the following classical reasoning. When we discussed the physics of conductivity in Sec. 4.2, we implied that the current (and electric field) frequency $\omega$ is either zero or sufficiently low. In the classical Drude reasoning (see Sec. 4.2), this is acceptable while $\omega \tau \ll 1$, where $\tau$ is the effective carrier scattering time participating in Eqs. (4.12)-(4.13). If this condition is not satisfied, we should take into account the charge carrier inertia; moreover, in the opposite limit $\omega \tau \gg 1$ we may neglect the scattering at all. Classically, we can describe the charge carriers in such a "perfect conductor" as particles that are accelerated by the electric field in accordance with the $2^{\text {nd }}$ Newton law (4.11) at all times,

$$
\begin{equation*}
\dot{\mathbf{v}}=\frac{1}{m} \mathbf{F}=\frac{q}{m} \mathbf{E}, \tag{6.33}
\end{equation*}
$$

so that the current density $\mathbf{j}=q n \mathbf{v}$ they create changes in time as

$$
\begin{equation*}
\dot{\mathbf{j}}=\frac{q^{2} n}{m} \mathbf{E} \tag{6.34}
\end{equation*}
$$

In terms of the Fourier amplitudes (see the previous section), this means

$$
\begin{equation*}
-i \omega \mathbf{j}_{\omega}=\frac{q^{2} n}{m} \mathbf{E}_{\omega} \tag{6.35}
\end{equation*}
$$

Comparing this formula with the relation $\mathbf{j}_{\omega}=\sigma \mathbf{E}_{\omega}$ implied in the last section, we see that we can use all its results with the following replacement:

$$
\begin{equation*}
\sigma \rightarrow i \frac{q^{2} n}{m \omega} \tag{6.36}
\end{equation*}
$$

This change replaces the characteristic equation (24) with

$$
\begin{equation*}
-i \omega=\frac{\kappa^{2} m \omega}{i q^{2} n \mu} \tag{6.37}
\end{equation*}
$$

i.e. replaces the skin effect with the field penetration by the following frequency-independent depth:

[^289]\[

$$
\begin{equation*}
\delta=\left(\frac{m}{\mu q^{2} n}\right)^{1 / 2} \tag{6.38}
\end{equation*}
$$

\]

Superficially, this means that the field decay into the superconductor does not depend on frequency:

$$
\begin{equation*}
H(x, t)=H(0, t) \exp \left\{-\frac{x}{\delta}\right\} \tag{6.39}
\end{equation*}
$$

explaining the Meissner-Ochsenfeld effect.
However, there are two problems with this result. First, for the parameters typical for good metals ( $q=-e, n \sim 10^{29} \mathrm{~m}^{-3}, m \sim m_{e}, \mu \approx \mu_{0}$ ), Eq. (38) gives $\delta \sim 10^{-8} \mathrm{~m}$, a factor of $10-10^{2}$ lower than the typical experimental values of $\delta_{\mathrm{L}}$. Experiment also shows that the penetration depth diverges at $T \rightarrow T_{c}$, which is not predicted by Eq. (38). Another, much more fundamental problem with Eq. (38) is that it has been derived for $\omega \tau \gg 1$. Even is we assume that somehow there are no collisions at all, i.e. $\tau=\infty$, at $\omega \rightarrow 0$ both parts of the characteristic equation (37) vanish, and we cannot make any conclusion about $k$. This is not just a mathematical artifact we could ignore. For example, let us place a non-magnetic metal at $T>T_{c}$ into a static external magnetic field. The field will completely penetrate into the sample. Now let us cool it. As soon as the temperature drops below $T_{c}$, our calculations become valid, forbidding the penetration into the superconductor of any change of the field, so that the initial field would be "frozen" inside the sample. The experiment shows something completely different: as $T$ is lowered below $T_{c}$, the initial field is being pushed out of the sample.

The resolution of these contradictions has been provided by quantum mechanics. As was explained in 1957 in a seminal work by J. Bardeen, L. Cooper, and J. Schrieffer (commonly referred to the BSC theory), superconductivity is due to the correlated motion of electron pairs, with opposite spins and nearly opposite momenta. Such Cooper pairs, each with the electric charge $q=-2 e$ and zero spin, may form only in a narrow energy layer near the Fermi surface, of certain thickness $\Delta(T)$. Parameter $\Delta(T)$, which may be also considered as the binding energy of the pair, tends to zero at $T \rightarrow T_{\mathrm{c}}$, while at $T$ $\ll T_{c}$ it has a virtually constant value $\Delta(0) \approx 3.5 k_{\mathrm{B}} T_{c}$, of the order of a few meV for most superconductors. This fact readily explains the relatively low spatial density of the Cooper pairs: $n_{p}(T) \sim$ $n \Delta(T) / \varepsilon_{\mathrm{F}} \sim 10^{26} \mathrm{~m}^{-3}$. With the correction $n \rightarrow n_{p}$, our Eq. (38) for the penetration depth becomes

$$
\begin{equation*}
\delta \rightarrow \delta_{\mathrm{L}}=\left(\frac{m}{\mu q^{2} n_{p}(T)}\right)^{1 / 2} \tag{6.40}
\end{equation*}
$$

London penetration depth

This expression diverges at $T \rightarrow T_{c}$, and generally fits the experimental data reasonably well, at least for the so-called "clean" superconductors (with the mean free path $l \equiv v \tau$ much longer that the Cooper pair size $\xi$ - see below).

The smallness of the coupling energy $\Delta(T)$ is also a key factor in the explanation of the Meissner-Ochsenfeld effect, as well as several macroscopic quantum phenomena in superconductors. Because of Heisenberg's quantum uncertainty relation $\delta r \delta p \sim \hbar$, the Cooper-pair size (the so-called coherence length) is relatively large: $\xi \sim \delta r \sim \hbar / \delta p \sim \hbar \nu_{\mathrm{F}} / \Delta(T) \sim 10^{-6} \mathrm{~m}$. As a result, $n_{p} \xi^{3} \gg 1$, meaning that Cooper pairs are strongly overlapped in space. Now, due to their integer spin, Cooper pairs behave like bosons, which means in particular that at low temperature they exhibit the so-called Bose-Einstein
condensation onto the same energy level. ${ }^{19}$ This means that the frequency $\omega=E / \hbar$ of the time evolution of each pair's wavefunction $\Psi=\psi \exp \{-i \omega t\}$ is the same, i.e. that the phases $\varphi$ of the wavefunctions, defined by equation

$$
\begin{equation*}
\psi=|\psi| e^{i \varphi} \tag{6.41}
\end{equation*}
$$

become equal, so that the current is carried not by individual Cooper pairs but rather their Bose-Einstein condensate described by a single wavefunction. Due to this coherence, the quantum effects (which are, in usual Fermi-liquids of single electrons, masked by the statistical spread of phases $\varphi$ ), become very explicit - "macroscopic".

To illustrate this, let us write the well-known quantum-mechanical formula for the probability current of a free, non-relativistic particle, ${ }^{20}$

$$
\begin{equation*}
\mathbf{j}_{p}=\frac{i \hbar}{2 m}\left(\psi \nabla \psi^{*}-\text { c.c. }\right)=\frac{1}{2 m}\left[\psi^{*}(-i \hbar \nabla) \psi-\text { c.c. }\right] . \tag{6.42}
\end{equation*}
$$

Now let me borrow one result that will be proved later in the course (in Sec. 9.7) when we discuss the analytical mechanics of a charged particle moving in an electromagnetic field. Namely, in order to account for the magnetic field effects, particle's kinetic momentum $\mathbf{p}$, equal to $m \mathbf{v}$ (where $\mathbf{v} \equiv d \mathbf{r} / d t$ is particle's velocity) has to be distinguished from its canonical momentum, ${ }^{21}$

$$
\begin{equation*}
\mathbf{P} \equiv \mathbf{p}+q \mathbf{A} . \tag{6.43}
\end{equation*}
$$

where $\mathbf{A}$ is the vector-potential of the field - see Eq. (5.27). In contrast with Cartesian components $p_{j}=$ $m u_{j}$ of momentum $\mathbf{p}$, the canonical momentum components are the generalized momenta corresponding to components $r_{j}$ of the radius-vector $\mathbf{r}$, considered as generalized coordinates of the particle: $P_{j}=$ $\partial \mathcal{L} / \partial v_{j}$, where $\mathcal{L}$ is the particle's Lagrangian function. According to the general rules of transfer from classical to quantum mechanics, ${ }^{22}$ it is vector $\mathbf{P}$ whose operator (in the Schrödinger picture) equals $-i \hbar \nabla$, so that the operator of kinetic momentum $\mathbf{p}=\mathbf{P}-q \mathbf{A}$ is equal to $-i \hbar \nabla-q \mathbf{A}$. Hence, the in order to account for the magnetic field effects, we should make the following replacement:

$$
\begin{equation*}
-i \hbar \nabla \rightarrow-i \hbar \nabla-q \mathbf{A} . \tag{6.44}
\end{equation*}
$$

In particular, Eq. (42) has to be replaced with

$$
\begin{equation*}
\mathbf{j}_{p}=\frac{1}{2 m}\left[\psi^{*}(-i \hbar \nabla-q \mathbf{A}) \psi-\text { c.c. }\right] . \tag{6.45}
\end{equation*}
$$

This expression becomes more transparent if we take the wavefunction in form (41):

[^290]\[

$$
\begin{equation*}
\mathbf{j}_{p}=\frac{\hbar}{m}|\psi|^{2}\left(\nabla \varphi-\frac{q}{\hbar} \mathbf{A}\right) . \tag{6.46}
\end{equation*}
$$

\]

This relation means, in particular, that in order to keep $\mathbf{j}$ invariant, the gauge transformation (8)-(9) has to be accompanied by a simultaneous transformation of the wavefunction phase:

$$
\begin{equation*}
\varphi \rightarrow \varphi+\frac{q}{\hbar} \chi \tag{6.47}
\end{equation*}
$$

It is fascinating that the quantum-mechanical wavefunction (more exactly, its phase) is not gaugeinvariant - meaning that you may change it in your mind - at will! Again, this does not change any observable (such as $\mathbf{j}$ or the probability density $\psi \psi^{*}$ ), i.e. any experimental results.

For the electric current density of the whole superconducting condensate, Eq. (46) yields

$$
\begin{equation*}
\mathbf{j}=\frac{\hbar q n_{p}(T)}{m}\left(\nabla \varphi-\frac{q}{\hbar} \mathbf{A}\right) . \tag{6.48}
\end{equation*}
$$

This equation shows that this supercurrent may be induced by dc magnetic field alone and does not require any electric field. Indeed, for the simplest, 1D geometry shown in Fig. 2a, $\mathbf{j}(\mathbf{r})=j(x) \mathbf{n}_{z}, \mathbf{A}(\mathbf{r})=$ $A(x) \mathbf{n}_{z}$, and $\partial / \partial z=0$, so that the Coulomb gauge condition (5.48) is satisfied for any choice of the gauge function $\chi(x)$, and for the sake of simplicity we can choose it to provide $\varphi(\mathbf{r}) \equiv$ const, ${ }^{23}$ so that

$$
\begin{equation*}
\mathbf{j}=-\frac{q^{2} n_{p}(T)}{m} \mathbf{A} . \tag{6.49}
\end{equation*}
$$

This is the so-called London equation, proposed (in a different form) by brothers F. and H. London in 1935 for a phenomenological description of the Meissner-Ochsenfeld effect. Combining it with Eq. (5.47), generalized for an arbitrary uniform media by the replacement $\mu_{0} \rightarrow \mu$, we get

$$
\begin{equation*}
\nabla^{2} \mathbf{A}=\frac{\mu q^{2} n_{p}(T)}{m} \mathbf{A} \tag{6.50}
\end{equation*}
$$

This simple differential equation, similar in structure to Eq. (18), has a similar exponential solution,

$$
\begin{equation*}
A(x)=A(0) \exp \left\{-\frac{x}{\delta_{L}}\right\}, \quad B(x)=B(0) \exp \left\{-\frac{x}{\delta_{L}}\right\}, \quad j(x)=j(0) \exp \left\{-\frac{x}{\delta_{L}}\right\}, \tag{6.51}
\end{equation*}
$$

that shows that the magnetic field and supercurrent penetrate into a superconductor only by the London's penetration depth $\delta_{\mathrm{L}}$, given by Eq. (40), regardless of frequency. ${ }^{24}$ By the way, integrating the last result through the penetration layer, and using Eqs. (34), (43) and the vector-potential definition, B $=\nabla \times \mathbf{A}$ (for our geometry, giving $B(x)=d A(x) / d x=-\delta_{\mathrm{L}} A(x)$ ) we may check that the linear density $\mathbf{J}$ of the surface supercurrent still satisfies the universal relation (30).

[^291]Let me hope that the physical intuition of the reader enables him or her to make the following semi-quantitative generalization of the quantitative solution (51) to superconductor sample of arbitrary shape: B and $\mathbf{j}$ may only penetrate into the sample by distances of the order of $\delta_{\mathrm{L}}(0)$. In particular, for samples much larger than $\delta_{\mathrm{L}}$, the London theory gives the following "macroscopic" description of the Meissner-Ochsenfeld effect: $\mathbf{j}=0$ and $\mathbf{B}=0$ everywhere inside a superconductor. In this coarse description, the bulk superconductor sample behaves as an ideal diamagnet, with $\mu=0 .{ }^{25}$ In particular, we can use this analogy and the first of Eqs. (5.125) to immediately obtain the magnetic field distribution outside a superconducting sphere:

$$
\begin{equation*}
\mathbf{B}=\mu_{0} \mathbf{H}=-\mu_{0} \nabla \phi_{m}, \quad \phi_{m}=H_{0}\left(-r-\frac{R^{3}}{2 r^{2}}\right) \cos \theta \tag{6.52}
\end{equation*}
$$

Figure 3 shows the corresponding surfaces of equal potential $\phi_{m}$. It is evident that the magnetic field lines (normal to the equipotential surfaces) bend to become parallel to the superconductor's surface. By the way, this pattern illustrates the answer to the question that might arise at making assumption (19): what happens to superconductors in a normal magnetic field? The answer is: the field is deformed outside the superconductor to provide $B_{n}=0$ at the surface - otherwise, due to the continuity of $B_{n}$, the magnetic field would penetrate the superconductor, which is impossible. Of course this answer should be taken with a grain of salt: strong magnetic fields do penetrate into superconductors, destroying superconductivity (completely or partly), thus violating the Meissner-Ochsenfeld effect. Such a penetration by itself features several interesting electrodynamic effects, for whose discussion we unfortunately do not have time. ${ }^{26}$

Fig. 6.3. Surfaces of constant scalar potential $\phi_{m}$ of magnetic field around a superconducting sphere of radius $R \gg \delta_{\mathrm{L}}$, placed into a weak uniform, vertical magnetic field.

### 6.4. Electrodynamics of macroscopic quantum phenomena

We have seen that for the ac magnetic field penetration, the quantum theory of superconductivity gives essentially the same result as the classical theory of a perfect conductor - cf. Eqs. (39) and (51) with the "only" conceptual exception that the former theory extends the effect to dc fields. However, the

[^292]quantum theory of superconductors is much more rich. For example, let us use Eq. (48) to derive the fascinating effect of magnetic flux quantization. Consider a closed ring made of a superconducting "wire" with a cross-section much larger than $\delta_{\mathrm{L}}{ }^{2}$ (Fig. 4a).

Fig. 6.4. (a) Closed, flux-quantizing superconducting ring, (b) a ring cut with a narrow slit, and (c) a Superconducting QUantum Interference Device (SQUID).

From the last section's analysis, we know that deep inside the wire the supercurrent is exponentially small. Integrating Eq. (48) along any closed contour $C$ that does not approach the surface closer than a few $\delta_{\mathrm{L}}$ at any point, we get

$$
\begin{equation*}
\oint_{C} \nabla \varphi \cdot d \mathbf{r}-\frac{q}{\hbar} \oint_{C} \mathbf{A} \cdot d \mathbf{r}=0 . \tag{6.53}
\end{equation*}
$$

The first integral, i.e. the difference of $\varphi$ in the initial and final points, has to be equal to either zero or an integer number of $2 \pi$, because the change $\varphi \rightarrow \varphi+2 \pi n$ does not change condensate's wavefunction:

$$
\begin{equation*}
\psi^{\prime}=|\psi| e^{i(\varphi+2 \pi n)}=|\psi| e^{i \varphi}=\psi \tag{6.54}
\end{equation*}
$$

On the other hand, the second integral in Eq. (53) is just the magnetic flux $\Phi$ (1) through the contour and, due to the Meissner-Ochsenfeld effect, through the superconducting ring as a whole. As a result, we get

$$
\begin{equation*}
\Phi=n \Phi_{0}, \quad \Phi_{0} \equiv \frac{2 \pi \hbar}{q}=\frac{h}{q}, \quad n=0, \pm 1, \pm 2, \ldots \tag{6.55}
\end{equation*}
$$

i.e. the magnetic flux can only take values multiple of the flux quantum $\Phi_{0}$. This effect, predicted in 1950 by the same Fritz London (who expected $q$ to be equal to the electron charge $-e$ ), was confirmed experimentally in $1961,{ }^{27}$ with $|q|=2 e$ (so that in superconductors $\Phi_{0}=h / 2 e \approx 2.07 \times 10^{-15} \mathrm{~Wb}$ ). Historically, this observation gave a decisive support to the BSC theory of the Cooper pairs as the basis of superconductivity, which had been put forward just 4 years before. ${ }^{28}$

[^293]The flux quantization is just one of the so-called macroscopic quantum effects in superconductivity. Consider, for example, a superconducting ring interrupted with a very narrow slit (Fig. 4b). Integrating Eq. (48) along the current-free path from point 1 to point 2, along the dashed line in Fig. 4 (again, deeper than $\delta_{\mathrm{L}}(T)$ from the surface), we get

$$
\begin{equation*}
0=\int_{1}^{2}\left(\nabla \varphi-\frac{q}{\hbar} \mathbf{A}\right) \cdot d \mathbf{r}=\varphi_{2}-\varphi_{1}-\frac{q}{\hbar} \Phi . \tag{6.56}
\end{equation*}
$$

Using the flux quantum definition (55), this result may be rewritten as

phase difference

$$
\begin{equation*}
\varphi \equiv \varphi_{1}-\varphi_{2}=\frac{2 \pi}{\Phi_{0}} \Phi \tag{6.57}
\end{equation*}
$$

where $\varphi$ is called the Josephson phase difference. In contrast to each of the phases $\varphi_{1,2}$, their difference $\varphi$ is gauge-invariant, because it is directly related to the gauge-invariant magnetic flux.

Can this $\varphi$ be measured? Yes, using the Josephson effect. ${ }^{29}$ In order to understand his prediction, let us take two (for the argument simplicity, similar) superconductors, connected with some sort of weak link, for example a tunnel barrier or a short normal-metal bridge, through that a small Cooper pair current can flow. (Such system of two coupled superconductors is now called a Josephson junction.) Let us think what this supercurrent I may be a function of. For that, the reverse thinking is helpful: let us imagine we can change current from outside; what parameter of the superconducting condensate can it affect?

If the current is weak, it cannot perturb the superconducting condensate density, proportional to $|\psi|^{2}$; hence it may only change the Cooper condensate phases $\varphi_{1,2}$. However, according to Eq. (41), the phases are not gauge-invariant, while the current should be, hence I may affect - or should be a function of - the phase difference $\varphi$ defined by Eq. (57). Moreover, just has already been argued during the flux quantization discussion, a change of any of $\varphi_{1,2}$ (and hence of $\varphi$ ) by $2 \pi$ or any of its multiples should not change the current. In addition, if the wavefunction is the same in both superconductors $(\varphi=0)$, supercurrent should vanish due to the system symmetry. Hence function $I(\varphi)$ should satisfy conditions

$$
\begin{equation*}
I(0)=0, \quad I(\varphi+2 \pi)=I(\varphi) \tag{6.58}
\end{equation*}
$$

With this understanding, we should not be terribly surprised by the following Josephson's result that for the weak link provided by weak tunneling, ${ }^{30}$

$$
\begin{equation*}
I(\varphi)=I_{c} \sin \varphi, \tag{6.59}
\end{equation*}
$$

superconductors, whose coherence length $\xi$ is smaller than the London's penetration depth $\delta_{\mathrm{L}}(T)$, in the form of self-formed tubes surrounded by vortex-shaped supercurrents - the so-called Abrikosov vortices, with the superconductivity suppressed near the middle of each tube. This suppression makes each flux tube topologically equivalent to a superconducting ring, with the magnetic flux through it equal to one flux quantum, and its ends being magnetically similar to magnetic monopoles - see Sec. 5.6 above.
${ }^{29}$ It was predicted in 1961 by B. Josephson (then a PhD student!), and observed experimentally by several groups soon after that.
${ }^{30}$ For some other types of weak links, function $I(\varphi)$ may deviate from the sine form (59) rather considerably, still satisfying the general requirements (58).
where constant $I_{c}$, which depends on of the strength of the weak link and temperature, is called the critical current.

Let me show how such expression may be derived, for a narrow and short weak link made of a normal metal or a superconductor. ${ }^{31}$ Microscopic theory of superconductivity shows that, within certain limits, the Bose-Einstein condensate of Cooper pairs may be described by the following nonlinear Schrödinger equation ${ }^{32}$

$$
\begin{equation*}
\frac{1}{2 m}(-i \hbar \nabla-q \mathbf{A})^{2} \psi+U(r) \psi=\varepsilon \psi+\psi \times\left(\text { a nonlinear function of }|\psi|^{2}\right) . \tag{6.60}
\end{equation*}
$$

The first three terms of this equation are similar to those of the usual Schrödinger equation (which conserves the number of particles), while the nonlinear function in the last term describes the formation and dissolution of Cooper pairs, and in particular gives the equilibrium value of $n_{s}$ as a function of temperature. Now let the weak link size scale $a$ be much smaller than both the Cooper pair size $\xi$ and the London's penetration depth $\delta_{\mathrm{L}}$. The first of these relations ( $a \ll \xi$ ) makes the first term in Eq. (60), that scales as $1 / a^{2}$, much larger than all other terms, while the latter relation ( $a \ll \delta_{\mathrm{L}}$ ) allows one to neglect magnetic field effects, and hence drop term ( $-q \mathbf{A}$ ) from the parenthesis in Eq. (60), reducing it to just our familiar Laplace equation for the wavefunction:

$$
\begin{equation*}
\nabla^{2} \psi=0 \tag{6.61}
\end{equation*}
$$

Since the weak coupling cannot change $|\psi|$ in bulk superconducting electrodes, Eq. (61) may be solved with the following simple boundary conditions:

$$
\psi(r) \rightarrow \begin{cases}|\psi| e^{i \varphi_{1}}, & \text { for } \mathbf{r} \rightarrow \mathbf{r}_{1}  \tag{6.62}\\ |\psi| e^{i \varphi_{2}}, & \text { for } \mathbf{r} \rightarrow \mathbf{r}_{2}\end{cases}
$$

where $\mathbf{r}_{1}$ and $\mathbf{r}_{2}$ are some points well inside the corresponding superconductors, i.e. at distances much larger than $a$ from the weak link center. It is straightforward to verify that the solution of this boundary problem for complex function $\psi$ may be expressed as follows,

$$
\begin{equation*}
\psi(\mathbf{r})=|\psi| e^{i \varphi_{1}} f(\mathbf{r})+|\psi| e^{i \varphi_{1}}(1-f(\mathbf{r})) \tag{6.63}
\end{equation*}
$$

via the real function $f(\mathbf{r})$ that satisfies the Laplace equation and the following boundary conditions:

$$
f(\mathbf{r}) \rightarrow \begin{cases}1, & \text { for } \mathbf{r} \rightarrow \mathbf{r}_{1}  \tag{6.64}\\ 0, & \text { for } \mathbf{r} \rightarrow \mathbf{r}_{2}\end{cases}
$$

Function $f(\mathbf{r})$ depends on the weak link geometry and may be rather complicated, but we do not

[^294]need to know it to get the most important result. Indeed, plugging this solution into Eq. (48) (with term $q \mathbf{A}$ ignored as being negligibly small), we get
\[

$$
\begin{equation*}
\mathbf{j}_{p}=-\frac{\hbar}{m}|\psi|^{2} \nabla f \sin \varphi, \quad \text { so that } \mathbf{j}=-\frac{\hbar q n_{p}(T)}{m} \nabla f \sin \varphi . \tag{6.65}
\end{equation*}
$$

\]

Integrating this relation over any cross-section $S$ of the weak link, we arrive at Josephson's result (59), with the following critical current:

$$
\begin{equation*}
I_{c}=-\frac{\hbar q n_{p}(T)}{m} \int_{S}(\nabla f)_{n} d^{2} r . \tag{6.66}
\end{equation*}
$$

This expression may be readily evaluated via the resistance of the same weak link in the "normal" (non-superconducting) state, say at $T>T_{c}$. Indeed, as we know from Sec. 4.3, the distribution of the electrostatic potential $\phi$ at normal conduction also obeys the Laplace equation, with boundary conditions that may be taken in the form

$$
\phi(\mathbf{r}) \rightarrow \begin{cases}V, & \text { for } \mathbf{r} \rightarrow \mathbf{r}_{1}  \tag{6.67}\\ 0, & \text { for } \mathbf{r} \rightarrow \mathbf{r}_{2}\end{cases}
$$

Comparing the boundary problem for $\phi(\mathbf{r})$ with that for function $f(\mathbf{r})$, we get $\phi=V f$. This means that the gradient $\nabla f$, which participates in Eq. (66), is just $(-E / V)=(-\mathbf{j} / \sigma V)$. Hence the integral in that formula is just $-I / \sigma V=-1 / \sigma R_{n}$, where $R_{n}$ is the resistance of the Josephson junction in its normal state. As a result, Eq. (66) yields

$$
\begin{equation*}
I_{c}=\frac{\hbar q n_{p}(T)}{m \sigma} \frac{1}{R_{n}}, \tag{6.68}
\end{equation*}
$$

showing that the $I_{c} R_{n}$ product does not depend on the junction geometry, though it does depend on temperature, vanishing, together with $n_{p}(T)$, at $T \rightarrow T_{\mathrm{c}}$. (Well below the critical temperature, $I_{c} R_{n}$ of a sufficiently short weak links is of the order of $\Delta(0) / e$, i.e. of the order of a few mV .)

Now let us see what happens if a Josephson junction is placed into the gap in a superconductor ring - see Fig. 4c. In this case, we can combine Eqs. (57) and (59), getting

Macroscopic quantum interference

$$
\begin{equation*}
I=I_{c} \sin 2 \pi \frac{\Phi}{\Phi_{0}} \tag{6.69}
\end{equation*}
$$

This effect of periodic dependence of the current on flux is called the macroscopic quantum interference, ${ }^{33}$ while the system shown in Fig. 4b, a superconducting quantum interference device, abbreviated as SQUID (with all letters capital, please :-). The low value of the magnetic flux quantum $\Phi_{0}$, and hence the high sensitivity of $\varphi$ to the magnetic field, allows using SQUIDs as ultrasensitive magnetometers. Indeed, for a superconducting ring of area $\sim 1 \mathrm{~cm}^{2}$, one period of the change of supercurrent (69) is produced by magnetic filed change of the order of $10^{-11} \mathrm{~T}\left(10^{-7} \mathrm{Gs}\right)$, while sensitive electronics allows to measure a tiny fraction of this period - limited by thermal noise at a level of the

[^295]order of a few pT . This sensitivity allows measurements, for example, of the magnetic fields induced by the beating human heart, and even by brain activity, outside of the body.

An important aspect of the quantum interference is the so-called Aharonov-Bohm (AB) effect. ${ }^{34}$ Let the magnetic field lines be limited to the central part of the SQUID ring, so that no appreciable magnetic field ever touches the superconducting ring material. (This may be done experimentally with very good accuracy, for example using high- $\mu$ magnetic cores - see their discussion in Sec. 5.6.) As predicted by Eq. (69), and confirmed by several careful experiments carried out in the mid-1960s, ${ }^{35}$ this restriction does not matter - the interference is observed anyway. This means that not only the magnetic field $\mathbf{B}$, but also the vector-potential $\mathbf{A}$ represents physical reality, albeit quite a peculiar one remember the gauge transformation?

Actually, the magnetic flux quantization (55) and the macroscopic quantum interference (69) are not completely different effects, but just two manifestations of the whole group of inter-related macroscopic quantum phenomena. In order to show that, one should note that if critical current $I_{c}$ (or rather its product by loop's self-inductance $L$ ) is high enough, flux $\Phi$ in the SQUID loop is due not only to the external magnetic field flux $\Phi_{e}$, but also has a self-field component - cf. Eq. (5.61):36

$$
\begin{equation*}
\Phi=\Phi_{\mathrm{ext}}-L I, \quad \text { where } \Phi_{\mathrm{ext}} \equiv \int_{S}\left(B_{\mathrm{ext}}\right)_{n} d^{2} r . \tag{6.70}
\end{equation*}
$$

Now the relation between $\Phi$ and $\Phi_{\text {ext }}$ may be found by solving this equation together with Eq. (69). Figure 5 shows this relation for several values of the dimensionless parameter $\lambda \equiv 2 \pi L I_{c} / \Phi_{0}$.

Fig. 6.5. Function $\Phi\left(\Phi_{\text {ext }}\right)$ for SQUIDs with various values of the normalized $L I_{c}$ product. Dashed arrows show the flux leaps as the external field is changed. (The branches with $d \Phi / d \Phi_{\text {ext }}<0$ are unstable.)

[^296]These plots show that if the critical current or (or the inductance) is low, $\lambda \ll 1$, the self-effects are negligible, and the total flux follows the external field (i.e., $\Phi_{\text {ext }}$ ) quite faithfully. However, at $\lambda>1$, the dependence $\Phi\left(\Phi_{\mathrm{ext}}\right)$ becomes hysteretic, and at $\lambda \gg 1$ the positive-slope (stable) branches of this function are nearly flat, with the total flux values corresponding to Eq. (55). Thus, a superconducting ring closed by a high- $I_{c}$ Josephson junction exhibits a nearly-perfect flux quantization.

The self-field effects described by Eq. (70) create certain technical problems for SQUID magnetometry, but they are the basis for one more application of these devices: ultrafast computing. Indeed, Fig. 5 shows that at the values of $\lambda$ modestly above 1 (e.g., $\lambda \approx 3$ ), and within a certain range of applied field, the SQUID has two stable flux states that differ by $\Delta \Phi \approx \Phi_{0}$ and may be used for coding binary 0 and 1 . For practical superconductors (like Nb ), the time of switching between these states (see dashed arrows in Fig. 4) are of the order of a picosecond, while the energy dissipated at such event may be as low as $\sim 10^{-19} \mathrm{~J}$. (This bound is determined not by device's physics, by the fundamental requirement for the energy barrier between the two states to be much higher than the thermal fluctuation energy scale $k_{\mathrm{B}} T$, ensuring a sufficiently long information retention time.) While the picosecond switching speed may be also achieved with some semiconductor devices, the power consumption of the SQUID-based digital devices may be 5 to 6 orders of magnitude lower, enabling VLSI circuits with $100-\mathrm{GHz}$-scale clock frequencies and manageable power dissipation. Unfortunately, the range of practical application of these Rapid Single-Flux-Quantum (RSFQ) logic circuits is still narrow, due to the inconvenience of their deep refrigeration to temperatures below $T_{c} .{ }^{37}$

Since we have already got the basic relations (57) and (59) describing the macroscopic quantum phenomena in superconductivity, let me mention in brief two other members of this group, called the Josephson effects. Differentiating Eq. (57) over time, and using the Faraday induction law (2), we get ${ }^{38}$

$$
\begin{equation*}
\frac{d \varphi}{d t}=\frac{2 e}{\hbar} V . \tag{6.71}
\end{equation*}
$$

This famous phase-to-voltage relation should be valid regardless of the way how voltage $V$ has been created, ${ }^{39}$ so let us apply Eqs. (59) and (71) to the simplest circuit with a non-superconducting source of dc voltage - see Fig. 6.

Fig. 6.6. DC-voltage-biased Josephson junction.

[^297]If current $I$ is below the critical value,

$$
\begin{equation*}
-I_{c}<I<+I_{c}, \tag{6.72}
\end{equation*}
$$

Eq. (59) allows phase $\varphi$ to have a time-independent value

$$
\begin{equation*}
\varphi=\sin ^{-1} \frac{I}{I_{c}} \tag{6.73}
\end{equation*}
$$

and hence, according to Eq. (71), a vanishing voltage drop across the junction: $V=0$. This dc Josephson effect is not quite surprising - indeed, we have postulated from the very beginning that the Josephson junction may pass a certain supercurrent. Much more fascinating is the so-called ac Josephson effect that takes place if voltage across the junction has a nonvanishing average (dc) component $V_{0}$. For simplicity, let us assume that this is the only voltage component: $V(t)=V_{0}=$ const, ${ }^{40}$ then Eq. (71) may be readily integrated to give $\varphi=\omega_{\mathrm{J}} t+\varphi_{0}$, where

$$
\begin{equation*}
\omega_{\mathrm{J}} \equiv \frac{2 e}{\hbar} V_{0} . \tag{6.74}
\end{equation*}
$$

This result, plugged into Eq. (59), shows that supercurrent oscillates,

$$
\begin{equation*}
I(\varphi)=I_{c} \sin \left(\omega_{\mathrm{J}} t+\varphi_{0}\right) \tag{6.75}
\end{equation*}
$$

with the Josephson frequency $\omega_{\mathrm{J}}$ (74), which is proportional to the applied dc voltage. For practicable voltages, frequency $f_{\mathrm{J}}=\omega_{\mathrm{J}} / 2 \pi$ corresponds to the GHz or even THz ranges, because the proportionality coefficient in Eq. (74) is very high: $f_{\mathrm{J}} / V_{0}=2 e / h \approx 483 \mathrm{MHz} / \mu \mathrm{V} .41$ An important experimental fact is the universality of this coefficient. For example, in the mid-1980s, the group led by Prof. J. Lukens of our department proved that this factor is material-independent with the relative accuracy of at least $10^{-15}$. Very few experiments, especially in solid state physics, have ever reached such precision.

This fundamental nature of the Josephson voltage-to-frequency relation (74) allows an important application of the ac Josephson effect in metrology. Namely, phase locking the Josephson oscillations with an external microwave signal derived from an atomic frequency standards one can get the most precise dc voltage than from any other source. In NIST and other metrological institutions around the globe, this effect is used for the calibration of simpler "secondary" voltage standards that can operate at room temperature. ${ }^{42}$

### 6.5. Inductors, transformers, and ac Kirchhoff laws

Let a wire coil (meaning either a single loop illustrated in Fig. 5.4b, or a series of such loops, such as one of the solenoids shown in Fig. 5.6) have size $a$ that satisfies, at frequencies of our interest, the quasistatic limit condition $a \ll \lambda$. Moreover, let the coil's self-inductance $L$ be much larger than that of the wires connecting it to other components of our system: ac voltage sources, voltmeters, etc. (Since,

[^298]according to Eq. (5.75), (5.113), $L$ scales as the number $N$ of wire turns squared, this is easier to achieve at $N \gg 1$.) Then in a system consisting of such lumped induction coils and external wires (and other circuit elements such as resistors, capacitances, etc.), we may neglect the electromagnetic induction effects everywhere outside the coil, so that the electric field in those external regions is potential. Then the voltage $V$ between coil's terminals may be defined (as in electrostatics) as the difference of values of scalar potential $\phi$ between the terminals, i.e. as integral
\[

$$
\begin{equation*}
V=\int \mathbf{E} \cdot d \mathbf{r} \tag{6.76}
\end{equation*}
$$

\]

between the coil terminals along any path outside the coil. This voltage has to be balanced by the induction e.m.f. (2) in the coil, so that if the Ohmic resistance of the coil is negligible, ${ }^{43}$ we may write

$$
\begin{equation*}
V=\frac{d \Phi}{d t} \tag{6.77}
\end{equation*}
$$

where $\Phi$ is the magnetic flux in the coil. If the flux is due to the current $I$ in the same coil only (i.e. if it is magnetically uncoupled from other coils), we may use Eq. (5.70) to get the well-known relation

$$
\begin{equation*}
V=L \frac{d I}{d t} \tag{6.78}
\end{equation*}
$$

where the compliance with the Lenz sign rule is achieved by selecting the relations between the assumed voltage polarity and current direction as shown in Fig. 7a.

Fig. 6.7. (a) Induction coil, (b) two inductively coupled coils, and (c) an ac transformer.

If similar conditions are satisfied for two magnetically coupled coils (Fig. 7b), then, in Eq. (77), we need to use Eqs. (5.69) instead, getting

$$
\begin{equation*}
V_{1}=L_{1} \frac{d I_{1}}{d t}+M \frac{d I_{2}}{d t}, \quad V_{2}=L_{2} \frac{d I_{2}}{d t}+M \frac{d I_{1}}{d t} \tag{6.79}
\end{equation*}
$$

where the repeating index is dropped for notation simplicity. Such systems of inductively coupled coils have numerous applications in electrical engineering and physical experiment. ${ }^{44}$ Probably the most important is the ac transformer (Fig. 7c) where both coils share a common soft-ferromagnetic core. As we already know, such material (with $\mu \gg \mu_{0}$ ) tries to not let any magnetic field lines out, so that the magnetic flux $\Phi(t)$ in the core is nearly the same in each of its cross-sections. This gives

$$
\begin{equation*}
V_{1} \approx N_{1} \frac{d \Phi}{d t}, \quad V_{2} \approx N_{2} \frac{d \Phi}{d t} \tag{6.80}
\end{equation*}
$$

[^299]where $N_{1,2}$ is the number of wire turns in each coil, so that the voltage ratio is completely determined by the $N_{1} / N_{2}$ ratio.

Now we may generalize, to the ac current case, the notion of an electric circuit, already discussed in Chapter 4 - see Fig. 4.3 reproduced in Fig. 8a below. Let not only wire inductances but also wire capacitances be negligible in comparison with those of compact (lumped) capacitances. Then we may present the circuit as the connection of lumped circuit elements with ideal (voltage- and charge-free wires), with the list of its circuit elements now including not only resistors and current sources (as in the dc case), but also induction coils (including magnetically coupled ones) and capacitors - see Fig. 8b.

(b)

Fig. 6.8. (a) Typical ac system obeying ac Kirchhoff laws in the quasistatic approximation, and (b) the simplest circuit elements.

In the quasi-static limit, current through each wire is conserved, so that the "node rule", i.e. the $1^{\text {st }}$ Kirchhoff law (4.7),

$$
\begin{equation*}
\sum_{j} I_{j}=0 . \tag{6.81}
\end{equation*}
$$

remains valid. Also, if the electromagnetic induction effect is restricted to the interiors of lumped induction coils as discussed above, voltage drops $V_{k}$ across each circuit element may be still presented, just as in dc circuits, as differences of potentials of the adjacent nodes, so that the "loop rule", i.e. $2^{\text {nd }}$ Kirchhoff law given by Eq. (4.8),

$$
\begin{equation*}
\sum_{k} V_{k}=0 \tag{6.82}
\end{equation*}
$$

is also valid.
In contrast to the dc case, Eqs. (81) and (82) are now the (ordinary) differential equations. However, if all circuit elements are linear (as in the examples presented in Fig. 8b), these equations may be readily reduced to linear algebraic equations using the Fourier expansion. (In the most common case of sinusoidal ac sources, the final stage of Fourier series summation is unnecessary.) I do not have time to discuss even the simplest examples of such circuits, such as $L C, L R, R C$, and $L R C$ loops and periodic structures, ${ }^{45}$ but my experience shows that the potential readers of these notes are well familiar with these problems from their undergraduate studies. Let me only emphasize again that the standard ac

[^300]circuit theory is only valid within the quasistatic limit $a \ll \lambda$, and only under the condition of the electric and magnetic field confinement inside lumped circuit elements.

### 6.6. Displacement currents

The electromagnetic induction is not the only new effect arising in non-stationary electrodynamics. Indeed, though Eqs. (16) are adequate for the description of quasistatic phenomena, a deeper analysis shows that one of these equations, namely $\nabla \times \mathbf{H}=\mathbf{j}$, cannot be exact. To see that, let us take the divergence of its both sides of this equation:

$$
\begin{equation*}
\nabla \cdot(\nabla \times \mathbf{H})=\nabla \cdot \mathbf{j} . \tag{6.83}
\end{equation*}
$$

But, as the divergence of any curl, ${ }^{46}$ the left hand part should equal zero. Hence we get

$$
\begin{equation*}
\nabla \cdot \mathbf{j}=0 \tag{6.84}
\end{equation*}
$$

This is fine in statics, but in dynamics this equation forbids any charge accumulation, because according to the continuity relation (4.5),

$$
\begin{equation*}
\nabla \cdot \mathbf{j}=-\frac{\partial \rho}{\partial t} \tag{6.85}
\end{equation*}
$$

This discrepancy had been recognized by James Clerk Maxwell who suggested, in 1864, a way out of this contradiction. If we generalize the equation for $\boldsymbol{\nabla} \times \mathbf{H}$ by adding to term $\mathbf{j}$ (that describes real currents) the so-called displacement current term,

$$
\begin{equation*}
\mathbf{j}_{d} \equiv \frac{\partial \mathbf{D}}{\partial t} \tag{6.86}
\end{equation*}
$$

(that of course vanishes in statics), then the equation takes the form

$$
\begin{equation*}
\nabla \times \mathbf{H}=\mathbf{j}+\mathbf{j}_{d}=\mathbf{j}+\frac{\partial \mathbf{D}}{\partial t} . \tag{6.87}
\end{equation*}
$$

In this case, due to equation $\nabla \cdot \mathbf{D}=\rho$, the divergence of the right hand part equals zero due to the continuity relation (4.5), and the discrepancy is removed.

This conclusion, and equation (87), are so important that it is worthwhile to have one more look at its derivation, using a particular "electrical engineering" model shown in Fig. 9.47 Neglecting the fringe field effects, we may use Eq. (4.1) to describe the relation between current $I$ flowing through a wire and the electric charge $Q$ of the capacitor: ${ }^{48}$

[^301]\[

$$
\begin{equation*}
\frac{d Q}{d t}=I . \tag{6.88}
\end{equation*}
$$

\]

Now let us consider a closed contour $C$ drawn around the wire. (Solid points in Fig. 9 show the places where the contour intercepts the plane of drawing.) This contour may be seen as either the line limiting surface $S_{1}$ (crossed by the wire) or the line limiting surface $S_{2}$ (avoiding such crossing by passing through capacitor's gap). Applying the macroscopic Ampère law (5.117) to the former surface, we get

$$
\begin{equation*}
\oint_{C} \mathbf{H} \cdot d \mathbf{r}=\int_{S_{1}} j_{n} d^{2} r=I, \tag{6.89}
\end{equation*}
$$

while for the latter surface the same law gives a different result,

$$
\begin{equation*}
\oint_{C} \mathbf{H} \cdot d \mathbf{r}=\int_{S_{2}} j_{n} d^{2} r=0, \quad[\mathrm{WRONG}!] \tag{6.90}
\end{equation*}
$$

for the same integral. This is just an integral-form manifestation of the discrepancy outlined above, but it shows clearly how serious the problem is (or rather it was - before Maxwell).

Now let us see how the introduction of the displacement currents saves the day, considering for the sake of simplicity a plane capacitor of area $A$, with a constant electrode spacing. In this case, as we already know, the field inside it is uniform, with $D=\sigma$, so that the total capacitor's charge $Q=A \sigma=$ $A D$, and current (88) may represented as

$$
\begin{equation*}
I=\frac{d Q}{d t}=A \frac{d D}{d t} . \tag{6.91}
\end{equation*}
$$

So, instead of Eq. (90), the modified Ampère law gives

$$
\begin{equation*}
\oint_{C} \mathbf{H} \cdot d \mathbf{r}=\int_{S_{2}}\left(j_{d}\right)_{n} d^{2} r=\int_{S_{2}} \frac{\partial D_{n}}{\partial t} d^{2} r=\frac{d D}{d t} A=I, \tag{6.92}
\end{equation*}
$$

i.e. the Ampère integral becomes independent of the choice of the (imaginary!) surface limited by contour $C$ - as it should.

### 6.7. Finally, the full Maxwell equation system

This is a very special moment in the course: with the displacement current introduction, we have finally arrived at the full set of macroscopic Maxwell equations for time-dependent fields, ${ }^{49}$

$$
\begin{array}{ll}
\nabla \times \mathbf{E}+\frac{\partial \mathbf{B}}{\partial t}=0, & \nabla \times \mathbf{H}-\frac{\partial \mathbf{D}}{\partial t}=\mathbf{j} \\
\nabla \cdot \mathbf{D}=\rho, & \nabla \cdot \mathbf{B}=0 \tag{6.93b}
\end{array}
$$

whose validity has been confirmed in by an enormous body of experimental data. ${ }^{50}$ The most striking feature of these equations is that, even in the absence of (local) charges and currents, when all the equations become homogeneous,

$$
\begin{array}{ll}
\nabla \times \mathbf{E}=-\frac{\partial \mathbf{B}}{\partial t}, & \nabla \times \mathbf{H}=\frac{\partial \mathbf{D}}{\partial t}, \\
\nabla \cdot \mathbf{D}=0, & \nabla \cdot \mathbf{B}=0 \tag{6.94b}
\end{array}
$$

they still describe something very non-trivial: electromagnetic waves, including light. ${ }^{51}$ Indeed, one can interpret Eqs. (94a) in the following way: the change of magnetic field creates, via the Faraday induction effect, a vortex (divergence-free) electric field, while the dynamics of the electric field, in turn, creates a vortex magnetic field via the Maxwell's displacement currents.

We will carry out a detailed quantitative analysis of the waves in the next chapter, but it is easy (and very instructive) to use the Maxwell equations to estimate their velocity $v$ and the field amplitude ratio $E / H$ in a medium with $\mathbf{D}=\varepsilon \mathbf{E}, \mathbf{B}=\mu \mathbf{H}$, and $\mathbf{j}=0$. Indeed, let the solution of these equations, in a uniform, linear medium have a time period $T$, and hence the wavelength $\lambda=v T$. Then the magnitude of the left-hand part of the first of Eqs. (94a) is of the order of $E / \lambda \sim E / v T$, while that of its right-hand part may be estimated as $B / T=\mu H / T$. Using similar estimates for the second of Eqs. (94a), we arrive at the following two requirements for the $E / H$ ratio: ${ }^{52}$

$$
\begin{equation*}
\frac{E}{H} \sim \mu v \sim \frac{1}{\varepsilon v} . \tag{6.95}
\end{equation*}
$$

In order to insure the compatibility of these two relations, the wave speed should satisfy the estimate

$$
\begin{equation*}
v \sim \frac{1}{(\varepsilon \mu)^{1 / 2}} \tag{6.96}
\end{equation*}
$$

reduced to $v \sim 1 /\left(\varepsilon_{0} \mu_{0}\right)^{1 / 2} \equiv c$ in free space, while the ratio of the electric and magnetic field amplitudes should be of the following order:

[^302]\[

$$
\begin{equation*}
\frac{E}{H} \sim \mu v \sim \mu \frac{1}{(\varepsilon \mu)^{1 / 2}}=\left(\frac{\mu}{\varepsilon}\right)^{1 / 2} \tag{6.97}
\end{equation*}
$$

\]

In the next chapter we will see that these are indeed the exact results for a plane electromagnetic wave.
Now let me fulfill the promise given in Sec. 2 and establish the validity limits of the quasistatic approximation (16). For that, let the spatial scale of our system be $a$, generally unrelated to wavelength $\lambda=v T$, and carry real currents $\mathbf{j}$ producing certain magnetic field $H$. Then, according to Eqs. (94a), this magnetic field Faraday-induces electric field $E \sim \mu H a / T$, whose displacement currents, in turn, produce an additional magnetic field with magnitude

$$
\begin{equation*}
H^{\prime} \sim \frac{a \varepsilon}{T} E \sim \frac{a \varepsilon}{T} \frac{\mu a}{T} H \sim\left(\frac{a \lambda}{v T \lambda}\right)^{2} H=\left(\frac{a}{\lambda}\right)^{2} H \tag{6.98}
\end{equation*}
$$

Hence, at $a \ll \lambda$, the displacement current effect is indeed negligible.
Before going after the analysis of the full Maxwell equations in particular situations (that will be the main goal of all the next chapters of this course), let us have a look at the energy balance they yield for a certain volume $V$ - that may include both charged particles and the electromagnetic field. Since, according to Eq. (5.10), the magnetic field does no work on charged particles even if they move, the total power $\mathcal{P}$ being transferred from the field to the particles inside the volume is due to the electric field alone:

$$
\begin{equation*}
\mathcal{P}=\int_{V} p d^{3} r, \quad p=\mathbf{j} \cdot \mathbf{E}, \tag{6.99}
\end{equation*}
$$

where I have used Eq. (4.38). Expressing $\mathbf{j}$ from the corresponding Maxwell equation of system (93), and plugging it into Eq. (99), we get

$$
\begin{equation*}
\mathcal{P}=\int_{V}\left[\mathbf{E} \cdot(\nabla \times \mathbf{H})-\mathbf{E} \cdot \frac{\partial \mathbf{D}}{\partial t}\right] d^{3} r \tag{6.100}
\end{equation*}
$$

Let us pause here for a second, and transform the divergence of vector $\mathbf{E} \times \mathbf{H}$ using the wellknown vector algebra identity: ${ }^{53}$

$$
\begin{equation*}
\nabla \cdot(\mathbf{E} \times \mathbf{H})=\mathbf{H} \cdot(\nabla \times \mathbf{E})-\mathbf{E} \cdot(\nabla \times \mathbf{H}) \tag{6.101}
\end{equation*}
$$

The last term in the right-hand part of this equation is exactly the first term in the square brackets of Eq. (100), so that we can rewrite that formula as

$$
\begin{equation*}
\mathcal{P}=\int_{V}\left[-\nabla \cdot(\mathbf{E} \times \mathbf{H})+\mathbf{H} \cdot(\nabla \times \mathbf{E})-\mathbf{E} \cdot \frac{\partial \mathbf{D}}{\partial t}\right] d^{3} r . \tag{6.102}
\end{equation*}
$$

However, according to the Maxwell equation for $\nabla \times \mathbf{E}$, it is equal to $-\partial \mathbf{B} / \partial t$, so that the second term in the square brackets of Eq. (102) equals $-\mathbf{H} \cdot \partial \mathbf{B} / \partial t$ and, according to Eq. (5.128), is just the (minus) time derivative of the magnetic energy per unit volume. Similarly, according to Eq. (3.82), the third term under the integral is the minus time derivative of the electric energy per unit volume. Finally, we can use the divergence theorem to transform the integral of the first term to a 2D integral over the surface $S$

[^303]limiting volume $V$. As the result, we get the so-called Poynting theorem ${ }^{54}$ for the power balance in the system:

Poynting theorem

Electromagnetic energy density
so that for an isotropic, linear, and dispersion-free medium, with $\mathbf{D}(t)=\varepsilon \mathbf{E}(t), \mathbf{B}(t)=\mu \mathbf{H}(t)$,

$$
\begin{equation*}
u=\frac{\mathbf{E} \cdot \mathbf{D}}{2}+\frac{\mathbf{H} \cdot \mathbf{B}}{2}=\frac{\varepsilon E^{2}}{2}+\frac{B^{2}}{2 \mu} \tag{6.104b}
\end{equation*}
$$

and $\mathbf{S}$ is the Poynting vector defined as ${ }^{55}$

$$
\begin{equation*}
\int_{V}\left(p+\frac{\partial u}{\partial t}\right) d^{3} r+\oint_{S} S_{n} d^{2} r=0 \tag{6.103}
\end{equation*}
$$

Here $u$ is the density of the total (electric plus magnetic) energy of the electromagnetic field, with

$$
\begin{equation*}
\delta u \equiv \mathbf{E} \cdot \delta \mathbf{D}+\mathbf{H} \cdot \delta \mathbf{B} \tag{6.104a}
\end{equation*}
$$

The first integral in Eq. (103) is evidently the net change of the energy of the system (particles + field) in unit time, so that the second (surface) integral is certainly the power flowing out from the system through the surface, and it is tempting to interpret the Poynting vector $\mathbf{S}$ locally, as the power flow density at the given point. ${ }^{56}$ In many cases such a local interpretation of vector $\mathbf{S}$ is legitimate; however, in some cases it may lead to wrong conclusions. Indeed, let us consider a simple system shown in Fig. 10: a planar capacitor placed into a static and uniform external magnetic field so that the electric and magnetic fields are mutually perpendicular. In this static situation, no charges are moving, both $\boldsymbol{p}$ and $\partial / \partial t$ equal to zero, and there should be no power flow in the system. However, Eq. (105) shows that the Poynting vector is not equal to zero inside the capacitor, being directed as shown in Fig. 10.

Fig. 6.10. The Poynting vector paradox.

From the point of view of our only unambiguous corollary of the Maxwell equations, Eq. (103), there is no contradiction here, because the fluxes of vector $\mathbf{S}$ through the walls of any volume $V$, for example the side walls of the volume shown with dashed lines in Fig. 10, are equal and opposite (and they are zero for other faces of this rectilinear volume), so that the total flux of the Poynting vector

[^304]equals zero, as it should. It is, however, useful to recall this example each time before giving the local interpretation to vector $\mathbf{S}$.

Finally, to complete the initial discussion of the Maxwell equations, ${ }^{57}$ let us rewrite them in terms of potentials $\mathbf{A}$ and $\phi$, because this is more convenient for the solution of some (though not all!) problems. Even when dealing with a more general system (93) of Maxwell equations than before, Eqs. (7) and (5.27),

$$
\begin{equation*}
\mathbf{E}=-\nabla \phi-\frac{\partial \mathbf{A}}{\partial t}, \quad \mathbf{B}=\nabla \times \mathbf{A} \tag{6.106}
\end{equation*}
$$

are still used as potential definitions. It is straightforward to verify that with these definitions, two homogeneous Maxwell equations (93b) are satisfied automatically. Plugging Eqs. (106) into the inhomogeneous equations (93a), and considering, for simplicity, a linear, uniform medium with frequency-independent $\varepsilon$ and $\mu$, we get

$$
\begin{align*}
& \nabla^{2} \phi+\frac{\partial}{\partial t}(\nabla \cdot \mathbf{A})=-\frac{\rho}{\varepsilon} \\
& \nabla^{2} \mathbf{A}-\varepsilon \mu \frac{\partial^{2} \mathbf{A}}{\partial t^{2}}-\nabla\left(\nabla \cdot \mathbf{A}+\varepsilon \mu \frac{\partial \phi}{\partial t}\right)=-\mu \mathbf{j} . \tag{6.107}
\end{align*}
$$

This is a more complex result than what we would like to get. However, let us select a special gauge that is frequently called (especially for the free space case, when $v=c$ ) the Lorenz gauge condition ${ }^{58}$

$$
\begin{equation*}
\nabla \cdot \mathbf{A}+\varepsilon \mu \frac{\partial \phi}{\partial t}=0 \tag{6.108}
\end{equation*}
$$

which is a natural generalization of the Coulomb gauge (5.48) for time-dependent phenomena. With this condition, Eqs. (107) are reduced to a simpler, beautifully symmetric form: ${ }^{59}$

$$
\begin{align*}
& \nabla^{2} \phi-\frac{1}{v^{2}} \frac{\partial^{2} \phi}{\partial t^{2}}=-\frac{\rho}{\varepsilon}  \tag{6.109}\\
& \nabla^{2} \mathbf{A}-\frac{1}{v^{2}} \frac{\partial^{2} \mathbf{A}}{\partial t^{2}}=-\mu \mathbf{j}
\end{align*}
$$

where $v^{2} \equiv 1 / \varepsilon \mu .{ }^{60}$
${ }^{57}$ We will return to their general discussion (in particular, to the analytical mechanics of the electromagnetic field, and its stress tensor) in Sec. 9.8, after we have got equipped with the special relativity theory.
${ }^{58}$ This condition, named after L. Lorenz, should not be confused with the Lorentz invariance condition of the relativity theory, due to H. Lorentz (note the names' spelling) - see Sec. 9.4.
${ }^{59}$ Note that Eqs. (109) are essentially a set of 4 similar equations for 4 scalar functions (namely, $\phi$ and three Cartesian components of vector $\mathbf{A}$ ) and thus clearly invite the 4 -component vector formalism of the relativity theory - which will be discussed in Chapter 9.
${ }^{60}$ Here I have to mention in passing the so-called Hertz vector potentials $\Pi_{e}$ and $\Pi_{m}$ (whose introduction may be traced to at least the 1904 work by E. Whittaker). They may be defined by the following relations:

$$
\mathbf{A}=\mu \frac{\partial \boldsymbol{\Pi}_{e}}{\partial t}+\mu \nabla \boldsymbol{\Pi}_{m}, \quad \phi=-\frac{1}{\varepsilon} \nabla \cdot \boldsymbol{\Pi}_{e},
$$

Electromagnetic field potentials

If $\phi$ and $\mathbf{A}$ depend on just one spatial coordinate, say $z$, in a region without field sources: $\rho=0, \mathbf{j}$ $=0$, Eqs. (109) are reduced to the well-known 1D wave equations

$$
\begin{align*}
& \frac{\partial^{2} \phi}{\partial^{2} z}-\frac{1}{v^{2}} \frac{\partial^{2} \phi}{\partial t^{2}}=0 \\
& \frac{\partial^{2} \mathbf{A}}{\partial^{2} z}-\frac{1}{v^{2}} \frac{\partial^{2} \mathbf{A}}{\partial t^{2}}=0 \tag{6.110}
\end{align*}
$$

describing waves propagating with velocity $v$. Note that due to the definitions of constants $\varepsilon_{0}$ and $\mu_{0}$, in free space $v$ is just the speed of light:

$$
\begin{equation*}
v=\frac{1}{\left(\varepsilon_{0} \mu_{0}\right)^{1 / 2}} \equiv c . \tag{6.110}
\end{equation*}
$$

Historically, the experimental observation of relatively low-frequency ( GHz -scale) electromagnetic waves and the proof that their speed in free space is equal to that of light, was the decisive proof of Maxwell's theory. ${ }^{61}$ A detailed study of this most important physical phenomenon is the main goal of the next chapters of this course.

### 6.8 Exercise problems

6.1. Prove that the electromagnetic induction e.m.f. $V_{\text {ind }}$ in a conducting loop may be measured:
(i) by measuring the current $I=V_{\text {ind }} / R$ induced in the closed loop with Ohmic resistance $R$, or
(ii) using a voltmeter inserted into the loop - see Fig. on the right.

6.2. The magnetic flux $\Phi$ that pierces a plane, round, uniform, resistive ring is being changed in time, while the magnetic field outside of the ring is negligibly low. A voltmeter is connected to a part the ring as shown in Fig. on the right. What would the voltmeter show?

6.3. A weak, uniform magnetic field $\mathbf{B}$ is applied to an axially-symmetric permanent magnet, with a dipole magnetic moment $\mathbf{m}$ directed along its symmetry axis, rapidly rotating about the same axis, with an angular momentum $\mathbf{L}$. Calculate the electric field resulting from field's application, and formulate the conditions of your result's validity.
which make the Lorenz gauge condition (108) automatically satisfied. These potentials are especially convenient for the solution of problems in which the electromagnetic field is excited by external sources characterized by externally fixed electric and magnetic polarizations $\mathbf{P}_{\text {ext }}$ and $\mathbf{M}_{\text {ext }}$ - rather than fixed charge and current densities $\rho$ and $\mathbf{j}$. Indeed, it is straightforward to check that both $\Pi_{e}$ and $\Pi_{m}$ satisfy equations similar to Eqs. (109), but with the right-hand parts equal to, respectively, $-\mathbf{P}_{\text {ext }}$ and $-\mathbf{M}_{\text {ext }}$.
${ }^{61}$ This was first accomplished in 1886 by H. Hertz, using specially designed electronic circuits and antennas.
6.4. Use the electromagnetic induction law (5) to derive Eq. (5.128) for the magnetic field energy variation.
6.5. A uniform, static magnetic field $\mathbf{B}$ is applied along the axis of a long round pipe of a radius $R$, and a very small thickness $\tau$, made of a material with Ohmic conductance $\sigma$. A sphere of mass $M$ and radius $R^{\prime}<R$, made of a linear magnetic with permeability $\mu \gg \mu_{0}$, is launched, with an initial velocity $v_{0}$, to fly ballistically along pipe's axis - see Fig. on the right. Use the quasistatic approximation to calculate the distance the sphere
 would pass before it stops. Formulate conditions of validity of your result.
6.6. AC current of frequency $\omega$ is being passed through a long uniform wire with a round crosssection of radius $R$ that is comparable with the skin depth $\delta_{s}$. In the quasistatic approximation, find the current density distribution across the wire. Analyze the limits $R \ll \delta_{s}$ and $R \gg \delta_{s}$.
6.7. A very long, round cylinder of radius $R$, made of a uniform Ohmic conductor with conductivity $\sigma$ and magnetic permittivity $\mu$, has been placed into a uniform ac magnetic field $\mathbf{H}_{\mathrm{ext}}=\mathbf{H}_{0} \cos \omega t$, directed along its symmetry axis see Fig. on the right. Calculate the spatial distribution of the magnetic field's amplitude, and in particular its value on cylinder's axis. Spell out the last result in the limits of relatively small and large $R$.

Hint: As shortcuts, you are welcome to reuse parts of the solution of the previous problem.

6.8. ${ }^{*}$ Define and calculate an appropriate spatial-temporal Green's function for Eq. (20), and use this function to analyze the dynamics of propagation of the external magnetic field, suddenly turned on at $t=0$ and then left constant:

$$
H(x=0, t)= \begin{cases}0, & \text { at } t<0 \\ H_{0}, & \text { at } t>0\end{cases}
$$

into an Ohmic conductor occupying half-space $x>0-$ see Fig. 6.2.
Hint: Try to use a function proportional to $\exp \left\{-\left(x-x^{\prime}\right)^{2} / 2(\delta x)^{2}\right\}$, with a suitable time dependence of parameter $\delta x$, and a properly selected pre-exponential factor.
6.9. Solve the previous problem using the variable separation method, and compare the results.
6.10. A small, planar wire loop, carrying current $I$, is located far from a plane surface of a superconductor. Within the "macroscopic" description of superconductivity $(\mathbf{B}=0)$, find:
(i) the energy of the loop-superconductor interaction,
(ii) the force and torque acting on the loop,
(iii) the distribution of supercurrents on the superconductor surface.
6.11. A straight, uniform magnet of length 21 , cross-section area $A$ $\ll l^{2}$, and mass $m$, with a permanent longitudinal magnetization $M_{0}$, is placed over a horizontal surface of a superconductor - see Fig. on the right. Within the macroscopic model of the Meissner-Ochsenfeld effect, find the stable equilibrium position of the magnet.
6.12. A plane superconducting wire loop, of area $A$ and inductance $L$, may rotate, without friction, about a horizontal axis 0 (in Fig. on the right, perpendicular to the plane of drawing) passing through its center of mass. Initially the loop was horizontal (with $\theta=0$ ), and carried supercurrent $I_{0}$ in such direction that its magnetic dipole vector was directed down. Then a uniform magnetic field $\mathbf{B}$, directed
 vertically up, was applied. Find all possible equilibrium positions (angles $\theta$ ) of the loop, analyze their stability, and give a physical interpretation of the results.
6.13. Use the London equation to analyze the penetration of external magnetic field into a thin $(t$ $\sim \delta_{\mathrm{L}}$ ), planar superconductor film whose plane is parallel to the field.
6.14. Use the London equation to calculate the distribution of supercurrent density $\mathbf{j}$ across the circular cross-section (with radius $R \sim \delta_{\mathrm{L}}$ ) of a long, straight superconducting wire carrying dc current $I$.
6.15.* Use the London equation to calculate the inductance (per unit length) of a long, uniform superconducting strip placed close to the surface of a similar superconductor see Fig. on the right, which shows the structure's cross-section.

Hint: Start from thinking how is the supercurrent
 distributed along the surfaces of the strip and the bulk superconductor.
6.16. Analyze the magnetic field shielding by a superconducting film of small thickness $t \ll \delta_{\mathrm{L}}$, by calculating the penetration of the field induced by current $I$ flowing in a thin wire which runs parallel to a wide, plane thin film, at distance $d \gg t$ from it, into the half-space behind the film.
6.17. Calculate the self-inductance of a superconducting cable with a round cross-section (see Fig. on the right) in the following limits:
(i) $\delta_{\mathrm{L}} \ll a, b, c-b$, and
(ii) $a \ll \delta_{\mathrm{L}} \ll b, c-b$.

6.18. Use Eqs. (59) and (71) to calculate the energy of a Josephson junction, and the full energy of the SQUID shown in Fig. 4c.
6.19. Analyze the possibility of wave propagation in a long, uniform chain of lumped inductances and capacitances - see Fig. on the right.

Hint: Readers without prior experience with electromagnetic
 wave analysis may like to use a substantial analogy between this effect and mechanical waves in a 1D chain of elastically coupled particles. ${ }^{62}$
6.20. A sinusoidal e.m.f. of amplitude $V_{0}$ and frequency $\omega$ is applied to an end of a long chain of similar, lumped resistors and capacitors (see Fig. on the right). Calculate the law of decay of the rf oscillation amplitude in the chain.

6.21. Calculate the pressure exerted by the magnetic field $\mathbf{B}$ inside a magnetic-free solenoid of length $l$, cross-section area $A \ll l^{2}$ and $N$ turns, on its "walls" (windings), and the force exerted by the field on solenoid's ends. Give a physical interpretation of the direction of these forces.
6.22. In Sec. 6 we have seen that the displacement current concept allows one to generalize the Ampère law to time-dependent processes as

$$
\oint_{C} \mathbf{H} \cdot d \mathbf{r}=I_{S}+\frac{\partial}{\partial t} \int_{S} D_{n} d^{2} r .
$$

We also have seen that such generalization makes $\int \mathbf{H} \cdot d \mathbf{r}$ over the contour C, which was shown in Fig. 9 (see also Fig. on the right), independent of the choice of surface $S$ limited by the contour. However, it may look like the situation is different for contour a $C^{\prime}$ drawn inside the capacitor. Indeed, if contour's radius $\rho$ is much larger than the capacitor's thickness $d$, the magnetic field $\mathbf{H}$, created by the linear current $I$ of the contour line is virtually the same as that of a continuous wire, and hence integral $\int \mathbf{H} \cdot d \mathbf{r}$ along contour $C^{\prime}$ is apparently the same as that along contour $C$, while the magnetic flux $\int D_{n} d^{2} r$ through the surface $S$ ' limited by contour $C^{\prime}$ is evidently smaller, while $I_{S^{\prime}}=I_{S}=0$, so that the above equation seems invalid. Resolve the paradox, for simplicity considering an axially-
 symmetric system.

[^305]
## Chapter 7. Electromagnetic Wave Propagation

This (long!) chapter focuses on the most important effect that follows from the time-dependent Maxwell equations, namely the electromagnetic waves, at this stage avoiding a discussion of their origin, i.e. radiation. I start from the simplest, plane waves in a uniform and isotropic media. The next step is a discussion non-uniform systems, in particular those with sharp boundaries between different materials, which bring in such new effects as wave reflection and refraction. Then I will proceed to the structure of electromagnetic waves propagating along various long, cylindrical structures, called transmission lines - such as coaxial cables, waveguides, and optical fibers. In the end of the chapter, electromagnetic oscillations in final-length fragments of such lines, serving as resonators, are also discussed.

### 7.1. Plane waves

Let us start from considering a spatial region that does not contain field sources $(\rho=0, \mathbf{j}=0)$, and is filled with a linear, uniform, isotropic medium, which obeys Eqs. (3.38) and (5.110):

$$
\begin{equation*}
\mathbf{D}=\varepsilon \mathbf{E}, \quad \mathbf{B}=\mu \mathbf{H} . \tag{7.1}
\end{equation*}
$$

Moreover, let us assume for a minute that these material equations hold for all frequencies of interest. As was already shown in Sec. 6.7, in this case the Lorenz gauge condition (6.108) allows the Maxwell equations to be recast into wave equations (6.110) for the vector and scalar potentials. However, for most our purposes it is more convenient to use directly the homogeneous Maxwell equations (6.94) for the electric and magnetic fields - which are independent of the gauge choice. After the elementary elimination of $\mathbf{D}$ and $\mathbf{B}$ using Eq. (1), ${ }^{1}$ these equations take a simple, symmetric form

equations for uniform linear media

$$
\begin{array}{ll}
\nabla \times \mathbf{E}+\mu \frac{\partial \mathbf{H}}{\partial t}=0, & \nabla \times \mathbf{H}-\varepsilon \frac{\partial \mathbf{E}}{\partial t}=0, \\
\nabla \cdot \mathbf{E}=0, & \nabla \cdot \mathbf{H}=0 . \tag{7.2b}
\end{array}
$$

Now, taking the curl $(\nabla \times)$ of each of Eqs. (2a), and using the vector algebra identity (5.31), whose first term, for both $\mathbf{E}$ and $\mathbf{H}$, vanishes due to Eqs. (2b), we get similar wave equations for the electric and magnetic fields:

$$
\begin{equation*}
\left(\nabla^{2}-\frac{1}{v^{2}} \frac{\partial^{2}}{\partial t^{2}}\right) \mathbf{E}=0, \quad\left(\nabla^{2}-\frac{1}{v^{2}} \frac{\partial^{2}}{\partial t^{2}}\right) \mathbf{H}=0, \tag{7.3}
\end{equation*}
$$

where parameter $v$ is defined by relation

EM wave velocity

$$
\begin{equation*}
v^{2} \equiv \frac{1}{\varepsilon \mu} \tag{7.4}
\end{equation*}
$$

with $v^{2}=1 / \varepsilon_{0} \mu_{0} \equiv c^{2}$ in free space.

[^306]Two vector equations (3) are of course six similar equations for three Cartesian components of two vectors $\mathbf{E}$ and $\mathbf{H}$. Each of these equations allows, in particular, the following solution,

$$
\begin{equation*}
f=f(z-v t) \tag{7.5}
\end{equation*}
$$

Plane wave
where $z$ is the Cartesian coordinate along a certain (arbitrary) direction $\mathbf{n}$. This solution describes a specific type of a wave, i.e. a certain field pattern moving, without deformation, along axis $z$, with velocity $v$. According to Eq. (5), each variable $f$ has the same value in each plane perpendicular to the direction $\mathbf{n}$ of wave propagation, hence the name - plane wave.

According to Eqs. (2), the independence of the wave equations (3) for vectors $\mathbf{E}$ and $\mathbf{H}$ does not mean that their plane-wave solutions are independent. Indeed, plugging solution (5) into Eqs. (2a), we get

$$
\begin{equation*}
\mathbf{H}=\frac{\mathbf{n} \times \mathbf{E}}{Z}, \quad \text { i.e. } \mathbf{E}=Z \mathbf{H} \times \mathbf{n}, \tag{7.6}
\end{equation*}
$$

Relation between the fields

$$
\begin{equation*}
Z \equiv \frac{E}{H}=\left(\frac{\mu}{\varepsilon}\right)^{1 / 2} \tag{7.7}
\end{equation*}
$$

The vector relation (6) means, first of all, that vectors $\mathbf{E}$ and $\mathbf{H}$ are perpendicular not only to vector $\mathbf{n}$ (such waves are called transverse), but also to each other (Fig. 1) - at any point of space and at any time instant.

Fig. 7.1. Field vectors in a plane electromagnetic wave propagating along direction $\mathbf{n}$.

Second, the field magnitudes are related by constant $Z$, called the wave impedance of the medium. Very soon we will see that the wave impedance plays a pivotal role in many problems, in particular at the wave reflection from the interface between two media. Since the dimensionality of $E$, in SI units, is $\mathrm{V} / \mathrm{m}$, and that of $H$ is $\mathrm{A} / \mathrm{m}$, Eq. (7) shows that $Z$ has the dimensionality of V/A, i.e. ohms $(\Omega) .{ }^{2}$ In particular, in free space,

$$
\begin{equation*}
Z=Z_{0} \equiv\left(\frac{\mu_{0}}{\varepsilon_{0}}\right)^{1 / 2}=4 \pi \times 10^{-7} c \approx 377 \Omega \tag{7.8}
\end{equation*}
$$

Now plugging Eq. (6) into Eqs. (6.104b) and (6.105), we get:

$$
u=\varepsilon E^{2}=\mu H^{2}
$$

Wave
impedance of free
space

Wave's
energy
per unit volume

[^307]Wave's power per unit area

$$
\begin{equation*}
\mathbf{S} \equiv \mathbf{E} \times \mathbf{H}=\mathbf{n} \frac{E^{2}}{Z}=\mathbf{n} Z H^{2}, \tag{7.9b}
\end{equation*}
$$

so that, according to Eqs. (4) and (7), wave's energy and power densities are universally related as

$$
\begin{equation*}
\mathbf{S}=\mathbf{n} u v . \tag{7.9c}
\end{equation*}
$$

In the view of the Poynting vector paradox discussed in Sec. 6.7 (see Fig. 6.10), one may wonder whether this expression may be interpreted as the actual density of power flow. In contrast to the static situation shown in Fig. 6.7, that limits the electric and magnetic fields to a vicinity of their sources, waves may travel far from them. As a result, they can form wave packets of finite length in free space see Fig. 2.

Fig. 7.2. Interpreting the Poynting vector in an electromagnetic wave.

Let us apply the Poynting theorem (6.103) to the cylinder shown by dashed lines in Fig. 2, with one lid inside the wave packet, and another lid in the region already passed by the wave. Then, according to Eq. (6.103), the rate of change of the full energy $\varepsilon$ inside the volume is $d \varepsilon / d t=-S A$ (where $A$ is the lid area), so that $S$ may be indeed interpreted as the power flow (per unit area) from the volume. Making a reasonable assumption that the finite length of a sufficiently long wave packet does not affect the physics inside it, we may indeed interpret the $\mathbf{S}$ given by Eq. (9) as the power flow density inside a plane electromagnetic wave.

As we will see later in this chapter, the free-space value $\mathrm{Z}_{0}$ of the wave impedance, given by Eq. (8), establishes the scale of wave impedances of virtually all wave transmission lines, so we may use is and Eq. (9) to get some sense of how different are the electric and magnetic field amplitudes in the waves, on the scale of typical electrostatics and magnetostatics experiments. For example, according to Eqs. (9), a wave of a modest intensity $S=1 \mathrm{~W} / \mathrm{m}^{2}$ (the power density we get from a usual electric bulb a few meters away from it) has $E \sim\left(S Z_{0}\right)^{1 / 2} \sim 20 \mathrm{~V} / \mathrm{m}$, quite comparable with the dc field created by an AA battery right outside it. On the other hand, the wave's magnetic field $H=\left(S / Z_{0}\right)^{1 / 2} \approx 0.05 \mathrm{~A} / \mathrm{m}$. For this particular case, the relation following from Eqs. (1), (4), and (7),

$$
\begin{equation*}
B=\mu H=\mu \frac{E}{Z}=\mu \frac{E}{(\mu / \varepsilon)^{1 / 2}}=(\varepsilon \mu)^{1 / 2} E=\frac{E}{v} \tag{7.10}
\end{equation*}
$$

gives $B=\mu_{0} H=E / c \sim 7 \times 10^{-8} \mathrm{~T}$, i.e. a magnetic field thousand times less than the Earth field, and about 8 orders of magnitude lower than the field of a typical permanent magnet. A possible interpretation of this huge difference is that the scale of magnetic fields $B \sim E / c$ in the waves is "normal" for
electromagnetism, while that of permanent magnet fields is abnormally high, because they are due to the ferromagnetic alignment of electron spins, essentially quantum objects - see the discussion in Sec. 5.5.

As soon as $\varepsilon$ and $\mu$ are simple constants, wave speed $v$ is also constant, and Eq. (5) is valid for an arbitrary function $f$ - defined by either initial or boundary conditions. In plain English, a medium with frequency-independent $\varepsilon$ and $\mu$ supports propagation of plane waves with an arbitrary waveform without either decay (attenuation) or deformation (dispersion). However, for any real medium but pure vacuum, this approximation is valid only within limited frequency intervals. We will discuss the effects of attenuation and dispersion in the next section and see that all our prior results remain valid even in that general case, provided that we limit them to single-frequency (i.e. sinusoidal, or monochromatic) waves. Such waves may be most conveniently presented as ${ }^{3}$

$$
\begin{equation*}
f=\operatorname{Re}\left[f_{\omega} e^{i(k z-\omega t)}\right] \tag{7.11}
\end{equation*}
$$

Monochromatic wave
where $f_{\omega}$ is the complex amplitude of the wave, and $k$ is its wave number (the magnitude of wave vector $\mathbf{k} \equiv \mathbf{n} k$ ), sometimes also called the spatial frequency. The last term is justified by the fact, evident from Eq. (11), that $k$ is related to the wavelength $\lambda$ exactly as the usual ("temporal") frequency $\omega$ is related to the time period $T$ :

$$
\begin{equation*}
k=\frac{2 \pi}{\lambda}, \quad \omega=\frac{2 \pi}{T} \tag{7.12}
\end{equation*}
$$

Spatial and temporal frequencies

Requiring Eq. (11) to be a particular form of Eq. (5), i.e. the argument $(k z-\omega t) \equiv k[z-(\omega / k) t]$ to be proportional to $(z-v t)$, so that $\omega / k=v$, we see that the wave number should equal

$$
\begin{equation*}
k=\frac{\omega}{v}=(\varepsilon \mu)^{1 / 2} \omega \tag{7.13}
\end{equation*}
$$

showing that in this "dispersion-free" case the dispersion relation $\omega(k)$ is linear.
Now note that Eq. (6) does not claim mean vectors $\mathbf{E}$ and $\mathbf{H}$ retain their direction in space. (The simple case when they do is called the linear polarization of the wave.) Indeed, nothing in the Maxwell equations prevents, for example, joint rotation of this pair of vectors around the fixed vector $\mathbf{n}$, while still keeping all these three vectors perpendicular to each other at all times. An arbitrary rotation law, or even an arbitrary constant frequency of such rotation, however, would violate the single-frequency (monochromatic) character of the elementary sinusoidal wave (11). In order to understand what is the most general type of polarization the wave may have without violating that condition, let us present two Cartesian components of one of these vectors (say, E) along any two fixed axes $x$ and $y$, perpendicular to each other and axis $z$ (i.e. vector $\mathbf{n}$ ), in the same form as used in Eq. (11):

$$
\begin{equation*}
E_{x}=\operatorname{Re}\left[E_{\omega x} e^{i(k z-\omega t)}\right], \quad E_{y}=\operatorname{Re}\left[E_{\omega y} e^{i(k z-\omega t)}\right] \tag{7.14}
\end{equation*}
$$

In order to keep the wave monochromatic, complex amplitudes $E_{\omega x}$ and $E_{\omega y}$ must be constant; however, they may have different magnitudes and an arbitrary phase shift between them.

[^308]In the simplest case when the arguments of the complex amplitudes are equal,

$$
\begin{equation*}
E_{\omega x, y}=\left|E_{\omega x, y}\right| e^{i \varphi} . \tag{7.15}
\end{equation*}
$$

the real field components have the same phase:

$$
\begin{equation*}
E_{x, y}=\left|E_{\omega x, y}\right| \cos (k z-\omega t+\varphi), \tag{7.16}
\end{equation*}
$$

so that their ratio is constant in time - see Fig. 3a. This means that the wave is linearly polarized, within the plane defined by relation

$$
\begin{equation*}
\tan \theta=\frac{\left|E_{\omega y}\right|}{\left|E_{\omega x}\right|} . \tag{7.17}
\end{equation*}
$$

Fig. 7.3. Time evolution of the electric field vector in (a) linearly-polarized, (b) circularly-polarized, and (c) elliptically-polarized waves.

Another simple case is when the moduli of the complex amplitudes $E_{\omega x}$ and $E_{\omega y}$ are equal, but their phases are shifted by $+\pi / 2$ or $-\pi / 2$ :

$$
\begin{equation*}
E_{\omega x}=\left|E_{\omega}\right| e^{i \varphi}, \quad E_{\omega y}=\left|E_{\omega}\right| e^{i(\varphi \pm \pi / 2)} . \tag{7.18}
\end{equation*}
$$

In this case

$$
\begin{equation*}
E_{x}=\left|E_{\omega}\right| \cos (k z-\omega t+\varphi), \quad E_{y}=\left|E_{\omega}\right| \cos \left(k z-\omega t+\varphi \pm \frac{\pi}{2}\right)=\mp\left|E_{\omega}\right| \sin (k z-\omega t+\varphi) \tag{7.19}
\end{equation*}
$$

This means that on the $[x, y]$ plane, the end of vector $\mathbf{E}$ moves, with wave's frequency $\omega$, either clockwise or counterclockwise around a circle - see Fig. 3b:

$$
\begin{equation*}
\theta(t)=\mp(\omega t-\varphi) . \tag{7.20}
\end{equation*}
$$

Such waves are called circularly-polarized. ${ }^{4}$ These particular solutions of the Maxwell equations are very convenient for quantum electrodynamics, because single electromagnetic field quanta with a

[^309]certain (positive or negative) spin direction may be considered as elementary excitations of the corresponding circularly-polarized wave. (This fact does not exclude, from the quantization scheme, waves of other polarizations, because any monochromatic wave may be presented as a linear combination of two circularly-polarized waves with opposite helicities, just as Eqs. (14) present it as a linear combination of two linearly-polarized waves.)

Finally, in the general case of arbitrary complex amplitudes $E_{\omega x}$ and $E_{\omega y}$, the electric field vector end moves along an ellipse on the $[x, y]$ plane (Fig. 3c), such wave is called elliptically polarized. The eccentricity and orientation of the ellipse are completely described by one complex number, the ratio $E_{\omega x} / E_{\omega y}$, i.e. two real numbers: $\left|E_{\omega x} / E_{\omega y}\right|$ and $\varphi=\arg \left(E_{\omega x} / E_{\omega y}\right)$.

The same information may be expressed via four so-called Stokes parameters $s_{0}, s_{1}, s_{2}, s_{3}$, which are popular in optics because they may be used for the description of not only completely coherent waves that are discussed here, but also of party coherent or even fully incoherent waves - including the natural light emitted by thermal sources like our Sun. In contrast to the notion of coherent waves whose complex amplitudes are considered deterministic numbers, the instant amplitudes of incoherent waves should be treated as stochastic variables. ${ }^{5}$

### 7.2. Attenuation and dispersion

Now let me show that any linear, isotropic medium may be characterized, by complex, frequency-dependent electric permittivity $\delta(\omega)$ and magnetic permeability $\mu(\omega)$. Indeed, starting from electric effects, the electric polarization of realistic elementary dipoles of the medium cannot follow the applied electric field instantly, if the field frequency $\omega$ is comparable with those of the internal processes - say, transitions between atomic energy levels. Let us consider the most general law of time evolution of polarization $P(t)$ for the case of arbitrary applied electric field $E(t),{ }^{6}$ but for a sufficiently dilute medium, so that the local electric field $\mathbf{E}_{\text {ef }}$ (3.63), acting on each elementary dipole, is essentially the microscopically-averaged field E. ${ }^{7}$ Then, due to the linear superposition principle, $P(t)$ should be a linear sum (integral) of the values of $E\left(t^{\prime}\right)$ at all previous moments of time, $t^{\prime}<t$, weighed by some function of $t$ and $t^{\prime}$ :

$$
\begin{equation*}
P(t)=\int_{-\infty}^{t} E\left(t^{\prime}\right) G\left(t, t^{\prime}\right) d t^{\prime} \tag{7.21}
\end{equation*}
$$

The condition $t^{\prime}<t$, which is implied by this relation, expresses a key principle of physics, the causal relation between a cause (in our case, the electric field applied to each dipole) and its effect (the

[^310]polarization it creates). Function $G(t, t$ ') is called the temporal Green's function for the electric polarization. ${ }^{8}$ In order to understand its physical sense, let us consider the case when the applied field $E(t)$ is a very short pulse at $t=t_{0}$, that may be approximated with the Dirac's delta-function:
\[

$$
\begin{equation*}
E(t)=\delta\left(t-t_{0}\right) . \tag{7.22}
\end{equation*}
$$

\]

Then Eq. (21) yields just $P(t)=G\left(t, t_{0}\right)$, showing that the Green's function is just the polarization at moment $t$, created by a unit $\delta$-functional pulse of the applied field at moment $t^{\prime}$ (Fig. 4). Thus, the temporal $G$ is the exact time analog of the spatial Green's functions $G(\mathbf{r}, \mathbf{r}$ ') we have already studied in the electrostatics - see Sec. 2.7.

Fig. 7.4. Temporal Green's function for electric polarization (schematically).

What are the general properties of the temporal Green's function? First, the function is evidently real, since the dipole moment $\mathbf{p}$ and hence polarization $\mathbf{P}=n \mathbf{p}$ are real by the definition - see Eq. (3.6). Next, for systems without infinite internal memory, $G$ should tend to zero at $t-t^{\prime} \rightarrow \infty$, although the type of this approach (e.g., whether function $G$ oscillates approaching zero) depends on the medium. Finally, if parameters of the medium do not change in time, the polarization response to an electric field pulse should depend not on its absolute timing, but only on the time difference $\theta \equiv t-t$ ' between the pulse and observation instants:

$$
\begin{equation*}
P(t)=\int_{-\infty}^{t} E\left(t^{\prime}\right) G\left(t-t^{\prime}\right) d t^{\prime}=\int_{0}^{\infty} E(t-\theta) G(\theta) d \theta \tag{7.23}
\end{equation*}
$$

For a sinusoidal waveform, $E(t)=\operatorname{Re}\left[E_{\omega} e^{-i \omega t}\right]$, this equation yields

$$
\begin{equation*}
P(t)=\operatorname{Re} \int_{0}^{\infty} E_{\omega} e^{-i \omega(t-\theta)} G(\theta) d \theta=\operatorname{Re}\left\{\left[E_{\omega} \int_{0}^{\infty} G(\theta) e^{i \omega \theta} d \theta\right] e^{-i \omega t}\right\} . \tag{7.24}
\end{equation*}
$$

The expression in square brackets is of course nothing more that the complex amplitude $P_{\omega}$ of the polarization. This means that though even if the static relation (3.35) $P=\chi_{e} \varepsilon_{0} E$ is invalid for an arbitrary time-dependent process, we may still keep its Fourier analog,

$$
\begin{equation*}
P_{\omega}=\chi_{e}(\omega) \varepsilon_{0} E_{\omega}, \quad \text { with } \quad \chi_{e}(\omega) \equiv \frac{1}{\varepsilon_{0}} \int_{0}^{\infty} G(\theta) e^{i \omega \theta} d \theta \tag{7.25}
\end{equation*}
$$

[^311]for each sinusoidal component of the process, using it as the definition of the frequency-dependent electric susceptibility $\chi_{e}(\omega)$. Similarly, the frequency-dependent electric permittivity may be defined using the Fourier analog of Eq. (3.38):
\[

$$
\begin{equation*}
D_{\omega} \equiv \varepsilon(\omega) E_{\omega} . \tag{7.26}
\end{equation*}
$$

\]

Then, according to Eq. (3.36), the permittivity is related to the temporal Green's function by the usual Fourier transform:

$$
\begin{equation*}
\varepsilon(\omega) \equiv \varepsilon_{0}+\frac{P_{\omega}}{E_{\omega}}=\varepsilon_{0}+\int_{0}^{\infty} G(\theta) e^{i \omega \theta} d \theta \tag{7.27}
\end{equation*}
$$

It is evident from this expression that $\varepsilon(\omega)$ may be complex,

$$
\begin{equation*}
\varepsilon(\omega)=\varepsilon^{\prime}(\omega)+i \varepsilon^{\prime \prime}(\omega), \quad \varepsilon^{\prime}(\omega)=\varepsilon_{0}+\int_{0}^{\infty} G(\theta) \cos \omega \theta d \theta, \quad \varepsilon^{\prime \prime}(\omega)=\int_{0}^{\infty} G(\theta) \sin \omega \theta d \theta \tag{7.28}
\end{equation*}
$$

and that its real part $\varepsilon^{\prime}(\omega)$ is always an even function of frequency, while the imaginary part $\varepsilon^{\prime \prime}(\omega)$ is an odd function of $\omega$.

Absolutely similar arguments show that the linear magnetic properties may be characterized with complex, frequency-dependent permeability $\mu(\omega)$. Now rewriting Eqs. (1) for the complex amplitudes of the fields at a particular frequency, we may repeat all calculations of Sec. 1, and verify that all its results are valid for monochromatic waves even for a dispersive (but necessarily linear!) medium. In particular, Eqs. (7) and (13) now become

$$
\begin{equation*}
Z(\omega)=\left(\frac{\mu(\omega)}{\varepsilon(\omega)}\right)^{1 / 2}, \quad k(\omega)=\omega[\varepsilon(\omega) \mu(\omega)]^{1 / 2} \tag{7.28}
\end{equation*}
$$

so that the wave impedance and wave number may be both complex functions of frequency.
This fact has important consequences for the electromagnetic wave propagation. First, plugging the presentation of the complex wave number as the sum of its real and imaginary parts, $k(\omega) \equiv k^{\prime}(\omega)+$ $i k^{\prime \prime}(\omega)$, into Eq. (11):

$$
\begin{equation*}
f=\operatorname{Re}\left\{f_{\omega} e^{i[k(\omega) z-\omega t]}\right\}=e^{-k^{\prime \prime}(\omega) z} \operatorname{Re}\left\{f_{\omega} e^{i\left[k^{\prime}(\omega) z-\omega t\right]}\right\} \tag{7.29}
\end{equation*}
$$

we see that $k^{\prime \prime}(\omega)$ describes the rate of wave attenuation in the medium at frequency $\omega .{ }^{9}$ Second, if the waveform is not sinusoidal (and hence should be presented as a sum of several/many sinusoidal components), the frequency dependence of $k^{\prime}(\omega)$ provides for wave dispersion, i.e. the waveform deformation at the propagation, because the propagation velocity (4) of component waves is now different. ${ }^{10}$

[^312]Let us consider a simple but very important Lorentz oscillator model of a dispersive medium. ${ }^{11}$ In dilute atomic or molecular systems (including gases), electrons respond to the external electric field especially strongly when frequency $\omega$ is close to certain eigenfrequencies $\omega_{j}$ corresponding to the spectrum of quantum transitions of a single atom/molecule. An approximate, phenomenological description of this behavior may be obtained from a classical model of several externally-driven harmonic oscillators with finite damping. For an oscillator, driven by electric field's force $F(t)=q E(t)$, we can write the $2^{\text {nd }}$ Newton law as

$$
\begin{equation*}
m\left(\ddot{x}+2 \delta \ddot{x}+\omega_{0}^{2} x\right)=q E(t) \tag{7.30}
\end{equation*}
$$

where $\omega_{0}$ is the own frequency of the oscillator, and $\delta$ its damping coefficient. For a sinusoidal field, $E(t)=\operatorname{Re}\left[E_{\omega} \exp \{-i \omega t\}\right]$, we can look for a particular, forced-oscillation solution in a similar form $x(t)=$ $\operatorname{Re}\left[x_{\omega} \exp \{-i \omega t\}\right] .{ }^{12}$ Plugging this solution into Eq. (30), we can readily find the complex amplitude of these oscillations:

$$
\begin{equation*}
x_{\omega}=\frac{q}{m} \frac{E_{\omega}}{\left(\omega_{0}^{2}-\omega^{2}\right)-2 i \omega \delta} . \tag{7.31}
\end{equation*}
$$

Using this result to calculate the complex amplitude of the dipole moment as $p_{\omega}=q x_{\omega}$, and then the electric polarization $P_{\omega}=n p_{\omega}$ of a dilute medium with $n$ independent oscillators for unit volume, for its frequency-dependent permittivity (27) we get

$$
\begin{equation*}
\varepsilon(\omega)=\varepsilon_{0}+\frac{n q^{2}}{m} \frac{1}{\left(\omega_{0}^{2}-\omega^{2}\right)-2 i \omega \delta} . \tag{7.32}
\end{equation*}
$$

This result may be readily generalized to the case when the system has several types of oscillators with different eigenfrequencies:
$\varepsilon(\omega)$ in Lorentz oscillator model

$$
\begin{equation*}
\varepsilon(\omega)=\varepsilon_{0}+n \frac{q^{2}}{m} \sum_{j} \frac{f_{j}}{\left(\omega_{j}^{2}-\omega^{2}\right)-2 i \omega \delta_{j}} \tag{7.33}
\end{equation*}
$$

where $f_{j} \equiv n_{j} / n$ is the fraction of oscillators with eigenfrequency $\omega_{j}$, so that the sum of all $f_{j}$ equals 1. Figure 5 shows a typical behavior of the real and imaginary parts of the complex dielectric constant, described by Eq. (33), as functions of frequency. The effect of oscillator resonances is clearly visible, and dominates the media response at $\omega \approx \omega_{j}$, especially in the case of low damping, $\delta_{j} \ll \omega_{j}$. Note that in the low-damping limit, the imaginary part of the dielectric constant $\varepsilon$ ", and hence the wave attenuation $k$ ", are negligibly small at all frequencies besides small vicinities of frequencies $\omega_{j}$, where derivative $d \varepsilon^{\prime}(\omega) / d \omega$ is negative. ${ }^{13}$ Thus, for a system of for weakly-damped oscillators, Eq. (33) may be approximated, at most frequencies, as a sum of odd singularities ("poles"):
these effects are discussed in more detail in the quantum-mechanics part of my lecture notes (QM Sec. 2.1), because they are the crucial factor of Schrödinger's wave mechanics. (See also CM Sec. 5.3.)
${ }^{11}$ This example is focused on the frequency dependence of $\varepsilon$, because electromagnetic waves interact with "usual" media via their electric field much more than via the magnetic field. However, as will be discussed in Sec. 7, forgetting about the possible dispersion of $\mu(\omega)$ might result in missing some remarkable opportunities for manipulating the waves.
${ }^{12}$ If this point is not absolutely clear, please see CM Sec. 3.1.
${ }^{13}$ In optics, such behavior is called the anomalous dispersion.

$$
\begin{equation*}
\varepsilon(\omega) \approx \varepsilon_{0}+n \frac{q^{2}}{2 m} \sum_{j} \frac{f_{j}}{\omega_{j}-\omega}, \quad \text { for } \delta_{j} \ll\left|\omega-\omega_{j}\right| \ll\left|\omega_{j}-\omega_{j^{\prime}}\right| . \tag{7.34}
\end{equation*}
$$

This result is especially important because, according to quantum mechanics, ${ }^{14}$ Eq. (34) is also valid for a set of non-interacting, similar quantum systems (whose dynamics may be completely different from that of a harmonic oscillator!), provided that $\omega_{j}$ are replaced with frequencies of possible quantum interstate transitions, and coefficients $f_{j}$ are replaced with the so-called oscillator strengths of the transitions - which obey the same sum rule, $\Sigma_{j} f_{j}=1$.

Fig. 7.5. Typical frequency dependence of the real and imaginary parts of the electric permittivity of a media in the Lorentz oscillator model.

At $\omega \rightarrow 0$, the imaginary part of the permittivity also vanishes (for any $\delta_{j}$ ), while its real part approaches its electrostatic ("dc") value

$$
\begin{equation*}
\varepsilon(0)=\varepsilon_{0}+q^{2} \sum_{j} \frac{n_{j}}{m_{j} \omega_{j}^{2}} . \tag{7.35}
\end{equation*}
$$

Note that according to Eq. (30), the denominator in Eq. (35) is just the effective spring constant $\kappa_{j}=$ $m_{j} \omega_{j}^{2}$ of the $j^{\text {th }}$ oscillator, so that the oscillator masses $m_{j}$ as such are actually (and quite naturally) not involved in the static dielectric response.

In the opposite limit $\omega \gg \omega_{j}, \delta_{j}$, permittivity (33) also becomes real, and may be presented as

$$
\begin{equation*}
\varepsilon(\omega)=\varepsilon_{0}\left(1-\frac{\omega_{p}^{2}}{\omega^{2}}\right), \quad \text { where } \omega_{p}^{2} \equiv \frac{q^{2}}{\varepsilon_{0}} \sum_{j} \frac{n_{j}}{m_{j}} \tag{7.36}
\end{equation*}
$$

The last result is very important, because it is also valid at all frequencies if all $\omega_{j}$ and $\delta_{j}$ vanish, i.e. for a gas of free charged particles, in particular for plasmas - ionized atomic gases, with negligible collision effects. (This is why the parameter $\omega_{p}$ defined by Eq. (36) is called the plasma frequency.) Typically, the plasma as a whole is neutral, i.e. the density $n$ of positive atomic ions is equal to that of

[^313]$\varepsilon(\omega)$ in plasma
the free electrons. Since the ratio $n_{j} / m_{j}$ for electrons is much higher than that for ions, the general formula (36) for the plasma frequency is usually well approximated by the following simple expression:
\[

$$
\begin{equation*}
\omega_{p}^{2} \equiv \frac{n e^{2}}{\varepsilon_{0} m_{e}} . \tag{7.37}
\end{equation*}
$$

\]

This expression has a simple physical sense: the effective spring constant $\kappa_{\mathrm{ef}}=m_{e} \omega_{p}{ }^{2}=n e^{2} / \varepsilon_{0}$ describes the Coulomb force that appears when the electron subsystem of a plasma is shifted, as a whole, from its positive-ion subsystem, thus violating the electroneutrality. Indeed, consider such a small shift, $\Delta x$, perpendicular to the plane surface of a broad, plane slab filled with plasma. The uncompensated charges, with equal and opposite surface densities $\sigma=\mp e n \Delta x$, that appear at the slab surfaces, create inside the it, according to Eq. (2.3), a uniform electric field $E_{x}=e n \Delta x / \varepsilon_{0}$. This field exerts force $e E=\left(n e^{2} / \varepsilon_{0}\right) \Delta x$ on each positively charged ion. According to the $3^{\text {rd }}$ Newton law, the ions pull each electron back to its equilibrium position with the equal and opposite force $F=-e E=-\left(n e^{2} / \varepsilon_{0}\right)$ $\Delta x$, justifying the above expression for $\kappa_{\text {eff }}$. Hence it is not surprising that $\varepsilon(\omega)$ described by the first of Eqs. (36) turns into zero at $\omega=\omega_{p}$ : at this resonance frequency, finite free oscillations of charge (and hence of $D=\varepsilon E$ ) do not require a finite force (and hence $E$ ).

The behavior of electromagnetic waves in a medium that obeys Eq. (36), is very remarkable. If the wave frequency $\omega$ is above $\omega_{p}$, the dielectric constant and hence the wave number (28) are positive and real, and waves propagate without attenuation, following the dispersion relation,

Plasma dispersion relation

$$
\begin{equation*}
k(\omega)=\omega\left[\varepsilon(\omega) \mu_{0}\right]^{1 / 2}=\frac{1}{c}\left(\omega^{2}-\omega_{p}^{2}\right)^{1 / 2} \tag{7.38}
\end{equation*}
$$

which is shown in Fig. 6. (As we will see later in this chapter, many wave transmission systems obey such dispersion law as well.)

At $\omega \rightarrow \omega_{p}$ the wave number $k$ tends to zero. Beyond that point (at $\omega<\omega_{p}$ ), we still can use Eq. (38), but it is more instrumental to rewrite it in the mathematically equivalent form

$$
\begin{equation*}
k(\omega)=\frac{i}{c}\left(\omega_{p}^{2}-\omega^{2}\right)^{1 / 2}=\frac{i}{\delta}, \quad \text { where } \delta \equiv \frac{c}{\left(\omega_{p}^{2}-\omega^{2}\right)^{1 / 2}} \tag{7.39}
\end{equation*}
$$

According to Eq. (29), this means that the electromagnetic field exponentially decreases with distance:

$$
\begin{equation*}
f=\operatorname{Re} f_{\omega} e^{i(k z-\omega t)}=\exp \left\{-\frac{z}{\delta}\right\} \operatorname{Re} f_{\omega} e^{-i \omega t} \tag{7.40}
\end{equation*}
$$

Does this mean that the wave is being absorbed in the plasma? Answering this question is a good pretext to calculate the time average of the Poynting vector $\mathbf{S}=\mathbf{E} \times \mathbf{H}$ of a monochromatic electromagnetic wave in an arbitrary dispersive (but still linear!) medium. First, let us spell out fields' time dependence:

$$
\begin{equation*}
E(t)=\operatorname{Re}\left[E_{\omega}(z) e^{-i \omega t}\right]=\frac{1}{2}\left[E_{\omega} e^{-i \omega t}+\text { c.c. }\right], \quad H(t)=\operatorname{Re}\left[H_{\omega}(z) e^{-i \omega t}\right]=\frac{1}{2}\left[\frac{E_{\omega}}{Z(\omega)} e^{-i \omega t}+\text { c.c. }\right] . \tag{7.41}
\end{equation*}
$$

Now, a straightforward calculation yields ${ }^{15}$

$$
\begin{equation*}
\bar{S}=\overline{E(t) H(t)}=\frac{E_{\omega} E_{\omega}^{*}}{4}\left[\frac{1}{Z(\omega)}+\frac{1}{Z^{*}(\omega)}\right]=\frac{E_{\omega} E_{\omega}^{*}}{2} \operatorname{Re} \frac{1}{Z(\omega)} \equiv \frac{\left|E_{\omega}\right|^{2}}{2} \operatorname{Re}\left(\frac{\varepsilon(\omega)}{\mu(\omega)}\right)^{1 / 2} \tag{7.42}
\end{equation*}
$$

Let us apply this important general formula to our simple model of plasma at $\omega<\omega_{p}$. In this case $\mu(\omega)=\mu_{0}$, i.e. is positive and real, while $\delta(\omega)$ is real and negative, so that $1 / Z(\omega)=[\varepsilon(\omega) / \mu(\omega)]^{1 / 2}$ is purely imaginary, and the average Poynting vector (42) vanishes. This means that energy, on the average, does not flow along axis $z$ - as it would if it was absorbed in plasma. As we will see in the next section, waves with $\omega<\omega_{p}$ are rather reflected from plasma's boundary, without energy loss. Note that in the limit $\omega \ll \omega_{p}$, Eq. (39) yields

$$
\begin{equation*}
\delta \rightarrow \frac{c}{\omega_{p}}=\left(\frac{c^{2} \varepsilon_{0} m_{e}}{n e^{2}}\right)^{1 / 2}=\left(\frac{m_{e}}{\mu_{0} n e^{2}}\right)^{1 / 2} . \tag{7.43}
\end{equation*}
$$

But this is just a particular case (for $q=e$ and $\mu=\mu_{0}$ ) of the expression (6.38) that we have derived for the depth of magnetic field penetration into a lossless (collision-free) conductor in the quasistatic approximation. We see again that, as was already discussed in Sec. 6.7, that approximation (in which we neglect the displacement currents) gives an adequate description of the time-dependent phenomena at $\omega$ $\ll \omega_{p}$, i.e. at $\delta \ll c / \omega=1 / k=\lambda / 2 \pi$.

There are two most important examples of plasmas. For the Earth's ionosphere, i.e. the upper part of the atmosphere that is almost completely ionized by the UV and X-ray components of Sun's radiation, the maximum value of $n$, reached at about 300 km over the Earth surface, is between $10^{10}$ and $10^{12} \mathrm{~m}^{-3}$ (depending on the time of the day and Sun's activity), so that that the maximum plasma frequency (37) is between 1 and 10 MHz . This is much higher than the particle's reciprocal collision time $\tau^{-1}$, so that Eq. (36) gives a very good description of plasma's electric polarization. The effect of reflection of waves with $\omega<\omega_{p}$ from the ionosphere enables long-range (over-the-globe) radio communications and broadcasting at the so-called short waves, with frequencies of the order of 10 MHz .

[^314]Such waves may propagate in the flat channel formed by the Earth surface and the ionosphere, reflected repeatedly by these "walls". Unfortunately, due to the random variations of Sun's activity, and hence $\omega_{p}$, such natural communication channel is not too reliable, and in our age of fiber optics cables its practical importance is diminishing.

Another important example of plasmas is free electrons in metals and other conductors. For a typical metal, $n$ is of the order of $10^{23} \mathrm{~cm}^{-3}=10^{29} \mathrm{~m}^{-3}$, so that Eq. (37) yields $\omega_{p} \sim 10^{16} \mathrm{~s}^{-1}$. Note that this value of $\omega_{p}$ is somewhat higher than mid-optical frequencies $\left(\omega \sim 3 \times 10^{15} \mathrm{~s}^{-1}\right)$. This explains why planar, even, clean metallic surfaces, such as aluminum and silver films used in mirrors, are so shiny: at these frequencies the permittivity is almost exactly real and negative, leading to light reflection, with very little absorption. However, the considered model, which neglects electron scattering, becomes inadequate at lower frequencies, $\omega \tau \sim 1$.

A phenomenological way of extending the model by account of scattering is to take, in Eq. (33), the lowest eigenfrequency $\omega_{j}$ to be equal zero (to describe free electrons), while keeping the damping coefficient $\delta_{0}$ of this mode finite, to account for their energy loss due to scattering. Then Eq. (33) is reduced to

$$
\begin{equation*}
\varepsilon_{\mathrm{ef}}(\omega)=\varepsilon_{\mathrm{opt}}(\omega)+\frac{n_{0} q^{2}}{m} \frac{1}{-\omega^{2}-2 i \omega \delta_{0}}=\varepsilon_{\mathrm{opt}}(\omega)+\frac{i}{\omega} \frac{n_{0} q^{2}}{2 \delta_{0} m} \frac{1}{1-i \omega / 2 \delta_{0}}, \tag{7.44}
\end{equation*}
$$

where response $\varepsilon_{\text {opt }}(\omega)$ at high (in practice, optical) frequencies is still given by Eq. (33), but now with $j$ $\neq 0$.

Result (44) allows for a simple interpretation. To show that, let us incorporate into our calculations the Ohmic conduction, generalizing Eq. (4.7) as $\mathbf{j}_{\omega}=\sigma(\omega) \mathbf{E}_{\omega}$ to account for the possible frequency dependence of the Ohmic conductivity. Plugging this relation into the Fourier image of the relevant Maxwell equation, $\nabla \times \mathbf{H}_{\omega}=\mathbf{j}_{\omega}-i \omega \mathbf{D}_{\omega}=\mathbf{j}_{\omega}-i \omega \delta(\omega) \mathbf{E}_{\omega}$, we get

$$
\begin{equation*}
\nabla \times \mathbf{H}_{\omega}=[\sigma(\omega)-i \omega \varepsilon(\omega)] \mathbf{E}_{\omega} . \tag{7.45}
\end{equation*}
$$

This relation shows that for a sinusoidal process, the addition of the Ohmic current density $\mathbf{j}_{\omega}$ to the displacement current density is equivalent to addition of $\sigma(\omega)$ to $-i \omega \varepsilon(\omega)$, i.e. to the following change of the ac electric permittivity: ${ }^{16}$

$$
\begin{equation*}
\varepsilon(\omega) \rightarrow \varepsilon_{\mathrm{ef}}(\omega) \equiv \varepsilon_{\mathrm{opt}}(\omega)+i \frac{\sigma(\omega)}{\omega} . \tag{7.46}
\end{equation*}
$$

Now the comparison of Eqs. (44) and (46) shows that they coincide if we take

Generalized
Drude formula

$$
\begin{equation*}
\sigma(\omega)=\frac{n_{0} q^{2} \tau}{m_{0}} \frac{1}{1-i \omega \tau}=\sigma(0) \frac{1}{1-i \omega \tau} \tag{7.47}
\end{equation*}
$$

where the dc conductivity $\sigma(0)$ is described by the Drude formula (4.13), and the phenomenologically introduced coefficient $\delta_{0}$ is associated with $1 / 2 \tau$. Relation (47), which is frequently called the

[^315]generalized (or "ac", or "rf") Drude formula, ${ }^{17}$ gives a very reasonable (semi-quantitative) description of the ac conductivity of many metals almost all the way up to optical frequencies.

### 7.3. Kramers-Kronig relations

The results for the simple model of dispersion, discussed in the last section, imply that the frequency dependences of the real $\left(\varepsilon^{\prime}\right)$ and imaginary $\left(\varepsilon^{\prime \prime}\right)$ parts of the permittivity are not quite independent. For example, let us have one more look at the resonance peaks in Fig. 5. Each time the real part drops with frequency, $d \varepsilon^{\prime} / d \omega<0$, its imaginary part $\varepsilon^{\prime \prime}$ has a positive peak. R. de L. Kronig in 1926 and H. A. Kramers in 1927 independently showed that this is not an occasional coincidence pertinent only to the Lorentz oscillator model. Moreover, the full knowledge of function $\varepsilon^{\prime}(\omega)$ allows one to calculate function $\varepsilon^{\prime \prime}(\omega)$, and vice versa. The reason is that both these functions are always related to a single real function $G(\theta)$ by Eqs. (28).

To derive the Kramers-Kronig relations, let us consider Eq. (27) on the complex frequency plane, $\omega \rightarrow \omega^{\prime}+i \omega^{\prime \prime}$ :

$$
\begin{equation*}
f(\omega) \equiv \varepsilon(\omega)-\varepsilon_{0}=\int_{0}^{\infty} G(\theta) e^{i \omega \theta} d \theta=\int_{0}^{\infty} G(\theta) e^{i \omega^{\prime} \theta} e^{-\omega^{\prime \prime} \theta} d \theta \tag{7.48}
\end{equation*}
$$

For all stable physical systems, $G(\theta)$ has to be finite for all important values of the integration variable $(\theta>0)$, and tend to zero at $\theta \rightarrow 0$ and $\theta \rightarrow \infty$. Because of that, and thanks to factor $e^{-\omega \prime \theta}$, the expression under the integral tends to zero at $|\omega| \rightarrow \infty$ in all upper half-plane ( $\omega^{\prime \prime} \geq 0$ ). As a result, we may claim that the complex-variable function $f(\omega)$ is analytical in that half-plane, and allows us to apply to it the Cauchy integral formula ${ }^{18}$

$$
\begin{equation*}
f(\omega)=\frac{1}{2 \pi i} \oint_{C} f(\Omega) \frac{d \Omega}{\Omega-\omega}, \tag{7.49}
\end{equation*}
$$

with the integration contour of the form shown in Fig. 7, with radius $R$ of the larger semicircle tending to infinity, and radius $r$ that of the smaller semicircle (about the singular point $\Omega=\omega$ ) tending to zero.

Fig. 7.7. Integration path $C$ used in the Cauchy integral formula to derive the Kramers-Kronig dispersion relations.

[^316]Due to the exponential decay of $|f(\Omega)|$ at $|\Omega| \rightarrow \infty$, the contribution to the integral from the larger semicircle vanishes, ${ }^{19}$ while the contribution from the small semicircle, where $\Omega=\omega+r \exp \{i \varphi\}$, with $-\pi \leq \varphi \leq 0$, is

$$
\begin{equation*}
\lim _{r \rightarrow 0} \frac{1}{2 \pi i} \int_{\Omega=\omega+r \exp \{i \varphi)} f(\Omega) \frac{d \Omega}{\Omega-\omega}=\frac{f(\omega)}{2 \pi i} \int_{-\pi}^{0} \frac{i r \exp \{i \varphi\} d \varphi}{r \exp \{i \varphi\}}=\frac{f(\omega)}{2 \pi} \int_{-\pi}^{0} d \varphi=\frac{1}{2} f(\omega) . \tag{7.50}
\end{equation*}
$$

As a result, for our contour $C$, Eq. (49) yields

$$
\begin{equation*}
f(\omega)=\lim _{r \rightarrow 0} \frac{1}{2 \pi i}\left(\int_{-\infty}^{\omega-r}+\int_{\omega+r}^{+\infty}\right) f(\Omega) \frac{d \Omega}{\Omega-\omega}+\frac{1}{2} f(\omega) . \tag{7.51}
\end{equation*}
$$

Such an integral, excluding a symmetric infinitesimal vicinity of the pole singularity, is called the principal value of the (formally, diverging) integral from $-\infty$ to $+\infty$, and is denoted by letter P before it. ${ }^{20}$ Using this notation, subtracting $f(\omega) / 2$ from both parts of Eq. (51), and multiplying them by 2 , we get

$$
\begin{equation*}
f(\omega)=\frac{1}{\pi i} \mathrm{P} \int_{-\infty}^{+\infty} f(\Omega) \frac{d \Omega}{\Omega-\omega} . \tag{7.52}
\end{equation*}
$$

Now plugging into this complex equality the polarization-related difference $f(\omega) \equiv \varepsilon(\omega)-\varepsilon_{0}$ in the form $\left[\varepsilon^{\prime}(\omega)-\varepsilon_{0}\right]+i\left[\varepsilon^{\prime \prime}(\omega)\right]$, and requiring both real and imaginary components of both parts of Eq. (52) to be equal separately, we get the famous Kramers-Kronig dispersion relations

$$
\begin{equation*}
\varepsilon^{\prime}(\omega)=\varepsilon_{0}+\frac{1}{\pi} \mathrm{P} \int_{-\infty}^{+\infty} \varepsilon^{\prime \prime}(\Omega) \frac{d \Omega}{\Omega-\omega}, \quad \varepsilon^{\prime \prime}(\omega)=-\frac{1}{\pi} \mathrm{P} \int_{-\infty}^{+\infty}\left[\varepsilon^{\prime}(\Omega)-\varepsilon_{0}\right] \frac{d \Omega}{\Omega-\omega} . \tag{7.53}
\end{equation*}
$$

Kramersdispersion relations

Now we may use the already mentioned fact that $\varepsilon^{\prime}(\omega)$ is always an even, while $\varepsilon^{\prime \prime}(\omega)$ an odd function of frequency, to rewrite these relations in the following form

$$
\begin{equation*}
\varepsilon^{\prime}(\omega)=\varepsilon_{0}+\frac{2}{\pi} \mathrm{P} \int_{0}^{+\infty} \varepsilon^{\prime \prime}(\Omega) \frac{\Omega d \Omega}{\Omega^{2}-\omega^{2}}, \quad \varepsilon^{\prime \prime}(\omega)=-\frac{2 \omega}{\pi} \mathrm{P} \int_{0}^{+\infty}\left[\varepsilon^{\prime}(\Omega)-\varepsilon_{0}\right] \frac{d \Omega}{\Omega^{2}-\omega^{2}}, \tag{7.54}
\end{equation*}
$$

which is more convenient for most applications, because it involves only physical (positive) frequencies.
Though the Kramers-Kronig relations are "global" in frequency, in certain cases they allow an approximate calculation of dispersion from experimental data for absorption, collected even in a limited frequency range. For example, if a medium has a sharp absorption peak at some frequency $\omega_{j}$, we may approximate it as

$$
\begin{equation*}
\varepsilon^{\prime \prime}(\omega) \approx c \delta\left(\omega-\omega_{j}\right)+\text { a more smooth function of } \omega \tag{7.55}
\end{equation*}
$$

and the first of Eqs. (54) immediately gives

[^317]$$
\varepsilon^{\prime}(\omega) \approx \varepsilon_{0}+\frac{2 c}{\pi} \frac{\omega_{j}}{\omega_{j}^{2}-\omega^{2}}+\text { another smooth function of } \omega
$$
thus predicting the anomalous dispersion near such a point. This calculation shows that such behavior observed in the Lorentz oscillator model (Fig. 5) is by no means occasional or model-specific.

Let me emphasize again that the general, and hence very powerful Kramers-Kronig relations hinge on the causal, linear relation (21) between polarization $P(t)$ with the electric field $E\left(t^{\prime}\right)$. Hence, these relations are also valid for the complex functions relating Fourier images of any cause/effectrelated pair of variables. In particular, at a measurement of any linear response $r(t)$ of any experimental sample to any external applied field $f(t)$, whatever the nature of this response and physics behind it, we may be confident that there is a causal relation between the variables $r$ and $f$, so that the complex function $\chi(\omega) \equiv r_{\omega} / f_{\omega}$ does obey the Kramers-Kronig relations. However, it is still important to remember that a linear relation between the Fourier amplitudes of two variables does not necessarily imply the causal relationship between them. ${ }^{21}$

### 7.4. Reflection

The most important new effect arising in nonuniform media is wave reflection. Let us start its discussion from the simplest case of a plane electromagnetic wave that is normally incident on an interface between two uniform, linear, isotropic media.

If the interface is an ideal mirror, the description of reflection is very simple. Indeed, let us assume that one of the two media (say, located at $z>0$, see Fig. 8) cannot sustain any electric field at all:

$$
\begin{equation*}
\left.E\right|_{z \geq 0}=0 . \tag{7.57}
\end{equation*}
$$

This condition is evidently incompatible with the single traveling wave (5). However, this solution may be readily corrected using the fact that the dispersion-free 1D wave equation,

$$
\begin{equation*}
\left(\frac{\partial^{2}}{\partial z^{2}}-\frac{1}{v^{2}} \frac{\partial^{2}}{\partial t^{2}}\right) E=0 \tag{7.58}
\end{equation*}
$$

supports waves, propagating, with the same speed, in opposite directions. As a result, the following linear superposition of two such waves,

$$
\begin{equation*}
\left.E\right|_{z \leq 0}=f(z-v t)-f(-z-v t), \tag{7.59}
\end{equation*}
$$

satisfies both the equation and the boundary condition (57), for an arbitrary function $f$. The second term in Eq. (59) may be interpreted as the total reflection of the incident wave described by its first term, in this case with the change of electric field's sign. By the way, since vector $\mathbf{n}$ of the reflected wave is

[^318]opposite to that incident one (see arrows in Fig. 1), Eq. (6) shows that the magnetic field of the wave does not change its sign at the reflection:
\[

$$
\begin{equation*}
\left.H\right|_{z \leq 0}=\frac{1}{Z}[f(z-v t)+f(-z-v t)] . \tag{7.60}
\end{equation*}
$$

\]

Fig. 7.8. Spatial dependence of electric field at the reflection of a sinusoidal wave from a perfect conductor: the real pattern (red lines) and the crude, ideal-mirror approximation (blue lines). Dashed lines show the patterns after a half-period time delay $(\omega \Delta t=\pi)$.

Wave's total reflection
al red

Blue lines in Fig. 8 show the resulting pattern (59) for the simplest, sinusoidal waveform

$$
\begin{equation*}
\left.E\right|_{z \leq 0}=\operatorname{Re}\left[E_{\omega} e^{i(k z-\omega t)}-E_{\omega} e^{i(-k z-\omega t)}\right] \tag{7.61a}
\end{equation*}
$$

Depending on convenience in a particular context, this pattern may be legitimately interpreted either as a superposition (61a) of two traveling waves or a single standing wave,

$$
\begin{equation*}
\left.E\right|_{z \leq 0}=-2 \operatorname{Im}\left(E_{\omega} e^{-i \omega t}\right) \sin k z=2 \operatorname{Re}\left(i E_{\omega} e^{-i \omega t}\right) \sin k z \tag{7.61b}
\end{equation*}
$$

in which the electric and magnetic field oscillate with the phase shifts by $\pi / 2$ both in time and space:

$$
\begin{equation*}
\left.H\right|_{z \leq 0}=\operatorname{Re}\left[\frac{E_{\omega}}{Z} e^{i(k z-\omega t)}+\frac{E_{\omega}}{Z} e^{i(-k z-\omega t)}\right]=2 \operatorname{Re}\left(\frac{E_{\omega}}{Z} e^{-i \omega t}\right) \cos k z . \tag{7.62}
\end{equation*}
$$

As the result of this shift, the time average of the Poynting vector's magnitude,

$$
\begin{equation*}
S(z, t)=E H=\frac{1}{Z} \operatorname{Re}\left[E_{\omega}^{2} e^{-2 i \omega t}\right] \sin 2 k z, \tag{7.63}
\end{equation*}
$$

equals zero, showing that at the total reflection there is no average power flow. (This is natural, because the perfect mirror can neither transmit the wave nor absorb it.) However, Eq. (63) shows that the standing wave provides local oscillations of energy, transferring it periodically between the concentrations of the electric and magnetic fields, separated by distance $\Delta z=\pi / 2 k=\lambda / 4$.

For the case of the sinusoidal waves, the reflection effects may be readily explored even for the more general case of dispersive and/or lossy media in which $\varepsilon(\omega)$ and $\mu(\omega)$, and hence the wave vector $k(\omega)$ and wave impedance $Z(\omega)$, defined by Eqs. (28), are certain complex functions of frequency. The "only" new factors we have to account for is that in this case the reflection may not be full, and that
inside the second media we have to use the traveling-wave solution as well. Both these factors may be taken care of by looking for the solution of our boundary problem in the form

$$
\begin{equation*}
\left.E\right|_{z \leq 0}=\operatorname{Re}\left[E_{\omega}\left(e^{i k_{-} z}+R e^{-i k_{-} z}\right) e^{-i \omega t}\right],\left.\quad E\right|_{z \geq 0}=\operatorname{Re}\left[E_{\omega} T e^{i k_{+} z} e^{-i \omega t}\right] \tag{7.64}
\end{equation*}
$$

and hence, according to Eq. (6),

$$
\begin{equation*}
\left.H\right|_{z \leq 0}=\operatorname{Re}\left[\frac{E_{\omega}}{Z_{-}(\omega)}\left(e^{i k_{-} z}-R e^{-i k_{-} z}\right) e^{-i \omega t}\right],\left.\quad H\right|_{z \geq 0}=\operatorname{Re}\left[\frac{E_{\omega}}{Z_{+}(\omega)} T e^{i k_{+} z} e^{-i \omega t}\right] \tag{7.65}
\end{equation*}
$$

(Indices + and - correspond to, respectively, the media at $z>0$ and $z<0$.) Please note the following important features of these relations:
(i) Due to the problem linearity, we could (and did :-) take the complex amplitudes of the reflected and transmitted wave proportional to that $\left(E_{\omega}\right)$ of the incident wave, describing them by the dimensionless coefficients $R$ and $T$. The total reflection from an ideal mirror, that was discussed above, corresponds to the particular case $R=-1$ and $T=0$.
(ii) Since the incident wave, that we are considering, arrives from one side only (from $z=-\infty$ ), there is no need to include a term proportional to $\exp \left\{-i k_{+} z\right\}$ into Eqs. (64)-(65) - in our current problem. However, we would need such a term if the medium at $z>0$ was non-uniform (e.g., had at least one more interface or any other inhomogeneity), because the wave reflected from that additional inhomogeneity would be incident on our interface (located at $z=0$ ) from the right.
(iii) Solution (64)-(65) is sufficient even for the description of the cases when waves cannot propagate at $z \geq 0$, for example a conductor or a plasma with $\omega_{p}>\omega$. Indeed, the exponential drop of the field amplitude at $z>0$ in such cases is automatically described by the imaginary part of wave number $k_{+}$- see Eq. (29).

In order to find coefficients $R$ and $T$, we need to use boundary conditions at $z=0$. Since the reflection does not change the transverse character of the partial waves, at the normal incidence both vectors $\mathbf{E}$ and $\mathbf{H}$ remain tangential to the interface plane (in our notation, $z=0$ ). Reviewing the arguments that has led us, in statics, to boundary conditions (3.47) and (5.118) for these components, we see that they remain valid for the time-dependent situation as well, ${ }^{22}$ so that for our current case of purely transverse waves we can write:

$$
\begin{equation*}
\left.E\right|_{z=-0}=\left.E\right|_{z=+0},\left.\quad H\right|_{z=-0}=\left.H\right|_{z=+0} . \tag{7.66}
\end{equation*}
$$

Plugging Eqs. (64)-(65) into these conditions, we get

$$
\begin{equation*}
1+R=T, \quad \frac{1}{Z_{-}}(1-R)=\frac{1}{Z_{+}} T . \tag{7.67}
\end{equation*}
$$

[^319]Solving this simple system of equations, we get ${ }^{23}$

$$
\begin{equation*}
R=\frac{Z_{+}-Z_{-}}{Z_{+}+Z_{-}}, \quad T=\frac{2 Z_{+}}{Z_{+}+Z_{-}} . \tag{7.68}
\end{equation*}
$$

These formulas are very important, and much more general than one may think, because they are applicable for virtually any 1D waves - electromagnetic or not, if only the impedance $Z$ is defined in a proper way. ${ }^{24}$ Since in the general case the wave impedances $Z_{ \pm}$, defined by Eq. (28) with the corresponding indices, are complex functions of frequency, Eqs. (68) show that coefficients $R$ and $T$ may have imaginary parts as well. This fact has most important consequences at $z<0$ where the reflected wave, proportional to $R$, interferes with the incident wave. Indeed, plugging $R=|R| e^{i \varphi}$ (where $\varphi \equiv \arg R$ is a real phase shift) into the expression in parentheses in the first of Eqs. (64), we may rewrite it as

$$
\begin{align*}
\left(e^{i k-z}+R e^{-i k_{-} z}\right) & =(1-|R|+|R|) e^{i k_{-} z}+|R| e^{i \varphi} e^{-i k_{-} z} \\
& =(1-|R|) e^{i k_{-} z}+2|R| e^{i \varphi / 2} \sin \left[k_{-}\left(z-\delta_{-}\right)\right], \quad \text { where } \delta_{-} \equiv \frac{\varphi-\pi}{2 k_{-}} \tag{7.69}
\end{align*}
$$

This means that the field may be presented as a sum of a traveling wave and a standing wave, with amplitude proportional to $|R|$, shifted by distance $\delta$. toward the interface, relatively to the ideal-mirror pattern (61b). This effect is frequently used for the experimental measurements of an unknown impedance $Z_{+}$of some medium, provided than $Z_{-}$is known (e.g., for the free space, $Z_{-}=Z_{0}$ ). For that, a small antenna (the probe), not disturbing the field distribution too much, is placed into the wave field, and the amplitude of the ac voltage induced in it by the wave in the probe is measured by some detector (e.g., a semiconductor diode with a quadratic $I-V$ curve), as a function of $z$ (Fig. 9). From this measurement, it is straightforward to find both $|R|$ and $\delta$, and hence restore complex $R$, and then use Eq. (68) to calculate both modulus and argument of $Z_{+} .{ }^{25}$

Fig. 7.9. Measurement of the complex impedance of a medium (schematically).

Now let us discuss what do these results give for waves incident from the free space ( $Z_{-}(\omega)=Z_{0}$ $=$ const, $k_{-}=k_{0}=\omega / c$ ) onto the surface of two particular media.

[^320](i) For a collision-free plasma (with negligible magnetization) we may use Eq. (36) with $\mu(\omega)=$ $\mu_{0}$, to present the impedance in either of two equivalent forms:
\[

$$
\begin{equation*}
Z_{+}=Z_{0} \frac{\omega}{\left(\omega^{2}-\omega_{p}^{2}\right)^{1 / 2}}=-i Z_{0} \frac{\omega}{\left(\omega_{p}^{2}-\omega^{2}\right)^{1 / 2}} \tag{7.70}
\end{equation*}
$$

\]

The former expression is more convenient in the case $\omega>\omega_{p}$, when the wave vector $k_{+}$and the wave impedance $Z_{+}$of plasma are real, so that a part of the incident wave propagates into the plasma. Plugging this expression into the latter of Eqs. (68), we see that the transmission coefficient is real:

$$
\begin{equation*}
T=\frac{2 \omega}{\omega+\left(\omega^{2}-\omega_{p}^{2}\right)^{1 / 2}} \tag{7.71}
\end{equation*}
$$

Note that according to this formula, somewhat counter-intuitively, $T>1$ for any frequency (above $\omega_{p}$ ). How can the transmitted wave be more intensive than the incident one that has induced it? For a better understanding of this result, let us compare the powers (rather than amplitudes) of these two waves, i.e. their average Poynting vectors (42):

$$
\begin{equation*}
\overline{S_{\text {incident }}}=\frac{\left|E_{\omega}\right|^{2}}{2 Z_{0}}, \quad \overline{S_{+}}=\frac{\left|T E_{\omega}\right|^{2}}{2 Z_{+}}=\frac{\left|E_{\omega}\right|^{2}}{2 Z_{0}} \frac{4 \omega\left(\omega^{2}-\omega_{p}^{2}\right)^{1 / 2}}{\left[\omega+\left(\omega^{2}-\omega_{p}^{2}\right)^{1 / 2}\right]^{2}} . \tag{7.72}
\end{equation*}
$$

It is easy to see that the ratio of these two values ${ }^{26}$ is always below 1 (and tends to zero at $\omega \rightarrow \omega_{p}$ ), so that only a fraction of the incident wave power may be transferred. Hence the result $T>1$ may be interpreted as follows: the interface between two media also works as an impedance transformer: though it can never transfer more power than the incident wave provides, i.e. can only decrease the product $S=$ $E H$, but since the ratio $Z=E / H$ changes at the interface, the amplitude of one of the fields may increase at the transfer.

Now let us proceed to case $\omega<\omega_{p}$, when the waves cannot propagate in the plasma. In this case, the latter of expressions (70) is more convenient, because it immediately shows that $Z_{+}$is purely imaginary, while $Z_{-}=Z_{0}$ is purely real. This means that $\left(Z_{+}-Z_{-}\right)=\left(Z_{+}+Z_{-}\right)^{*}$, i.e. according to the first of Eqs. (68), $|R|=1$, so that the reflection is total, i.e. no incident power (on the average) is transferred into the plasma - as was already discussed in Sec. 2. However, the complex $R$ has a finite argument,

$$
\begin{equation*}
\varphi=\arg R=2 \arg \left(Z_{+}-Z_{0}\right)=-2 \tan ^{-1} \frac{\omega}{\left(\omega_{p}^{2}-\omega^{2}\right)^{1 / 2}}, \tag{7.73}
\end{equation*}
$$

and hence provides a finite spatial shift (69) of the standing wave toward the plasma surface:

$$
\begin{equation*}
\delta_{-}=\frac{\varphi-\pi}{2 k_{0}}=\frac{c}{\omega} \tan ^{-1} \frac{\omega}{\left(\omega_{p}^{2}-\omega^{2}\right)^{1 / 2}} . \tag{7.74}
\end{equation*}
$$

On the other hand, we already know from Eq. (40) that the solution at $z>0$ is exponential, with the decay length $\delta$ that is described by Eq. (39). Calculating, from coefficient $T$, the exact coefficient before this exponent, it is straightforward to verify that the electric and magnetic fields are indeed

[^321]continuous at the interface, forming the pattern shown by red lines in Fig. 8. This penetration may be experimentally observed, for example, by bringing close to the interface the surface of another material transparent as frequency $\omega$. Even without solving this problem exactly, it is evident that if the distance between these two interfaces becomes comparable to $\delta$, a part of the exponential "tail" of the field is picked up by the second material, and induces a propagating wave. This is an electromagnetic analog of the quantum-mechanical tunneling through a potential barrier. ${ }^{27}$

Note that at $\omega \ll \omega_{p}$, both $\delta$ - and $\delta$ are reduced to the same frequency-independent value,

$$
\begin{equation*}
\delta, \delta_{-} \rightarrow \frac{c}{\omega_{p}}=\left(\frac{c^{2} \varepsilon_{0} m_{e}}{n e^{2}}\right)^{1 / 2}=\left(\frac{m_{e}}{\mu_{0} n e^{2}}\right)^{1 / 2} \tag{7.75}
\end{equation*}
$$

which is just the field penetration depth $\delta(6.38)$ calculated for a perfect conductor model (assuming $m=$ $m_{e}$ and $\mu=\mu_{0}$ ) in the quasistatic limit. This is natural, because the condition $\omega \ll \omega_{p}$ may be recast as $\lambda_{0}$ $=2 \pi c / \omega \gg 2 \pi c / \omega_{p}=2 \pi \delta$.
(ii) Now let us consider electromagnetic wave reflection from a nonmagnetic conductor. In the simplest low-frequency limit, when $\omega \tau$ is much less than 1 , the conductor may be described by a frequency-independent conductivity $\sigma .{ }^{28}$ According to Eq. (46), in this case we can take

$$
\begin{equation*}
Z_{+}=\left(\frac{\mu_{0}}{\varepsilon_{\mathrm{opt}}(\omega)+i \sigma / \omega}\right)^{1 / 2} . \tag{7.76}
\end{equation*}
$$

With this substitution, Eqs. (68) immediately give us all the results of interest. In particular, they show that now $R$ is complex, and hence some fraction $F$ of the incident wave is absorbed by the conductor. Using Eq. (42), we may calculate the fraction to be

$$
\begin{equation*}
F \equiv \frac{\overline{\left.S_{+}\right|_{z=+0}}}{\overline{S_{\text {incident }}}}=|T|^{2} \operatorname{Re} \frac{Z_{0}}{Z_{+}} . \tag{7.77}
\end{equation*}
$$

(Since power flow $S_{+}$into the conductor depends on $z$, tending to zero at distances $z \sim \delta$, it is important to calculate it directly at the interface to account for the absorption in the whole volume of the conductor.) Restricting ourselves, for the sake of simplicity, to the most important quasistatic limit, i.e. to $Z_{+}=\left(\mu_{0} \omega / i \sigma\right)^{1 / 2}$, and using Eq. (6.27) to express the impedance via the skin depth, $Z_{+}=$ $\pi(2 / i)^{1 / 2}\left(\delta_{s} / \lambda_{0}\right) Z_{0}$, we see that $\left|Z_{+}\right| \ll Z_{0}$, so that, according to Eq. (68), $T \approx 2 Z_{+} / Z_{0}$ and

Wave's
absorption conductor's surface

$$
\begin{equation*}
F \approx \frac{4\left|Z_{+}\right|^{2}}{Z_{0}^{2}} \operatorname{Re} \frac{Z_{0}}{Z_{+}}=2 \frac{\delta_{s}}{\lambda_{0}} \ll 1 \tag{7.78}
\end{equation*}
$$

Thus the absorbed power scales as the ratio of the skin depth to the free-space wavelength. This important result is widely used for the semi-qualitative evaluation of power losses in metallic waveguides and resonators, and immediately shows that in order to keep the losses low, the characteristic size of such systems (that gives a scale of the free-space wavelengths $\lambda_{0}$, at which they are

[^322]used) should be much larger than $\delta_{s}$. A more detailed theory of these structures will be discussed later in this chapter.

### 7.5. Refraction

Now let us consider the effects arising at the plane interface if the wave incidence angle $\theta$ (Fig. 10) is arbitrary, rather than equal to zero as in our previous analysis, for the simplest case of fully transparent media, with real $\varepsilon_{ \pm}$and $\mu_{ \pm}$.

Fig. 7.10. Plane wave reflection, transmission, and refraction at a plane interface. The plane of drawing is selected to contain all three wave vectors $\mathbf{k}_{+}, \mathbf{k}_{\text {-, }}$, and $\mathbf{k}^{\prime}$..

In contrast with the case of normal incidence, here the wave vectors $\mathbf{k}$., $\mathbf{k}_{-}^{\prime}$, and $\mathbf{k}_{+}$of the three component (incident, reflected, and transmitted) waves may have different directions. Hence now we have to start our analysis with writing a general expression for a single plane, monochromatic wave for the case when its wave vector $\mathbf{k}$ has all 3 Cartesian components, rather than one. An evident generalization of Eq. (11) to this case is

$$
\begin{equation*}
f(\mathbf{r}, t)=\operatorname{Re}\left[f_{\omega} e^{\left.i\left(k_{x} x+k_{y} y+k_{z} z\right)-\omega t\right)}\right]=\operatorname{Re}\left[f_{\omega} e^{i(\mathbf{k} \cdot \mathbf{r}-\omega t)}\right] . \tag{7.79}
\end{equation*}
$$

This relation enables a ready analysis of "kinematic" relations that are independent of the media impedances. Indeed, it is sufficient to notice that in order to satisfy any linear, homogeneous boundary conditions at the interface $(z=0)$, all waves have the same temporal and spatial dependence on this plane. Hence if we select plane $x z$ so that vector $\mathbf{k}$. lies in it, then $\left(k_{-}\right)_{y}=0$, and $\mathbf{k}_{+}$and $\mathbf{k}_{\text {- ' cannot have }}$ any $y$-component either, i.e. all three vectors lie in the same plane - that is selected as the plane of drawing of Fig. 10. Moreover, due to the same reason their $x$-components should be equal:

$$
\begin{equation*}
k_{-} \sin \theta=k_{-}^{\prime} \sin \theta^{\prime}=k_{+} \sin r \text {. } \tag{7.80}
\end{equation*}
$$

From here we immediately have the well-known laws of reflection

$$
\begin{equation*}
\theta^{\prime}=\theta \tag{7.81}
\end{equation*}
$$

and refraction: ${ }^{29}$

[^323]Snell law

$$
\begin{equation*}
\frac{\sin r}{\sin \theta}=\frac{k_{-}}{k_{+}} \tag{7.82}
\end{equation*}
$$

In this form, the laws are valid for plane waves of any nature. In optics, the Snell law (82) is frequently presented in the form

$$
\begin{equation*}
\frac{\sin r}{\sin \theta}=\frac{n_{-}}{n_{+}} \tag{7.83}
\end{equation*}
$$

where $n_{ \pm}$is the index of refraction (also called the "refractive index") of the corresponding medium, defined as its wave number normalized so that of the free space (at wave's frequency):

$$
\begin{equation*}
n_{ \pm} \equiv \frac{k_{ \pm}}{k_{0}}=\left(\frac{\varepsilon_{ \pm} \mu_{ \pm}}{\varepsilon_{0} \mu_{0}}\right)^{1 / 2} \tag{7.84}
\end{equation*}
$$

Perhaps the most famous corollary of the Snell law is that if a wave propagates from a medium with a higher index of refraction to that with a lower one (i.e. if $n_{-}>n_{+}$in Fig. 10), for example from water into air, there is always a certain critical value $\theta_{c}$ of the incidence angle,
at which angle $r$ reaches $\pi / 2$. At a larger $\theta$, i.e. within the range $\theta_{c}<\theta<\pi / 2$, the boundary conditions cannot be satisfied with a refracted wave with a real wave vector, so that the wave experiences the socalled total internal reflection. This effect is very important for practice, because it shows that dielectric surfaces may be used as mirrors, in particular in optical fibers - to be discussed in more detail in Sec. 8 below. This is very fortunate for all the telecommunication technology, because the light reflection from metals is rather imperfect. Indeed, according to Eq. (78), in the optical range ( $\lambda_{0} \sim 0.5 \mu \mathrm{~m}$, i.e. $\omega \sim 10^{15}$ $\mathrm{s}^{-1}$ ), even the best conductors (with $\sigma \sim 6 \times 10^{8} \mathrm{~S} / \mathrm{m}$ and hence the normal skin depth $\delta_{\mathrm{s}} \sim 1.5 \mathrm{~nm}$ ) provide relatively high losses $F \sim 1 \%$ at each reflection.

Note, however, that even within the range $\theta_{\mathrm{c}}<\theta<\pi / 2$ the field at $z>0$ is not identically equal to zero: just as it does at the normal incidence $(\theta=0)$, it penetrates into the less dense media by a distance of the order of $\lambda_{0}$, exponentially decaying inside it. At $\theta \neq 0$ the penetrating field still changes sinusoidally, with wave number (80), along the interface. Such a field, exponentially dropping in one direction but still propagating as a wave in another direction, is frequently called the evanescent wave.

One more remark: just as at the normal incidence, the field penetration into another medium causes a phase shift of the reflected wave - see, e.g., Eq. (69) and its discussion. A new feature of this phase shift, arising at $\theta \neq 0$, is that it also has a component parallel to the interface - the so-called called the Goos-Hänchen effect. In geometric optics, this effect leads to an image shift (relative to that its position in a perfect mirror) with components both normal and parallel to the interface.

Now let us carry out an analysis of the "dynamic" relations that determine amplitudes of the refracted and reflected waves. For this we need to write explicitly the boundary conditions at the interface (i.e. plane $z=0$ ). Since now the electric and/or magnetic fields may have components normal to the plane, in addition to the continuity of their tangential components, which we have repeatedly discussed,

$$
\begin{equation*}
\left.E_{x, y}\right|_{z=-0}=\left.E_{x, y}\right|_{z=+0},\left.\quad H_{x, y}\right|_{z=-0}=\left.H_{x, y}\right|_{z=+0}, \tag{7.86}
\end{equation*}
$$

we also need relations for the normal components. As it follows from the homogeneous macroscopic Maxwell equations (6.94b), they are also the same as in statics ( $D_{n}=$ const, $B_{n}=$ const), for our reference frame choice (Fig. 10) giving

$$
\begin{equation*}
\left.\varepsilon_{-} E_{z}\right|_{z=-0}=\left.\varepsilon_{+} E_{z}\right|_{z=+0},\left.\quad \mu_{-} H_{z}\right|_{z=-0}=\left.\mu_{+} H_{z}\right|_{z=+0} . \tag{7.87}
\end{equation*}
$$

The expressions of these components via amplitudes $E_{\omega}, R E_{\omega}$, and $T E_{\omega}$ of the incident, reflected and transmitted waves depend on the incident wave's polarization. For example, for a linearly-polarized wave with the electric field vector perpendicular to the plane of incidence (Fig. 11a), i.e. parallel to the interface plane, the reflected and refracted waves are similarly polarized.

(b)

Fig. 7.11. Reflection and refraction at two different linear polarizations of the incident wave.

As a result, all $E_{z}$ are equal to zero (so that the first of Eqs. (87) is inconsequential), while the tangential components of the electric field are just equal to their full amplitudes, just as at the normal incidence, so we still can use Eqs. (64) to express these components via coefficients $R$ and $T$. However, at $\theta \neq 0$ the magnetic fields have not only tangential components

$$
\begin{equation*}
\left.H_{x}\right|_{z=-0}=\operatorname{Re}\left[\frac{E_{\omega}}{Z_{-}}(1-R) \cos \theta e^{-i \omega t}\right],\left.\quad H_{x}\right|_{z=+0}=\operatorname{Re}\left[\frac{E_{\omega}}{Z_{+}} T \cos r e^{-i \omega t}\right], \tag{7.88}
\end{equation*}
$$

but also normal components (Fig. 11a):

$$
\begin{equation*}
\left.H_{z}\right|_{z=-0}=\operatorname{Re}\left[\frac{E_{\omega}}{Z_{-}}(1+R) \sin \theta e^{-i \omega t}\right],\left.\quad H_{z}\right|_{z=+0}=\operatorname{Re}\left[\frac{E_{\omega}}{Z_{+}} T \sin r e^{-i \omega t}\right] . \tag{7.89}
\end{equation*}
$$

Plugging these expressions into the boundary conditions expressed by Eqs. (86) (in this case, for $y$ components only) and the second of Eqs. (87), we get three equations for two unknown coefficients $R$ and $T$. However, two of these equations duplicate each other because of the Snell law, and we get just two independent equations,

$$
\begin{equation*}
1+R=T, \quad \frac{1}{Z_{-}}(1-R) \cos \theta=\frac{1}{Z_{+}} T \cos r, \tag{7.90}
\end{equation*}
$$

which are a very natural generalization of Eqs. (67), with replacements $Z_{-} \rightarrow Z_{-} \cos r, Z_{+} \rightarrow Z_{+} \cos \theta$. As a result, we can immediately use Eq. (68) to write the solution of system (90):30

$$
\begin{equation*}
R=\frac{Z_{+} \cos \theta-Z_{-} \cos r}{Z_{+} \cos \theta+Z_{-} \cos r}, \quad T=\frac{2 Z_{+} \cos \theta}{Z_{+} \cos \theta+Z_{-} \cos r} . \tag{7.91a}
\end{equation*}
$$

If we want to express the coefficients via the angle of incidence alone, we should use the Snell law (82) to eliminate angle $r$, getting

$$
\begin{equation*}
R=\frac{Z_{+} \cos \theta-Z_{-}\left[1-\left(k_{-} / k_{+}\right)^{2} \sin ^{2} \theta\right]^{1 / 2}}{Z_{+} \cos \theta+Z_{-}\left[1-\left(k_{-} / k_{+}\right)^{2} \sin ^{2} \theta\right]^{1 / 2}}, \quad T=\frac{2 Z_{+} \cos \theta}{Z_{+} \cos \theta+Z_{-}\left[1-\left(k_{-} / k_{+}\right)^{2} \sin ^{2} \theta\right]^{1 / 2}} . \tag{7.91b}
\end{equation*}
$$

However, my strong preference is to use the kinematic relation (82) and dynamic relations (91a) separately, because Eq. (91b) obscures the very important physical fact that and the ratio of $k_{ \pm}$, i.e. of the wave velocities of the two media, is only involved in the Snell law (79), while the dynamic relations essentially include only the ratio of wave impedances - just as in the case of normal incidence.

In the opposite case of the linear polarization of the electric field within the plane of incidence (Fig. 11b), it is the magnetic field that does not have a normal component, so it is now the second of Eqs. (87) that does not participate in the solution. However, now the electric fields in two media have not only tangential components,

$$
\begin{equation*}
\left.E_{x}\right|_{z=-0}=\left.\operatorname{Re}\left[E_{\omega}(1+R) \cos \theta e^{-i \omega t}\right] \quad E_{x}\right|_{z=+0}=\operatorname{Re}\left[E_{\omega} T \cos r e^{-i \omega t}\right], \tag{7.92}
\end{equation*}
$$

but also normal components (Fig. 11b):

$$
\begin{equation*}
\left.E_{z}\right|_{z=-0}=E_{\omega}(-1+R) \sin \theta,\left.\quad E_{z}\right|_{z=+0}=-E_{\omega} T \sin r . \tag{7.93}
\end{equation*}
$$

As a result, instead of Eqs. (90), the reflection and transmission coefficients are related as

$$
\begin{equation*}
(1+R) \cos \theta=T \cos r, \quad \frac{1}{Z_{-}}(1-R)=\frac{1}{Z_{+}} T . \tag{7.94}
\end{equation*}
$$

Again, the solution of this system may be immediately written using the analogy with Eq. (67):

$$
\begin{equation*}
R=\frac{Z_{+} \cos r-Z_{-} \cos \theta}{Z_{+} \cos r+Z_{-} \cos \theta}, \quad T=\frac{2 Z_{+} \cos \theta}{Z_{+} \cos r+Z_{-} \cos \theta}, \tag{7.95a}
\end{equation*}
$$

or, alternatively, using the Snell law:

$$
\begin{equation*}
R=\frac{Z_{+}\left[1-\left(k_{-} / k_{+}\right)^{2} \sin ^{2} \theta\right]^{1 / 2}-Z_{-} \cos \theta}{Z_{+}\left[1-\left(k_{-} / k_{+}\right)^{2} \sin ^{2} \theta\right]^{1 / 2}+Z_{-} \cos \theta}, \quad T=\frac{2 Z_{+} \cos \theta}{Z_{+}\left[1-\left(k_{-} / k_{+}\right)^{2} \sin ^{2} \theta\right]^{1 / 2}+Z_{-} \cos \theta} . \tag{7.95b}
\end{equation*}
$$

[^324]For the particular case $\mu_{+}=\mu_{-}=\mu_{0}$, when $Z_{+} / Z-=\left(\varepsilon_{-} / \varepsilon_{+}\right)^{1 / 2}=k_{l} / k_{+}=n_{-} / n_{+}($which is approximately correct for traditional optical media), Eqs. (91b) and (95b) are called the Fresnel formulas. ${ }^{31}$ Most textbooks are quick to point out that there is a major difference between these cases: while for the electric field polarization within the plane of incidence (Fig. 11b), the reflected wave amplitude (proportional to coefficient $R$ ) turns to zero at a special value of $\theta$ (the so-called Brewster angle):32

$$
\begin{equation*}
\theta_{\mathrm{B}}=\tan ^{-1} \frac{n_{+}}{n_{-}}, \tag{7.96}
\end{equation*}
$$

while there is no such angle in the opposite case (Fig. 11a). ${ }^{33}$ However, that this statement, as well as Eq. (96), is true only for the case $\mu_{+}=\mu$. In the general case of different $\varepsilon$ and $\mu$, Eqs. (91) and (95) show that the reflected wave vanishes at $\theta=\theta_{\mathrm{B}}$ with

$$
\tan ^{2} \theta_{B}=\frac{\varepsilon_{-} \mu_{+}-\varepsilon_{+} \mu_{-}}{\varepsilon_{+} \mu_{+}-\varepsilon_{-} \mu_{-}} \times \begin{cases}\left(\mu_{+} / \mu_{-}\right), & \text {for } \mathbf{E} \perp \mathbf{n}_{z} \text { (Fig.11a), }  \tag{7.97}\\ \left(-\varepsilon_{+} / \varepsilon_{-}\right), & \text {for } \mathbf{H} \perp \mathbf{n}_{z} \text { (Fig.11b) }\end{cases}
$$

## Brewster <br> angle

Note the natural $\varepsilon \leftrightarrow \mu$ symmetry of these relations, resulting from the $\mathbf{E} \leftrightarrow \mathbf{H}$ symmetry for these two polarization cases (Fig. 11). They also show that for any set of parameters of the two media (with $\varepsilon_{ \pm}, \mu_{ \pm}>0$ ), $\tan ^{2} \theta_{\mathrm{B}}$ is positive (and hence a real Brewster angle $\theta_{\mathrm{B}}$ exists) only for one of these two polarizations. In particular, if the interface is due to the change of $\mu$ alone (i.e. $\varepsilon_{+}=\varepsilon_{-}$), the first of Eqs. (97) is reduced to the simple form (96) again, while for the polarization shown in Fig. 11b there is no Brewster angle, i.e. the reflected wave has a nonvanishing amplitude for any $\theta$.

Such account of both media parameters on an equal footing is especially necessary to describe the so-called negative refraction effects. ${ }^{34}$ As was shown in Sec. 2, in a medium with electric-fielddriven resonances, function $\delta(\omega)$ may be almost real and negative, at least within limited frequency intervals - see, in particular, Eq. (34) and Fig. 5. As have already been discussed, if, at these frequencies, function $\mu(\omega)$ is real and positive, then $k^{2}(\omega)=\omega^{2} \varepsilon(\omega) \mu(\omega)<0$, and $k$ may be presented as $i / \delta$ with real $\delta$, meaning the exponential field decay into the medium. However, let consider the case when both $\varepsilon(\omega)<0$ and $\mu(\omega)<0$ at a certain frequency. (This is evidently possible in a medium with both E-driven and $\mathbf{H}$-driven resonances, at proper relations between their eigenfrequencies.) Since in this case $k^{2}(\omega)=\omega^{2} \varepsilon(\omega) \mu(\omega)>0$, the wave vector is real, so that Eq. (79) describes a traveling wave, and one could think that there is nothing new in this case. Not quite so!

[^325]First of all, for a sinusoidal, plane wave (79), operator $\nabla$ is equivalent to the multiplication by $i \mathbf{k}$. As the Maxwell equations (2a) show, this means that at a fixed direction of vectors $\mathbf{E}$ and $\mathbf{k}$, the simultaneous reversal of signs of $\varepsilon$ and $\mu$ means the reversal of the direction of vector $\mathbf{H}$. Namely, if both $\varepsilon$ and $\mu$ are positive, these equations are satisfied with mutually orthogonal vectors $\mathbf{E}, \mathbf{H}$, and $\mathbf{k}$ forming the usual, right-hand system (see Fig. 1 and Fig. 12a), the name stemming from the popular "right-hand rule" used to determine the vector product direction. However, if both $\varepsilon$ and $\mu$ are negative, the vectors form a left-hand system - see Fig. 12b. (Due to this fact, the media with $\varepsilon<0$ and $\mu<0$ are frequently called the left-handed materials, LHM for short.) According to Eq. (6.97), that does not involve media parameters, this means that for a plane wave in a left-hand material, the Poynting vector $\mathbf{S}$ $=\mathbf{E} \times \mathbf{H}$, i.e. of the energy flow, is directed opposite to the wave vector $\mathbf{k}$.

Fig. 7.12. Directions of main vectors of a plane wave inside a medium with (a) positive and (b) negative $\varepsilon$ and $\mu$.

This fact may seems strange, but is in no contradiction with any fundamental principle. Let me remind you that, according to the definition of vector $\mathbf{k}$, its direction shows the direction of the phase velocity $v_{\mathrm{ph}}=\omega / k$ of a sinusoidal (and hence infinitely long) wave that cannot be used, for example, for signaling. Such signaling (by sending wave packets - see Fig. 13) is possible with the group velocity $v_{\mathrm{gr}}$ $=d \omega / d k$. This velocity in left-hand materials is always positive (directed along vector $\mathbf{S}$ ).

Fig. 7.13. Example of a wave packet moving along axis $z$ with a negative phase velocity, but positive group velocity. Blue lines show a packet snapshot a short time interval after the first snapshot (red lines).

Maybe the most fascinating effect possible with left-hand materials is the wave refraction at their interfaces with the usual, right-handed materials - first predicted by V. Veselago. Consider the example shown in Fig. 14a. In the incident wave, coming from the usual material, the directions of vectors $\mathbf{k}$. and S. coincide, and so they are in the reflected wave characterized by vectors $\mathbf{k}^{\prime}$. and $\mathrm{S}^{\prime}$.. This means that the electric and magnetic fields in the interface plane $(z=0)$ are, at our choice of coordinates, proportional to $\exp \left\{i k_{x} x\right\}$, with positive component $k_{x}=k_{-} \cos \theta$. In order to satisfy any linear boundary conditions, the refracted wave, going into the left-handed material, should match that dependence, i.e.
have a positive $x$-component of its wave vector $\mathbf{k}_{+}$. But in this medium, this vector has to be antiparallel to vector $\mathbf{S}$ that, in turn, should be directed out of the interface, because it presents the power flow from the interface into the material bulk. These conditions cannot be reconciled by the refracted wave propagating along the usual Snell-law direction (shown by the dashed line in Fig. 13a), but are all satisfied at refraction in the direction given by Snell's angle with negative sign. (Hence the term "negative refraction"). ${ }^{35}$

Fig. 7.14. Negative refraction: (a) waves at the interface between media with positive and negative values of $\varepsilon \mu$, and (b) the hypothetical perfect lens: a parallel plate made of a material with $\varepsilon=-\varepsilon_{0}$ and $\mu=-\mu_{0}$.

In order to understand how unusual the results of the negative refraction may be, let us consider a parallel slab of thickness $d$, made of a hypothetical left-handed material with $\varepsilon=-\varepsilon_{0}, \mu=-\mu_{0}$ (Fig. 14b), placed in free space. For such a material, the refraction angle $r=-\theta$, so that the rays from a point source, located at a distance $a<d$ from the slab, propagate as shown in that figure, i.e. all meet again at distance $a$ inside the plate, and then continue to propagate to the second surface of the slab. Repeating our discussion for this surface, we see that a point's image is also formed beyond the plate at distance $2 a$ $+2 b=2 a+2(d-a)=2 d$ from the object. Superficially, this looks like the usual lens, but the wellknown lens formula, which relates $a$ and $b$ with the focal length $f$, is not satisfied. (In particular, a parallel beam is not focused into a point at any finite distance.)

As an additional difference from the usual lens, the system shown in Fig. 14b does not reflect any part of the incident light. Indeed, it is straightforward to check that in order for all above formulas for $R$ and $T$ to be valid, the sign of the wave impedance $Z$ in left-handed materials has to be kept positive. Thus, for our particular choice of parameters ( $\varepsilon=-\varepsilon_{0}, \mu=-\mu_{0}$ ), Eqs. (91a) and (95a) are valid with $Z_{+}=Z_{-}=Z_{0}$ and $\cos r=\cos \theta=1$, giving $R=0$ for any linear polarization, and hence for any other wave polarization - circular, elliptic, natural, etc.

The perfect lens suggestion has triggered a wave of efforts to implement left-hand materials experimentally. (Attempts to found such materials in nature have failed so far.) Most progress in this direction has been achieved using the so-called metamaterials, which are essentially quasi-periodic arrays of specially designed electromagnetic resonators, ideally with high density $n \gg \lambda^{-3}$. For example,

[^326]Fig. 15a shows the metamaterial that was used for the first demonstration of negative refractivity in the microwave region, i.e. a few-GHz frequencies - see Fig. 15b. It combines straight strips of a metallic film, working as lumped resonators with a large electric dipole moment (hence strongly coupled to wave's electric field $\mathbf{E}$ ), and several almost-closed film loops (so-called split rings), working as lumped resonators with large magnetic dipole moments, coupled to field $\mathbf{H}$. By designing the resonance frequencies close to each other, the negative refractivity may be achieved - see the black line in Fig. 15b, which shows experimental data. Recently, the negative refractivity was demonstrated in the optical range, albeit at relatively large absorption that spoils all potentially useful features of the left-handed materials.

Fig. 7.15. The first artificial left-hand material with experimentally demonstrated negative refraction in a microwave region. Adapted from R. Shelby et al., Science 292, 77 (2001). © AAAS.

This progress has stimulated the development of other potential uses of metamaterials (not necessarily the left-handed ones), in particular designs of nonuniform systems with engineered distributions $\varepsilon(\mathbf{r}, \omega)$ and $\mu(\mathbf{r}, \omega)$, which may provide electromagnetic wave propagation along the desired paths, e.g. around a certain region of space (Fig. 16), making it virtually invisible for an external observer - so far, within a limited frequency range, and a certain wave polarization only. Due to these restrictions, the practical value of this work on such invisibility cloaks in not yet clear (at least to this author); but so much attention is focused on this issue ${ }^{36}$ that the situation should become much more clear in just a few years.

[^327]
### 7.6. Transmission lines: TEM waves

So far, we have analyzed plane the electromagnetic waves with infinite cross-section. The crosssection may be limited, still sustaining wave propagation, using wave transmission lines (also called waveguides): cylindrically-shaped structures made of either good conductors or dielectrics. Let us first discuss the first option. In order to keep our analysis (relatively :-) simple, let us assume that:
(i) the structure is a cylinder (not necessarily with a round cross-section, see Fig. 17) filled with a usual (right-handed), uniform dielectric material with negligible losses: $\varepsilon=\varepsilon^{\prime}>0, \mu=\mu^{\prime}>0$, and
(ii) the wave attenuation due to the skin effect is also negligibly low. (As Eq. (78) indicates, for that the characteristic size $a$ of waveguide's cross-section has to be much larger than the skin-depth $\delta_{\mathrm{s}}$ of its wall material. The effect of skin-effect losses will be analyzed in Sec. 10 below.)

After such exclusion of attenuation, we may look for a particular solution of the Maxwell equations in the form of a monochromatic wave traveling along the waveguide:

$$
\begin{equation*}
\mathbf{E}(\mathbf{r}, t)=\operatorname{Re}\left[\mathbf{E}_{\omega}(x, y) e^{i\left(k_{z} z-\omega t\right)}\right] \quad \mathbf{H}(\mathbf{r}, t)=\operatorname{Re}\left[\mathbf{H}_{\omega}(x, y) e^{i\left(k_{z} z-\omega t\right)}\right], \tag{7.98}
\end{equation*}
$$

with real $k_{z}$. Note that this form allows an account for a substantial coordinate dependence of the electric and magnetic field in the plane $\{x, y\}$ of the waveguide's cross-section, as well as for longitudinal components of the fields, so that solution (98) is substantially more complex than the plane waves we have discussed above. We will see in a minute that as a result of this dependence, constant $k_{z}$ may be very much different from the plane-wave value (13), $k \equiv \omega(\varepsilon \mu)^{1 / 2}$, in the same material.

Fig. 7.17. Decomposition of the electric field in a waveguide.

In order to describe these effects explicitly, let us decompose the complex amplitudes of the fields into the longitudinal and transverse components (Fig. 17) ${ }^{37}$

$$
\begin{equation*}
\mathbf{E}_{\omega}=E_{z} \mathbf{n}_{z}+\mathbf{E}_{t}, \quad \mathbf{H}_{\omega}=H_{z} \mathbf{n}_{z}+\mathbf{H}_{t} . \tag{7.99}
\end{equation*}
$$

Plugging Eqs. (98)-(99) into the homogeneous Maxwell equations (2), and requiring the longitudinal and transverse components to be balanced separately, we get

[^328]\[

$$
\begin{array}{ll}
i k_{z} \mathbf{n}_{z} \times \mathbf{E}_{t}-i \omega \mu \mathbf{H}_{t}=-\nabla_{t} \times\left(E_{z} \mathbf{n}_{z}\right), & i k_{z} \mathbf{n}_{z} \times \mathbf{H}_{t}+i \omega \varepsilon \mathbf{E}_{t}=-\nabla_{t} \times\left(H_{z} \mathbf{n}_{z}\right), \\
\nabla_{t} \times \mathbf{E}_{t}=i \omega \mu H_{z} \mathbf{n}_{z}, & \nabla_{t} \times \mathbf{H}_{t}=-i \varepsilon \omega E_{z} \mathbf{n}_{z},  \tag{7.100}\\
\nabla_{t} \cdot \mathbf{E}_{t}=-i k_{z} E_{z}, & \nabla_{t} \cdot \mathbf{H}_{t}=-i k_{z} H_{z} .
\end{array}
$$
\]

where $\nabla_{t}$ is the 2D del operator acting in the transverse plane $[x, y]$ only (so that $\nabla=\nabla_{t}+\mathbf{n}_{z} \partial / \partial z$ ). These equations may look even more bulky than the original Maxwell equations, but actually are much simpler for analysis. Indeed, eliminating the transverse components from these equations (or, even simpler, just plugging Eq. (99) into Eqs. (3) and keeping just their $z$-components), we may get a pair of selfconsistent equations for the longitudinal components of the fields, ${ }^{38}$
where $k$ is still defined by Eq. (13), $k=(\varepsilon \mu)^{1 / 2} \omega$, and

After distributions $E_{z}(x, y)$ and $H_{z}(x, y)$ have been found from these equations, they provide right-hand parts for rather simple, closed system of equations (100) for the transverse components of field vectors. Moreover, as we will see below, each of the following three types of solutions:
(i) with $E_{z}=0$ and $H_{z}=0$ (called the transverse, or TEM waves),
(ii) with $E_{z}=0$, but $H_{z} \neq 0$ (called either $T E$ waves or, more frequently, $H$ modes), and
(iii) with $E_{z} \neq 0$, but $H_{z}=0$ (TM waves or $E$ modes),
has its own dispersion law and hence wave propagation velocity; as a result, these modes (the term meaning the field distribution pattern) may be considered separately.

Let us start with the simplest, TEM waves with no longitudinal components of either field. For them, the top two equations of system (100) immediately give Eqs. (6) and (13), and $k_{z}=k$. In plain English, this means that $\mathbf{E}=\mathbf{E}_{t}$ and $\mathbf{H}=\mathbf{H}_{t}$ are proportional to each other and mutually perpendicular (just as in the plane wave) at each point of the cross-section, and that the TEM wave impedance $Z \equiv E / \mathrm{H}$ and dispersion law $\omega(k)$, and hence the propagation speed, are the same as in a plane wave in the material filling the waveguide. In particular, if $\varepsilon$ and $\mu$ are frequency-independent within a certain frequency range, the dispersion law is linear, $\omega=k /(\varepsilon \mu)^{1 / 2}$, and wave's speed does not depend on its frequency. For practical applications to telecommunications, this is a very important advantage of TEM waves over their TM and TE counterparts - to be discussed below.

Unfortunately, such waves cannot propagate in every waveguide. In order to show this, let us have a look at the two last lines of Eqs. (100). For the TEM waves ( $E_{z}=0, H_{z}=0, k_{z}=k$ ), they yield

$$
\begin{array}{ll}
\nabla_{t} \times \mathbf{E}_{t}=0, & \nabla_{t} \times \mathbf{H}_{t}=0 \\
\nabla_{t} \cdot \mathbf{E}_{t}=0, & \nabla_{t} \cdot \mathbf{H}_{t}=0 \tag{7.103}
\end{array}
$$

In the macroscopic approximation of the boundary conditions (i. e., neglecting the screening and skin depths), we have to require that the wave does not penetrate the walls, so that inside them, $\mathbf{E}=\mathbf{H}=0$. Close to the wall but inside the waveguide, the normal component $E_{n}$ of the electric field may be

[^329]different from zero, because surface charges may sustain its jump (see Sec. 2.1). Similarly, the tangential component $H_{\tau}$ of the magnetic field may have a finite jump at the surface due to skin currents. However, the tangential component of the electric field and the normal component of magnetic field cannot experience such jump, and in order to have them vanishing inside the walls they have to equal zero near the walls inside the waveguide as well:
\[

$$
\begin{equation*}
\mathbf{E}_{\tau}=0, \quad H_{n}=0 . \tag{7.104}
\end{equation*}
$$

\]

But the left columns of Eqs. (103) and (104) coincide with the formulation of the 2D boundary problem of electrostatics for the electric field induced by electric charges of the conducting walls, with the only difference that in our current case the value of $\varepsilon$ should be replaced with $\varepsilon(\omega)$. Similarly, the right columns of those relations coincide with the formulation of the 2D boundary problem of magnetostatics for the magnetic field induced by currents in the walls, with $\mu=\mu(\omega)$. The only difference is that in our current case the magnetic fields should not penetrate inside the conductors.

Now we immediately see that in waveguides with a singly-connected wall topology (see, e.g., the particular example shown in Fig. 17), TEM waves are impossible, because there is no way to create a finite electrostatic field inside a conductor with such cross-section. Fortunately, such fields (and hence TEM waves) are possible in structures with cross-sections consisting of two or more disconnected (dcinsulated) parts - see, e.g., Fig. 18. (Such structures are more frequently called the transmission lines rather than waveguides, the last term being mostly reserved for the lines with singly-connected crosssections of the walls.)

Fig. 7.18. Example of the cross-section of a transmission line that may support the TEM wave propagation.

Now we can readily derive some "global" relations for each conductor, independent on the exact shape of its cross-section. Indeed, consider contour $C$ drawn very close to the conductor's surface (see, e.g., the red dashed line in Fig. 18). First, we can consider it as a cross-section of a cylindrical Gaussian volume of certain length $d z \ll \lambda \equiv 2 \pi / k$. Using the generalized Gauss law (3.29), get

$$
\begin{equation*}
\oint_{C}\left(\mathbf{E}_{t}\right)_{n} d r=\frac{\lambda_{\omega}}{\varepsilon}, \tag{7.105}
\end{equation*}
$$

where $\lambda_{\omega}$ (not to be confused with wavelength $\lambda!$ ) is the linear density of electric charge of the conductor. Second, the same contour $C$ may be used in the generalized Ampère law (5.131) to write

$$
\begin{equation*}
\oint_{C}\left(\mathbf{H}_{t}\right)_{\tau} d r=I_{\omega}, \tag{7.106}
\end{equation*}
$$

where $I_{\omega}$ is the total current flowing along the conductor (or rather its complex amplitude). But, as was mentioned above, in the TEM wave the ratio $E_{t} / H_{t}$ of the field components participating in these two integrals is constant and equal to $Z=(\mu / \varepsilon)^{1 / 2}$, so that Eqs. (105)-(106) give the following simple relation between the "global" characteristics of the conductor:

$$
\begin{equation*}
I_{\omega}=\frac{\lambda_{\omega} / \varepsilon}{Z}=\frac{\lambda_{\omega}}{(\varepsilon \mu)^{1 / 2}}=\frac{\omega}{k} \lambda_{\omega} \tag{7.107}
\end{equation*}
$$

This relation may be also obtained by a different means; let me describe it, because it has an independent value. Let us consider a small segment $d z \ll \lambda=2 \pi / k$ of the conductor (limited by the red dashed line in Fig. 18) and apply the electric charge conservation law (4.1) to the instant values of the linear charge density and current. The cancellation of $d z$ in both parts yields

$$
\begin{equation*}
\frac{\partial \lambda(z, t)}{\partial t}=-\frac{\partial I(z, t)}{\partial z} \tag{7.108}
\end{equation*}
$$

(If we accept the sinusoidal waveform, $\exp \{i(k z-\omega t)\}$, for both these variables, we immediately recover Eq. (107) for their complex amplitudes, so that the result just expresses the charge continuity law. However, Eq. (108) is valid for any waveform.)

The global equation (108) may be made more specific in the case when the frequency dependence of $\varepsilon$ and $\mu$ is negligible, and the transmission line consists of just two isolated conductors (see, e.g., Fig. 18). In this case, in order to have the wave well localized in the space near the two conductors, we need a sufficiently fast convergence of its electric field at large distances. ${ }^{39}$ For that, their linear charge densities for each value of $z$ should be equal and opposite, and we can simply relate them to the potential difference $V$ between the conductors:

$$
\begin{equation*}
\frac{\lambda(z, t)}{V(z, t)}=C_{0} \tag{7.109}
\end{equation*}
$$

where $C_{0}$ is the mutual capacitance of the conductors per unit length - that was repeatedly discussed in Chapter 2. Then Eq. (108) takes the form

$$
\begin{equation*}
C_{0} \frac{\partial V(z, t)}{\partial t}=-\frac{\partial I(z, t)}{\partial z} \tag{7.110}
\end{equation*}
$$

Next, let us consider the contour shown with the red dashed line in Fig. 19 (which shows a crosssection of the transmission line by a plane containing the wave propagation axis $z$ ), and apply to it the Faraday induction law (6.3). Since the electric field is zero inside the conductors (in Fig. 19, on the horizontal parts of the contour), the total e.m.f. equals the difference of voltages $V$ at the end of the segment $d z$, while the only source of the magnetic flux through the area limited by the contour are the (equal and opposite) currents $\pm I$ in the conductors, we can use Eq. (5.70) to express it. As a result, canceling $d z$ in both parts of the equation, we get

$$
\begin{equation*}
L_{0} \frac{\partial I(z, t)}{\partial t}=-\frac{\partial V(z, t)}{\partial z} \tag{7.111}
\end{equation*}
$$

[^330]where $L_{0}$ is the mutual inductance of the conductors per unit length. The only difference between $L_{0}$ and the dc mutual inductances discussed in Chapter 5 is that at the high frequencies we are analyzing now, $L_{0}$ should be calculated neglecting its penetration into the conductors. (In the dc case, we had the same situation for superconductor electrodes, within their crude, ideal-diamagnetic description.)

Fig. 7.19. Electric current, magnetic flux, and voltage in a two-conductor transmission line.

The system of Eqs. (110) and (111) is frequently called the telegrapher's equations. Combined, they give for any "global" variable $f$ (either $V$, or $I$, or $\lambda$ ) a 1 D wave equation,

$$
\begin{equation*}
\frac{\partial^{2} f}{\partial z^{2}}-L_{0} C_{0} \frac{\partial^{2} f}{\partial t^{2}}=0 \tag{7.112}
\end{equation*}
$$

which describes the dispersion-free TEM wave propagation. Again, this equation is only valid within the frequency range where the frequency dependence of both $\varepsilon$ and $\mu$ is negligible. If it is not so, the global approach may still be used for sinusoidal waves $f=\operatorname{Re}\left[f_{\omega} \exp \{i(k z-\omega t)\}\right]$. Repeating the above arguments, instead of Eqs. (110)-(111) we get algebraic equations

$$
\begin{equation*}
\omega C_{0} V_{\omega}=k I_{\omega}, \quad \omega L_{0} I_{\omega}=k V_{\omega}, \tag{7.113}
\end{equation*}
$$

in which $L_{0} \propto \mu$ and $C_{0} \propto \varepsilon$ may now depend on frequency.
Two linear equations (113) are consistent only if

$$
\begin{equation*}
L_{0} C_{0}=\frac{k^{2}}{\omega^{2}} \equiv \frac{1}{v^{2}} \equiv \varepsilon \mu \tag{7.114}
\end{equation*}
$$

```
LoCo
product
invariance
```

Besides the fact we have already known (that the TEM wave speed is the same as that of the plane wave), Eq. (114) gives us a result that I confess I have not emphasized enough in Chapter 5: the product $L_{0} C_{0}$ does not depend on the shape or size of line's cross-section (provided that the magnetic field penetration into the conductors is negligible). Hence, if we have calculated the mutual capacitance $C_{0}$ of a system of two cylindrical conductors, the result immediately gives us their mutual inductance: $L_{0}=$ $\varepsilon \mu / C_{0}$. This relation stems from the fact that both the electric and magnetic fields may be expressed via the solution of a 2D Laplace equation for system's cross-section.

With Eq. (114) satisfied, any of Eqs. (113) gives the same result for ratio

$$
\begin{equation*}
Z_{W} \equiv \frac{V_{\omega}}{I_{\omega}}=\left(\frac{L_{0}}{C_{0}}\right)^{1 / 2} \tag{7.115}
\end{equation*}
$$

Transmission line's TEM Impedance
that is called the transmission line's impedance. This parameter has the same dimensionality (in SI units, ohms) as the wave impedance (7),

$$
\begin{equation*}
Z \equiv \frac{E_{\omega}}{H_{\omega}}=\left(\frac{\mu}{\varepsilon}\right)^{1 / 2} \tag{7.116}
\end{equation*}
$$

but these parameters should not be confused, because $Z_{W}$ depends on cross-section's geometry, while $Z$ does not. In particular, $Z_{W}$ is the only important parameter of a transmission line for matching with a lumped load circuit (Fig. 20) in the important case when both the cable cross-section's size and the load's linear dimensions are much smaller than the wavelength. (The ability of TEM lines to have such a small cross-section is their another important advantage.) Indeed, in this case we may consider the load in the quasistatic limit and write

$$
\begin{equation*}
V_{\omega}\left(z_{0}\right)=Z_{L}(\omega) I_{\omega}\left(z_{0}\right), \tag{7.117}
\end{equation*}
$$

where $Z_{L}(\omega)$ is the (generally complex) impedance of the load. Taking $V(z, t)$ and $I(z, t)$ in the form similar to Eqs. (61) and (62), and writing two Kirchhoff's laws for point $z=z_{0}$, we get for the reflection coefficient a result similar to Eq. (68):

$$
\begin{equation*}
R=\frac{Z_{L}(\omega)-Z_{W}}{Z_{L}(\omega)+Z_{W}} . \tag{7.118}
\end{equation*}
$$

This formula shows that for the perfect matching (i.e. the total wave absorption in the load), load's impedance $Z_{L}(\omega)$ should be real and equal to $Z_{W}$ - but not necessarily to $Z$.

Fig. 7.20. Transmission line impedance matching.

As an example, let us consider one of the simplest (and the most important) transmission lines: the coaxial cable (Fig. 21). ${ }^{40}$

Fig. 7. 21. Cross-section of a coaxial cable with arbitrary (possibly, dispersive) dielectric filling.

For this geometry, we already know expressions for both $L_{0}$ and $C_{0}$, though they have to be modified for the dielectric constant and the magnetic field non-penetration into the conductors. After that modification,

[^331]$$
C_{0}=\frac{2 \pi \varepsilon}{\ln (b / a)}, \quad L_{0}=\frac{\mu}{2 \pi} \ln (b / a) .
$$

Coaxial
cable's $C_{0}$ and $L_{0}$

So, the universal relation (114) is indeed valid! For cable's impedance (115), Eqs. (119) yield

$$
\begin{equation*}
Z_{W}=\left(\frac{\mu}{\varepsilon}\right)^{1 / 2} \frac{\ln (b / a)}{2 \pi}=Z \frac{\ln (b / a)}{2 \pi} \neq Z . \tag{7.120}
\end{equation*}
$$

For standard TV antenna cables (such as RG-6/U, with $b / a \sim 3, \varepsilon / \varepsilon_{0} \approx 2.2$ ), $Z_{W}=75$ ohms, while for most computer component connections, cables with $Z_{W}=50$ ohms (such as RG-58/U) are prescribed by electronic engineering standards. Such cables are broadly used for transfer of electromagnetic waves with frequencies (limited mostly by cable attenuation; see Sec. 10 below) up to 1 GHz over distances of a few km , and up to $\sim 20 \mathrm{GHz}$ on the tabletop scale (a few meters).

Another important example of TEM transmission lines is the set of two parallel wires. In the form of twisted pairs, ${ }^{41}$ they allow communications, in particular long-range telephone and DSL Internet connections, at frequencies up to a few hundred kHz , as well as relatively short Ethernet and TV cables at frequencies up to $\sim 1 \mathrm{GHz}$, limited mostly by the mutual interference and parasitic radiation effects.

## 7.7. $H$ and $E$ waves in metallic waveguides

Let us now return to Eqs. (100) and explore the TE and TM waves - with, respectively, either $H_{z}$ or $E_{z}$ different from zero. At the first sight, they may seem more complex. However, equations (101), which determine the distribution of these longitudinal components over the cross-section, are just 2D Helmholtz equations for scalar functions. For simple cross-section geometries may be solved using the methods discussed for the Laplace equation in Chapter 2, in particular the variable separation. After the solution of such an equation has been found, the transverse components of the fields may be calculated by differentiation, using the simple formulas,

$$
\begin{equation*}
\mathbf{E}_{t}=\frac{i}{k_{t}^{2}}\left[k_{z} \nabla_{t} E_{z}-k Z\left(\mathbf{n}_{z} \times \nabla_{t} H_{z}\right)\right], \quad \mathbf{H}_{t}=\frac{i}{k_{t}^{2}}\left[k_{z} \nabla_{t} H_{z}+\frac{k}{Z}\left(\mathbf{n}_{z} \times \nabla_{t} E_{z}\right)\right], \tag{7.121}
\end{equation*}
$$

which follow from the two equations in the first line of Eqs. (100). ${ }^{42}$
In comparison with the electro- and magnetostatics problems, the only conceptually new feature of Eqs. (101), with appropriate boundary conditions, is that they form the so-called eigenproblems, with typically many solutions (eigenfunctions), each describing a specific wave mode, and corresponding to a specific eigenvalue of parameter $k_{t}$. The good news here is that these values of $k_{t}$ are determined by this 2D boundary problem and hence do not depend on $k_{z}$. As a result, the dispersion law $\omega\left(k_{z}\right)$ of each mode, that follows from the last form of Eq. (102),

$$
\begin{equation*}
\omega=\left(\frac{k_{z}^{2}+k_{t}^{2}}{\varepsilon \mu}\right)^{1 / 2}=\left(v^{2} k_{z}^{2}+\omega_{c}^{2}\right)^{1 / 2} \tag{7.122}
\end{equation*}
$$

[^332]is functionally the same as that of plane waves in a plasma (see Eq. (38), Fig. 6, and their discussion), with the only differences that $c$ is now replaced with $v=1 /(\varepsilon \mu)^{1 / 2}$, the speed of plane (or any TEM) waves in the medium filling the waveguide, and $\omega_{p}$ is replaced with the so-called cutoff frequency
\[

$$
\begin{equation*}
\omega_{c} \equiv v k_{t}, \tag{7.123}
\end{equation*}
$$

\]

specific for each mode. (As Eq. (101) implies, and as we will see from several examples below, $k_{t}$ has the order of $1 / a$, where $a$ is the characteristic dimension of waveguide's cross-section, so that the critical value of the free-space wavelength is of the order of $a$.) Below the cutoff frequency of each particular mode, it cannot propagate in the waveguide. ${ }^{43}$ As a result, modes with the lowest values of $\omega_{c}$ present special practical interest, because the choice of the signal frequency $\omega$ between two lowest values of cutoff frequency guarantees that the waves propagate in the form of only one mode, with the lowest $k_{t}$. Such a choice allows to simplify the excitation of the desired mode by wave generators, and to avoid the parasitic transfer of electromagnetic wave energy to undesirable modes by (unavoidable) small inhomogeneities of the system.

The boundary conditions for the Helmholtz equations (101) depend on the propagating wave type. For TM waves (i.e. $E$ modes, with $H_{z}=0$ but $E_{z} \neq 0$ ), in the macroscopic approximation the boundary condition $E_{\tau}=0$ immediately gives

$$
\begin{equation*}
\left.E_{z}\right|_{C}=0 \tag{7.124}
\end{equation*}
$$

where $C$ is the contour limiting the conducting wall's cross-section. For TE waves (the $H$ modes, with $E_{z}$ $=0$ but $H_{z} \neq 0$ ), the boundary condition is slightly less obvious and may be obtained using, for example, the second equation of system (100), vector-multiplied by $\mathbf{n}_{z}$. Indeed, for the component perpendicular to the conductor surface the equation gives

$$
\begin{equation*}
i k_{z}\left(\mathbf{H}_{t}\right)_{n}-i \frac{k}{Z}\left(\mathbf{n}_{z} \times \mathbf{E}_{t}\right)_{n}=\frac{\partial H_{z}}{\partial n} . \tag{7.125}
\end{equation*}
$$

But the first term in the left-hand part of this equation must be zero on the wall surface, because of the second of Eqs. (104), while according to the first of Eqs. (104), vector $\mathbf{E}_{t}$ in the second term cannot have a component tangential to the wall. As a result, the vector product in that term cannot have a normal component, so that the term should equal zero as well, and Eq. (125) is reduced to

$$
\begin{equation*}
\left.\frac{\partial H_{z}}{\partial n}\right|_{C}=0 . \tag{7.126}
\end{equation*}
$$

Let us see what does this approach give for a simple but practically important example of a metallic-wall waveguide with a rectangular cross-section. In this case it is natural to use the Cartesian coordinates shown in Fig. 22, so that both Eqs. (101) take the simple form

[^333]\[

\left(\frac{\partial^{2}}{\partial x^{2}}+\frac{\partial^{2}}{\partial y^{2}}+k_{t}^{2}\right) f=0, \quad f=\left\{$$
\begin{array}{lc}
E_{z}, & \text { for TM waves, }  \tag{7.127}\\
H_{z}, & \text { for TE waves }
\end{array}
$$\right.
\]

From Chapter 2 we know that the most effective way of solution of such equations in a rectangular region is the variable separation, in which the general solution is represented as a sum of partial solutions of the type

$$
\begin{equation*}
f=X(x) Y(y) \tag{7.128}
\end{equation*}
$$

Plugging this expression into Eq. (127), and dividing each term by $X Y$, we get the equation,

$$
\begin{equation*}
\frac{1}{X} \frac{d^{2} X}{d x^{2}}+\frac{1}{Y} \frac{d^{2} Y}{d y^{2}}+k_{t}^{2}=0 \tag{7.129}
\end{equation*}
$$

that should be satisfied for all values of $x$ and $y$ within the waveguide's interior. This is only possible if each term of the sum equals a constant. Taking the $X$-term and $Y$-term constants in the form $\left(-k_{x}^{2}\right)$ and ( $k_{y}{ }^{2}$ ), respectfully, and solving the corresponding ordinary differential equations, ${ }^{44}$ for eigenfunction (128) we get

$$
\begin{equation*}
f=\left(c_{x} \cos k_{x} x+s_{x} \sin k_{x} x\right)\left(c_{y} \cos k_{y} y+s_{y} \sin k_{y} y\right), \quad \text { with } k_{x}^{2}+k_{y}^{2}=k_{t}^{2}, \tag{7.130}
\end{equation*}
$$

where constants $c$ and $s$ should be found from the boundary conditions. Here the difference between the $H$ modes and $E$ modes pitches in.

Fig. 7.22. Rectangular waveguide, and the transverse field distribution in the basic mode $H_{10}$ (schematically).

For the former modes (TE waves), Eq. (130) is valid for $H_{z}$, and we should use condition (126) on all metallic walls of the waveguide ( $x=0$ and $a ; y=0$ and $b-$ see Fig. 22). As a result, we get very simple expressions for eigenfunctions and eigenvalues:

$$
\begin{gather*}
\left(H_{z}\right)_{n m}=H_{l} \cos \frac{\pi n x}{a} \cos \frac{\pi m y}{b}  \tag{7.131}\\
k_{x}=\frac{\pi n}{a}, \quad k_{y}=\frac{\pi m}{b}, \quad\left(k_{t}\right)_{n m}=\left(k_{x}^{2}+k_{y}^{2}\right)^{1 / 2}=\pi\left[\left(\frac{n}{a}\right)^{2}+\left(\frac{m}{b}\right)^{2}\right]^{1 / 2}, \tag{7.132}
\end{gather*}
$$

[^334]where $H_{l}$ is the longitudinal field amplitude, and $n$ and $m$ are two arbitrary integer numbers, besides that they cannot equal to zero simultaneously. (Otherwise, function $H_{z}(x, y)$ would be constant, so that, according to Eq. (121), the transverse components of the electric and magnetic field would equal zero. As a result, as the last two lines of Eqs. (100) show, the whole field would be zero for any $k_{z} \neq 0$.) Assuming, for certainty, that $a \geq b$ (as shown in Fig. 22), we see that the lowest eigenvalue of $k_{t}$, and hence the lowest cutoff frequency (123), is achieved for the so-called $H_{10}$ mode with $n=1$ and $m=0$, and hence
(thus confirming our prior estimate of $k_{t}$ ).
Depending on the $a / b$ ratio, the second lowest $k_{t}$ and cutoff frequency belong to either the $H_{11}$ mode with $n=1$ and $m=1$ :
\[

$$
\begin{equation*}
\left(k_{t}\right)_{11}=\pi\left(\frac{1}{a^{2}}+\frac{1}{b^{2}}\right)^{1 / 2}=\left[1+\left(\frac{a}{b}\right)^{2}\right]^{1 / 2}\left(k_{t}\right)_{10} \tag{7.134}
\end{equation*}
$$

\]

or to the $H_{20}$ mode with $n=2$ and $m=0$ :

$$
\begin{equation*}
\left(k_{t}\right)_{20}=\frac{2 \pi}{a}=2\left(k_{t}\right)_{10} . \tag{7.135}
\end{equation*}
$$

These values become equal at $a / b=\sqrt{ } 3 \approx 1.7$; in practical waveguides, the $a / b$ ratio is not too far from this value. For example, in the standard X-band waveguide WR90 with $a \approx 2.3 \mathrm{~cm}\left(f_{c} \equiv \omega_{c} / 2 \pi \approx 6.5\right.$ $\mathrm{GHz}), b \approx 1.0 \mathrm{~cm}$.

Now let us have a fast look at alternative TM waves ( $E$ modes). For them, we may still should use the general solution (130) with $f=E_{z}$, but now with boundary condition (124). This gives us eigenfunctions

$$
\begin{equation*}
\left(E_{z}\right)_{n m}=E_{l} \sin \frac{\pi n x}{a} \sin \frac{\pi m y}{b} \tag{7.136}
\end{equation*}
$$

and the same eigenvalue spectrum (132) as for the $H$ modes. However, now neither $n$ nor $m$ can be equal to zero; otherwise Eq. (136) would give the trivial solution $E_{z}(x, y)=0$. Hence the lowest cutoff frequency of TM waves is provided by the so-called $E_{11}$ mode with $n=1, m=1$, and the eigenvalue is again given by Eq. (134).

Thus the basic (or "fundamental") $H_{10}$ mode is certainly the most important wave in rectangular waveguides; let us have a better look at its field distribution. Plugging the corresponding solution (131) with $n=1$ and $m=0$ into the general Eqs. (121), we easily get

$$
\begin{align*}
& \left(H_{x}\right)_{10}=-i \frac{k_{z} a}{\pi} H_{l} \sin \frac{\pi x}{a}, \quad\left(H_{y}\right)_{10}=0,  \tag{7.137}\\
& \left(E_{x}\right)_{10}=0, \quad\left(E_{y}\right)_{10}=i \frac{k a}{\pi} Z H_{l} \sin \frac{\pi x}{a} . \tag{7.138}
\end{align*}
$$

This field distribution is (schematically) shown in Fig. 22. Neither of the fields depends on the vertical coordinate - which is very convenient, in particular, for microwave experiments with small samples.

The electric field has only one（vertical）component that vanishes at the side walls and reaches maximum at waveguide＇s center；its field lines are straight，starting and ending on wall surface charges （whose distribution propagates along the waveguide together with the wave）．In contrast，the magnetic field has two nonvanishing components $\left(H_{x}\right.$ and $H_{z}$ ），and its field lines are shaped as horizontal loops wrapped around the electric field maxima．

An important question is whether the $H_{10}$ wave may be usefully characterized by a unique impedance introduced similar to $Z_{W}$ of the TEM modes－see Eq．（115）．The answer is not，because the main value of $Z_{W}$ is a convenient description of the impedance matching of the transmission line with a lumped load－see Fig． 20 and Eq．（118）．As was discussed above，such simple description is possible （i．e．，does not depend on the exact geometry of the connection）only if both dimensions of line＇s cross－ section are much less than $\lambda$ ．But for the $H_{10}$ wave（and more generally，any non－TEM mode）this is impossible - see，e．g．，Eq．（129）：its lowest frequency corresponds to the TEM wavelength $\lambda_{\max }=$ $2 \pi /\left(k_{t}\right)_{\text {min }}=2 \pi /\left(k_{t}\right)_{10}=2 a .{ }^{45}$

Now let us consider metallic waveguides with round cross－section（Fig．23a）．In this single－ connected geometry，again，the TEM waves are impossible，while for the analysis of $H$ modes and $E$ modes the polar coordinates $\{\rho, \varphi\}$ are most natural．In these coordinates，the 2D Helmholtz equation （101）takes the form

$$
\left[\frac{1}{\rho} \frac{\partial}{\partial \rho}\left(\rho \frac{\partial}{\partial \rho}\right)+\frac{1}{\rho^{2}} \frac{\partial^{2}}{\partial \varphi^{2}}+k_{t}^{2}\right] f=0, \quad f=\left\{\begin{array}{lc}
E_{z}, & \text { for TM waves, }  \tag{7.139}\\
H_{z}, & \text { for TE waves. }
\end{array}\right.
$$

Separating the variables as $f=尺(\rho) \notin(\varphi)$ ，we get

$$
\begin{equation*}
\frac{1}{\rho 尺} \frac{d}{d \rho}\left(\rho \frac{d 尺}{d \rho}\right)+\frac{1}{\rho^{2} \neq \frac{d^{2} \neq}{d \varphi^{2}}+k_{t}^{2}=0 . . . . . . ~} \tag{7.140}
\end{equation*}
$$

Fig．7．23．（a）Metallic and（b）dielectric waveguides with circular cross－sections．

But this is exactly the Eq．（2．127）that was studied in the context of electrostatics，just with a replacement of notation：$\gamma \rightarrow k_{t}$ ．So we already know that in order to have $2 \pi$－periodic functions $\pi \varphi$ ）， and finite values $\mathcal{R}(0)$（which are necessary for our current case－see Fig．23a），the general solution is

[^335]given by Eq. (2.136), i.e. the eigenfunctions may be expressed via integer-order Bessel functions of the first kind: ${ }^{46}$
\[

$$
\begin{equation*}
f_{n m}=\operatorname{const} \times J_{n}\left(k_{n m} \rho\right) e^{i n \varphi}, \tag{7.141}
\end{equation*}
$$

\]

with eigenvalues $k_{n m}$ of the transverse wave number $k_{t}$ to be determined from appropriate boundary conditions.

As for the rectangular waveguide, let us start from $H$ modes $\left(f=H_{z}\right)$. Then the boundary condition on the wall surface $(\rho=R)$ is given by Eq. (126), which, for solution (141), takes the form

$$
\begin{equation*}
\frac{d}{d \xi} J_{n}(\xi)=0, \quad \xi \equiv k R \tag{7.142}
\end{equation*}
$$

This means that eigenvalues of Eq. (139) are

$$
\begin{equation*}
k_{t}=k_{n m}=\frac{\xi_{n m}^{\prime}}{R} \tag{7.143}
\end{equation*}
$$

where $\xi^{\prime}{ }_{n m}$ is the $m^{\text {th }}$ root of function $d J_{n}(\xi) / d \xi$. The approximate values of these roots for several lowest $n$ and $m$ may be read out from the plots in Fig. 2.16; their more accurate values are presented in Table 1 below.

Table 7.1. Roots $\xi_{n m}$ of function $d J_{n}(\xi) / \mathrm{d} \xi$ for a few values of Bessel function's index $n$ and root's number $m$.

|  | $m=1$ | 2 | 3 |
| :---: | :---: | :---: | :---: |
| $n=0$ | 3.83171 | 7.015587 | 10.1735 |
| 1 | 1.84118 | 5.33144 | 8.53632 |
| 2 | 3.05424 | 6.70613 | 9.96947 |
| 3 | 4.20119 | 8.01524 | 11.34592 |

It shows, in particular, that the lowest of the roots is $\xi^{\prime}{ }_{11} \approx 1.84$. Thus, a bit counter-intuitively, the basic mode, providing the lowest cutoff frequency $\omega_{c}=v k_{n m}$, is $H_{11}$ corresponding to $n=1$ rather than $n=0: 47$

$$
\begin{equation*}
H_{z}=H_{l} J_{1}\left(\xi_{11}^{\prime} \frac{\rho}{R}\right) e^{i \varphi} \tag{7.144}
\end{equation*}
$$

with the transverse wave vector $k_{t}=k_{11}=\xi^{\prime}{ }_{11} / R \approx 1.84 / R$, and hence the cutoff frequency corresponding to the TEM wavelength $\lambda_{\max }=2 \pi / k_{11} \approx 3.41 R$. Thus the ratio of $\lambda_{\max }$ to the waveguide diameter $2 R$ is

[^336]about 1.7, i.e. is close to the ratio $\lambda_{\text {max }} / a=2$ for the rectangular waveguide. The origin of this proximity is clear from Fig. 24, which shows the transverse field distribution in the $H_{11}$ mode. (It may be readily calculated from Eqs. (121) with $E_{z}=0$ and $H_{z}$ given by the real part of Eq. (144).)

Fig. 7.24. Transverse field components in the basic $H_{11}$ mode of a metallic, circular waveguide (schematically).

One can see that the field structure is actually very similar to that of the basic mode in the rectangular waveguide, shown in Fig. 22, despite the different nomenclature (due to the different type of used coordinates). However, note the arbitrary argument of complex constant $H_{l}$ in Eq. (144), indicating that in circular waveguides the transverse field polarization is arbitrary. For some practical applications, the degeneracy of these "quasi-linearly-polarized" waves creates problems; they may be avoided by using waves with circular polarization. ${ }^{48}$

As Table 1 shows, the next lowest $H$ mode is $H_{21}$, for which $k_{t}=k_{21}=\xi^{\prime}{ }_{21} / R \approx 3.05 / R$, almost twice larger than that of the basic mode, and only then comes the first mode with no angular dependence of the any field, $H_{01}$, with $k_{t}=k_{01}=\xi^{\prime}{ }_{01} / R \approx 3.83 / R .{ }^{49}$

For the $E$ modes, we may still use Eq. (141) (with $f=E_{z}$ ), but with boundary condition (124) at $\rho$ $=R$. This gives the following equation for the problem eigenvalues:

$$
\begin{equation*}
J_{n}\left(k_{n m} R\right)=0, \text { i.e. } k_{n m}=\frac{\xi_{n m}}{R} \tag{7.145}
\end{equation*}
$$

where $\xi_{n m}$ is the $m$-th root of function $J_{n}(\xi)$ - see Table 2.1. The table shows that the lowest $k_{t}$ equals to $\xi_{01} / R \approx 2.405 / R$. Hence the corresponding mode $\left(E_{01}\right)$, with

$$
\begin{equation*}
E_{z}=E_{l} J_{0}\left(\xi_{01} \frac{\rho}{R}\right), \tag{7.146}
\end{equation*}
$$

has the second lowest cutoff frequency, approximately $30 \%$ higher than that of the basic mode $H_{11}$.
Finally, let us discuss one more topic of general importance - the number $N$ of electromagnetic modes that may propagate in a waveguide within a certain range of relatively large frequencies $\omega \gg \omega_{c}$. This is easy to calculate for a rectangular waveguide, with its simple expressions (132) for the eigenvalues of $\left\{k_{x}, k_{y}\right\}$. Indeed, these expressions describe a rectangular mesh on the [ $k_{x}, k_{y}$ ] plane, so

[^337]that each point corresponds to the plane area $\Delta A_{k}=(\pi / a)(\pi / b)$, and the number of modes in a large $k$ plane area $A_{k} \gg \Delta A_{k}$ is $N=A_{k} / \Delta A_{k}=a b A_{k} / \pi^{2}=A A_{k} / \pi^{2}$, where $A$ is the waveguide's cross-section area. ${ }^{50}$ However, it is frequently more convenient to discuss transverse wave vectors $\mathbf{k}_{t}$ of arbitrary direction, i.e. with arbitrary sign their components $k_{x}$ and $k_{y}$. Taking into account that the opposite values of each component actually give the same wave, the actual number of different modes of each type $(E$ or $H$ ) is a factor of 4 lower than was calculated above. This means that the number of modes of both types is
\[

$$
\begin{equation*}
N=2 \frac{A_{k} A}{(2 \pi)^{2}} . \tag{7.147}
\end{equation*}
$$

\]

It may be convincingly argued that this mode counting rule is valid for waveguides with crosssection of any shape, and any boundary conditions on the walls, provided that $N \gg 1$.

### 7.8. Dielectric waveguides and optical fibers

Now let us discuss electromagnetic wave propagation in dielectric waveguides. The simplest, step-index waveguide (Figs. 23, 25) consists of an inner core and an outer shell (in the optical fiber technology, called cladding) with a higher wave propagation speed, i.e. lower index of refraction:

$$
\begin{equation*}
v_{+}>v_{-}, \quad \text { i.e. } k_{+}<k_{-}, \quad \varepsilon_{+} \mu_{+}<\varepsilon_{-} \mu_{-} . \tag{7.148}
\end{equation*}
$$

(In most cases the difference is achieved due to that in the dielectric constant, $\varepsilon_{-}<\varepsilon_{+}$, while magnetically both materials are almost passive: $\mu_{-} \approx \mu_{+} \approx \mu_{0}$, and I will assume that in my narrative.) The idea of the waveguide operation may be readily understood in the case when wavelength $\lambda$ is much smaller than the characteristic size $R$ of core's cross-section. If this "geometric optics" limit, at the distances of the order of $\lambda$ from the core-to-cladding interface, which determines the wave reflection, we can consider the interface as a plane. As we know from Sec. 5, if angle $\theta$ of plane wave incidence on such an interface is larger than the critical value $\theta_{c}$ specified by Eq. (82), the wave is totally reflected. As a result, the waves launched into the fiber core at such "grazing" angles, propagate inside the core, repeatedly reflected from the cladding - see Fig. 25.

Fig. 7.25. Wave propagation in a thick optical fiber.

The most important type of dielectric waveguides are optical fibers. ${ }^{51}$ Due to a heroic technological effort, in about three decades starting from the mid-1960s, the attenuation of glass fibers

[^338]has been decreased from the values of the order of $20 \mathrm{db} / \mathrm{km}$ (typical for the window glass) to the fantastically low values about $0.2 \mathrm{db} / \mathrm{km}$ (meaning a virtually perfect transparency of $10-\mathrm{km}$-long fiber segments!) - see Fig. 26a. It is remarkable that this ultralow power loss may be combined with an extremely low frequency dispersion, especially for near-infrared waves (Fig. 26b). In conjunction with the development of inexpensive erbium-based quantum amplifiers, this breakthrough has enabled intercontinental (undersea), broadband ${ }^{52}$ optical cables, which are the backbone of all the modern telecommunication infrastructure. The only bad news is that these breakthroughs were achieved for just one kind of materials (silica-based glasses) ${ }^{53}$ within a very narrow range of their chemical composition. As a result, the dielectric constants $\varepsilon_{ \pm} / \varepsilon_{0}$ of the cladding and core of practical optical fibers are both close to $2.2\left(n_{ \pm} \approx 1.5\right)$ and are very close to each other, so that the relative difference of the refraction indices,
\[

$$
\begin{equation*}
\Delta \equiv \frac{n_{-}-n_{+}}{n_{-}} \approx \frac{\varepsilon_{-}-\varepsilon_{+}}{2 \varepsilon_{ \pm}} \tag{7.149}
\end{equation*}
$$

\]

is typically below $0.5 \%$, thus limiting the fiber bandwidth - see below.

Fig. 7.26. (a) Attenuation and (b) dispersion of representative single-mode optical fibers. (Adapted, respectively, from http://olson-technology.com and http://www.timbercon.com.)

Practical optical fibers come in two flavors: multi-mode and single-mode ones. Multi-mode fibers, used for transfer of high optical power (up to as much as $\sim 10$ watts), have relatively thick cores, with a diameter $2 R$ of the order of $50 \mu \mathrm{~m}$, much larger than $\lambda \sim 1 \mu \mathrm{~m}$. In this case, the "geometricoptics" picture of the wave propagation discussed above is quantitatively correct, and we may use it to calculate the number of quasi-plane-wave modes that may propagate in the fiber. Indeed, for the complementary angle (Fig. 25)

[^339]\[

$$
\begin{equation*}
\vartheta \equiv \frac{\pi}{2}-\theta \tag{7.150}
\end{equation*}
$$

\]

Eq. (82) gives the propagation condition

$$
\begin{equation*}
\cos \vartheta>\frac{n_{+}}{n_{-}}=1-\Delta . \tag{7.151}
\end{equation*}
$$

For the case $\Delta \ll 1$, when the incidence angles $\theta>\theta_{c}$ of all propagating waves are close to $\pi / 2$, and hence the complimentary angles are small, we can keep only two first terms in the Taylor expansion of the left-hand part of Eq. (151) and get

$$
\begin{equation*}
\vartheta_{\max }^{2} \approx 2 \Delta \tag{7.152}
\end{equation*}
$$

Even for the higher-end value $\Delta=0.005$, this critical angle is only $\sim 0.1$ radian, i.e. close to $5^{\circ}$. Due to this smallness, we can approximate the maximum transverse component of the wave vector as

$$
\begin{equation*}
\left(k_{t}\right)_{\max }=k(\sin \vartheta)_{\max } \approx k \vartheta_{\max } \approx \sqrt{2} k \Delta, \tag{7.153}
\end{equation*}
$$

and use Eq. (147) to calculate number $N$ of propagating modes:

$$
\begin{equation*}
N \approx 2 \frac{\left(\pi R^{2}\right)\left(\pi k^{2} \vartheta_{\max }^{2}\right)}{(2 \pi)^{2}}=(k R)^{2} \Delta . \tag{7.154}
\end{equation*}
$$

For typical values $k=0.73 \times 10^{7} \mathrm{~m}^{-1}$ (corresponding to the free-space wavelength $\lambda_{0}=n \lambda=2 \pi n / k \approx 1.3$ $\mu \mathrm{m}$ ), $R=25 \mu \mathrm{~m}$, and $\Delta=0.005$, this formula gives $N \approx 150$.

The largest problem with using multi-mode fibers for communications is their high geometric dispersion, i.e. the difference of the mode propagation speed, which is usually characterized in terms of the signal delay time difference (traditionally measured in picoseconds per kilometer) between the fastest and the slowest mode. Within the geometric optics approximation, the difference of time delays of the fastest mode (with $k_{z}=k$ ) and the slowest mode (with $k_{z}=k \sin \theta_{c}$ ) at distance $l$ is

$$
\begin{equation*}
\Delta t=\Delta\left(\frac{l}{v_{z}}\right)=\Delta\left(\frac{k_{z} l}{\omega}\right)=\frac{l}{\omega} \Delta k_{z}=\frac{l}{v}\left(1-\sin \theta_{c}\right)=\frac{l}{v}\left(1-\frac{n_{+}}{n_{-}}\right)=\frac{l}{v} \Delta . \tag{7.155}
\end{equation*}
$$

For the example considered above, the TEM wave speed $v=c / n \approx 2 \times 10^{8} \mathrm{~m} / \mathrm{s}$, and the geometric dispersion $\Delta t / l$ is close to $25 \mathrm{ps} / \mathrm{m}$, i.e. $25,000 \mathrm{ps} / \mathrm{km}$. (This means, for example, that a $1-\mathrm{ns}$ pulse, being distributed between the modes, would spread to a $\sim 25-\mathrm{ns}$ pulse after passing a just $1-\mathrm{km}$ fiber segment.) Such disastrous dispersion should be compared with chromatic dispersion that is due to the frequency dependence of $\varepsilon_{ \pm}$, and has the steepness $(d t / d \lambda) / l$ of the order of $10 \mathrm{ps} / \mathrm{km} \cdot \mathrm{nm}$ (see the solid pink line in Fig. 26b). One can see that through the whole frequency band ( $d \lambda \sim 100 \mathrm{~nm}$ ) the total chromatic dispersion $d t / l$ is of the order of only $1,000 \mathrm{ps} / \mathrm{km}$.

Due to the large geometric dispersion, the multimode fibers are used for signal transfer over only short distances ( $\sim 100 \mathrm{~m}$ ), while long-range communications are based on single-mode fibers, with thin cores (typically with diameters $2 R \sim 5 \mu \mathrm{~m}$, i. e. of the order of $\lambda / \Delta^{1 / 2}$ ). For such structures, Eq. (154) yields $N \sim 1$, but in this case the geometric optics approximation is not quantitatively valid, and we should get back to the Maxwell equations. In particular, this analysis should take into an explicit
account the evanescent wave propagating in the cladding, because its penetration depth may be comparable with $R .{ }^{54}$

Since the cross-section of an optical fiber is not uniform and lacks metallic conductors, the Maxwell equations cannot be exactly satisfied with either a TEM, or a TE, or a TM solutions. Instead, the fibers can carry so-called $H E$ and $E H$ modes, with both fields having longitudinal components simultaneously. In such modes, both $E_{z}$ and $H_{z}$ inside the core $(\rho \leq R)$ have the form similar to Eq. (141):

$$
\begin{equation*}
f_{-}=f_{l} J_{n}\left(k_{t} \rho\right) e^{i n \varphi}, \text { with } k_{t}^{2}=k_{-}^{2}-k_{z}^{2}>0, \quad k_{-}^{2} \equiv \omega^{2} \varepsilon_{-} \mu_{-}, \tag{7.156}
\end{equation*}
$$

where amplitudes $f_{l}$ (i.e., $E_{l}$ and $H_{1}$ ) may be complex to account for the possible angular shift between these components. On the other hand, for the evanescent wave in the cladding, we may rewrite Eq. (102) as

$$
\begin{equation*}
\left(\nabla^{2}-\kappa_{t}^{2}\right) f_{+}=0, \quad \text { with } \quad \kappa_{t}^{2} \equiv k_{z}^{2}-k_{+}^{2}>0, \quad k_{+}^{2} \equiv \omega^{2} \varepsilon_{+} \mu_{+} \tag{7.157}
\end{equation*}
$$

Figure 27 illustrates the relation between $k_{t}, \kappa_{t}, k_{z}$, and $k_{ \pm}$; note that the following sum,

$$
\begin{equation*}
k_{t}^{2}+\kappa_{t}^{2} \equiv \omega^{2}\left(\varepsilon_{-}-\varepsilon_{+}\right) \mu_{0} \tag{7.158}
\end{equation*}
$$

is fixed (at fixed frequency) and, for typical fibers, very small ( $\sim 2 \Delta k^{2} \ll k^{2}$ ). By the way, Fig. 27 shows that neither of $k_{t}$ and $\kappa_{t}$ can be larger than $\omega\left[\left(\varepsilon_{-}-\varepsilon_{+}\right) \mu_{0}\right]^{1 / 2}=k \Delta^{1 / 2}$. In particular, this means that the depth $\delta=1 / \kappa_{t}$ of wave penetration into the cladding is at least $1 / k \Delta^{1 / 2}=\lambda / 2 \pi \Delta^{1 / 2} \gg \lambda / 2 \pi$. This is why the cladding layers in practical optical fibers are made as thick as $\sim 50 \mu \mathrm{~m}$, so that only a negligibly small tail of this evanescent wave field reaches their outer surfaces.

Fig. 7.27. Relation between the transverse exponents $k_{t}$ and $\kappa_{t}$ for waves in optical fibers.

In the polar coordinates, Eq. (157) becomes

$$
\begin{equation*}
\left[\frac{1}{\rho} \frac{\partial}{\partial \rho}\left(\rho \frac{\partial}{\partial \rho}\right)+\frac{1}{\rho^{2}} \frac{\partial^{2}}{\partial \varphi^{2}}-\kappa_{t}^{2}\right] f_{+}=0 \tag{7.159}
\end{equation*}
$$

instead of Eq. (139). From Sec. 2.5 we know that the eigenfunctions of Eq. (159) are the products of the angular factor $\exp \{\operatorname{in} \varphi\}$ by a linear combination of the modified Bessel functions $I_{n}$ and $K_{n}$, shown in

[^340]Fig. 2.20, now of argument $\kappa_{t} \rho$. In our case, the fields should vanish at $\rho \rightarrow \infty$, so that only the latter functions (of the second kind) can participate:

$$
\begin{equation*}
f_{+} \propto K_{n}\left(\kappa_{t} \rho\right) e^{i n \varphi} \tag{7.160}
\end{equation*}
$$

Now we have to reconcile Eqs. (156) and (160), using the boundary conditions at $\rho=R$ for both longitudinal and transverse components of both fields, with the latter fields first calculated from using Eqs. (121). Such a conceptually simple, but a bit bulky calculation (which I am leaving for reader's exercise :-), yields a system of two linear, homogeneous equations for complex amplitudes $E_{l}$ and $H_{l}$, that are compatible if

$$
\begin{equation*}
\left(\frac{k_{-}^{2}}{k_{t}} \frac{J_{n}{ }^{\prime}}{J_{n}}+\frac{k_{+}^{2}}{\kappa_{t}} \frac{K_{n}{ }^{\prime}}{K_{n}}\right)\left(\frac{1}{k_{t}} \frac{J_{n}{ }^{\prime}}{J_{n}}+\frac{1}{\kappa_{t}} \frac{K_{n}{ }^{\prime}}{K_{n}}\right)=\frac{n^{2}}{R^{2}}\left(\frac{k_{-}^{2}}{k_{t}^{2}}+\frac{k_{+}^{2}}{\kappa_{t}^{2}}\right)\left(\frac{1}{k_{t}^{2}}+\frac{1}{\kappa_{t}^{2}}\right), \tag{7.161}
\end{equation*}
$$

where prime means the derivative of each function over its full argument: $k_{t} \rho$ for $J_{n}$, and $\kappa_{t} \rho$ for $K_{n}$.
For any given frequency $\omega$, the system of Eqs. (158) and (161) determines the values of $k_{t}$ and $\kappa_{t}$, and hence $k_{z}$. Actually, for any $n>0$, this system provides two different solutions: one corresponding to the so-called $H E$ wave with larger ratio $E_{z} / H_{z}$, and the $E H$ wave, with a smaller value of that ratio. For angular-symmetric modes with $n=0$ (for whom we might naively expect the lowest cutoff frequency), the equations may be satisfied by fields having just one finite longitudinal component (either $E_{z}$ or $H_{z}$ ), and the $H E$ modes are the usual $E$ waves, while the $E H$ modes are the $H$ waves. For the $H$ modes, the characteristic equation is reduced to the requirement that the second parentheses in the left-hand part of Eq. (161) equals to zero. Using the identities $J^{\prime}{ }_{0}=-J_{1}$ and $K_{0}^{\prime}=-K_{1}$, this equation may be rewritten as

$$
\begin{equation*}
\frac{1}{k_{t}} \frac{J_{1}\left(k_{t} R\right)}{J_{0}\left(k_{t} R\right)}=-\frac{1}{\kappa_{t}} \frac{K_{1}\left(\kappa_{t} R\right)}{K_{0}\left(\kappa_{t} R\right)} . \tag{7.162}
\end{equation*}
$$

Using the simple relation between $k_{t}$ and $\kappa_{t}$ given by Eq. (158), we may plot both parts of Eq. (162) as a function of the same argument, say, $\xi \equiv k_{t} R$ - see Fig. 28.

Fig. 7.28. Two sides of the characteristic equation (162), plotted as a function of $k_{1} R$, for two values of its dimensionless parameter: $V=8$ (blue line) and $V=3$ (red line). Note that according to Eq. (158), the argument of functions $K_{0}$ and $K_{1}$ is just
$\kappa_{t} R=\left[V^{2}-\left(k_{t} R\right)^{2}\right]^{1 / 2}=\left(V^{2}-\xi^{2}\right)^{1 / 2}$.

The right-hand part of Eq. (162) depends not only on $\xi$ but also on the dimensionless parameter $V$ defined as the normalized right-hand part of Eq. (158):

$$
\begin{equation*}
V^{2} \equiv \omega^{2}\left(\varepsilon_{-}-\varepsilon_{+}\right) \mu_{0} R^{2} \approx 2 \Delta k_{ \pm}^{2} R^{2} . \tag{7.163}
\end{equation*}
$$

(According to Eq. (155), if $V \gg 1$, it gives the doubled number of the fiber modes - the conclusion confirmed by Fig. 28, taking into account that it describes only the $H$ modes.) Since the ratio $K_{1} / K_{0}$ is positive for all values of their argument (see, e.g., the right panel of Fig. 2.20), the right-hand part of Eq. (162) is always negative, so that the equation may have solutions only in the intervals where the ratio $J_{1} / J_{0}$ is negative, i.e. at

$$
\begin{equation*}
\xi_{01}<k_{t} R<\xi_{11}, \quad \xi_{02}<k_{t} R<\xi_{12}, \ldots \tag{7.164}
\end{equation*}
$$

where $\xi_{n m}$ is the $m$-th zero of function $J_{n}(\xi)$ - see Table 2.1. The right-hand part of the characteristic equation diverges at $\kappa_{t} R \rightarrow 0$, i.e. at $k_{t} R \rightarrow V$, so that no solutions are possible if $V$ is below the critical value $V_{c}=\xi_{01} \approx 2.405$. At this cutoff point, Eq. (163) yields $k_{ \pm} \approx \xi_{01} / R(2 \Delta)^{1 / 2}$. Hence, the cutoff frequency for the lowest $H$ mode corresponds to the TEM wavelength

$$
\begin{equation*}
\lambda_{\max }=\frac{2 \pi R}{\xi_{01}}(2 \Delta)^{1 / 2} \approx 3.7 R \Delta^{1 / 2} \tag{7.165}
\end{equation*}
$$

For typical parameters $\Delta=0.005$ and $R=2.5 \mu \mathrm{~m}$, this result yields $\lambda_{\max } \sim 0.65 \mu \mathrm{~m}$, corresponding to the free-space wavelength $\lambda_{0} \sim 1 \mu \mathrm{~m}$. A similar analysis of the first parentheses in the left-hand part of Eq. (161) shows that at $\Delta \rightarrow 0$, the cutoff frequency for the $E$ modes is similar.

This situation may look exactly like that in metallic waveguides, with no waves possible at frequencies below $\omega_{c}$, but this is not so. The basic reason for the difference is that in metallic waveguides, the approach to $\omega_{c}$ results in the divergence of the longitudinal wavelength $\lambda_{z} \equiv 2 \pi / k_{z}$. On the contrary, in dielectric waveguides this approach leaves $\lambda_{z}$ finite $\left(k_{z} \rightarrow k_{+}\right)$. Due to this difference, a certain linear superposition of $H E$ and $E H$ modes with $n=1$ can propagate at frequencies well below the cutoff frequency for $n=0$, which we have just calculated. ${ }^{55}$ This mode, in the limit $\varepsilon_{+} \approx \varepsilon_{-}$(i.e. $\Delta \ll 1$ ) allows a very interesting and simple description using the Cartesian (rather than polar) components of the fields, but still expressed as functions of polar coordinates $\rho$ and $\varphi$. The reason is that this mode is very close to a linearly polarized TEM wave. (Due to this reason, this mode is referred to as $L P_{01}$.)

Let us select axis $x$ parallel to the transverse component of the magnetic field vector, so that $\left.E_{x}\right|_{\rho=0}=0$, but $\left.E_{y}\right|_{\rho=0} \neq 0$, and $\left.H_{x}\right|_{\rho=0} \neq 0$, but $\left.H_{y}\right|_{\rho=0}=0$. The only suitable solutions of the 2D Helmholtz equation (that should be obeyed not only by $z$-components of the field, but also their $x$ - and $y$ components) are proportional to $J_{0}\left(k_{t} \rho\right)$, with zero coefficients for $E_{x}$ and $H_{y}$ :

$$
\begin{equation*}
E_{x}=0, \quad E_{y}=E_{0} J_{0}\left(k_{t} \rho\right), \quad H_{x}=H_{0} J_{0}\left(k_{t} \rho\right), \quad H_{y}=0, \quad \text { for } \rho \leq R . \tag{7.166}
\end{equation*}
$$

Now we can readily calculate the longitudinal components, using the last two equations of Eqs. (100):

$$
\begin{equation*}
E_{z}=\frac{1}{-i k_{z}} \frac{\partial E_{y}}{\partial y}=-i \frac{k_{t}}{k_{z}} E_{0} J_{1}\left(k_{t} \rho\right) \sin \varphi, \quad H_{z}=\frac{1}{-i k_{z}} \frac{\partial H_{x}}{\partial x}=-i \frac{k_{t}}{k_{z}} H_{0} J_{1}\left(k_{t} \rho\right) \cos \varphi \tag{7.167}
\end{equation*}
$$

where I have used mathematical identities $J_{0}^{\prime}=-J_{1}, \partial \rho / \partial x=x / \rho=\cos \varphi$, and $\partial \rho / \partial y=y / \rho=\sin \varphi$. As a sanity check, we see that the longitudinal component or each field is a (legitimate!) eigenfunction of the

[^341]type (141) with $n=1$. Note also that if $k_{t} \ll k_{z}$ (this relation is always true if $\Delta \ll 1-$ see Fig. 27), the longitudinal components of the fields are much smaller than their transverse counterparts, so that the wave is indeed very close to the TEM one. Because of that, the ratio of the electric and magnetic field amplitudes is also close to that in the TEM wave: $E_{0} / H_{0} \approx Z_{-} \approx Z_{+}$.

Now in order to ensure the continuity of the fields at the core-to-cladding interface $(\rho=R)$, we need to have a similar angular dependence of these components at $\rho \geq R$. The longitudinal components of the fields are tangential to the interface and thus should be continuous. Using the solutions similar to Eq. (160) with $n=1$, we get

$$
\begin{equation*}
E_{z}=-i \frac{k_{t}}{k_{z}} \frac{J_{1}\left(k_{t} R\right)}{K_{1}\left(\kappa_{t} R\right)} E_{0} K_{1}\left(\kappa_{t} \rho\right) \sin \varphi, \quad H_{z}=-i \frac{k_{t}}{k_{z}} \frac{J_{1}\left(k_{t} R\right)}{K_{1}\left(\kappa_{t} R\right)} H_{0} K_{1}\left(\kappa_{t} \rho\right) \cos \varphi, \quad \text { for } \rho \geq R \tag{7.168}
\end{equation*}
$$

For the transverse components, we should require the continuity of the normal magnetic field $\mu H_{n}$, for our simple field structure equal to just $\mu H_{x} \cos \varphi$, of the tangential electric field $E_{\tau}=E_{y} \sin \varphi$, and of the normal component of $D_{n}=\varepsilon E_{n}=\varepsilon E_{y} \cos \varphi$. Assuming that $\mu_{-}=\mu_{+}=\mu_{0}$, and $\varepsilon_{+} \approx \varepsilon_{-}{ }^{56}$ we can satisfy these conditions with the following solutions

$$
\begin{equation*}
E_{x}=0, \quad E_{y}=\frac{J_{0}\left(k_{t} R\right)}{K_{0}\left(\kappa_{t} R\right)} E_{0} K_{0}\left(\kappa_{t} \rho\right), \quad H_{x}=\frac{J_{0}\left(k_{t} R\right)}{K_{0}\left(k_{t} R\right)} H_{0} K_{0}\left(\kappa_{t} \rho\right), \quad H_{y}=0, \quad \text { for } \rho \geq R . \tag{7.169}
\end{equation*}
$$

From here, we can calculate components from $E_{z}$ and $H_{z}$, using the same approach as for $\rho \leq R$ :

$$
\begin{align*}
& E_{z}=\frac{1}{-i k_{z}} \frac{\partial E_{y}}{\partial y}=-i \frac{\kappa_{t}}{k_{z}} \frac{J_{0}\left(k_{t} R\right)}{K_{0}\left(\kappa_{t} R\right)} E_{0} K_{1}\left(\kappa_{t} \rho\right) \sin \varphi,  \tag{7.170}\\
& H_{z}=\frac{1}{-i k_{z}} \frac{\partial H_{x}}{\partial x}=-i \frac{\kappa_{t}}{k_{z}} \frac{J_{0}\left(k_{t} R\right)}{K_{0}\left(\kappa_{t} R\right)} H_{0} K_{1}\left(\kappa_{t} \rho\right) \cos \varphi, \quad \text { for } \rho \geq R .
\end{align*}
$$ equation

We see that this equation provides the same functional dependence of the fields as Eqs. (166), i.e. the internal and external fields are compatible, but their amplitudes coincide only if

$$
\begin{equation*}
k_{t} \frac{J_{1}\left(k_{t} R\right)}{J_{0}\left(k_{t} R\right)}=\kappa_{t} \frac{K_{1}\left(\kappa_{t} R\right)}{K_{0}\left(\kappa_{t} R\right)} . \tag{7.171}
\end{equation*}
$$

This characteristic equation (which may be also derived from Eq. (161) with $n=1$ in the limit $\Delta \rightarrow 0$ ) looks close to Eq. (162), but functionally is much different from it - see Fig. 29. Indeed, its righthand part is always positive, and the left-hand part tends to zero at $k_{t} R \rightarrow 0$. Due to this, Eq. (171) may have a solution for arbitrary small values of parameter $V$, defined by Eq. (163), i.e. for arbitrary low frequencies. This is why this mode is used in practical single-mode fibers: there are no other modes that can propagate at $\omega<\omega_{c}$, so that the geometric dispersion problem is avoided.

It is easy to use the Bessel function approximations given by the first term of the expansion (2.132) and also Eq. (2.157) to show that in the limit $V \rightarrow 0$ (i.e. $V \ll 1$ ), $\kappa_{t} R$ tends to zero much faster

[^342]than $k_{t} R \approx V: \kappa_{t} R \rightarrow 2 \exp \{-1 / V\} \ll V$. This means that the scale $\rho_{c} \equiv 1 / \kappa_{t}$ of the radial distribution of the $L P_{01}$ wave's fields in the cladding becomes very large. In this limit, this mode may be interpreted as a virtually TEM wave propagating in the cladding, just slightly deformed (and guided) by the fiber core. The drawback of this feature is that it requires very thick cladding, in order to avoid energy losses in outer ("buffer" and "jacket") layers that defend the silica components from the elements, but lack their low optical absorption. Due to this reason, the core radius is usually selected so that parameter $V$ is just slightly less than the critical value $V_{c}=\xi_{01} \approx 2.4$ for higher modes, thus ensuring the single-mode operation and eliminating the geometric dispersion problem.

Fig. 7.29. Two sides of the characteristic equation (167) for the $L P_{01}$ mode, plotted as a function of $k_{t} R$, for two values of the dimensionless parameter: $V=8$ (blue line) and $V=1$ (red line).

In order to reduce the field spread into the cladding, the step-index fibers considered above may be replaced with graded-index fibers whose the dielectric constant $\varepsilon_{r}$ is gradually and slowly decreased from the center to the periphery. Keeping only the main two terms in the Taylor expansion of the function $\varepsilon(\rho)$ at $\rho=0$, we may approximate such reduction as

$$
\begin{equation*}
\varepsilon(\rho) \approx \varepsilon(0)\left(1-\frac{\zeta}{2} \rho^{2}\right) \tag{7.172}
\end{equation*}
$$

where $\zeta \equiv-\left[\left(d^{2} \varepsilon / d \rho^{2}\right) / \varepsilon\right]_{\rho=0}$ is a positive constant characterizing the fiber composition gradient. ${ }^{57}$ Moreover, if this constant is sufficiently small $\left(\zeta \ll k^{2}\right)$, the field distribution across the fiber's crosssection may be described by the same 2D Helmholtz equation, but with the space-dependent transverse wave vector: ${ }^{58}$

$$
\begin{equation*}
\left[\nabla_{t}^{2}+k_{t}^{2}(\rho)\right] f=0, \quad \text { where } k_{t}^{2}(\rho) \equiv k^{2}(\rho)-k_{z}^{2}=\omega^{2} \varepsilon(\rho) \mu_{0}-k_{z}^{2}=k_{t}^{2}(0)\left(1-\frac{\zeta}{2} \rho^{2}\right) \tag{7.173}
\end{equation*}
$$

Surprisingly for such axially-symmetric problem, because of its special dependence on the radius, this equation may be most readily solved in Cartesian coordinates. Indeed, rewriting it as

[^343]\[

$$
\begin{equation*}
\left[\frac{\partial^{2}}{\partial x^{2}}+\frac{\partial^{2}}{\partial y^{2}}+k_{t}^{2}(0)\left(1-\frac{\zeta}{2} x^{2}-\frac{\zeta}{2} y^{2}\right)\right] f=0 \tag{7.174}
\end{equation*}
$$

\]

and separating variables as $f=X(x) Y(y)$, we get

$$
\begin{equation*}
\frac{1}{X} \frac{d^{2} X}{d x^{2}}+\frac{1}{Y} \frac{d^{2} Y}{d y^{2}}+k_{t}^{2}(0)\left(1-\frac{\zeta}{2} x^{2}-\frac{\zeta}{2} y^{2}\right)=0 \tag{7.175}
\end{equation*}
$$

so that functions $X$ and $Y$ obey similar differential equations, for example

$$
\begin{equation*}
\frac{d^{2} X}{d x^{2}}+\left[k_{x}^{2}-k_{t}^{2}(0) \frac{\zeta}{2} x^{2}\right] X=0 \tag{7.176}
\end{equation*}
$$

with the separation constants satisfying the following relation:

$$
\begin{equation*}
k_{x}^{2}+k_{y}^{2}=k_{t}^{2}(0) \equiv \omega^{2} \varepsilon(0) \mu_{0}-k_{z}^{2} . \tag{7.177}
\end{equation*}
$$

Equation (176) is well known from the elementary quantum mechanics, because the Schrödinger equation for the perhaps most important quantum system, a 1D harmonic oscillator, may be rewritten in this form. Their eigenvalues are described by a simple formula

$$
\begin{equation*}
\left(k_{x}^{2}\right)_{n}=k_{t}(0)\left(\frac{\zeta}{2}\right)^{1 / 2}(2 n+1), \quad\left(k_{y}^{2}\right)_{m}=k_{t}(0)\left(\frac{\zeta}{2}\right)^{1 / 2}(2 m+1), \quad n, m=0,1,2, \ldots \tag{7.178}
\end{equation*}
$$

but eigenfunctions $X_{n}(x)$ and $Y_{m}(y)$ have to be expressed via not quite elementary functions - the Hermite polynomials. ${ }^{59}$ For our purposes, however, the lowest eigenfunctions $X_{0}(x)$ and $Y_{0}(y)$ are sufficient, because they correspond to the lowest $k_{x, y}$ and hence to the lowest cutoff frequency:

$$
\begin{equation*}
\omega_{c}^{2} \varepsilon(0) \mu_{0}=\left(k_{x}^{2}\right)_{0}+\left(k_{y}^{2}\right)_{0}=\zeta . \tag{7.179}
\end{equation*}
$$

(Note that at $\zeta \rightarrow 0$, the cutoff frequency tends to zero, as it should be for a wave in a uniform medium.) The eigenfunctions corresponding to the lowest eigenvalues are simple:

$$
\begin{equation*}
f_{0}(x)=\text { const } \times \exp \left\{-\frac{\zeta x^{2}}{2}\right\} \tag{7.180}
\end{equation*}
$$

so that the field distribution follows the Gaussian ("bell curve") function

$$
\begin{equation*}
f_{0}(\rho)=f_{0}(0) \exp \left\{-\frac{\zeta\left(x^{2}+y^{2}\right)}{2}\right\}=f_{0}(0) \exp \left\{-\frac{\zeta \rho^{2}}{2}\right\} . \tag{7.181}
\end{equation*}
$$

This is the so-called Gaussian beam, very convenient for some applications. Still, the graded-index fibers have higher attenuation than their step-index counterparts, and are not used as broadly.

Speaking of the Gaussian beams (or more generally, any beams with axially-symmetric profile $f_{0}(\rho)$ ), I cannot help noticing the very curious option of forming so-called helical waves with complex amplitude $f_{0}(\rho) \exp \{i l \varphi\}$, where $l$ is an integer constant, and $\varphi$ is the azimuthal angle (so that in our notation $x=\rho \cos \varphi, y=\rho \sin \varphi$ ). Let me leave it for reader's exercise to prove that the electromagnetic

[^344]field of such a wave has an angular momentum vector $\mathbf{L}=L_{z} \mathbf{n}_{z}$, with $L_{z}$ proportional to $l .{ }^{60}$ Quantization of the helical field gives $L_{z}=l \hbar$ per photon. The case $l= \pm 1$ is possible for infinite-width beams (i.e. plane waves) and means their circular polarization, quantum-mechanically corresponding to spin $\pm 1$ of their photons - see the discussion in the end of Sec. 1. In contrast, the implementation of higher values of $|l|$ requires space-limited beams (with $f_{0} \rightarrow 0$ at $\rho \rightarrow \infty$ ) and may be interpreted as giving the wave an additional "orbital" angular momentum. ${ }^{61}$

### 7.9. Resonators

Resonators are the distributed oscillators, i.e. structures that may sustain standing waves (in electrodynamics, oscillations of the electric and magnetic field at each point) even without a source, until the oscillation amplitude slowly decreases in time due to unavoidable energy losses. If the resonator quality (described by the so-called $Q$-factor, which will be defined and discussed in the next section) is high, this decay takes many oscillation periods. Alternatively, high- $Q$ resonators may sustain oscillating fields permanently, if fed with a relatively weak incident wave.

Conceptually the simplest resonator is the Fabry-Pérot interferometer ${ }^{62}$ that may be obtained by placing two well-conducting planes parallel to each other. ${ }^{63}$ Indeed, in Sec. 1 we have seen that if a plane wave is normally incident on such a "perfect mirror", located at $z=0$, its reflection, at negligible skin depth, results in a standing wave described by Eq. (61) - that may be rewritten as

$$
\begin{equation*}
E(z, t)=\operatorname{Re}\left(2 E_{\omega} e^{-i \omega t+i \pi / 2}\right) \sin k z \tag{7.182}
\end{equation*}
$$

Hence the wave would not change if we had suddenly put the second mirror (isolating the segment of length $l$ from the external wave source) at any position $z=l$ with $\sin k l=0$, i.e.

$$
\begin{equation*}
k l=p \pi, \quad \text { where } p=1,2, \ldots \tag{7.183}
\end{equation*}
$$

This condition, which also determines the eigen- (or resonance) frequency spectrum of the resonator of fixed length $l$,

$$
\begin{equation*}
\omega_{p}=v k_{p}=\frac{\pi v}{a} p, \quad v=\frac{1}{(\varepsilon \mu)^{1 / 2}} \tag{7.184}
\end{equation*}
$$

[^345]has a simple physical sense: the resonator length $l$ equals exactly $p$ half-waves of frequency $\omega_{p}$. Though this is all very simple, please note a considerable change of philosophy from what we have been doing in the previous sections: the main task in resonator analysis is finding its eigenfrequencies $\omega_{p}$ that are now determined by the system geometry rather than by an external wave source.

Before we move to more complex resonators, let us use Eq. (62) to present the magnetic field in the Fabry-Pérot interferometer:

$$
\begin{equation*}
H(z, t)=\operatorname{Re}\left(2 \frac{E_{\omega}}{Z} e^{-i \omega t}\right) \cos k z \tag{7.185}
\end{equation*}
$$

Expressions (182) and (185) show that in contrast to traveling waves, each field of the standing wave changes simultaneously (proportionately) at all points of the Fabry-Pérot resonator, turning to zero everywhere twice a period. At those instants the electric field energy of the resonator vanishes, but the total energy stays constant, because the magnetic field oscillates (also simultaneously at all points) with the phase shift $\pi / 2$. Such behavior is typical for all electromagnetic resonators.

Another, more technical remark is that we can readily get the same results (182)-(185) by solving the Maxwell equations from the scratch. For example, we already know that in the absence of dispersion, losses, and sources, they are reduced to wave equations (3) for any field components. For the Fabry-Pérot resonator's analysis, we can use their 1D form, say, for the transverse component of the electric field:

$$
\begin{equation*}
\left(\frac{\partial^{2}}{\partial z^{2}}-\frac{1}{v^{2}} \frac{\partial^{2}}{\partial t^{2}}\right) E=0 \tag{7.186}
\end{equation*}
$$

and solve it as a part of an eigenvalue problem with the corresponding boundary conditions. Indeed, separating time and space variables as $E(z, t)=Z(z) \pi t)$, we get

$$
\begin{equation*}
\frac{1}{Z} \frac{d^{2} Z}{d z^{2}}-\frac{1}{v^{2}} \frac{1}{T} \frac{d^{2} T}{d t^{2}}=0 \tag{7.187}
\end{equation*}
$$

Calling the separation constant $k^{2}$, we get two similar ordinary differential equations,

$$
\begin{gather*}
\frac{d^{2} Z}{d z^{2}}+k^{2} Z=0  \tag{7.188}\\
\frac{d^{2} T}{d t^{2}}+k^{2} v^{2} T=0 \tag{7.189}
\end{gather*}
$$

both with sinusoidal solutions, so that their product is a standing wave with a wave vector $k$ and frequency $\omega=k v$, which may be presented by Eq. (182). ${ }^{64}$ Now using the boundary conditions $E(0, t)=$ $\mathrm{E}(l, t)=0,{ }^{65}$ we get the eigenvalue spectrum for $k_{p}$ and hence for $\omega_{p}=\nu k_{p}$, given by Eqs. (183) and (184).

[^346]Lessons from this simple case study may be readily generalized for an arbitrary resonator: there are (at least :-) two methods of finding the eigenfrequency spectrum:
(i) We may look at a traveling wave solution and find where reflecting mirrors may be inserted without affecting the wave's structure. Unfortunately, this method is limited to simple geometries.
(ii) We may solve the general 3D wave equation,

$$
\begin{equation*}
\left(\nabla^{2}-\frac{1}{v^{2}} \frac{\partial^{2}}{\partial t^{2}}\right) f(\mathbf{r}, t)=0 \tag{7.190}
\end{equation*}
$$

for field components, as an eigenvalue problem with appropriate boundary conditions. If system parameters (and hence coefficient $v$ ) do not change in time, the spatial and temporal variables of Eq. (185) may be always separated by taking

$$
\begin{equation*}
f(\mathbf{r}, t)=R(\mathbf{r}) T(t), \tag{7.191}
\end{equation*}
$$

where function $\pi t$ ) always obeys the same equation (189), having the sinusoidal solution of frequency $\omega$ $=v k$. Plugging this solution back into Eq. (190), for the spatial distribution of the field we get the $3 D$ Helmholtz equation,

$$
\begin{equation*}
\left(\nabla^{2}+k^{2}\right) 尺(\mathbf{r})=0 \tag{7.192}
\end{equation*}
$$

whose solution (for non-symmetric geometries) may be much more complex.
Let us use these methods to find the eigenfrequency spectrum of a few simple, but practically important resonators. First of all, the first method is completely sufficient for the analysis of any resonator formed as a fragment of a uniform TEM transmission line (e.g., a coaxial cable) between two conducting lids perpendicular to the line direction. Indeed, since in such lines $k_{z}=k=\omega / v$, and the electric field is perpendicular to the propagation axis, e.g., parallel to the lid surface, the boundary conditions are exactly the same as in the Fabry-Pérot resonator, and we again arrive at the eigenfrequency spectrum (184).

Now let us analyze a slightly more complex system: a rectangular metallic-wall cavity of volume $a \times b \times l$ - see Fig. 30. In order to use the first method, let us consider the resonator as a finite-length ( $\Delta \mathrm{z}=$ $l$ ) of the rectangular waveguide stretched along axis $z$, which was analyzed in detail in Sec. 7. As a reminder, for $a<b$, in the basic $H_{10}$ traveling wave mode, both $\mathbf{E}$ and $\mathbf{H}$ do not depend on $y$, with vector E having only $y$-component. On the contrary, vector $\mathbf{H}$ has both components $H_{x}$ and $H_{z}$, with the phase shift $\pi / 2$ between them, with component $H_{x}$ having the same phase as $E_{y}$ - see Eqs. (131), (137), and (138). Hence, if a plane, perpendicular to axis $z$, is placed so that the electric field vanishes on it, $H_{x}$ also vanishes, so that all the boundary conditions (104) pertinent to a perfect metallic wall are fulfilled simultaneously.

Fig. 7.30. Rectangular metallic resonator as a finite section of a waveguide with the crosssection shown in Fig. 25.

As a result, the $H_{10}$ wave would not be perturbed by two metallic walls separated by an integer number of half-wavelength $\lambda_{z} / 2$ corresponding to the wave number given by Eqs. (102) and (133):

$$
\begin{equation*}
k_{z}=\left(k^{2}-k_{t}^{2}\right)^{1 / 2}=\left(\frac{\omega^{2}}{v^{2}}-\frac{\pi^{2}}{a^{2}}\right) . \tag{7.193}
\end{equation*}
$$

Using this expression, we see that the smallest of these distances, $l=\lambda_{z} / 2=\pi / k_{z}$, gives resonance frequency ${ }^{66}$

$$
\begin{equation*}
\omega_{101}=v\left[\left(\frac{\pi}{a}\right)^{2}+\left(\frac{\pi}{l}\right)^{2}\right]^{1 / 2} \tag{7.194}
\end{equation*}
$$

with the indices showing the number of half-waves along each dimension of the system. This is the lowest (fundamental) eigenfrequency of the resonator (if $b<a, l$ ).

The field distribution in this mode is close to that in the corresponding waveguide mode $H_{10}$ (Fig. 22), with the important difference that phases of the magnetic and electric fields are shifted by phase $\pi / 2$ both in space and time, just as in the Fabry-Pérot resonator - see Eqs. (182) and (185). Such time shift allows for a very simple interpretation of the $H_{101}$ mode that is especially adequate for very flat resonators, with $b \ll a, l$. At the instant when the electric field reaches maximum (Fig. 31a), i.e. the magnetic field vanishes in the whole volume, the surface electric charge of the walls (with density $\sigma=$ $E_{n} / \varepsilon$ ) is largest, being localized mostly in the middle of the broadest (in Fig. 31, horizontal) faces of the resonator. At later times, the walls start to recharge via surface currents whose density $J$ is largest in the side walls, and reaches its maximal value in a quarter period of the oscillation period of frequency $\omega_{101}-$ see Fig. 31b. The currents generate the vortex magnetic field, with looped field lines in the plane of the broadest face. The surface currents continue to flow in this direction until (in one more quarter period) the broader walls of the resonator are fully recharged in the polarity opposite to that shown in Fig. 31a. After that, the surface currents stat to flow in the direction opposite to that shown in Fig. 31b. This process, that repeats again and again, is conceptually similar to the well-known oscillations in a lumped $L C$ circuit, with the role of (now, distributed) capacitance played mostly by the broadest faces of the resonator, and that of distributed inductance, mostly by its narrower walls.
(a)

(b)

Fig. 7.31. Fields, charges, and currents in the basic $H_{101}$ mode of a rectangular metallic resonator, at two instants separated by $\Delta t=\pi / 2 \omega_{101}$ schematically.

In order to generalize result (194) to higher oscillation modes, the second method discussed above is more prudent. Separating variables as $\mathbb{Z}(\mathbf{r})=X(x) Y(y) Z(z)$ in the Helmholtz equation (192), we

[^347]see that $X, Y$, and $Z$ have to be sinusoidal functions of their arguments, with wave vector components satisfying the characteristic equation
\[

$$
\begin{equation*}
k_{x}^{2}+k_{y}^{2}+k_{z}^{2}=k^{2} \equiv \frac{\omega^{2}}{v^{2}} . \tag{7.195}
\end{equation*}
$$

\]

In contrast to the wave propagation problem, now we are dealing with standing waves along all three dimensions, and have to satisfy the boundary conditions on all sets of parallel walls. It is straightforward to check that the macroscopic boundary conditions $\left(E_{\tau}=0, H_{n}=0\right)$ are fulfilled at the following field component distribution:

$$
\begin{array}{lll}
E_{x}=E_{1} \cos k_{x} x \sin k_{y} y \sin k_{z} z, & H_{x}=H_{1} \sin k_{x} x \cos k_{y} y \cos k_{z} z, \\
E_{y}=E_{2} \sin k_{x} x \cos k_{y} y \sin k_{z} z, & H_{y}=H_{2} \cos k_{x} x \sin k_{y} y \cos k_{z} z,  \tag{7.196}\\
E_{z}=E_{3} \sin k_{x} x \sin k_{y} y \cos k_{z} z, & H_{z}=H_{3} \cos k_{x} x \cos k_{y} y \sin k_{z} z,
\end{array}
$$

with each of the wave vector components having the equidistant spectrum similar to the one given by Eq. (183):

$$
\begin{equation*}
k_{x}=\frac{\pi n}{a}, \quad k_{y}=\frac{\pi m}{b}, \quad k_{z}=\frac{\pi p}{l} \tag{7.197}
\end{equation*}
$$

so that the full spectrum of eigenfrequencies is given by the following formula,

$$
\begin{equation*}
\omega_{n m p}=v k=v\left[\left(\frac{\pi n}{a}\right)^{2}+\left(\frac{\pi m}{b}\right)^{2}+\left(\frac{\pi p}{l}\right)^{2}\right]^{1 / 2} \tag{7.198}
\end{equation*}
$$

which is a natural generalization of Eq. (194). Note, however, that of 3 integers $m, n$, and $p$ at least two have to be different from zero, in order to keep the fields (196) nonvanishing.

Let us use Eq. (199) to evaluate the number of different modes in a relatively small region $d^{3} k$ $\ll k^{3}$ (which is still much larger than the reciprocal volume, $1 / V=1 / a b l$, of the resonator) of the wave vector space. Taking into account that each eigenfrequency (198), with $n m l \neq 0$, corresponds to two field modes with different polarizations, ${ }^{67}$ the argumentation absolutely similar to the one used in the end of Sec. 7 for the 2D case yields

$$
\begin{equation*}
d N=2 V \frac{d^{3} k}{(2 \pi)^{3}} \tag{7.199}
\end{equation*}
$$

[^348]This property, valid for resonators of arbitrary shape, is broadly used in classical and quantum statistical physics, ${ }^{68}$ in the following form. If some electromagnetic mode property, $f(\mathbf{k})$, is a smooth function of the wave vector, and volume $V$ is large enough, then Eq. (199) may be used to approximate the sum over the modes by an integral:

[^349]\[

$$
\begin{equation*}
\sum_{\mathbf{k}} f(\mathbf{k}) \approx \int_{N} f(\mathbf{k}) d N=\int_{\mathbf{k}} f(\mathbf{k}) \frac{d N}{d^{3} k} d^{3} k=2 \frac{V}{(2 \pi)^{3}} \int_{\mathbf{k}} f(\mathbf{k}) d^{3} k . \tag{7.200}
\end{equation*}
$$

\]

Finally, note that low-loss resonators may be also formed by finite-length sections of not only metallic waveguides with different cross-sections, but also of the dielectric waveguides. Moreover, even the a simple slab of a dielectric material with a $\mu / \varepsilon$ ratio substantially different from that of its environment (say, the free space) may be used as a high- $Q$ Fabry-Pérot interferometer (Fig. 32), due to an effective wave reflection from its surfaces at normal and especially inclined incidence - see, respectively, Eqs. (68) and Eqs. (91) and (95).

Fig. 7.32. Dielectric Fabry-Pérot interferometer.

Actually, such dielectric Fabry-Pérot interferometer is frequently more convenient for practical purposes than a metallic resonator, due to its natural coupling to environment, that enables a ready way of wave insertion and extraction. The back side of the same medal is that this coupling to environment provides an additional mechanism of power losses, limiting the resonance quality - see the next section.

### 7.10. Energy loss effects

Inevitable energy losses ("power dissipation") in passive media lead, in two different situations, to two different effects. In a long transmission line fed by a constant wave source at one end, the losses lead to a gradual attenuation of the wave, i.e. to the decrease of its amplitude, and hence power $\mathcal{P}$, with the distance $z$ along the line. In linear materials, the losses are proportional to the wave amplitude squared, i.e. to the time- average of the power itself, so that the energy balance on a small segment $d z$ takes the form

$$
\begin{equation*}
d \mathcal{P}=-\frac{d \mathcal{P}_{\text {loss }}}{d z} d z=-\alpha \mathcal{P} d z \tag{7.201}
\end{equation*}
$$

Coefficient $\alpha$, participating in the last form of Eq. (201) and defined by relation

$$
\begin{equation*}
\alpha \equiv \frac{d \mathcal{P}_{\text {loss }} / d z}{\mathcal{P}} \tag{7.202}
\end{equation*}
$$

is called the attenuation constant. ${ }^{69}$ Comparing the evident solution of Eq. (201),
${ }^{69}$ In engineering, attenuation is frequently measured in decibels per meter (acronymed as $\mathrm{db} / \mathrm{m}$ or just dbm ):

$$
\left.\alpha\right|_{\mathrm{db} / \mathrm{m}} \equiv 10 \log _{10} \frac{\mathcal{P}(z=0)}{\mathcal{P}(z=1 \mathrm{~m})}=10 \log _{10} e^{\alpha[1 / \mathrm{m}]}=\frac{10}{\ln 10} \alpha\left[\mathrm{~m}^{-1}\right] \approx 4.34 \alpha\left[\mathrm{~m}^{-1}\right] .
$$

$$
\begin{equation*}
\mathcal{P}(z)=\mathbb{P}(0) e^{-\alpha z} \tag{7.203}
\end{equation*}
$$

with Eq. (29), where $k$ is replaced with $k_{z}$, we see that $\alpha$ may expressed as

$$
\begin{equation*}
\alpha=2 \operatorname{Im} k_{z}, \tag{7.204}
\end{equation*}
$$

where $k_{z}$ is the component of the wave vector along the transmission line. In the most important limit when the losses are low in the sense $\alpha \ll\left|k_{z}\right| \approx \operatorname{Re} k_{z}$, its effects on the field distributions along the line's cross-section are negligible, making the calculation of $\alpha$ rather straightforward. In particular, in this limit the contributions to attenuation from two major sources, energy losses in the filling dielectric, and the skin effect in conducting walls, are independent and additive.

The dielectric losses are especially simple to describe. Indeed, a review of our calculations in Secs. 6-8 shows that all of them remain valid if either $\varepsilon(\omega)$, or $\mu(\omega)$, or both, and hence $k(\omega)$, have small imaginary parts:

$$
\begin{equation*}
k^{\prime \prime}=\omega \operatorname{Im}\left[\varepsilon^{1 / 2}(\omega) \mu^{1 / 2}(\omega)\right] \ll k^{\prime} \tag{7.205}
\end{equation*}
$$

In TEM transmission lines, $k=k_{z}$, and hence Eq. (205) yields

$$
\begin{equation*}
\alpha_{\text {dielectric }}=2 k^{\prime \prime}=2 \omega \operatorname{Im}\left[\varepsilon^{1 / 2}(\omega) \mu^{1 / 2}(\omega)\right] \tag{7.206}
\end{equation*}
$$

[^350]For dielectric waveguides, in particular optical fibers, these losses are the main attenuation mechanism. As we already know from Sec. 8, in practical optical fibers $\kappa_{t} R \gg$ 1, i.e. most of the field propagates (as the evanescent wave) in the cladding, and the wave mode is very close to TEM. This is why it is sufficient to use Eq. (206) for the cladding material alone.

In waveguides with non-TEM waves, we can readily use the relations between $k_{z}$ and $k$ derived above to re-calculate $k$ " into $\operatorname{Im} k_{z}$. (Note that as such re-calculation, values of $k_{t}$ stay real, because they are just the eigenvalues of the Helmholtz equation (101), which does not include $k$.).

In waveguides and transmission lines with metallic conductors, much higher energy losses may come from the skin effect. Let us calculate them, assuming that we know the field distribution in the wave, in particular, the tangential component $H$ of the magnetic field at conductor surface. Then, if the wavelength $\lambda$ is much larger than $\delta_{s}$, as it usually is, ${ }^{70}$ we may use the results of the quasistatic approximation derived in Sec. 6.2, in particular Eqs. (6.27)-(6.28) for the relation between the complex amplitudes of the current density in the conductor and the tangential magnetic field

$$
\begin{equation*}
j_{\omega}(x)=k_{-} H_{\omega}(x), \quad k_{-}=-\frac{(1-i)}{\delta_{s}}, \quad \delta_{s}^{2}=\frac{2}{\mu \omega \sigma} . \tag{7.207}
\end{equation*}
$$

The power loss density (per unit volume) may be now calculated by time averaging of Eq. (4.39):

$$
\begin{equation*}
\mathcal{P}_{\text {loss }}(x)=\frac{\left|j_{\omega}(x)\right|^{2}}{2 \sigma}=\frac{\left|k_{-}\right|^{2}\left|H_{\omega}(x)\right|^{2}}{2 \sigma}=\frac{\left|H_{\omega}(x)\right|^{2}}{\delta_{s}^{2} \sigma} \tag{7.208}
\end{equation*}
$$

[^351]and its integration along the normal to the surface (through all the skin depth), using the exponential law (6.26). This (elementary) integration yields the following power loss per unit area: ${ }^{71}$
\[

$$
\begin{equation*}
\frac{d \mathcal{P}_{\text {loss }}}{d A} \equiv \int_{0}^{\infty} p_{\text {loss }}(x) d x=\left|H_{\omega}(0)\right|^{2} \frac{\mu \omega \delta_{s}}{4} . \tag{7.209}
\end{equation*}
$$

\]

The total power loss $d \mathcal{P}_{\text {loss }} / d z$ per unit length of a waveguide, i.e. the right-hand part of Eq. (201), now may be calculated by the integration of the ratio $\mathcal{P}_{\text {loss }} / A$ along the contour(s) limiting the cross-section of all conductors of the line. Since our calculation is only valid for low losses, we may ignore their effect on the field distribution, so that the unperturbed distribution may be used both in Eq. (209), i.e. the numerator of Eq. (202), and also for the calculation of the average propagating power, i.e. the denominator of Eq. (202), as the integral of the Poynting vector over the cross-section of the waveguide.

Let us see how this approach works for the TEM mode in one of the simplest TEM transmission lines, the coaxial cable (Fig. 19). As we already know from Sec. 6, in the absence of losses, the distribution of TEM mode fields is the same as in statics, namely:

$$
\begin{equation*}
H_{z}=0, \quad H_{\rho}=0, \quad H_{\varphi}(\rho)=H_{0} \frac{a}{\rho}, \tag{7.210}
\end{equation*}
$$

where $H_{0}$ is the field's amplitude on the surface of the inner conductor, and

$$
\begin{equation*}
E_{z}=0, \quad E_{\rho}(\rho)=Z H_{\varphi}(\rho)=Z H_{0} \frac{a}{\rho}, \quad E_{\varphi}=0, \quad Z \equiv\left(\frac{\mu}{\varepsilon}\right)^{1 / 2} . \tag{7.211}
\end{equation*}
$$

Now we can, neglecting losses for now, use Eq. (42) to calculate the time-averaged Poynting vector

$$
\begin{equation*}
\bar{S}=\frac{Z\left|H_{\varphi}(\rho)\right|^{2}}{2}=\frac{Z\left|H_{0}\right|^{2}}{2}\left(\frac{a}{\rho}\right)^{2} \tag{7.212}
\end{equation*}
$$

and from it, the total power propagating through the cross-section:

$$
\begin{equation*}
\mathcal{P}=\int_{A} \bar{S} d^{2} r=\frac{Z\left|H_{0}\right|^{2} a^{2}}{2} 2 \pi \int_{a}^{b} \frac{\rho d \rho}{\rho^{2}}=\pi Z\left|H_{0}\right|^{2} a^{2} \ln \frac{b}{a} . \tag{7.213}
\end{equation*}
$$

For the particular case of the coaxial cable (Fig. 19), the contours limiting the wall cross-sections are circles of radii $\rho=a$ (where the surface field amplitude $H_{\omega}(0)$ equals, in our notation, $H_{0}$ ), and $\rho=b$ (where, according to Eq. (204), the field is a factor of $b / a$ lower). As a result, for the power loss per unit length, Eq. (209) yields

$$
\begin{equation*}
\frac{d \mathcal{P}_{\text {loss }}}{d z}=\left(2 \pi a\left|H_{0}\right|^{2}+2 \pi b\left|H_{0} \frac{a}{b}\right|^{2}\right) \frac{\mu_{0} \omega \delta_{s}}{4}=\frac{\pi}{2} a\left(1+\frac{a}{b}\right) \mu \omega \delta_{s}\left|H_{0}\right|^{2} . \tag{7.214}
\end{equation*}
$$

Note that at $a \ll b$, the losses in the inner conductor dominate, despite its smaller surface, because of the higher surface field. Now we may plug Eqs. (213)-(214) into the definition (202) of $\alpha$, to calculate the part of the attenuation constant associated with the skin effect:

[^352]\[

$$
\begin{equation*}
\alpha_{\text {skin }} \equiv \frac{d \mathcal{P}_{\text {loss }} / d z}{\mathcal{P}}=\frac{1}{2 \ln (b / a)}\left(\frac{1}{a}+\frac{1}{b}\right) \frac{\mu \omega \delta_{s}}{Z}=\frac{k \delta_{s}}{2 \ln (b / a)}\left(\frac{1}{a}+\frac{1}{b}\right) . \tag{7.215}
\end{equation*}
$$

\]

We see that the relative (dimensionless) attenuation, $\alpha / k$, scales approximately as the ratio $\delta_{s} / \min [a, b]$. This result is should be compared with Eq. (78) for the normal incidence of plane waves on a conducting surface.

Let us evaluate $\alpha$ for the standard TV cable RG-6/U (with copper conductors of diameters $2 a=$ $1 \mathrm{~mm}, 2 b=4.7 \mathrm{~mm}$, and $\left.\varepsilon \approx 2.2 \varepsilon_{0}, \mu \approx \mu_{0}\right)$. According to Eq. ( 6.27 a ), for $f=100 \mathrm{MHz}\left(\omega \approx 6.3 \times 10^{8} \mathrm{~s}^{-1}\right)$ the skin depth of pure copper at room temperature (with $\sigma \approx 6.0 \times 10^{7} \mathrm{~S} / \mathrm{m}$ ) is close to $6.5 \times 10^{-6} \mathrm{~m}$, while $k=\omega(\varepsilon \mu)^{1 / 2}=\left(\varepsilon / \varepsilon_{0}\right)^{1 / 2}(\omega / c) \approx 3.1 \mathrm{~m}^{-1}$. As a result, the attenuation is rather low: $\alpha_{\text {skin }} \approx 0.016 \mathrm{~m}^{-1}$, so that the attenuation length scale $\mathcal{L} \equiv 1 / \alpha$ is about 60 m . Hence the attenuation in a cable connecting a roof TV antenna to a TV set in the same house is not a big problem, though using a worse conductor, e.g., steel, would make the losses rather noticeable. (Hence the current worldwide shortage of copper.) However, an attempt to use the same cable in the X-band ( $f \sim 10 \mathrm{GHz}$ ) is more problematic. Indeed, though the skin depth $\delta_{\mathrm{s}} \propto \omega^{-1 / 2}$ decreases with frequency, the wave length drops, i.e. $k$ increases, even faster $(k \propto \omega)$, so that the attenuation $\alpha_{\text {skin }} \propto \omega^{1 / 2}$ becomes close to 0.16 m , and $\mathcal{L}$ to $\sim 6 \mathrm{~m}$. This is why at such frequencies, it is more customary to use rectangular waveguides, with their larger internal dimensions $a, b \sim 1 / k$, and hence lower attenuation. Let me leave the calculation of this attenuation, using Eq. (209) and the results derived in Sec. 9, for reader's exercise.

The power loss effect on free oscillations in resonators is different: there it leads to a gradual decay of oscillation energy $\varepsilon$ in time. The useful measure of this decay, called the $Q$ factor, may be introduced by writing the temporal analog of Eq. (201):

$$
\begin{equation*}
d \varepsilon=-\mathcal{P}_{\text {loss }} d t=-\frac{\omega}{Q} \varepsilon d t \tag{7.216}
\end{equation*}
$$

where $\omega$ in the eigenfrequency in the loss-free limit, and the dimensional $Q$ factor is defined by a relation parallel to Eq. (202): ${ }^{72}$

$$
\begin{equation*}
\frac{\omega}{Q} \equiv \frac{\mathcal{P}_{\text {loss }}}{\varepsilon} . \tag{7.217}
\end{equation*}
$$

The solution to Eq. (216),

$$
\begin{equation*}
\varepsilon(t)=\varepsilon(0) e^{-t / \tau}, \quad \text { with } \tau \equiv \frac{Q}{\omega}=\frac{Q / 2 \pi}{\omega / 2 \pi}=\frac{Q T}{2 \pi}, \tag{7.218}
\end{equation*}
$$

which is an evident temporal analog of Eq. (203), shows the physical meaning of the $Q$ factor: the characteristic time $\tau$ of the oscillation energy decay is $(Q / 2 \pi)$ times longer than the oscillation period $T$ $=2 \pi / \omega$. (Another interpretation of $Q$ comes from the relation ${ }^{73}$

$$
\begin{equation*}
Q=\frac{\omega}{\Delta \omega}, \tag{7.219}
\end{equation*}
$$

[^353]$Q$-factor's definition

Oscillation energy decay

FWHM bandwidth
where $\Delta \omega$ is the so-called $F W H M^{74}$ bandwidth of the resonance, namely the difference between the two values of the external signal frequency, one above and one below $\omega$, at which the energy of forced oscillations induced in the resonator by an input signal is twice lower than its resonant value.)

In the important particular case of resonators formed by insertion of metallic walls into a TEM transmission line of small cross-section (with the linear size scale $a$ much less than the wavelength $\lambda$ ), there is no need to calculate the $Q$ factor directly if the line attenuation coefficient $\alpha$ is already known. In fact, as was discussed in Sec. 9 above, the standing waves in such a resonator, of the length given by Eq. (183): $l=p(\lambda / 2)$ with $p=1,2, \ldots$, may be understood as an overlap of two TEM waves running in opposite directions, or in other words, a traveling wave and its reflection from one of the ends, the whole roundtrip taking time $\Delta t=2 l / v=p \lambda / v=2 \pi p / \omega=p T$. According to Eq. (201), at this distance the wave's power should drop by $\exp \{-2 \alpha l\}=\exp \{-p \alpha \lambda\}$. On the other hand, the same decay may be viewed as happening in time, and according to Eq. (216), result in the drop by $\exp \{-\Delta t / \tau\}=\exp \{-$ $(p T) /(Q / \omega)\}=\exp \{-2 \pi p / Q\}$. Comparing these two exponents, we get

$$
\begin{equation*}
Q=\frac{2 \pi}{\alpha \lambda}=\frac{k}{\alpha} \tag{7.220}
\end{equation*}
$$

This simple relation neglects the losses at wave reflection from the walls limiting the resonator length. Such approximation is indeed legitimate at $a \ll \lambda$; if this relation is violated, or if we are dealing with more complex resonator modes (such as those based on the reflection of $E$ or $H$ waves), the $Q$ factor may be smaller than that given by Eq. (220), and needs to be calculated directly. A substantial relief for such a direct calculation is that, just at the calculation of small attenuation in waveguides, in the low-loss limit ( $Q \gg 1$ ), both the numerator and denominator of the right-hand part of Eq. (217) may be calculated neglecting the effects of the power loss on the field distribution in the resonator. I am leaving such a calculation, for the simplest (rectangular and circular) resonators, for reader's exercise.

To conclude this chapter, the last remark: in some resonators (including certain dielectric resonators and metallic resonators with holes in their walls), additional losses due to wave radiation into the environment are also possible. In some simple cases (say, the Fabry-Pérot interferometer shown in Fig. 32) the calculation of these radiative losses is straightforward, but sometimes it requires more elaborated approaches, which will be discussed in the next chapter.

### 7.11. Exercise problems

7.1.* Find the temporal Green's function of a medium whose complex dielectric constant obeys Eq. (32), using:
(i) the Fourier transform, and
(ii) the direct solution of Eq. (30), which describes the corresponding model of the medium.

Hint: For the Fourier transform, you may like to use the Cauchy integral. ${ }^{75}$
7.2. The electric polarization of a material responds in the following way to an electric field step: ${ }^{76}$

[^354]\[

P(t)=\varepsilon_{1} E_{0}\left(1-e^{-t / \tau}\right), \quad if E(t)=E_{0} \times $$
\begin{cases}0, & \text { for } t<0, \\ 1, & \text { for } 0<t\end{cases}
$$
\]

where $\tau$ is a positive constant. Calculate the complex permittivity $\varepsilon(\omega)$ of this material, and discuss a possible simple physical model giving such dielectric response.
7.3. Calculate the complex dielectric constant $\varepsilon(\omega)$ for a material whose dielectric-response Green's function, defined by Eq. (23), is

$$
G(\theta)=G_{0}\left(1-e^{-\theta / \tau}\right)
$$

with some positive constants $G_{0}$ and $\tau$. What is the difference between this dielectric response and the apparently similar one considered in the previous problem?
7.4. Use the Lorentz oscillator model of an atom, given by Eq. (30), to calculate the average potential energy of the atom in a uniform, sinusoidal ac electric field, and use the result to calculate the potential profile created for the atom by a standing electromagnetic wave with the electric field amplitude $E_{\sigma}(\mathbf{r})$. Discuss the conditions of validity of your result.
7.5. The solution of the previous problem shows that a standing plane wave exerts a timeaveraged force on a non-relativistic charged particle. Reveal the physics of this force by writing and solving the equations of motion of a free particle in:
(i) a linearly-polarized, monochromatic, plane traveling wave, and
(ii) a similar but standing wave.

Discuss the conditions of validity of your result.
7.6. Calculate, sketch and discuss the dispersion relation for electromagnetic waves propagating in a Lorentz oscillator medium described by Eq. (32), for the case of negligible damping.
7.7. As was briefly discussed in Sec. $2,{ }^{77}$ a wave pulse of a finite but relatively large spatial extension $\Delta r \gg \lambda \equiv 2 \pi / k$ may be represented with a wave packet - a sum of sinusoidal waves with wave vectors $\mathbf{k}$ within a relatively narrow interval. Consider an electromagnetic plane wave packet of this type, with the electric field distribution

$$
\mathbf{E}(\mathbf{r}, t)=\operatorname{Re} \int_{-\infty}^{+\infty} \mathbf{E}_{k} e^{i\left(k z-\omega_{k} t\right)} d k, \quad \text { with } \omega_{k}\left[\varepsilon\left(\omega_{k}\right) \mu\left(\omega_{k}\right)\right]^{1 / 2} \equiv|k|
$$

propagating along axis $z$ in an isotropic, linear, and loss-free (but not necessarily dispersion-free) medium. Express the full energy of the packet (per unit area of wave's front) via complex amplitudes $\mathbf{E}_{k}$, and discuss its dependence of time.

[^355]7.8. ${ }^{*}$ Analyze the effect of a constant, uniform magnetic field $\mathbf{B}_{0}$, parallel to the direction $\mathbf{n}$ of electromagnetic wave propagation, on the wave dispersion in plasma, within the same simple model that was used in the lecture notes for derivation of Eq. (7.38). (Limit your analysis to relatively weak waves, whose magnetic field is negligible in comparison with $\mathbf{B}_{0}$.)

Hint: You may like to represent the incident wave as a linear superposition of two circularly polarized waves, with the left- and right-hand polarization.
7.9. A monochromatic, plane electromagnetic wave is normally incident from free space on a uniform slab of a material with electric permittivity $\varepsilon$ and magnetic permeability $\mu$, with the slab thickness $d$ comparable with the wavelength.
(i) Calculate the power transmission coefficient $T$, i.e. the fraction of the incident power, that is transmitted through the slab.
(ii) Assuming that $\varepsilon$ and $\mu$ are frequency-independent and positive, analyze in detail the frequency dependence of $\tau$. In particular, how does function $\pi(\omega)$ depend on the film thickness $d$ and the wave impedance $Z=(\mu / \varepsilon)^{1 / 2}$ of its material?
7.10. A monochromatic, plane electromagnetic wave with free-space wave number $k_{0}$ is normally incident on a plane conducting film of thickness $d \sim \delta_{\mathrm{s}} \ll 1 / k_{0}$. Calculate the power transmission coefficient of the system, i.e. the fraction of incident wave's power propagating beyond the film. Analyze the result in the limits of small and large ratios $d / \delta_{\text {s }}$.
7.11. A plane wave of frequency $\omega$ is normally incident, from free space, on a plane surface of a material with real values of the electric permittivity $\varepsilon^{\prime}$ and magnetic permeability $\mu^{\prime}$. To minimize wave reflection from the surface, you may cover it with a layer, of thickness $d$, of another transparent material - see Fig. on the right. Calculate the optimal values of $\varepsilon, \mu$, and $d$.

7.12. A monochromatic, plane wave is incident from inside a medium with $\varepsilon \mu>\varepsilon_{0} \mu_{0}$ on its plane surface, at the angle of incidence $\theta$ larger than the critical angle $\theta_{\mathrm{c}}=$ $\sin ^{-1}\left(\varepsilon_{0} \mu_{0} / \varepsilon \mu\right)^{1 / 2}$. Calculate the depth $\delta$ of the evanescent wave penetration into the free space and analyze its dependence on $\theta$. Does the result depend on the wave polarization?
7.13. Analyze the possibility of propagation of surface electromagnetic waves along a plane boundary between plasma and free space. In particular, calculate and analyze the dispersion relation of the waves.

Hint: Assume that the magnetic field of the wave is parallel to the boundary and perpendicular to the wave propagation direction. (After solving the problem, justify this mode choice.)
7.14. Calculate the characteristic impedance $Z_{W}$ of the long, straight TEM transmission lines formed by metallic electrodes with cross-sections shown in Fig. below:

(iii)
(i) two round, parallel wires, separated by distance $d \gg R$,
(ii) microstrip line of width $w \gg d$,
(iii) stripline with $w \gg d_{1} \sim d_{2}$,
in all cases using the macroscopic boundary conditions on metallic surfaces. Assume that the conductors are embedded into a linear dielectric with constant $\varepsilon$ and $\mu$.
7.15. Modify results of Problem 10(ii) for a superconductor microstrip line, taking into account the magnetic field penetration into both the strip and the ground plane.
7.16. * What lumped ac circuit would be equivalent to the system shown in Fig. 20, with incident wave's power $\mathcal{P}_{i}$ ? Assume that the wave reflected from the load circuit does not return to it.
7.17. Find the lumped ac circuit equivalent to a loss-free TEM transmission line of length $l \sim \lambda$, with a small cross-section area $A \ll \lambda^{2}$, as "seen" (measured) from one end, if the line's conductors are galvanically connected ("shortened") at the other end
 - see Fig. on the right. Discuss result's dependence on the signal frequency.
7.18. Represent the fundamental $H_{10}$ wave in a rectangular waveguide (Fig. 22) with a sum of two plane waves, and discuss the physics behind such a representation .
7.19. ${ }^{*}$ For a metallic coaxial cable with the circular cross-section (Fig. 21), find the lowest nonTEM mode and calculate its cutoff frequency.
7.20. Two coaxial cable sections are connected coaxially - see Fig. on the right, which shows system's cut along its symmetry axis. Relations (118) and (120) seem to imply that if the ratios $b / a$ of these sections are equal, their impedance matching is perfect, i.e. a TEM wave incident from one side on the connection would pass it without any reflection at all: $R=0$. Is this statement correct?

7.21. * Use the recipe outlined in Sec. 8 to prove the characteristic equation (161) for the $H E$ and EH modes in a round, step-index optical fiber.
7.22. Find the lowest eigenfrequencies, and corresponding oscillation modes, of a round cylindrical resonator (see Fig. on the right) with perfectly conducting walls.

7.23. A plane, monochromatic wave propagates through a medium whose Ohmic conductance $\sigma$ dominates the power losses, while the electric and magnetic polarization effects are negligible. Calculate the wave attenuation coefficient and relate the result with some calculation carried out in Chapter 6.
7.24. Generalize the telegrapher's equations (110)-(111) by taking into account small energy losses in:
(i) transmission line's conductors, and
(ii) the media separating the conductors, using their simplest (Ohmic) models. Formulate the conditions of validity of the resulting equations.
7.25. Calculate the skin-effect contribution to the attenuation coefficient $\alpha$, defined by Eq. (202), for the basic $\left(H_{10}\right)$ mode propagating in a waveguide with the rectangular cross-section - see Fig. 22. Use the results to evaluate $\alpha$ and $L$ for a 10 GHz wave in the standard X-band waveguide WR-90 (with copper walls, $a=23 \mathrm{~mm}, b=10 \mathrm{~mm}$, and no dielectric filling), at room temperature. Compare the estimate with that, made in Sec. 10, for a standard coaxial cable, for the same frequency.
7.26. ${ }^{*}$ Calculate the skin-effect contribution to the attenuation coefficient $\alpha$ of
(i) the basic $\left(H_{11}\right)$ mode, and
(ii) the $H_{01}$ mode
in a metallic waveguide with the circular cross-section (Fig. 23a), and analyze the low-frequency ( $\omega$ $\left.\rightarrow \omega_{\mathrm{c}}\right)$ and high-frequency $\left(\omega \gg \omega_{\mathrm{c}}\right)$ behaviors of $\alpha$ for each of these modes.
7.27. For a rectangular metallic-wall resonator with dimensions $a \times b \times l(b \leq a, l)$, calculate the $Q$ factor in the fundamental (lowest) oscillation mode, due to the skin-effect losses in the walls. Evaluate the factor (and the lowest eigenfrequency) for a $23 \times 23 \times 10 \mathrm{~mm}^{3}$ resonator with copper walls, at room temperature.
7.28.* Calculate the lowest eigenfrequency and $Q$ factor (due to the skin-effect losses) of the toroidal (axially-symmetric) resonator with metallic walls and interior's cross-section shown in Fig. on the right, within the limit $d \ll r, R$.

7.29. Express the contribution to the damping coefficient (the reciprocal $Q$-factor) of a resonator, due to small energy losses in the dielectric that fills it, via dielectric's complex functions $\varepsilon(\omega)$ and $\mu(\omega)$ of the material.
7.30. For the dielectric Fabry-Pérot resonator (Fig. 32) with the normal wave incidence, find the $Q$-factor due to radiation losses in the limit of strong impedance mismatch ( $Z \gg Z_{0}$ ), using two methods:
(i) from the energy balance, using Eq. (217), and
(ii) from the frequency dependence of the power transmission coefficient, using Eq. (219). Compare the results.

## Chapter 8. Radiation, Scattering, Interference, and Diffraction

This chapter continues the discussion of the electromagnetic wave propagation, now focusing on the results of wave incidence on a passive object. Depending on the object's shape, the result of this interaction is called either scattering, or diffraction, or interference. However, as we will see below, the boundary between these effects is blurry, and their mathematical description may be conveniently based on a single key calculation - the electric dipole radiation of a spherical wave by a small source. Naturally, I will start the chapter from this calculation, deriving it from an even more general result the "retarded potentials" solution of the Maxwell equations.

### 8.1. Retarded potentials

Let us start from the general solution of the Maxwell equations in a dispersion-free, linear, uniform, isotropic medium, characterized by frequency-independent, real $\varepsilon$ and $\mu$ - for example, free space. ${ }^{1}$ The easiest way to perform this calculation is to use the scalar $(\phi)$ and vector (A) potentials of electromagnetic field, that are defined via the electric and magnetic fields by Eqs. (6.106):

$$
\begin{equation*}
\mathbf{E}=-\nabla \phi-\frac{\partial \mathbf{A}}{\partial t}, \quad \mathbf{B}=\nabla \times \mathbf{A} . \tag{8.1}
\end{equation*}
$$

As was discussed in Chapter 6, imposing upon the potentials the Lorenz gauge condition (6.108),

$$
\begin{equation*}
\nabla \cdot \mathbf{A}+\frac{1}{v^{2}} \frac{\partial \phi}{\partial t}=0, \quad v^{2} \equiv \frac{1}{\varepsilon \mu}, \tag{8.2}
\end{equation*}
$$

(which does not affect fields $\mathbf{E}$ and $\mathbf{B}$ ) the macroscopic Maxwell equations for the fields may be recast into a pair of very similar, simple equations (6.109) for the potentials:

$$
\begin{align*}
& \nabla^{2} \phi-\frac{1}{v^{2}} \frac{\partial^{2} \phi}{\partial t^{2}}=-\frac{\rho}{\varepsilon}  \tag{8.3a}\\
& \nabla^{2} \mathbf{A}-\frac{1}{v^{2}} \frac{\partial^{2} \mathbf{A}}{\partial t^{2}}=-\mu \mathbf{j} \tag{8.3b}
\end{align*}
$$

Let us calculate the fields induced by the stand-alone electric charge and current densities $\rho(\mathbf{r}, t)$ and $\mathbf{j}(\mathbf{r}, t)$, thinking of them as known functions. ${ }^{2}$ The idea how this may be done may be borrowed from electro- and magnetostatics. Indeed, for the stationary case $(\partial / \partial t=0)$, the solutions of Eqs. (8.3) are given, by the evident generalization of, respectively, Eq. (1.38) and by Eq. (5.28) to the uniform, linear medium:

$$
\begin{equation*}
\phi(\mathbf{r})=\frac{1}{4 \pi \varepsilon} \int \rho\left(\mathbf{r}^{\prime}\right) \frac{d^{3} r^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|}, \tag{8.4a}
\end{equation*}
$$

[^356]\[

$$
\begin{equation*}
\mathbf{A}(\mathbf{r}) \equiv \frac{\mu}{4 \pi} \int \mathbf{j}\left(\mathbf{r}^{\prime}\right) \frac{d^{3} r^{\prime}}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} \tag{8.4b}
\end{equation*}
$$

\]

As we know, these expressions may be derived by, first, calculating the potential of a point source, and then using the linear superposition principle for a system of such sources.

Let us do the same for the time-dependent case, starting from the field induced by a timedependent point charge at origin: ${ }^{3}$

$$
\begin{equation*}
\rho(\mathbf{r}, t)=q(t) \delta(\mathbf{r}) \tag{8.5}
\end{equation*}
$$

In this case Eq. (3a) is homogeneous everywhere but the origin:

$$
\begin{equation*}
\nabla^{2} \phi-\frac{1}{v^{2}} \frac{\partial^{2} \phi}{\partial t^{2}}=0, \quad \text { at } r \neq 0 \tag{8.6}
\end{equation*}
$$

Due to the spherical symmetry of the problem, it is natural to look for a spherically-symmetric solution to this equation. ${ }^{4}$ Thus, we may simplify the Laplace operator ${ }^{5}$ correspondingly, and reduce Eq. (6) to

$$
\begin{equation*}
\left[\frac{1}{r^{2}} \frac{\partial}{\partial r}\left(r^{2} \frac{\partial}{\partial r}\right)-\frac{1}{v^{2}} \frac{\partial^{2}}{\partial t^{2}}\right] \phi=0, \quad \text { at } r \neq 0 . \tag{8.7}
\end{equation*}
$$

If we now introduce a new variable $\chi \equiv r \phi$, Eq. (7) is reduced to the 1 D wave equation

$$
\begin{equation*}
\left(\frac{\partial^{2}}{\partial r^{2}}-\frac{1}{v^{2}} \frac{\partial^{2}}{\partial t^{2}}\right) \chi=0, \quad \text { at } r \neq 0 . \tag{8.8}
\end{equation*}
$$

From the discussion in Chapter $7,{ }^{6}$ we know that its general solution may be presented as

$$
\begin{equation*}
\chi(r, t)=\chi_{\text {out }}\left(t-\frac{r}{v}\right)+\chi_{\text {in }}\left(t+\frac{r}{v}\right) \tag{8.9}
\end{equation*}
$$

where $\chi_{\text {in }}$ and $\chi_{\text {out }}$ are (so far) arbitrary functions of one variable. The physical sense of $\phi_{\text {out }}=\chi_{\text {out }} / r$ is a spherical wave propagating from our source (at $r=0$ ) to outer space, i.e. exactly the solution we are looking for. On the other hand, $\phi_{\text {in }}=\chi_{\text {in }} / r$ describes a spherical wave that could be created by some distant spherically-symmetric source, that converges on our charge located at the origin - evidently not the effect we want to consider here. Discarding this term, and returning to $\phi=\chi / r$, we can write the solution (7) as

$$
\begin{equation*}
\phi(r, t)=\frac{1}{r} \chi_{\text {out }}\left(t-\frac{r}{v}\right) \tag{8.10}
\end{equation*}
$$

[^357]In order to find function $\chi_{\text {out }}$, let us consider distances $r$ so small that the time derivative in Eq. (3a), with the right-hand part (5),

$$
\begin{equation*}
\nabla^{2} \phi-\frac{1}{v^{2}} \frac{\partial^{2} \phi}{\partial t^{2}}=-\frac{q(t)}{\varepsilon} \delta(\mathbf{r}) \tag{8.11}
\end{equation*}
$$

is much smaller that the spatial derivative (that diverges at $r \rightarrow 0$ ). Then Eq. (11) is reduced to the electrostatic equation whose solution (4a), for source (5), is

$$
\begin{equation*}
\phi(r \rightarrow 0, t)=\frac{q(t)}{4 \pi \varepsilon r} . \tag{8.12}
\end{equation*}
$$

Now requiring the two solutions, (10) and (12), to coincide at $r \ll \nu t$, we get $\chi_{\text {out }}(t)=q(t) / 4 \pi \varepsilon r$, so that Eq. (10) becomes

$$
\begin{equation*}
\phi(r, t)=\frac{1}{4 \pi \varepsilon r} q\left(t-\frac{r}{v}\right) \tag{8.13}
\end{equation*}
$$

Just as had been done in statics, this result may be readily generalized for the arbitrary position $r^{\prime}$ of the point charge:

$$
\begin{equation*}
\rho(\mathbf{r}, t)=q(t) \delta\left(\mathbf{r}-\mathbf{r}^{\prime}\right) \equiv q(t) \delta(\mathbf{R}), \tag{8.14}
\end{equation*}
$$

where $R$ is the distance between the field observation point $\mathbf{r}$ and the source position point $\mathbf{r}$ ', i.e. the length of the vector,

$$
\begin{equation*}
\mathbf{R} \equiv \mathbf{r}-\mathbf{r}^{\prime} \tag{8.15}
\end{equation*}
$$

connecting these points - see Fig. 1.

Now we can use the linear superposition principle to write, for the arbitrary charge distribution $\rho(\mathbf{r}, t)$,

$$
\begin{equation*}
\phi(\mathbf{r}, t)=\frac{1}{4 \pi \varepsilon} \int \rho\left(\mathbf{r}^{\prime}, t-\frac{R}{v}\right) \frac{d^{3} r^{\prime}}{R} \tag{8.17a}
\end{equation*}
$$

where integration is extended over all charges of the system under analysis. Acting absolutely similarly, for the vector potential we get

$$
\begin{equation*}
\mathbf{A}(\mathbf{r}, t)=\frac{\mu}{4 \pi} \int \mathbf{j}\left(\mathbf{r}^{\prime}, t-\frac{R}{v}\right) \frac{d^{3} r^{\prime}}{R} \tag{8.17b}
\end{equation*}
$$

(Now nothing prevents functions $\rho(\mathbf{r}, t)$ and $\boldsymbol{j}(\mathbf{r}, t)$ from satisfying the continuity relation.)
Solutions (17) are called the retarded potentials, the name signifying that the observed fields are "retarded" (delayed) in time by $\Delta t=R / v$ relative to the source variations, due to the finite speed $v$ of the electromagnetic wave propagation. These solutions are so important that they deserve at least a couple of general remarks.

First, remarkably, these simple expressions are exact solutions of the Maxwell equations (93) in a uniform medium for an arbitrary distribution of stand-alone charges and currents. They also may be considered as the general solutions of these equations, provided that the integration is extended over all field sources in the Universe - or at least in its part that affects our observations.

Second, if functions $\rho(\mathbf{r}, t)$ and $\mathbf{j}(\mathbf{r}, t)$ include the microscopic (bound) charges and currents as well, the macroscopic Maxwell equations (6.93) are valid with the replacement $\varepsilon \rightarrow \varepsilon_{0}$ and $\mu \rightarrow \mu_{0}$, so that the retarded potentials solutions (17) are also valid - with the same replacement.

Finally, Eqs. (17) may be plugged into Eqs. (1), giving (after an explicit differentiation) the socalled Jefimenko equations for fields $\mathbf{E}$ and $\mathbf{B}$ - similar in structure to Eqs. (17), but more cumbersome. Conceptually, the existence of such equations is a good news, because they are free from the gauge ambiguity pertinent to potentials $\phi$ and $\mathbf{A}$. However, the practical value of these explicit expressions for the fields is not too high: for all applications I am aware of, it is easier to use Eqs. (17) to calculate the particular expressions for the potentials first, and only then calculate the fields from Eqs. (1). Let me present the (apparently most important) example of this approach.

### 8.2. Electric dipole radiation

Consider again the problem that was discussed in electrostatics (Sec. 3.1), namely the field of a localized source with linear dimensions $a \ll r$ (Fig. 1), but now with time-dependent charge and/or current distribution. Using the arguments of that discussion, in particular the condition expressed by Eq. (3.1), $r^{\prime} \ll r$, we may apply the Taylor expansion (3.3),

$$
\begin{equation*}
f(\mathbf{R})=f(\mathbf{r})-\mathbf{r}^{\prime} \cdot \nabla f(\mathbf{r})+\ldots \tag{8.18}
\end{equation*}
$$

to function $f(\mathbf{R}) \equiv R$ (for which $\nabla f(\mathbf{r})=\nabla R=\mathbf{n}$, where $\mathbf{n} \equiv \mathbf{r} / r$ is the unit vector directed toward the observation point, see Fig. 1) to approximate distance $R$ as

$$
\begin{equation*}
R \approx r-\mathbf{r}^{\prime} \cdot \mathbf{n} . \tag{8.19}
\end{equation*}
$$

In each of the retarded potential formulas (17), $R$ participates in two places: in the denominator and in the source time argument. If $\rho$ and $\mathbf{j}$ change in time on scale $\sim 1 / \omega$, where $\omega$ is some characteristic frequency, then any change of argument $(t-R / v)$ on that time scale, for example due to a change of $R$ on the spatial scale $\sim v / \omega=1 / k$, may substantially change these functions. Thus, expansion (18) may be applied to $R$ in the argument $(t-R / v)$ only if $k a \ll 1$, i.e. if the system size $a$ is much smaller than the radiation wavelength $\lambda=2 \pi / k$. On the other hand, function $1 / R$ changes relatively slowly, and for it even the first term expansion (19) gives a good approximation as soon as $a \ll r, R$. In this approach, Eq. (17a) yields

$$
\begin{equation*}
\phi(\mathbf{r}, t) \approx \frac{1}{4 \pi \varepsilon r} \int \rho\left(\mathbf{r}^{\prime}, t-\frac{R}{v}\right) d^{3} r^{\prime}=\frac{1}{4 \pi \varepsilon r} Q\left(t-\frac{R}{v}\right) \tag{8.20}
\end{equation*}
$$

where $Q(t)$ is the net electric charge of the localized system Due to the charge conservation, this charge cannot change with time, so that the approximation (20) describes gives just a static Coulomb field of our localized source, rather than a radiated wave.

Let us, however, apply a similar approximation to the vector potential (17b):

$$
\begin{equation*}
\mathbf{A}(\mathbf{r}, t) \approx \frac{\mu}{4 \pi r} \int \mathbf{j}\left(\mathbf{r}^{\prime}, t-\frac{R}{v}\right) d^{3} r^{\prime} \tag{8.21}
\end{equation*}
$$

According to Eq. (5.87), in statics the right-hand part of this expression would vanish, but in dynamics this is no longer true. For example, if the current is due to a non-relativistic motion ${ }^{7}$ of a system of charges $q_{k}$, we can write

$$
\begin{equation*}
\int \mathbf{j}\left(\mathbf{r}^{\prime}, t\right) d^{3} r^{\prime}=\sum_{k} q_{k} \dot{\mathbf{r}}_{k}(t)=\frac{d}{d t} \sum_{k} q_{k} \mathbf{r}_{k}(t) \equiv \dot{\mathbf{p}}(t), \tag{8.22}
\end{equation*}
$$

where $\mathbf{p}(t)$ is the dipole moment of the localized system, defined by Eq. (3.6). Now, after the integration, we may keep only the first term of approximation (19) in the argument $(t-R / v)$ as well, getting

$$
\begin{equation*}
\mathbf{A}(\mathbf{r}, t) \approx \frac{\mu}{4 \pi r} \dot{\mathbf{p}}\left(t-\frac{r}{v}\right) \tag{8.23}
\end{equation*}
$$

Let us analyze what exactly does this result, valid in the limit $k a \ll 1$, describe. The second of Eqs. (1) allows us to calculate the magnetic field by the spatial differentiation of A. At large distances $r$ $\gg \lambda$ (i.e. in the so-called far field zone), where Eq. (23) describes a virtually plane wave, the main contribution into this derivative is given by the dipole moment factor:

$$
\begin{equation*}
\mathbf{B}(\mathbf{r}, t)=\frac{\mu}{4 \pi r} \nabla \times \dot{\mathbf{p}}\left(t-\frac{r}{v}\right)=-\frac{\mu}{4 \pi r v} \mathbf{n} \times \ddot{\mathbf{p}}\left(t-\frac{r}{v}\right) \tag{8.24}
\end{equation*}
$$

This expression means that the magnetic field, at the observation point, is perpendicular to vectors $\mathbf{n}$ and (the retarded value of) $\ddot{\mathbf{p}}$, and its magnitude is

$$
\begin{equation*}
B=\frac{\mu}{4 \pi r v} \ddot{p}\left(t-\frac{r}{v}\right) \sin \theta, \quad \text { i.e. } H=\frac{1}{4 \pi r v} \ddot{p}\left(t-\frac{r}{v}\right) \sin \theta \tag{8.25}
\end{equation*}
$$

where $\theta$ is the angle between those two vectors - see Fig. 2. ${ }^{8}$

[^358]The most important feature of this result is that the time-dependent field decreases very slowly (only as $1 / r$ ) with the distance from the source, so that the radial component of the corresponding Poynting vector (7.7), $S_{r}=Z H^{2}$, drops as $1 / r^{2}$, i.e. the full power $\mathcal{P}$ of the emitted spherical wave, that scales as $r^{2} S_{r}$, does not depend on the distance from the source - as it should for radiation. Equation (25) allows us to be more quantitative; for the instantaneous radiation intensity we may plug it into Eq. (7.9) to get

$$
\begin{equation*}
S_{r}=Z H^{2}=\frac{Z}{(4 \pi v r)^{2}}\left[\ddot{p}\left(t-\frac{r}{v}\right)\right]^{2} \sin ^{2} \theta . \tag{8.26}
\end{equation*}
$$

Fig. 8.2. Far zone fields of a localized source, contributing into its electric dipole radiation.

This is the famous formula for the electric dipole radiation; this is the dominating component of radiation by a localized system of charges - unless $\ddot{\mathbf{p}}=0$. Please notice its angular dependence: the radiation vanishes at the axis of the retarded vector $\ddot{\mathbf{p}}$ (where $\theta=0$ ), and reaches its maximum in the plane perpendicular to that axis. Integration of $S_{r}$ over all directions, i.e. over the whole sphere of radius $r$, gives the total instant power of the dipole radiation: ${ }^{9}$

$$
\begin{equation*}
\mathcal{P} \equiv \oint_{r=\text { const }} S_{r} d^{2} r=\frac{Z}{(4 \pi v)^{2}} \ddot{p}^{2} 2 \pi \int_{0}^{\pi} \sin ^{3} \theta d \theta=\frac{Z}{6 \pi v^{2}} \ddot{p}^{2} \tag{8.27}
\end{equation*}
$$

In order to find the average power, this expression has to be averaged over a sufficiently long time. In particular, if the source is monochromatic, $\mathbf{p}(t)=\operatorname{Re}\left[\mathbf{p}_{\omega} \exp \{-i \omega t\}\right.$, with time-independent vector $\mathbf{p}_{\omega}$, such averaging may be carried out just over one period, giving an extra factor 2 in the denominator:

$$
\begin{equation*}
\overline{\mathcal{P}}=\frac{Z \omega^{4}}{12 \pi v^{2}}\left|p_{\omega}\right|^{2} \tag{8.28}
\end{equation*}
$$

[^359]The easiest example of application of the formula is to a point charge oscillating, with frequency $\omega$, along a straight line (that we may take for axis $z$ ), with amplitude $a$. In this case, $\mathbf{p}=q \mathbf{n}_{z} z(t)=q a \operatorname{Re}$ [ $\exp \{-i \omega t\}$ ], and if the charge velocity amplitude, $a \omega$, is much less than the wave speed $v$, we may use Eq. (28) with $p_{\omega}=q a$, giving

[^360]\[

$$
\begin{equation*}
\overline{\mathcal{P}}=\frac{Z q^{2} a^{2} \omega^{4}}{12 \pi v^{2}} . \tag{8.29}
\end{equation*}
$$

\]

Applied to an electron ( $q=-e \approx-1.6 \times 10^{-19} \mathrm{C}$ ), rotating about a nuclei at an atomic distance $a \sim 10^{-10} \mathrm{~m}$, the Larmor formula shows ${ }^{10}$ that the energy loss due to the dipole radiation is so large that it would cause electron's collapse on atom's nuclei in just $\sim 10^{-10} \mathrm{~s}$. In the beginning of the 1900 s , this classical result was one of the main arguments for the development of quantum mechanics that prevents such collapse of electrons in their lowest-energy (ground) state.

Another example of a very useful application of Eq. (28) is the radio wave radiation by a short, straight, symmetric antenna which is fed, for example, by a TEM transmission line such as a coaxial cable - see Fig. 3.

Fig. 8.3. Dipole antenna.

The exact solution of this problem is rather complex, because the law $I_{\omega}(z)$ of the current variation along antenna's length should be calculated self-consistently with the distribution of the electromagnetic field that is induced by the current in the surrounding space. (This fact is unfortunately ignored in some textbooks.) However, one may argue that at $l \ll \lambda$, the current should be largest in the feeding point (in Fig. 3, taken for $z=0$ ), vanish at antenna's ends ( $z= \pm l / 2$ ), and that the only possible scale of the current variation in the antenna is $l$ itself, so that the linear function,

$$
\begin{equation*}
I_{\omega}(z)=I_{\omega}(0)\left(1-\frac{2}{l}|z|\right), \tag{8.30}
\end{equation*}
$$

gives a good approximation - as it indeed does. Now we can use the continuity equation $\partial Q / \partial t=I$, i.e. $i \omega Q_{\omega}=I_{\omega}$, to calculate the complex amplitude $Q_{\omega}(z)=i I_{\omega}(z) \operatorname{sgn}(z) / \omega$ of the electric charge $Q(z, t)=$ $\operatorname{Re}\left[Q_{\omega} \exp \{-i \omega t\}\right]$ of the wire beyond point $z$, and from it, the amplitude of the linear density of charge

$$
\begin{equation*}
\lambda_{\omega}(z) \equiv \frac{d Q_{\omega}(z)}{d|z|}=-i \frac{2 I_{\omega}(0)}{\omega l} \operatorname{sgn} z . \tag{8.31}
\end{equation*}
$$

From here, the dipole moment's amplitude is

$$
\begin{equation*}
p_{\omega}=2 \int_{0}^{l / 2} \lambda_{\omega}(z) z d z=-i \frac{I_{\omega}(0)}{2 \omega} l \tag{8.32}
\end{equation*}
$$

[^361]so that Eq. (28) yields
\[

$$
\begin{equation*}
\bar{P}=Z \frac{\omega^{4}}{12 \pi v^{2}} \frac{\left|I_{\omega}(0)\right|^{2}}{4 \omega^{2}} l^{2}=\frac{Z(k l)^{2}}{24 \pi} \frac{\left|I_{\omega}(0)\right|^{2}}{2} \tag{8.33}
\end{equation*}
$$

\]

where $k=\omega / \mathrm{v}$. The analogy between this result and the dissipation power, $\mathcal{P}=\operatorname{Re} Z\left(I_{\omega}{ }^{2} / 2\right)$, in a lumped linear circuit element, allows the interpretation of the first fraction in the last form of Eq. (33) as the real part of antenna's impedance:

$$
\begin{equation*}
\operatorname{Re} Z_{A}=Z \frac{(k l)^{2}}{24 \pi} \tag{8.34}
\end{equation*}
$$

as felt by the transmission line. (Indeed, according to Eq. (7.118), the wave traveling along the line toward the antenna is fully radiated, i.e. not reflected back, only if $Z_{A}$ equals to $Z_{W}$ of the line.) As we know from Chapter 7, for typical TEM lines, $Z_{W} \sim Z_{0}$, while Eq. (34), that is only valid in the limit $k l \ll$ 1 , shows that for radiation into free space $\left(Z=Z_{0}\right), \operatorname{Re} Z_{A}$ is much less than $Z_{0}$.

Hence in order to reach the impedance matching condition $Z_{W}=Z_{A}$, antenna's length should be increased - as a more involved theory shows, to $l \sim \lambda / 2$. However, in many cases, practical considerations make short antennas necessary. The most frequently met example met nowadays are the cell phone antennas, which use frequencies close to 1 or 2 GHz , with free-space wavelengths $\lambda$ between 15 and 30 cm , i.e. much larger than the phone size. The quadratic dependence of antenna's efficiency on $l$, following from Eq. (34), explains why every millimeter counts in the design of such antennas, and why the designs are carefully optimized using software packages for (virtually exact) numerical solution of time-dependent Maxwell equations for the specific shape of the antenna and other phone parts. ${ }^{11}$

To conclude this section, let me note that if the wave source is not monochromatic, so that $\mathbf{p}(t)$ should presented as a Fourier series,

$$
\begin{equation*}
\mathbf{p}(t)=\operatorname{Re} \sum_{\omega} \mathbf{p}_{\omega} e^{-i \omega t} \tag{8.35}
\end{equation*}
$$

the terms corresponding to interference of spectral components with different frequencies $\omega$ are averaged out at the time averaging of the Poynting vector, so that the average radiated power is just a sum of contributions (28) from all substantial frequency components.

### 8.3. Wave scattering

The formalism described above may be immediately used in the theory of scattering - the phenomenon illustrated by Fig. 4. Generally, scattering is a complex problem. However, in many cases it allows the so-called Born approximation, ${ }^{12}$ in which scattered wave's field applied to the scattering object is assumed to be much weaker than that of the incident wave, and is neglected.

[^362]

Fig. 8.4. Scattering (schematically).

As the first example of this approach, let us consider scattering of a plane wave, propagating in free space $\left(Z=Z_{0}, v=c\right)$, by a free ${ }^{13}$ charged particle whose motion may be described by non-relativistic classical mechanics. (This requires, in particular, the incident wave to be of a modest intensity, so that the speed of the induced charge motion is much less than the speed of light.) In this case the magnetic component of the Lorentz force (5.8),

$$
\begin{equation*}
\mathbf{F}_{m}=q \dot{\mathbf{r}} \times \mathbf{B}, \tag{8.36}
\end{equation*}
$$

exerted on the charge by the magnetic field of a plane wave, is much smaller than force $\mathbf{F}_{e}=q \mathbf{E}$ exerted by its electric field. Indeed, according to Eq. (7.8), $H=E / Z=E /(\mu / \varepsilon)^{1 / 2}, B=\mu H=E / v$, so that the ratio $F_{m} / F_{e}$ equals to the ratio of particle'e speed, $|\dot{\mathbf{r}}|$, to wave's speed $v \sim c$.

Thus, assuming that the incident wave is linearly-polarized along axis $x$, the equation of particle's motion in the Born approximation is just $m \ddot{x}=q E(t)$, so that for the $x$-component $p_{x}=q x$ of its dipole moment we can write

$$
\begin{equation*}
\ddot{p}=q \ddot{x}=\frac{q^{2}}{m} E(t) . \tag{8.37}
\end{equation*}
$$

As we already know from Sec. 2, oscillations of the dipole moment lead to radiation of a wave with a wide angular distribution of intensity; in our case this is the scattered wave - see Fig. 4. Its full power may be found by plugging Eq. (37) into Eq. (27):

$$
\begin{equation*}
\mathcal{P}=\frac{Z_{0}}{6 \pi c^{2}} \ddot{p}^{2}=\frac{Z_{0} q^{4}}{6 \pi c^{2} m^{2}} E^{2}(t), \text { i.e. } \bar{P}=\frac{Z_{0} q^{4}}{12 \pi c^{2} m^{2}}\left|E_{\omega}\right|^{2} . \tag{8.38}
\end{equation*}
$$

Since the power is proportional to incident wave's intensity $S$, it is customary to characterize scattering ability of the object by the ratio,

Full crosssection: definition

$$
\begin{equation*}
\sigma \equiv \frac{\overline{\mathcal{P}}}{\overline{S_{\text {incident }}}}=\frac{\bar{P}}{\left|E_{\omega}\right|^{2} / 2 Z_{0}} \tag{8.39}
\end{equation*}
$$

which evidently has the dimension of area and is called the full cross-section of scattering. For this measure, Eq. (38) yields the famous result

[^363]\[

$$
\begin{equation*}
\sigma=\frac{Z_{0}^{2} q^{4}}{6 \pi c^{2} m^{2}}=\frac{\mu_{0}^{2} q^{4}}{6 \pi m^{2}} \tag{8.40}
\end{equation*}
$$

\]

which is called the Thomson scattering formula, ${ }^{14}$ especially when applied to an electron. This relation is most frequently presented in the form ${ }^{15}$

$$
\begin{equation*}
\sigma=\frac{8 \pi}{3} r_{c}^{2}, \quad \text { with } r_{c} \equiv \frac{q^{2}}{4 \pi \varepsilon_{0}} \cdot \frac{1}{m c^{2}}=10^{-7} \frac{q^{2}}{m} \text {. } \tag{8.41}
\end{equation*}
$$

Thomson scattering formula

Constant $r_{c}$ is called the classical radius of the particle (or sometimes the "Thomson scattering length"); for electron $\left(q=-e, m=m_{e}\right)$ it is close to $2.82 \times 10^{-15} \mathrm{~m}$. Its possible interpretation is evident from the first form of Eq. (41) for $r_{c}$ : at that distance between two similar particles, the potential energy $q^{2} / 4 \pi \varepsilon_{0} r$ of their electrostatic interaction is equal to particle's rest-mass energy $m c^{2}{ }^{2} .{ }^{16}$

Now we have to go back and establish the conditions at which the Born approximation, when the field of the scattered wave is negligible, is indeed valid for a point-object scattering. Since the scattered wave's intensity, described by Eq. (26), diverges as $1 / r^{2}$, according to the definition (39) of the crosssection, it may become comparable to $S_{\text {incident }}$ at $r^{2} \sim \sigma$. However, Eq. (38) itself is only valid if $r \gg \lambda$, so that the Born approximation does not lead to any contradiction if

$$
\begin{equation*}
\sigma \ll \lambda^{2} \tag{8.42}
\end{equation*}
$$

For the Thompson scattering by an electron, this condition means $\lambda \gg r_{c} \sim 3 \times 10^{-15} \mathrm{~m}$ and is fulfilled for all frequencies up to very hard $\gamma$ rays with energies $\sim 100 \mathrm{MeV}$.

Possibly the most notable feature of result (40) is its independence of the wave frequency. As it follows from its derivation, particularly from Eq. (37), this independence is intimately related with the unbound character of charge motion. For bound charges, say for electrons in a gas molecule, this result is only valid if the wave frequency $\omega$ is much higher all eigenfrequencies $\omega_{j}$ of molecular resonances. In the opposite limit, $\omega \ll \omega_{j}$, the result is dramatically different. Indeed, in this limit we can approximate the molecule's dipole moment by its static value (3.39)

$$
\begin{equation*}
\mathbf{p}=4 \pi \varepsilon_{0} \alpha_{\mathrm{mol}} \mathbf{E} \tag{8.43}
\end{equation*}
$$

In the Born approximation, and in the absence of the molecular field effects discussed in Sec. 3.5, E in this expression is just the incident wave's field, and we can use Eq. (28) to calculate the power of the wave scattered by a single molecule:

[^364]\[

$$
\begin{equation*}
\overline{\mathcal{P}}=\frac{4 \pi Z_{0} \omega^{4} \varepsilon_{0}^{2}}{c^{2}} \alpha_{\mathrm{mol}}^{2}\left|E_{\omega}\right|^{2} . \tag{8.44}
\end{equation*}
$$

\]

Now, using the last form of definition (39) of the cross-section, we get a very simple result,

$$
\begin{equation*}
\sigma=\frac{8 \pi Z_{0}^{2} \varepsilon_{0}^{2} \omega^{4}}{3 c^{2}} \alpha_{\mathrm{mol}}^{2}=\frac{8 \pi k^{4}}{3} \alpha_{\mathrm{mol}}^{2}, \tag{8.45}
\end{equation*}
$$

showing that in contrast to Eq. (40), at low frequencies $\sigma$ grows as fast as $\omega^{4}$.
Now let us explore the effect of such Rayleigh scattering ${ }^{17}$ on wave propagation in a gas, with relatively low density $n_{1}$. We can expect (and will prove in the next section) that due to the randomness of molecule positions, the waves scattered by each molecules may be treated as incoherent, so that the total scattering power may be calculated just as the sum of those scattered by each molecule. We can use this additivity to write the balance of the incident's wave intensity on a small volume $d V$ of length (along the incident wave direction) $d z$, and area $A$ in across it. Since such a segment includes $n d V=$ $n A d z$ molecules, and, according to definition (39), each of them scatters power $S \sigma=\mathcal{P} / A$, the total scattered power is $n$ Podz; hence the incident power's change is

$$
\begin{equation*}
d \mathcal{P} \equiv-n \sigma \mathcal{P} d z \tag{8.46}
\end{equation*}
$$

Comparing this equation with the general definition (7.202) of the attenuation constant, we see that scattering gives the following contribution to attenuation: $\alpha=n \sigma$. From here, using Eq. (3.41) to write $\alpha_{\mathrm{mol}}=\left(\varepsilon_{r}-1\right) / 4 \pi n$, and Eq. (45), we get

$$
\begin{equation*}
\alpha=\frac{k^{4}}{6 \pi n}\left(\varepsilon_{r}-1\right)^{2} . \tag{8.47}
\end{equation*}
$$

This is the famous Rayleigh scattering formula, which in particular explains the colors of blue sky and red sunsets. Indeed, through the visible light spectrum, $\omega$ changes almost two-fold; as a result, scattering of blue components of sunlight is an order of magnitude higher than that of its red components. More qualitatively, for air near the Earth surface, $\varepsilon_{r}-1 \approx 6 \times 10^{-4}$, and $n \sim 2.5 \times 10^{25} \mathrm{~m}^{-3}$ - see Sec. 3.3. Plugging these numbers into Eq. (47), we see that the characteristic length $\mathcal{L} \equiv 1 / \alpha$ of scattering is $\sim 30 \mathrm{~km}$ for blue light and $\sim 200 \mathrm{~km}$ for red light. ${ }^{18}$ The Earth atmosphere is thinner ( $h \sim 10$ km ), so that the Sun looks just a bit yellowish during most of the day. However, elementary geometry shows that on sunset, the light should pass length $l \sim\left(R_{\mathrm{E}} h\right)^{1 / 2} \approx 300 \mathrm{~km}$ to reach an Earth-surface observer; as a result, the blue components of Sun's light spectrum are almost completely scattered out, and even the red components are weakened considerably.

To conclude the discussion of Eq. (47), let me note that its comparison with the condition of the direct applicability of the Born approximation for a distributed object of size $a$ :

$$
\begin{equation*}
\alpha a \ll 1, \tag{8.48}
\end{equation*}
$$

[^365]implies, in particular, that if the electric polarizability of the material is small, $\varepsilon_{r} \rightarrow 1$, we may be able to use the approximation for an analysis of scattering by even relatively large objects, with size of the order of, or even larger than $\lambda$. However, for such extended objects, the phase difference factors (neglected above) step in, leading in particular to the important effects of interference and diffraction, to whose discussion we now proceed.

### 8.4. Interference and diffraction

These effects show up not as much in the total power of scattered radiation, as in its angular distribution. It is traditional to characterize this distribution by the differential cross-section defined as

$$
\begin{equation*}
\frac{d \sigma}{d \Omega} \equiv \frac{\bar{S}_{r} r^{2}}{\overline{S_{\text {incident }}}} \tag{8.49}
\end{equation*}
$$

Differential
crosssection: definition
where $r$ is the distance from the scatterer, at which the scattered wave is observed. Both the definition and notation become more clear if we notice that according to Eq. (26), at large distances ( $r \gg a$ ), the numerator in the right-hand part of Eq. (49), and hence the differential cross-section as the whole, does not depend on $r$, and that its integral over the total solid angle $\Omega=4 \pi$ coincides with the total crosssection defined by Eq. (39):

$$
\begin{equation*}
\oint_{4 \pi} \frac{d \sigma}{d \Omega} d \Omega=\frac{1}{\overline{S_{\text {incident }}}} r^{2} \oint_{4 \pi} \bar{S}_{r} d \Omega=\frac{1}{\overline{S_{\text {incident }}}} \oint_{r=\text { const }} \overline{S_{r}} d^{2} r=\frac{\overline{\mathcal{P}}}{\overline{S_{\text {incident }}}} \equiv \sigma . \tag{8.50}
\end{equation*}
$$

For example, according to Eq. (26), the angular distribution of radiation scattered by a point linear dipole, in the Born approximation, is rather broad; in particular, in the low-frequency limit (43),

$$
\begin{equation*}
\frac{d \sigma}{d \Omega}=k^{4} \alpha_{\mathrm{mol}}^{2} \sin ^{2} \theta \tag{8.51}
\end{equation*}
$$

If the wave is scattered by a small dielectric body, with a characteristic size $a \ll \lambda$ (i.e., $k a \ll 1$ ), then all its parts re-radiate the incident wave coherently. Hence, we can calculate it in the similar way, just replacing the molecular dipole moment (43) with the total dipole moment of the object - see Eq. (3.37):

$$
\begin{equation*}
\mathbf{p}=\mathbf{P} V=\left(\varepsilon_{r}-1\right) \varepsilon_{0} \mathbf{E} V, \tag{8.52}
\end{equation*}
$$

where $V \sim a^{3}$ is body's volume. As a result, the differential cross-section may be obtained from Eq. (51) with the replacement $\alpha_{\mathrm{mol}} \rightarrow V\left(\varepsilon_{r}-1\right) / 4 \pi$.

$$
\begin{equation*}
\frac{d \sigma}{d \Omega}=\frac{k^{4} V^{2}}{(4 \pi)^{2}}\left(\varepsilon_{r}-1\right)^{2} \sin ^{2} \theta, \tag{8.53}
\end{equation*}
$$

i.e. follows the same $\sin ^{2} \theta$ law. The situation for extended objects, with at least one dimension of the order, or larger than the wavelength, is different: here we have to take into account that the phase shifts introduced by various parts of the body are different. Let us analyze this issue for an arbitrary collection of similar point scatterers located at points $\mathbf{r}_{j}$.

If wave vector of the incident plane wave is $\mathbf{k}_{0}$, the field the wave has the phase factor $\exp \left\{i \mathbf{k}_{0} \cdot \mathbf{r}\right\}$ - see Eq. (7.79). At the location of $j$-th scattering center, the factor equals to $\exp \left\{i \mathbf{k}_{0} \cdot \mathbf{r}_{j}\right\}$, so that the local polarization vector $\mathbf{p}$, and the scattered wave it creates, are proportional to this factor. On
its way to the observation point $\mathbf{r}$, the scattered wave, with wave vector $\mathbf{k}$ (with $k=k_{0}$ ), acquires an additional phase factor $\exp \left\{i \mathbf{k} \cdot\left(\mathbf{r}-\mathbf{r}_{j}\right)\right\}$, so that the scattered wave field is proportional to

$$
\begin{equation*}
\exp \left\{i \mathbf{k}_{0} \cdot \mathbf{r}_{j}+i \mathbf{k}\left(\mathbf{r}-\mathbf{r}_{j}\right)\right\}=\exp \left\{i\left(\mathbf{k}_{0}-\mathbf{k}\right) \cdot \mathbf{r}_{j}+i \mathbf{k} \cdot \mathbf{r}\right\}=e^{i \mathbf{k} \cdot \mathbf{r}} \exp \left\{-i\left(\mathbf{k}-\mathbf{k}_{0}\right) \cdot \mathbf{r}_{j}\right\} \tag{8.54}
\end{equation*}
$$

Since the first factor in the last expression does not depend on $\mathbf{r}_{j}$, in order to calculate the total scattering wave, it is sufficient to sum up the elementary phase factors $\exp \left\{-\mathrm{i} \mathbf{q} \cdot \mathbf{r}_{j}\right\}$, where vector

$$
\begin{equation*}
\mathbf{q} \equiv \mathbf{k}-\mathbf{k}_{0} \tag{8.55}
\end{equation*}
$$

has the physical sense of the wave vector change at scattering. ${ }^{19}$ It may look like the phase factor depends on the choice of origin. However, according to Eq. (7.42), the average intensity of the scattered wave is proportional to $E_{\omega} E_{\omega}{ }^{*}$, i.e. to the following real scalar function of vector $\mathbf{q}$ :

Scattering function

$$
\begin{equation*}
F(\mathbf{q})=\left(\sum_{j} \exp \left\{-i \mathbf{q} \cdot \mathbf{r}_{j}\right\}\right)\left(\sum_{j^{\prime}} \exp \left\{-i \mathbf{q} \cdot \mathbf{r}_{j^{\prime}}\right\}\right)^{*}=\sum_{j, j^{\prime}} \exp \left\{i \mathbf{q} \cdot\left(\mathbf{r}_{j}-\mathbf{r}_{j^{\prime}}\right)\right\} \equiv|I(\mathbf{q})|^{2} \tag{8.56}
\end{equation*}
$$

where the complex function

$$
\begin{equation*}
I(\mathbf{q}) \equiv \sum_{j} \exp \left\{-i \mathbf{q} \cdot \mathbf{r}_{j}\right\} \tag{8.57}
\end{equation*}
$$

is called the phase sum, may be calculated within any reference frame, without affecting the final result (56). The double-sum form of Eq. (56) is convenient to notice that for a system of many ( $N \gg 1$ ) of similar but randomly located scatterers, only the terms with $j=j$ ' accumulate at summation, so that $F(\mathbf{q})$ scales as $N$, rather than $N^{2}$ - thus justifying the above treatment of the Rayleigh scattering problem.

Let us start using Eq. (56) by applying it to the simplest problem of just two similar small scatterers, separated by a fixed distance $a$ :

$$
\begin{equation*}
F(\mathbf{q})=\sum_{j, j^{\prime}=1}^{2} \exp \left\{i \mathbf{q} \cdot\left(\mathbf{r}_{j}-\mathbf{r}_{j^{\prime}}\right)\right\}=2+\exp \left\{-i q_{a} a\right\}+\exp \left\{i q_{a} a\right\}=2\left(1+\cos q_{a} a\right)=4 \cos ^{2} \frac{q_{a} a}{2} \tag{8.58}
\end{equation*}
$$

where $q_{a} \equiv \mathbf{q} \cdot \mathbf{a} / a$ is the component of vector $\mathbf{q}$ along vector a connecting the scatterers. The apparent simplicity of this result may be a bit misleading, because the mutual plane of vectors $\mathbf{k}$ and $\mathbf{k}_{0}$ (and hence of vector $\mathbf{q}$ ) does not necessarily coincide with the mutual plane of vectors $\mathbf{k}_{0}$ and $\mathbf{E}_{\omega}$, so that the scattering angle $\alpha$ between vectors $\mathbf{k}$ and $\mathbf{k}_{0}$ is generally different from ( $\pi / 2-\theta$ ) - see Fig. 5.

Fig. 8.5. Angles important for the general scattering problem.

[^366]Moreover, vectors $\mathbf{q}$ and a may have another common plane, and angle between them is one more parameter that may be considered as independent from both $\alpha$ and $\theta$. As a result, the angular dependence of the scattered wave's intensity (and hence $d \sigma / d \Omega$ ), that depends on all three angles, may be rather complex.

This is why let me consider only the simple case when vectors $\mathbf{k}, \mathbf{k}_{0}$, and $\mathbf{a}$ are all in the same plane (Fig. 6a), with $\mathbf{k}_{0}$ perpendicular to a (leaving the general analysis for readers' exercise). Then, with our choice of coordinates, $q_{a}=q_{x}=k \sin \alpha$, and Eq. (58) is reduced to

$$
\begin{equation*}
F(\mathbf{q})=4 \cos ^{2} \frac{k a \sin \alpha}{2} \tag{8.59}
\end{equation*}
$$

This function always has two maxima, at $\alpha=0$ and $\alpha=\pi$, and possibly (if the product ka is large enough) other maxima at special angles $\alpha_{n}$ that satisfy the famous Bragg condition ${ }^{20}$

$$
\begin{equation*}
k a \sin \alpha_{n}=2 \pi n, \quad \text { i.e. } a \sin \alpha_{n}=n \lambda . \tag{8.60}
\end{equation*}
$$

Fig. 8.6. The simplest geometries for (a) interference and (b) diffraction.

As evident from Fig. 6a, this condition may be readily understood as the in-phase addition (frequently called the constructive interference) of two coherent waves scattered by the two points, when the difference between their paths toward the observer, $a \sin \alpha$, equals to an integer number of wavelengths. At each such maximum, $F=4$, due to the doubling of the wave amplitude and hence quadrupling its power.

If the distance between the point scatterers is large ( $k a \gg 1$ ), the first Bragg maxima correspond to small angles, $\alpha \ll 1$. For this region, Eq. (59) in reduced to a simple sinusoidal dependence of function $F$ on angle $\alpha$. Moreover, within the range of small $\alpha$, the polarization factor $\sin ^{2} \theta$ is virtually constant, so that the scattered wave intensity, and hence the differential cross-section

$$
\begin{equation*}
\frac{d \sigma}{d \Omega} \propto F(\mathbf{q})=4 \cos ^{2} \frac{k a \alpha}{2} \tag{8.61}
\end{equation*}
$$

Young's interference pattern

This is of course the well-known interference pattern, well known from the Young's two-slit experiment. ${ }^{21}$ (As will be discussed in the next section, theoretical description of the two-slit experiment

[^367]is more complex than that of the Born scattering, but is preferable experimentally, because at scattering, the wave of intensity (61) has to be observed on the backdrop of a stronger incident wave that propagates in almost the same direction, $\alpha=0$.)

The Bragg condition (60) does not change at scattering from $N>2$ similar, equidistant scatterers, located along the same straight line (because the condition is applicable to each pair of adjacent scatterers), but the interference pattern changes. Leaving the analysis of the case of arbitrary $N$ for reader's exercise, let me jump to the limit $N \rightarrow 0$, in which we may ignore the scatterer discreteness. The resulting pattern is similar to that at scattering by a continuous thin rod, so let us first discuss the Born scattering by an arbitrary distributed object - say an extended dielectric body with a constant value of $\varepsilon_{r}$. Transferring Eq. (56) from the sum to an integral, for the differential cross-section we get

$$
\begin{equation*}
\frac{d \sigma}{d \Omega}=\frac{k^{4}}{(4 \pi)^{2}}\left(\varepsilon_{r}-1\right)^{2} F(\mathbf{q}) \sin ^{2} \theta=\frac{k^{4}}{(4 \pi)^{2}}\left(\varepsilon_{r}-1\right)^{2}|I(\mathbf{q})|^{2} \sin ^{2} \theta, \tag{8.62}
\end{equation*}
$$

where $I(\mathbf{q})$ now becomes the phase integral, ${ }^{22}$

> Phase integral

$$
\begin{equation*}
I(\mathbf{q})=\int_{V} \exp \left\{-i \mathbf{q} \cdot \mathbf{r}^{\prime}\right\} d^{3} r^{\prime} \tag{8.63}
\end{equation*}
$$

with the dimensionality of volume.
Now we may return to the particular case of a thin rod (with both dimensions of the crosssection's area much smaller than $\lambda$, but an arbitrary length $a$ ), otherwise keeping the same simple geometry as for two point scatterers - see Fig. 6b. In this case the phase integral is just

$$
\begin{equation*}
I(\mathbf{q})=A \int_{-a / 2}^{+a / 2} \exp \left\{-i q_{x} x^{\prime}\right) d x^{\prime}=A \frac{\exp \left\{-i q_{x} a / 2\right\}-\exp \left\{-i q_{x} a / 2\right\}}{-i q}=V \frac{\sin \xi}{\xi} \tag{8.64}
\end{equation*}
$$

where $V=A a$ is the volume of the rod, and $\xi$ is a dimensionless parameter defined as

$$
\begin{equation*}
\xi \equiv \frac{q_{x} a}{2}=\frac{k a \sin \alpha}{2} . \tag{8.65}
\end{equation*}
$$

The fraction participating in Eq. (64) is met in physics so frequently that is has deserved the special name sinc (not "sync", please!) function:

$$
\begin{equation*}
\operatorname{sinc} \xi \equiv \frac{\sin \xi}{\xi} \tag{8.66}
\end{equation*}
$$

Obviously, this function, plotted in Fig. 7, vanishes at all points $\xi_{n}=\pi n$, with integer $n$, besides point $n$ $=0: \operatorname{sinc} \xi_{0}=\operatorname{sinc} 0=1$.

[^368]

Fig. 8.7. Sinc function.

The function $F(\mathbf{q})=V^{2} \operatorname{sinc}^{2} \xi$, resulting from Eq. (64), is plotted by red line in Fig. 8, and is called the Fraunhofer diffraction pattern.

Fig. 8.8. The Fraunhofer diffraction pattern (solid red line) and its envelope $1 / \xi^{2}$ (dashed line). For comparison, the blue line shows the standard interference pattern $\cos ^{2} \xi$ - cf. Eq. (59).

Note that it oscillates with the same argument period $\Delta(k a \sin \alpha)=2 \pi / k a \ll 1$ as the interference pattern (59) from two point scatterers (shown with the blue line in Fig. 8). However, at the interference, the scattered wave intensity vanishes at angles $\alpha_{n}$ ' that satisfy condition

$$
\begin{equation*}
\frac{k a \sin \alpha_{n}^{\prime}}{2 \pi}=n+\frac{1}{2}, \tag{8.67}
\end{equation*}
$$

when the optical paths difference $a \sin \alpha$ equals to a semi-integer number of wavelengths $\lambda / 2=\pi / \mathrm{k}$, and hence the two waves from the scatterers arrive to the observer in anti-phase (the so-called destructive interference). On the other hand, for the diffraction from a continuous rod the minima occur at a different set of angles,

$$
\begin{equation*}
\frac{k a \sin \alpha_{n}}{2 \pi}=n \tag{8.68}
\end{equation*}
$$

i.e. exactly where the two-point interference pattern has its maxima. The reason for this relation is that the wave diffraction on the rod may be considered as a simultaneous interference of waves from all its fragments, and exactly at the observation angles when the rod edges give waves with phases shifted by $2 \pi n$, the interior point of the rod give waves with all possible phases, with their algebraic sum equal to
zero. Even more visibly in Fig. 8, at diffraction the intensity oscillations are limited by a rapidly decreasing envelope function $1 / \xi^{2}$. The reason for this fast decrease is that with each Fraunhofer diffraction period, a smaller and smaller fraction of the road gives an unbalanced contribution to the scattered wave.

If rod's length is small ( $k a \ll$ 1, i.e. $a \ll \lambda$ ), then sinc's argument $\xi$ is small at all scattering angles $\alpha$, so $I(\mathbf{q}) \approx V$, and Eq. (64) is reduced to Eq. (53). In the opposite limit, $a \gg \lambda$, the first zeros of function $I(\mathbf{q})$ correspond to very small angles $\alpha$, for which $\sin \theta \approx 1$, so that the differential crosssection is

$$
\begin{equation*}
\frac{d \sigma}{d \Omega}=\frac{k^{4} V^{2}}{(4 \pi)^{2}}\left(\varepsilon_{r}-1\right)^{2} \operatorname{sinc}^{2} \frac{k a \alpha}{2}, \tag{8.69}
\end{equation*}
$$

i.e. Fig. 8 shows the scattering intensity as a function of the diffraction direction - if the pattern is observed within the plane containing the rod.

### 8.5. The Huygens principle

The Born approximation allows tracing the basic features of (and the difference between) the phenomena of interference and diffraction. Unfortunately, this approximation, based on the relative weakness of the scattered wave, cannot be used for more popular experimental implementations of these phenomena, for example, the Young's two-slit experiment, or diffraction on a single slit or orifice - see, e.g. Fig. 9. Indeed, at such experiments, the orifice size $a$ is typically much larger than light's wavelength, and as a result, no clear decomposition of the fields to the incident and "scattered" waves is possible.

Fig. 8.9. Typical geometry for the Huygens principle application.

However, for such experiments, another approximation, called the Huygens (or "HuygensFresnel") principle, ${ }^{23}$ is very instrumental: the passed wave may be presented as a linear superposition of spherical waves of the type (17), as if they were emitted by every point of the orifice (or more physically, by every point of the incident wave's front that has arrived at the orifice). This approximation is valid if the following strong conditions are satisfied:

[^369]\[

$$
\begin{equation*}
\lambda \ll a \ll r \tag{8.70}
\end{equation*}
$$

\]

where $r$ is the distance of the observation point from the orifice. In addition, as we have seen in the last section, at small $\lambda / a$ the diffraction phenomena are confined to angles $\alpha \sim 1 / k a \sim \lambda / a \ll 1$. For observation at such small angles, the mathematical expression of the Huygens principle, for a complex amplitude $f_{\omega}(\mathbf{r})$ of a monochromatic wave $f(\mathbf{r}, t)=\operatorname{Re}\left[f_{\omega} e^{-i \omega t}\right]$, is given by the following simple formula

$$
\begin{equation*}
f_{\omega}(\mathbf{r})=C \int_{\text {orifice }} f_{\omega}\left(\mathbf{r}^{\prime}\right) \frac{e^{i k R}}{R} d^{2} r^{\prime} \tag{8.71}
\end{equation*}
$$

Here $f$ is any transverse component of any of wave's fields (either $\mathbf{E}$ or $\mathbf{H}$ ), ${ }^{24} R$ is the distance between point $\mathbf{r}^{\prime}$ at the orifice and the observation point $\mathbf{r}$ (i.e. the magnitude of vector $\mathbf{R} \equiv \mathbf{r}-\mathbf{r}$ '), and $C$ is a complex constant.

Before describing the proof of Eq. (71), let me carry out its sanity check - which also will give us the constant $C$. Let us see what happens if the field under the integral is the usual plane wave $f_{\omega}(z)$ propagating along axis $z$ (i.e. there is no opaque screen at all), so we should take the whole $x-y$ plane, say with $z^{\prime}=0$, as the integration area (Fig. 10).

Fig. 8.10. The Huygens principle applied to a plane wave.

Then, for the observation point with coordinates $x=0, y=0$, and $z \gg \lambda$, Eq. (71) yields

$$
\begin{equation*}
f_{\omega}(z)=C f_{\omega}(0) \int d x^{\prime} \int d y^{\prime} \frac{\exp \left\{i k\left(x^{\prime 2}+y^{\prime 2}+z^{2}\right)^{1 / 2}\right\}}{\left(x^{\prime 2}+y^{\prime 2}+z^{2}\right)^{1 / 2}} \tag{8.72}
\end{equation*}
$$

Before specifying the integration limits, let us consider the range $\left|x^{\prime}\right|,\left|y^{\prime}\right| \ll z$. In this range the square root, met in Eq. (72) twice, may be approximated as

$$
\begin{equation*}
\left(x^{\prime 2}+y^{\prime 2}+z^{2}\right)^{1 / 2}=z\left(1+\frac{x^{\prime 2}+y^{\prime 2}}{z^{2}}\right)^{1 / 2} \approx z\left(1+\frac{x^{\prime 2}+y^{\prime 2}}{2 z}\right)=z+\frac{x^{\prime 2}+y^{\prime 2}}{2 z} \tag{8.73}
\end{equation*}
$$

The denominator of Eq. (72) is a much slower function of $x^{\prime}$ and $y^{\prime}$ than the exponent, and in it (as we will check a posteriori), it is sufficient to keep just the main, first term of expansion (73). With that, Eq. (72) becomes

[^370]\[

$$
\begin{equation*}
f_{\omega}(z)=C f_{\omega}(0) \frac{e^{i k z}}{z} \int d x^{\prime} \int d y^{\prime} \exp \frac{i k\left(x^{\prime 2}+y^{\prime 2}\right)}{2 z}=C f_{\omega}(0) \frac{e^{i k z}}{z} I_{x} I_{y} \tag{8.74}
\end{equation*}
$$

\]

where $I_{x}$ and $I_{y}$ are two similar integrals; for example,

$$
\begin{equation*}
I_{x}=\int \exp \frac{i k x^{\prime 2}}{2 z} d x^{\prime}=\left(\frac{2 z}{k}\right)^{1 / 2} \int \exp \left\{i \xi^{2}\right\} d \xi=\left(\frac{2 z}{k}\right)^{1 / 2}\left[\int \cos \left(\xi^{2}\right) d \xi+i \int \sin \left(\xi^{2}\right) d \xi\right] \tag{8.75}
\end{equation*}
$$

where $\xi \equiv(k / 2 z)^{1 / 2} x^{\prime}$. These are the so-called Fresnel integrals. I will discuss them in more detail in the next section, and right now, only one property of these integrals is important for us: if taken in symmetric limits $\left[-\xi_{0},+\xi_{0}\right]$, both of them rapidly converge to the same value, $(\pi / 2)^{1 / 2}$, as soon as $\xi_{0}$ becomes much larger than 1.25 This means that even if we do not impose any exact limits on the integration area in Eq. (72), this integral converges to value

$$
\begin{equation*}
f_{\omega}(z)=C f_{\omega}(0) \frac{e^{i k z}}{z}\left\{\left(\frac{2 z}{k}\right)^{1 / 2}\left[\left(\frac{\pi}{2}\right)^{1 / 2}+i\left(\frac{\pi}{2}\right)^{1 / 2}\right]\right\}^{2}=\left(C \frac{2 \pi i}{k}\right) f_{\omega}(0) e^{i k z} \tag{8.76}
\end{equation*}
$$

due to contributions from the central area with linear size of the order of $\Delta \xi \sim 1$, i.e.

$$
\begin{equation*}
\Delta x \sim \Delta y \sim\left(\frac{z}{k}\right)^{1 / 2} \sim(\lambda z)^{1 / 2} \tag{8.77}
\end{equation*}
$$

so that the contribution by front points $\mathbf{r}$ ' well beyond the range (77) is negligible. ${ }^{26}$ (Within our assumptions (70), which in particular require $\lambda$ to be much less than $z$, the diffraction angle $\Delta x / z \sim \Delta y / z$ $\sim(\lambda / z)^{1 / 2}$, corresponding to the important area of the front, is small.) In order to sustain the plane wave propagation, $f_{\omega}(\mathrm{z})=f_{\omega}(0) e^{i k z}$, constant $C$ in Eq. (76) has to be taken equal to $k / 2 \pi i$. Thus, the Huygens principle's prediction (71), in its final form, reads

Huygens principle's expression

$$
\begin{equation*}
f_{\omega}(\mathbf{r})=\frac{k}{2 \pi i} \int_{\text {orifice }} f_{\omega}\left(\mathbf{r}^{\prime}\right) \frac{e^{i k R}}{R} d^{2} r^{\prime} \tag{8.78}
\end{equation*}
$$

and describes, in particular, the straight propagation of the plane wave (in a uniform media).
Let me pause to emphasize how nontrivial this result is. It would be a natural corollary of Eq. (25) (and the linear superposition principle) if all points of the orifice were filled with point scatterers that re-emit all the incident waves into spherical waves. However, as it follows from the above proof, the Huygens principle is also valid if there is nothing in the orifice but the free space!

This is why it is important a proof of the principle, ${ }^{27}$ based on the Green's theorem (2.207). Let us apply this theorem to function $f=f_{\omega}$, where $f_{\omega}$ is the complex amplitude of a scalar component of one of wave's fields, which satisfies the Helmholtz equation (7.192),

[^371]\[

$$
\begin{equation*}
\left(\nabla^{2}+k^{2}\right) f_{\omega}(\mathbf{r})=0 \tag{8.79}
\end{equation*}
$$

\]

and function $g=g_{\omega}$, which is the time Fourier image of the corresponding Green's function. It may be defined, as usual, as the solution to the same equation with the added delta-functional right-hand part with an arbitrary coefficient, for example,

$$
\begin{equation*}
\left(\nabla^{2}+k^{2}\right) g_{\omega}\left(\mathbf{r}, \mathbf{r}^{\prime}\right)=-4 \pi \delta\left(\mathbf{r}-\mathbf{r}^{\prime}\right) \tag{8.80}
\end{equation*}
$$

With Eqs. (79) and (80) used to express the Laplace operators of functions $f_{\omega}$ and $g_{\omega}$, Eq. (2.207) becomes

$$
\begin{equation*}
\int_{V}\left\{f_{\omega}\left[-k^{2} g_{\omega}\left(\mathbf{r}, \mathbf{r}^{\prime}\right)-4 \pi \delta\left(\mathbf{r}-\mathbf{r}^{\prime}\right)\right]-g_{\omega}\left(\mathbf{r}, \mathbf{r}^{\prime}\right)\left[-k^{2} f_{\omega}\right]\right\} d^{3} r=\oint_{S}\left[f_{\omega} \frac{\partial g_{\omega}\left(\mathbf{r}, \mathbf{r}^{\prime}\right)}{\partial n}-g_{\omega}\left(\mathbf{r}, \mathbf{r}^{\prime}\right) \frac{\partial f_{\omega}}{\partial n}\right] d^{2} r, \tag{8.81}
\end{equation*}
$$

where $\mathbf{n}$ is the outward normal to the surface $S$ limiting volume $V$. Two terms in the left-hand side of this relation cancel, so that after swapping $\mathbf{r}$ and $\mathbf{r}$ ' we get

$$
\begin{equation*}
-4 \pi f_{\omega}(\mathbf{r})=\oint_{S}\left[f_{\omega}\left(\mathbf{r}^{\prime}\right) \frac{\partial g_{\omega}\left(\mathbf{r}^{\prime}, \mathbf{r}\right)}{\partial n^{\prime}}-g_{\omega}\left(\mathbf{r}^{\prime}, \mathbf{r}\right) \frac{\partial f_{\omega}\left(\mathbf{r}^{\prime}\right)}{\partial n^{\prime}}\right] d^{2} r^{\prime} . \tag{8.82}
\end{equation*}
$$

This relation is only correct if the selected volume $V$ includes point $\mathbf{r}$ (otherwise we would not get its left-hand part from the integration of the delta-function), but does not include the genuine source of the wave (otherwise Eq. (79) would have a nonvanishing right-hand part). Let $\mathbf{r}$ be the field observation point, $V$ all the source-free half-space (for example, the half-space right of the screen in Fig. 9), so that $S$ is the surface of the screen, including the orifice. Then the right-hand part of Eq. (82) describes the field in the observation point $\mathbf{r}$ induced by the wave passing through the orifice points $\mathbf{r}$ '. Since no waves are emitted by the opaque parts of the screen, we can limit the integration by the orifice area. ${ }^{28}$ Assuming also that the opaque parts of the screen do not re-emit waves "radiated" by the orifice, we can take the solution of Eq. (80) to be the retarded potential for the free space: ${ }^{29}$

$$
\begin{equation*}
g_{\omega}\left(\mathbf{r}, \mathbf{r}^{\prime}\right)=\frac{e^{i k R}}{R} \tag{8.83}
\end{equation*}
$$

Plugging this expression into Eq. (82), we get

$$
\begin{equation*}
-4 \pi f_{\omega}(\mathbf{r})=\oint_{\text {orifice }}\left[f_{\omega}\left(\mathbf{r}^{\prime}\right) \frac{\partial}{\partial n^{\prime}}\left(\frac{e^{i k R}}{R}\right)-\left(\frac{e^{i k R}}{R}\right) \frac{\partial f_{\omega}\left(\mathbf{r}^{\prime}\right)}{\partial n^{\prime}}\right] d^{2} r^{\prime} \tag{8.84}
\end{equation*}
$$

This is the so-called Kirchhoff (or "Fresnel-Kirchhoff") integral. ${ }^{30}$ Now, let us make the two additional approximations. The first of them stems from Eq. (70): at $k a \gg 1$, the wave's spatial dependence in the orifice area may be presented as

[^372]\[

$$
\begin{equation*}
f_{\omega}\left(\mathbf{r}^{\prime}\right)=\left(\text { a slow function of } \mathbf{r}^{\prime}\right) \times \exp \left\{i \mathbf{k}_{0} \cdot \mathbf{r}^{\prime}\right\} \tag{8.85}
\end{equation*}
$$

\]

where "slow" means a function that changes on the scale of $a$ rather than $\lambda$. If, also, $k R \gg 1$, then the differentiation in Eq. (84) may be, in both instances, limited to the rapidly changing exponents, giving

$$
\begin{equation*}
-4 \pi f_{\omega}(\mathbf{r})=\oint_{A} i\left(\mathbf{k}+\mathbf{k}_{\mathbf{0}}\right) \cdot \mathbf{n}^{\prime} \frac{e^{i k R}}{R} f\left(\mathbf{r}^{\prime}\right) d^{2} r^{\prime}, \tag{8.86}
\end{equation*}
$$

Second, if all observation angles are small, we can take $\mathbf{k} \cdot \mathbf{n}^{\prime} \approx \mathbf{k}_{0} \cdot \mathbf{n}^{\prime} \approx-k$. With that, Eq. (86) is reduced to Eq. (78) expressing the Huygens principle.

It is clear that the principle immediately gives a very simple description of the interference of waves passing through two small holes in the screen. Indeed, if the hole size is negligible in comparison with distance $a$ between them (though still much larger than the wavelength!), Eq. (78) yields

$$
\begin{equation*}
f_{\omega}(\mathbf{r})=c_{1} e^{i k R_{1}}+c_{2} e^{i k R_{2}}, \quad \text { with } c_{1,2} \equiv \frac{k f_{1,2} A_{1,2}}{2 \pi i R_{1,2}} \tag{8.87}
\end{equation*}
$$

where $R_{1,2}$ are the distances between the holes and the observation point, and $A_{1,2}$ are the hole areas. For the interference wave intensity, Eq. (87) yields

$$
\begin{equation*}
\bar{S} \propto f_{\omega} f_{\omega}^{*}=\left|c_{1}\right|^{2}+\left|c_{2}\right|^{2}+2\left|c_{1}\right|\left|c_{2}\right| \cos \left[k\left(R_{1}-R_{2}\right)+\varphi\right], \quad \varphi \equiv \arg c_{1}-\arg c_{2} . \tag{8.88}
\end{equation*}
$$

The first two terms in this result clearly represent the intensities of partial waves passed through each hole, while the last one the result of their interference. The interference pattern's contrast ratio

$$
\begin{equation*}
R \equiv \frac{\bar{S}_{\max }}{\bar{S}_{\min }}=\left(\frac{\left|c_{1}\right|+\left|c_{2}\right|}{\left|c_{1}\right|-\left|c_{2}\right|}\right)^{2} \tag{8.89}
\end{equation*}
$$

is largest (infinite) when both waves have equal amplitudes.
The analysis of the interference pattern is simple if the line connecting the holes is perpendicular to wave vector $\mathbf{k} \approx \mathbf{k}_{0}-$ see Fig. 6a. Selecting the coordinate axes as shown in that figure, and using for distances $R_{1,2}$ the same expansion as in Eq. (73), for the interference term in Eq. (88) we get

$$
\begin{equation*}
\cos \left[k\left(R_{1}-R_{2}\right)+\varphi\right] \approx \cos \left(\frac{k x a}{z}+\varphi\right) . \tag{8.90}
\end{equation*}
$$

This means that the intensity does not depend on $y$, i.e. the interference pattern in the plane of constant $z$ presents straight, parallel strips, perpendicular to vector a, with the period given by Eq. (60), i.e. by the Bragg law. ${ }^{31}$ Note that this (somewhat counter-intuitive) result is strictly valid only at ( $x^{2}+y^{2}$ ) << z ${ }^{2}$; it is straightforward to use the next term in the Taylor expansion (73) to show that farther from the interference pattern center the strips start to diverge.

[^373]
### 8.6. Diffraction on a slit

Now let us use the Huygens principle to analyze a more complex problem: plane wave's diffraction on a long straight slit of constant width $a$ (Fig. 11).

Fig. 8.11. Diffraction on a slit.

According to Eq. (70), in order to use the Huygens principle for the problem analysis we need to have $\lambda \ll a \ll z$. Moreover, the simple formulation (78) of the principle is only valid for small observation angles, $|x| \ll z$. Note, however, that the relation between two small dimensionless numbers, $z / a$ and $a / \lambda$ is so far arbitrary; as we will see in a minute, this relation will determine the type of the observed diffraction pattern.

Let us apply Eq. (78) to our current problem (Fig. 11), for the sake of simplicity assuming the normal wave incidence, and taking $z=0$ at the screen plane:

$$
\begin{equation*}
f_{\omega}(x, z)=f_{0} \frac{k}{2 \pi i} \int_{-a}^{+a} d x^{\prime} \int_{-\infty}^{+\infty} d y^{\prime} \frac{\exp \left\{i k\left[\left(x-x^{\prime}\right)^{2}+y^{\prime 2}+z^{2}\right]^{1 / 2}\right\}}{\left[\left(x-x^{\prime}\right)^{2}+y^{\prime 2}+z^{2}\right]^{1 / 2}}, \tag{8.91}
\end{equation*}
$$

where $f_{0} \equiv f_{\omega}(x, 0)=$ const is the incident wave's amplitude. This is the same integral as in Eq. (72), except for the finite limits for $x^{\prime}$, and may be simplified similarly, using the small-angle condition ( $x-$ $\left.x^{\prime}\right)^{2}+y^{\prime 2} \ll z^{2}$ :

$$
\begin{equation*}
f(x, z) \approx f_{0} \frac{k}{2 \pi i} \frac{e^{i k z}}{z} \int_{-a / 2}^{+a / 2} d x^{\prime} \int_{-\infty}^{+\infty} d y^{\prime} \exp \frac{i k\left[\left(x-x^{\prime}\right)^{2}+y^{\prime 2}\right]}{2 z}=f_{0} \frac{k}{2 \pi i} \frac{e^{i k z}}{z} I_{x} I_{y} . \tag{8.92}
\end{equation*}
$$

The integral over $y$ is the same as in the last section:

$$
\begin{equation*}
I_{y} \equiv \int_{-\infty}^{+\infty} \exp \frac{i k y^{\prime 2}}{2 z} d y^{\prime}=\left(\frac{2 \pi i z}{k}\right)^{1 / 2} \tag{8.93}
\end{equation*}
$$

but the integral over $x$ is more complicated, because of its finite limits:

$$
\begin{equation*}
I_{x} \equiv \int_{-a / 2}^{+a / 2} \exp \frac{i k\left(x-x^{\prime}\right)^{2}}{2 z} d x^{\prime} \tag{8.94}
\end{equation*}
$$

It may be simplified in the following two (opposite) limits.
(i) Fraunhofer diffraction takes place when $z / a \gg a / \lambda$ - the relation which may be rewritten either as $a \ll(z \lambda)^{1 / 2}$, or as $k a^{2} \ll z$. In this limit the ratio $k x^{, 2} / z$ is negligibly small for all values of $x^{\prime}$ under the integral, and we can approximate it as

$$
\begin{align*}
I_{x} & =\int_{-a / 2}^{+a / 2} \exp \frac{i k\left(x^{2}-2 x x^{\prime}+x^{\prime 2}\right)}{2 z} d x^{\prime} \approx \int_{-a / 2}^{+a / 2} \exp \frac{i k\left(x^{2}-2 x x^{\prime}\right)}{2 z} d x^{\prime}  \tag{8.95}\\
& =\exp \frac{i k x^{2}}{2 z} \int_{-a / 2}^{+a / 2} \exp \left\{-\frac{i k x x^{\prime}}{z}\right\} d x^{\prime}=\frac{2 z}{k x} \exp \left\{\frac{i k x^{2}}{2 z}\right\} \sin \frac{k x a}{2 z},
\end{align*}
$$

so that Eq. (92) yields

$$
\begin{equation*}
f_{\omega}(x, z) \approx f_{0} \frac{k}{2 \pi i} \frac{e^{i k z}}{z} \frac{2 z}{k x}\left(\frac{2 \pi i z}{k}\right)^{1 / 2} \exp \left\{\frac{i k x^{2}}{2 z}\right\} \sin \frac{k x a}{2 z}, \tag{8.96}
\end{equation*}
$$

and hence the relative wave intensity is

Fraunhofer diffraction pattern

$$
\begin{equation*}
\frac{\bar{S}(x, z)}{S_{0}}=\left|\frac{f_{\omega}(x, z)}{f_{0}}\right|^{2}=\frac{8 z}{\pi k x^{2}} \sin ^{2} \frac{k x a}{2 z}=\frac{2}{\pi} \frac{k a^{2}}{z} \operatorname{sinc}^{2}\left(\frac{k a \alpha}{2}\right), \tag{8.97}
\end{equation*}
$$

where $S_{0}$ is the (average) intensity of the incident wave, and $\alpha \equiv x / z \ll 1$ is the scattering angle. Comparing this expression with Eq. (69), we see that this the diffraction pattern is exactly the same as that of a similar (uniform, 1D) object in the Born approximation - see the red line in Fig. 8. Note again that the angular width $\delta \alpha$ of the Fraunhofer pattern is of the order of $1 / k a$, so that its linear width $\delta x=$ $z \delta \alpha \sim z / k a \sim z \lambda / a .{ }^{32}$ Hence the condition of the Fraunhofer approximation validity may be also presented as $a \ll \delta x$.
(ii) Fresnel diffraction. In the opposite limit of a relatively wide slit, with $a \gg \delta x=z \delta \alpha \sim z / k a \sim$ $z \lambda / a$, i.e. $k a^{2} \gg z$, the diffraction patterns at two slit edges are well separated. Hence, near each edge (for example, near $x^{\prime}=-a / 2$ ) we may simplify Eq. (94) as

$$
\begin{equation*}
I_{x}(x) \approx \int_{-a / 2}^{+\infty} \exp \frac{i k\left(x-x^{\prime}\right)^{2}}{2 z} d x^{\prime}=\left(\frac{2 z}{k}\right)^{1 / 2} \int_{(k / 2 z)^{1 / 2}(x+a / 2)}^{+\infty} \exp \left\{i \zeta^{2}\right\} d \zeta \tag{8.98}
\end{equation*}
$$

and express it via the special functions called the Fresnel integrals: ${ }^{33}$

Fresnel
integrals

$$
\begin{equation*}
\ell(\xi) \equiv\left(\frac{2}{\pi}\right)^{1 / 2} \int_{0}^{\xi} \cos \left(\zeta^{2}\right) d \zeta, \quad S(\xi) \equiv\left(\frac{2}{\pi}\right)^{1 / 2} \int_{0}^{\xi} \sin \left(\zeta^{2}\right) d \zeta, \tag{8.99}
\end{equation*}
$$

whose plots are shown in Fig. 12. As was mentioned above, at large values of their argument ( $\xi$ ), both functions tend to $1 / 2$.

[^374]

Fig. 8. 12. Fresnel integrals.

Plugging this expression into Eq. (92) and (98), for the diffracted wave intensity, in the Fresnel limit (i.e. at $|x+a / 2| \ll a$ ), we get

$$
\begin{equation*}
\frac{\bar{S}(x, z)}{S_{0}}=\frac{1}{2}\left\{\left[C\left(\left(\frac{k}{2 z}\right)^{1 / 2}\left(x+\frac{a}{2}\right)\right)+\frac{1}{2}\right]^{2}+\left[S\left(\left(\frac{k}{2 z}\right)^{1 / 2}\left(x+\frac{a}{2}\right)\right)+\frac{1}{2}\right]^{2}\right\} \tag{8.100}
\end{equation*}
$$

A plot of this function (Fig. 13) shows that the diffraction pattern is very peculiar: while in the "shade" region $x<-a / 2$ the wave intensity fades monotonically, the transition to the "light" region within the gap ( $x>-a / 2$ ) is accompanied by intensity oscillations, just as at the Fraunhofer diffraction - cf. Fig. 8.

Fig. 8.13. Fresnel diffraction pattern.

This behavior, which is described by the following asymptotes,

$$
\frac{\bar{S}}{S_{0}} \rightarrow\left\{\begin{array}{cc}
1+\frac{1}{\sqrt{\pi}} \frac{\sin \left(\xi^{2}-\pi / 4\right)}{\xi}, & \text { for } \xi \equiv\left(\frac{k}{2 z}\right)^{1 / 2}\left(x+\frac{a}{2}\right) \rightarrow+\infty  \tag{8.101}\\
\frac{1}{4 \pi \xi^{2}}, & \text { for } \xi \rightarrow-\infty
\end{array}\right.
$$

is essentially an artifact of observing just the wave intensity (i.e. its real amplitude) rather than its phase as well. Indeed, as may be seen even more clearly from the parametric presentation of the Fresnel
integrals (Fig. 14), these functions oscillate similarly at large positive and negative values of their argument. Physically, this means that the wave diffraction by the slit edge leads to similar oscillations of its phase at $x<-a / 2$ and $x>-a / 2$; however, in the latter region (i.e. inside the slit) the diffracted wave overlaps the incident wave passing through the slit directly, and their interference reveals the phase oscillations, making them visible in the measured intensity as well.

Fig. 8.14. Parametric representation of the Fresnel integrals. This pattern is called either the Euler spiral or Cornu spiral.

Note that according to Eq. (100), the linear scale of the Fresnel diffraction pattern is $(2 z / k)^{1 / 2}$, i.e. is complied with estimate (77). If the slit is gradually narrowed, so that width $a$ becomes comparable to that scale, ${ }^{34}$ the Fresnel interference patterns from both edges start to "collide" (interfere). The resulting wave, fully described by Eq. (94), is just a sum of two contributions of the type (98) from the both edges of the slit. The resulting interference pattern is somewhat complicated, and only $a \ll \delta x$ it is reduced to the simple Fraunhofer pattern (97). Of course, this crossover from the Fresnel to Fraunhofer diffraction may be also observed, at fixed wavelength $\lambda$ and slit width $a$, by increasing $z$, i.e. by measuring the diffraction pattern farther and farther from the slit.

Note that the Fraunhofer limit is always valid if the diffraction measured as a function of the diffraction angle $\alpha$ alone, i.e. effectively at infinity, $z \rightarrow \infty$. This may be done, for example, by collecting the diffracted wave with a "positive" (converging) lense, and observing the diffraction pattern in its focal plane.

### 8.7. Geometrical optics placeholder

Behind all these details, I would not like the reader to miss the main feature of diffraction, that has an overwhelming practical significance. Namely, besides narrow diffraction "cones" (actually, parabolic-shaped regions) with lateral scale $\Delta x \sim(\lambda z)^{1 / 2}$, the wave far behind a slit of width $a \gg \lambda$ repeats the field just behind the slit, i.e. reproduces the unperturbed incident wave inside the slit, and has negligible intensity in the shade regions outside it. An evident generalization of this fact is that when a plane wave (in particular an electromagnetic wave) passes any opaque object of large size $a \gg \lambda$, it propagates around it, by distances $z$ up to $\sim a^{2} / \lambda$, along straight lines, with virtually negligible diffraction

[^375]effects. This fact gives the strict foundation for the very notion of the wave ray (or beam), as the line perpendicular to the local front of a quasi-plane wave. In a uniform media such ray is a straight line, but changes in accordance with the Snell law at the interface of two media with different wave speed $v$, i.e. different values of the refraction index. The notion of rays enables the whole field of geometric optics, devoted mostly to ray tracing in various (sometimes very complex) systems.

This is why, at this point, an E\&M course that followed the scientific logic more faithfully than this one, would give an extended discussion of the geometric and quasi-geometric optics, including (as a minimum ${ }^{35}$ ) such vital topics as

- the so-called lensmaker's equation expressing the focus length $f$ of a lens via the curvature radii of its spherical surfaces and the refraction index of the lens material,
- the thin lens formula relating the image distance from the lens via $f$ and the source distance,
- the concepts of basic optical instruments such as telescopes and microscopes,
- the concepts of the spherical, angular, and chromatic aberrations (image distortions);
- wave effects in optical instruments, including the so-called Abbe limit ${ }^{36}$ on the focal spot size. ${ }^{37}$

However, since I have made a (possibly, wrong) decision to follow the common tradition in selecting the main topics for this course, I do not have time left for such discussion. Still, I am placing this "placeholder" pseudo-section to relay my conviction that any educated physicist has to know the geometric optics basics. If the reader has not had an exposure to this subject during his or her undergraduate studies, I highly recommend at least browsing one of available textbooks. ${ }^{38}$

### 8.8. Fraunhofer diffraction from more complex scatterers

So far, our discussion of diffraction has been limited to a very simple geometry - a single slit in an otherwise opaque screen (Fig. 11). However, in the most important Fraunhofer limit, $z \gg k a^{2}$, it is easy to get a very simple expression for the plane wave diffraction/interference by a plane orifice (with linear size $\sim a$ ) of an arbitrary shape. Indeed, the evident 2D generalization of approximation (93)-(94) is

$$
\begin{align*}
I_{x} I_{y} & =\int_{\text {orifice }} \exp \frac{i k\left[\left(x-x^{\prime}\right)^{2}+\left(y-y^{\prime}\right)^{2}\right]}{2 z} d x^{\prime} d y^{\prime} \\
& \approx \exp \left\{\frac{i k\left(x^{2}+y^{2}\right)}{2 z}\right\} \int_{\text {orifice }} \exp \left\{-i \frac{k x x^{\prime}}{z}-i \frac{k y y^{\prime}}{z}\right\} d x^{\prime} d y^{\prime} \tag{8.102}
\end{align*}
$$

${ }^{35}$ Admittedly, even this list leaves aside several spectacular effects due to crystal anisotropy, including such a beauty as conical refraction in biaxial crystals - see, e.g., Chapter 15 of the classical textbook by M. Born and E. Wolf, cited in the end of Sec. 7.1.
${ }^{36}$ Reportedly, due to not only E. Abbe (1873), but also to H. von Helmholtz (1874).
${ }^{37}$ In contrast to other topics of this list, whose study may be based on the ray approach, i.e. on purely geometric optics, the description of these effects requires at least an approximate account of wave properties of light. Such account may be based either on the Huygens principle or on the so-called paraxial equation

$$
\partial a / \partial z=(1 / 2 i k) \nabla_{x, y}^{2} a,
$$

for the complex amplitude $a(\mathbf{r})$ of the field represented in the form $f(\mathbf{r})=a(\mathbf{r}) e^{i k z}$. The paraxial approximation follows from the Helmholtz equation (7.192) in essentially the same limit $(|\nabla a| \ll k ;|x|,|y| \ll z)$ as Eq. (78).
${ }^{38}$ My top recommendation for that purpose would be Chapters 3-6 and Sec. 8.6 in Born and Wolf. A simpler alternative is Chapter 10 in G. R. Fowles, Introduction to Modern Optics, $2^{\text {nd }}$ ed., Dover, 1989.
so that besides the inconsequential total phase factor, Eq. (92) is reduced to

$$
\begin{equation*}
f(\boldsymbol{\rho}) \propto f_{0} \int_{\text {orifice }} \exp \left\{-\mathbf{i} \mathbf{\kappa} \cdot \boldsymbol{\rho}^{\prime}\right\} d^{2} \rho^{\prime}=f_{0} \int_{\text {screen }} T\left(\boldsymbol{\rho}^{\prime}\right) \exp \left\{-\mathbf{i} \mathbf{\kappa} \cdot \boldsymbol{\rho}^{\prime}\right\} d^{2} \rho^{\prime} \tag{8.103}
\end{equation*}
$$

where the 2 D vector $\kappa$ (not to be confused with wave vector $\mathbf{k}$ that is virtually perpendicular to $\kappa!$ ) is defined as

$$
\begin{equation*}
\boldsymbol{\kappa} \equiv k \frac{\mathbf{\rho}}{Z} \approx \mathbf{q} \equiv \mathbf{k}-\mathbf{k}_{0}, \tag{8.104}
\end{equation*}
$$

$\rho=\{x, y\}$ and $\rho^{\prime}=\left\{x^{\prime}, y^{\prime}\right\}$ are 2D radius-vectors in, respectively, the observation and screen planes (both nearly normal to vectors $\mathbf{k}$ and $\mathbf{k}_{0}$ ), function $T\left(\rho^{\prime}\right)$ describes screen's transparency at point $\rho^{\prime}$, and the last integral in Eq. (103) is over the whole screen plane $z^{\prime}=0$. (Though the strict equivalence of the two forms of Eq. (103) is only valid if $T\left(\rho^{\prime}\right)$ equals to either 1 or 0 , its last form may be readily obtained from Eq. (78) with $f\left(\mathbf{r}^{\prime}\right)=T\left(\rho^{\prime}\right) f_{0}$ for any transparency profile, provided that $T\left(\rho^{\prime}\right)$ is an arbitrary function but changes only at distances much larger than $\lambda \equiv 2 \pi / k$.)

From the mathematical point of view, the last form of Eq. (103) is the 2D spatial Fourier transform of function $T\left(\rho^{\prime}\right)$, with the reciprocal variable $\kappa$ revealed by the observation point position: $\rho$ $=(z / k) \kappa=(z \lambda / 2 \pi) \kappa$. This interpretation is useful because of the experience we all have with the Fourier transform, mostly in the context of its time/frequency applications. For example, if the orifice is a single small hole, $T(\rho$ ') may be approximated by a delta-function, so that Eq. (103) yields $f(\rho) \approx$ const. This corresponds (at least for the small diffraction angles $\alpha \equiv \rho / z$, for which the Huygens approximation is valid) to a spherical wave spreading from the point-like orifice. Next, for two small holes, Eq. (103) immediately gives the Young interference pattern (90). Let me now use Eq. (103) to analyze the simplest (and most important) 1D transparency profiles, leaving 2D cases for reader's exercise.
(i) A single slit of width $a$ (Fig. 11) may be described by transparency

$$
T\left(\boldsymbol{\rho}^{\prime}\right)=\left\{\begin{array}{lr}
1, & \text { for }\left|x^{\prime}\right|<a / 2  \tag{8.105}\\
0, & \text { otherwise }
\end{array}\right.
$$

Its substitution into Eq. (103) yields

$$
\begin{equation*}
f(\boldsymbol{\rho}) \propto f_{0} \int_{-a / 2}^{+a / 2} \exp \left\{-i \kappa_{x} x^{\prime}\right\} d x^{\prime}=f_{0} \frac{\exp \left\{-i \kappa_{x} a / 2\right\}-\exp \left\{i \kappa_{x} a / 2\right\}}{-i \kappa_{x}} \propto \operatorname{sinc}\left(\frac{\kappa_{x} a}{2}\right)=\operatorname{sinc}\left(\frac{k x a}{2 z}\right), \tag{8.106}
\end{equation*}
$$

naturally returning us to Eqs. (64) and (97), and hence to the red lines in Fig. 8 for the wave intensity. (Please note again that Eq. (103) describes only the Fraunhofer, but not the Fresnel diffraction!)
(ii) Two narrow similar, parallel slits with a much larger distance $a$ between them, may be described by taking

$$
\begin{equation*}
T\left(\boldsymbol{\rho}^{\prime}\right) \propto \delta\left(x^{\prime}-a / 2\right)+\delta\left(x^{\prime}+a / 2\right) \tag{8.107}
\end{equation*}
$$

so that Eq. (103) yields the generic interference pattern,

$$
\begin{equation*}
f(\boldsymbol{\rho}) \propto f_{0}\left[\exp \left\{-\frac{i \kappa_{x} a}{2}\right\}+\exp \left\{\frac{i \kappa_{x} a}{2}\right\}\right] \propto \cos \frac{\kappa_{x} a}{2}=\cos \frac{k x a}{2 z}, \tag{8.108}
\end{equation*}
$$

whose intensity is shown with the blue line in Fig. 8.
(iii) In a more realistic Young-type two-slit experiment, each slit has width (say, w) which is much larger than light wavelength $\lambda$, but still much smaller than slit spacing $a$. This situation may be described by the following transparency function

$$
T\left(\boldsymbol{\rho}^{\prime}\right)=\sum_{ \pm}\left\{\begin{array}{lr}
1, & \text { for }\left|x^{\prime} \pm a / 2\right|<w / 2  \tag{8.109}\\
0, & \text { otherwise },
\end{array}\right.
$$

for which Eq. (103) yields a natural combination of results (106) (with a replaced with $w$ ) and (108):

$$
\begin{equation*}
f(\mathbf{r}) \propto \operatorname{sinc}\left(\frac{k x w}{2 z}\right) \cos \left(\frac{k x a}{2 z}\right) . \tag{8.110}
\end{equation*}
$$

This is the usual interference pattern modulated by a Fraunhofer-diffraction envelope (shown with the dashed blue line Fig. 15). Since function $\operatorname{sinc}^{2} \xi$ decreases very fast beyond its first zeros at $\xi= \pm \pi$, the practical number of observable interference fringes is close to $2 a / w$.

Fig. 8.15. Young's double-slit interference pattern for a finite slit width.
(iv) A structure very useful for experimental and engineering practice is a set of many parallel slits, called the diffraction grating. ${ }^{39}$ Indeed, if the slit width is much less than the grating period $d$, then the transparency function may be approximated as

$$
\begin{equation*}
T\left(\boldsymbol{\rho}^{\prime}\right) \propto \sum_{n=-\infty}^{+\infty} \delta\left(x^{\prime}-n d\right) \tag{8.111}
\end{equation*}
$$

and Eq. (103) yields

$$
\begin{equation*}
f(\boldsymbol{\rho}) \propto \sum_{n=-\infty}^{n=+\infty} \exp \left\{-i n \kappa_{x} d\right\}=\sum_{n=-\infty}^{n=+\infty} \exp \left\{-i \frac{n k x d}{z}\right\} . \tag{8.112}
\end{equation*}
$$

This sum vanishes for all values of $\kappa_{x} d$ that are not multiples of $2 \pi$, so that the result describes sharp intensity peaks at diffraction angles

[^376]\[

$$
\begin{equation*}
\alpha_{m} \equiv\left(\frac{x}{z}\right)_{m}=\left(\frac{\kappa_{x}}{k}\right)_{m}=\frac{2 \pi}{k d} m=\frac{\lambda}{d} m . \tag{8.113}
\end{equation*}
$$

\]

Taking into account that this result is only valid for small angles $\left|\alpha_{m}\right| \ll 1$, it may be interpreted exactly as Eq. (59) - see Fig. 6a. However, in contrast with the interference (108) from two slits, the destructive interference from many slits kills the net wave as soon as the angle is even slightly different from each Bragg angle (60). This is very convenient for spectroscopic purposes, because the diffraction lines produced by multi-frequency waves do not overlap even if the frequencies of their adjacent components are very close.

Two features of practical diffraction gratings make their properties different from this simple picture. First, the finite number $N$ of slits, which may be described by limiting sum (112) to interval $n=$ $[-N / 2,+N / 2]$, results in the finite spread, $\delta \alpha / \alpha \sim 1 / N$, of each diffraction peak, and hence in the reduction of grating's spectral resolution. (Unintentional variations of the inter-slit distance $d$ have a similar effect, so that before the advent of high-resolution photolithography, special high-precision mechanical tools have been used for grating fabrication.)

Second, the finite slit width $w$ leads to the diffraction peak pattern modulation by a $\operatorname{sinc}^{2}(k w \alpha / 2)$ envelope, similarly to pattern shown in Fig. 15. Actually, for spectroscopic purposes such modulation is a plus, because only one diffraction peak (say, with $m= \pm 1$ ) is practically used, and if the frequency spectrum of the analyzed wave is very broad (cover more than one octave), the higher peaks produce undesirable hindrance. Because of this reason, $w$ is frequently selected to be equal exactly to $d / 2$, thus suppressing each other diffraction maximum. Moreover, sometimes semi-transparent films are used to make the transparency function $T\left(\mathbf{r}^{\prime}\right)$ continuous and close to the sinusoidal one:

$$
\begin{equation*}
T\left(\boldsymbol{\rho}^{\prime}\right) \approx T_{0}+T_{1} \cos \frac{2 \pi x^{\prime}}{d}=T_{0}+\frac{T_{1}}{2}\left(\exp \left\{i \frac{2 \pi x^{\prime}}{d}\right\}+\exp \left\{-i \frac{2 \pi x^{\prime}}{d}\right\}\right) \tag{8.114}
\end{equation*}
$$

Plugging the last expression into Eq. (103) and integrating, we see that the output wave consists of just 3 components: the direct-passing wave (proportional to $T_{0}$ ) and two diffracted waves (proportional to $T_{1}$ ) propagating in the directions of the two lowest Bragg angles, $\alpha_{ \pm 1}= \pm \lambda / d$.

Relation (103) may be also readily used to obtain one more general (and rather curious) result called the Babinet principle. Consider two experiments with diffraction of similar plane waves on two "complementary" screens who together would cover the whole plane, without a hole or an overlap. (Think, for example, about an opaque disk of radius $R$ and a large opaque screen with a round orifice of the same radius.) Then, according to the Babinet principle, the diffracted wave patterns produced by these two screens in all directions with $\alpha \neq 0$ are identical. The proof of this principle is straightforward: since the transparency functions produced by the screens are complementary in the following sense:

$$
\begin{equation*}
T\left(\boldsymbol{\rho}^{\prime}\right) \equiv T_{1}\left(\boldsymbol{\rho}^{\prime}\right)+T_{2}\left(\boldsymbol{\rho}^{\prime}\right)=1, \tag{8.115}
\end{equation*}
$$

and (in the Fraunhofer approximation (103) only!) the diffracted wave is a linear Fourier transform of $T\left(\rho^{\prime}\right)$, we get

$$
\begin{equation*}
f_{1}(\boldsymbol{\rho})+f_{2}(\boldsymbol{\rho})=f_{0}(\boldsymbol{p}) \tag{8.116}
\end{equation*}
$$

where $f_{0}$ is the wave "scattered" by the composite screen with $T_{0}(\rho$ ' $) \equiv 1$, i.e. the unperturbed initial wave propagating in the initial direction $(\alpha=0)$. In all other directions, $f_{1}=-f_{2}$, i.e. the diffracted waves
are indeed similar besides the difference in sign - which is equivalent to a phase shift by $\pm \pi$. However, it is important to remember that the Babinet principle notwithstanding, in real experiments the diffracted waves may interfere with the unperturbed plane wave $f_{0}(\rho)$, leading to different diffraction pattern in cases 1 and $2-$ see, e.g., Fig. 13 and its discussion.

### 8.9. Magnetic dipole and electric quadrupole radiation

Throughout this chapter, we have seen how many important results may be obtained from Eq. (26) for the electric dipole radiation by a small-size source (Fig. 1). Only in rare cases when such radiation is absent, for example if the dipole moment $\mathbf{p}$ of the source equals zero (or does not change at time - either at all, or at the frequency of our interest), higher-order effects may be important. I will discuss the main two of them, the quadrupole electric and dipole magnetic radiation - mostly for reference purposes, because we would not have much time to discuss their applications.

In Sec. 2 above, the electric dipole radiation was calculated by plugging the first, leading term of expansion (19) into the exact formula (17b) for the retarded vector-potential $\mathbf{A}(\mathbf{r}, t)$. Let us make a more exact calculation, by keeping the second term of that expansion as well:

$$
\begin{equation*}
\mathbf{j}\left(\mathbf{r}^{\prime}, t-\frac{R}{v}\right) \approx \mathbf{j}\left(\mathbf{r}^{\prime}, t-\frac{r}{v}+\frac{\mathbf{r}^{\prime} \cdot \mathbf{n}}{v}\right)=\mathbf{j}\left(\mathbf{r}^{\prime}, t^{\prime}+\frac{\mathbf{r}^{\prime} \cdot \mathbf{n}}{v}\right), \quad \text { where } \quad t^{\prime} \equiv t-\frac{r}{v} . \tag{8.117}
\end{equation*}
$$

Since this expansion is only valid if the last term in the second argument is relatively small, in the Taylor expansion of $\mathbf{j}$ with respect to that argument we may keep just the first two leading terms:

$$
\begin{equation*}
\mathbf{j}\left(\mathbf{r}^{\prime}, t^{\prime}+\frac{\mathbf{r}^{\prime} \cdot \mathbf{n}}{v}\right) \approx \mathbf{j}\left(\mathbf{r}^{\prime}, t^{\prime}\right)+\frac{1}{v} \frac{\partial}{\partial t^{\prime}} \mathbf{j}\left(\mathbf{r}^{\prime}, t^{\prime}\right)\left(\mathbf{r}^{\prime} \cdot \mathbf{n}\right) \tag{8.118}
\end{equation*}
$$

so that Eq. (17b) yields $\mathbf{A}=\mathbf{A}_{e}+\mathbf{A}^{\prime}$, where $\mathbf{A}_{e}$ is the electric dipole contribution as given by Eq. (23), and $\mathbf{A}^{\prime}$ is the new term of the next order in small parameter $r^{\prime} \ll r$ :

$$
\begin{equation*}
\mathbf{A}^{\prime}(\mathbf{r}, t)=\frac{\mu}{4 \pi r v} \frac{\partial}{\partial t^{\prime}} \int \mathbf{j}\left(\mathbf{r}^{\prime}, t^{\prime}\right)\left(\mathbf{r}^{\prime} \cdot \mathbf{n}\right) d^{3} r^{\prime} \tag{8.119}
\end{equation*}
$$

Just as was done in Sec. 2, let us evaluate this term for a system of non-relativistic particles with electric charges $q_{k}$ and radius-vectors $\mathbf{r}_{k}(t)$ :

$$
\begin{equation*}
\mathbf{A}^{\prime}(\mathbf{r}, t)=\frac{\mu}{4 \pi r v}\left[\frac{d}{d t} \sum_{k} q_{k} \dot{\mathbf{r}}_{k}\left(\mathbf{r}_{k} \cdot \mathbf{n}\right)\right]_{t=t^{\prime}} \tag{8.120}
\end{equation*}
$$

Using the "bac minus cab" identity of the vector algebra again, ${ }^{40}$ Eq. (120) may be rewritten as

$$
\begin{align*}
\dot{\mathbf{r}}_{k}\left(\mathbf{r}_{k} \cdot \mathbf{n}\right) & =\frac{1}{2} \dot{\mathbf{r}}_{k}\left(\mathbf{r}_{k} \cdot \mathbf{n}\right)+\frac{1}{2} \dot{\mathbf{r}}_{k}\left(\mathbf{n} \cdot \mathbf{r}_{k}\right)=\frac{1}{2}\left(\mathbf{r}_{k} \times \dot{\mathbf{r}}_{k}\right) \times \mathbf{n}+\frac{1}{2} \mathbf{r}_{k}\left(\mathbf{n} \cdot \dot{\mathbf{r}}_{k}\right)+\frac{1}{2} \dot{\mathbf{r}}_{k}\left(\mathbf{n} \cdot \mathbf{r}_{k}\right) \\
& =\frac{1}{2}\left(\mathbf{r}_{k} \times \dot{\mathbf{r}}_{k}\right) \times \mathbf{n}+\frac{1}{2} \frac{d}{d t}\left[\mathbf{r}_{k}\left(\mathbf{n} \cdot \mathbf{r}_{k}\right)\right], \tag{8.121}
\end{align*}
$$

so that the right-hand part of Eq. (120) may be presented as a sum of two terms, $\mathbf{A}^{\prime}=\mathbf{A}_{m}+\mathbf{A}_{q}$, where

[^377]\[

$$
\begin{gather*}
\mathbf{A}_{m}(\mathbf{r}, t)=\frac{\mu}{4 \pi r v} \dot{\mathbf{m}}\left(t^{\prime}\right) \times \mathbf{n}=\frac{\mu}{4 \pi r v} \dot{\mathbf{m}}\left(t-\frac{r}{v}\right) \times \mathbf{n}, \quad \text { with } \mathbf{m}(t) \equiv \frac{1}{2} \sum_{k} \mathbf{r}_{k}(t) \times q_{k} \dot{\mathbf{r}}_{k}(t),  \tag{8.122}\\
\mathbf{A}_{q}(\mathbf{r}, t)=\frac{\mu}{8 \pi r v}\left[\frac{d^{2}}{d t^{2}} \sum_{k} q_{k} \mathbf{r}_{k}\left(\mathbf{n} \cdot \mathbf{r}_{k}\right)\right]_{t=t^{\prime}} \tag{8.123}
\end{gather*}
$$
\]

Comparing the second of Eqs. (122) with Eq. (5.91), we see that $\mathbf{m}$ is just the magnetic moment of the source. On the other hand, the first of Eqs. (122) is absolutely similar in structure to Eq. (23), with $\mathbf{p}$ replaced by $(\mathbf{m} \times \mathbf{n}) / v$, so that for the corresponding component of the magnetic field it gives (in the same approximation $r \gg \lambda$ ) the result similar to Eq. (24):

$$
\begin{equation*}
\mathbf{B}_{m}(\mathbf{r}, t)=\frac{\mu}{4 \pi r v} \nabla \times\left[\dot{\mathbf{m}}\left(t-\frac{r}{v}\right) \times \mathbf{n}\right]=-\frac{\mu}{4 \pi r v^{2}} \mathbf{n} \times\left[\ddot{\mathbf{m}}\left(t-\frac{r}{v}\right) \times \mathbf{n}\right] . \tag{8.124}
\end{equation*}
$$

According to this expression, just as at the electric dipole radiation, vector $\mathbf{B}$ is perpendicular to vector $\mathbf{n}$, and its magnitude is also proportional to the $\sin \theta$, where $\theta$ is now the angle between the direction toward the observation point and the second time derivative of vector $\mathbf{m}$ rather than $\mathbf{p}$ :

$$
\begin{equation*}
B_{m}=\frac{\mu}{4 \pi r v^{2}} \ddot{m}\left(t-\frac{r}{v}\right) \sin \theta . \tag{8.125}
\end{equation*}
$$

As the result, the intensity of this magnetic dipole radiation has the similar angular distribution:

$$
\begin{equation*}
S_{r}=Z H^{2}=\frac{Z}{\left(4 \pi v^{2} r\right)^{2}}\left[\ddot{m}\left(t-\frac{r}{v}\right)\right]^{2} \sin ^{2} \theta \tag{8.126}
\end{equation*}
$$

- cf. Eq. (26). Note, however, that this radiation is usually much weaker than its electric counterpart. For example, for a non-relativistic particle with electric charge $q$, moving on a trajectory with of size $\sim a$, the electric dipole moment is of the order of $q a$, while its magnetic moment scales as $q a^{2} \omega$, where $\omega$ is the motion frequency. As a result, the ratio of the magnetic and electric dipole radiation intensities is of the order of $(a \omega / v)^{2}$, i.e. the squared ratio of particle's speed to the speed of emitted waves - that has to be much smaller than 1 for our non-relativistic estimate to be valid.

The angular distribution of the electric quadrupole radiation, described by Eq. (123), is more complicated. In order to show this, we may add to $\mathbf{A}_{q}$ a vector parallel to $\mathbf{n}$ (i.e. along the wave propagation), getting

$$
\begin{equation*}
\mathbf{A}_{q}(\mathbf{r}, t) \rightarrow \frac{\mu}{24 \pi r v} \ddot{\mathbf{Q}}\left(t-\frac{r}{v}\right), \quad \text { where } \mathbf{Q} \equiv \sum_{k} q_{k}\left\{3 \mathbf{r}_{k}\left(\mathbf{n} \cdot \mathbf{r}_{k}\right)-\mathbf{n} r_{k}^{2}\right\}, \tag{8.127}
\end{equation*}
$$

because this addition does not give any contribution to the transverse component of the electric and magnetic fields, i.e. to the radiated wave. According to the above definition of vector $\mathbf{Q}$, its Cartesian components may be presented as ${ }^{41}$

[^378]\[

$$
\begin{equation*}
Q_{j}=\sum_{j^{\prime}=1}^{3} Q_{i j}, n_{j^{\prime}} \tag{8.128}
\end{equation*}
$$

\]

where $Q_{i j}$, are elements of the so-called electric quadrupole tensor $\mathcal{Q}$ of the system:42

$$
\begin{equation*}
\mathcal{Q}_{j j^{\prime}}=\sum_{k} q_{k}\left(3 r_{j} r_{j^{\prime}}-r^{2} \delta_{j j^{\prime}}\right)_{k} . \tag{8.129a}
\end{equation*}
$$

For clarity, let me spell out the tensor in its matrix form:

$$
Q=\sum_{k} q_{k}\left(\begin{array}{ccc}
2 x^{2}-y^{2}-z^{2} & 3 x y & 3 x z  \tag{8.129b}\\
3 x y & 2 y^{2}-x^{2}-z^{2} & 3 y z \\
3 x z & 3 y z & 2 z^{2}-x^{2}-y^{2}
\end{array}\right)_{k}
$$

Differentiating the first of Eqs. (127) at $r \gg \lambda$, we get

$$
\begin{equation*}
\mathbf{B}_{q}(\mathbf{r}, t)=-\frac{\mu}{24 \pi r v^{2}} \mathbf{n} \times \dddot{\mathbf{Q}}\left(t-\frac{r}{v}\right) . \tag{8.130}
\end{equation*}
$$

Superficially, this expression is similar to Eqs. (24) or (124), but according to Eqs. (127) and (129), components of vector $\mathbf{Q}$ depend on the direction of vector $\mathbf{n}$, leading to a different angular dependence of $S_{r}$.

As the simplest example, let us consider a system of two equal point electric charges moving at equal distances $d(t) \ll \lambda$ from a stationary center (Fig. 16).

Fig. 8.16. The simplest system emitting electric quadrupole radiation.

Due to the symmetry of the system, its dipole moments $\mathbf{p}$ and $\mathbf{m}$ (and hence its electric and magnetic dipole radiation) vanish, but the quadrupole tensor (129) still has nonvanishing components. With the coordinate choice shown in Fig. 16, these components are diagonal:

$$
\begin{equation*}
Q_{x x}=Q_{y y}=-2 q d^{2}, \quad Q_{z z}=4 q d^{2} . \tag{8.131}
\end{equation*}
$$

With axis $x$ in the plane of the direction $\mathbf{n}$ toward the source (Fig. 16), so that $n_{x}=\sin \theta, n_{y}=0, n_{z}=\cos$ $\theta$, Eq. (128) yields

$$
\begin{equation*}
Q_{x}=-2 q d^{2} \sin \theta, \quad Q_{y}=0, \quad Q_{z}=4 q d^{2} \cos \theta \tag{8.132}
\end{equation*}
$$

[^379]Electric quadrupole
radiation field
so that the vector product in Eq. (130) has only one nonvanishing Cartesian component:

$$
\begin{equation*}
(\mathbf{n} \times \dddot{\mathbf{Q}})_{y}=n_{z} \dddot{Q}_{x}-n_{x} \dddot{Q}_{z}=-6 q \sin \theta \cos \theta \frac{d^{3}}{d t^{3}}\left[d^{2}(t)\right] . \tag{8.133}
\end{equation*}
$$

As a result, the radiation intensity is proportional to $\sin ^{2} \theta \cos ^{2} \theta$, i.e. vanishes not only along the symmetry axis (as the dipole radiation does), but also in all directions perpendicular to this axis, reaching its maximum at $\theta=\pi / 4$.

For more complex systems, the angular distribution of the electric quadrupole radiation may be different, but its total power may be always presented in a simple form

$$
\begin{equation*}
P_{q}=\frac{Z}{1440 \pi v^{4}} \sum_{j, j^{\prime}=1}^{3}\left(\dddot{Q}_{j j^{\prime}}\right)^{2} \tag{8.134}
\end{equation*}
$$

Let me finish this section by giving, without proof, one more fact important for applications: due to their different spatial structure, the magnetic dipole and electric quadrupole radiation fields do not interfere, i.e. the total power of radiation (neglecting higher multipole terms) may be found as the sum of these components, calculated independently.

### 8.10. Exercise problems

8.1.* In the electric dipole approximation, calculate the angular distribution and total power of electromagnetic radiation by the following classical model of the hydrogen atom: an electron rotating, at a constant distance $r$, about a much heavier proton. Use the latter result to evaluate the classical lifetime of the atom, borrowing the initial value of $R$ from quantum mechanics: $R(0)=r_{\mathrm{B}} \approx 0.53 \times 10^{-10} \mathrm{~m}$.
8.2. A non-relativistic particle of mass $m$ with the electric charge $q$ is placed into a uniform magnetic field $\mathbf{B}$. Derive the law of decrease of particle's kinetic energy due to its electromagnetic radiation at the cyclotron frequency $\omega_{c}=q B / m$. Evaluate the rate of such radiation cooling for electrons in a magnetic field of 1 T , and estimate the electron energy interval in which this result is qualitatively correct.

Hint: The cyclotron motion will be discussed in detail (for arbitrary particle velocities $v \sim c$ ) in Sec. 9.6 below, but I hope that the reader knows that in the non-relativistic case ( $v \ll c$ ) the above formula for $\omega_{c}$ may be readily obtained by combining the $2^{\text {nd }}$ Newton law $m v_{\perp}{ }^{2} / R=q v_{\perp} B$ for the circular motion of the particle under the effect of the magnetic component of the Lorentz force (5.10), and the geometric relation $v_{\perp}=R \omega_{c}$. (Here $\mathbf{v}_{\perp}$ is particle's velocity within the plane normal to vector $\mathbf{B}$.)
8.3. Solve the dipole antenna radiation problem discussed in Sec. 2 (see Fig. 3) for the optimal length $l=\lambda / 2$, assuming ${ }^{43}$ that the current distribution in each of its arms is sinusoidal:

$$
I(z, t)=I_{0} \cos \frac{\pi z}{l} \cos \omega t
$$

[^380]8.4. Use the harmonic oscillator model of a bound charge, given by Eq. (7.30), to explore the transition between two scattering limits discussed in Sec. 3, in particular the resonant scattering taking place at $\omega \approx \omega_{0}$. In this context, discuss the contribution of scattering into oscillator's damping.
8.5. ${ }^{*}$ A sphere of radius $R$, made of a material with constant permanent electric polarization $P_{0}$ and mass density $\rho$, is free to rotate about its center of mass. Calculate the total cross-section of scattering, by the sphere, of a linearly polarized electromagnetic wave of frequency $\omega \ll R / c$, propagating in free space, in the limit of small wave amplitude, assuming that the initial orientation of the polarization vector $\mathbf{P}_{0}$ is random.
8.6. Use the Born approximation to analyze the interference pattern produced by plane wave's scattering on a set of $N$ similar, equidistant points on a straight line normal to the direction of the incident wave's propagation - see Fig. on the right. Discuss the trend(s) of the pattern in the limit $N \rightarrow \infty$.

8.7. Use the Born approximation to calculate the differential cross-section of plane wave scattering by a dielectric cube of side $a$, with $\varepsilon \approx \varepsilon_{0}$. In the limits $k a \ll 1$ and $k a \gg 1$ (where $k$ is the wave vector), analyze the angular dependence of the differential cross-section. Calculate the full crosssection for the simplest case when the incident wave vector is parallel to one of cube's sides.
8.8. Use the Born approximation to calculate the differential cross-section of plane wave scattering by a nonmagnetic, uniform dielectric sphere with $\varepsilon \approx \varepsilon_{0}$, of an arbitrary radius $R$. In the limits $k R \ll 1$ and $1 \ll k R$ (where $k$ is the wave number), analyze the angular dependence of the differential cross-section, and calculate the full cross-section.
8.9. A sphere of radius $R$ is made of a uniform, nonmagnetic, linear dielectric material. Calculate its full cross-section of scattering of a low-frequency monochromatic wave, with $k \ll 1 / R$, for an arbitrary dielectric constant, and compare the result with the solution of the previous problem.
8.10. Solve the previous problem, also in the low-frequency limit $k R \ll 1$, for the case when the sphere's material has a frequency-independent Ohmic conductivity, and $\varepsilon_{\mathrm{opt}}=\varepsilon_{0}$, and a relatively large skin depth $\left(\delta_{s} \gg R\right)$, and compare the results.
8.11. Use the Born approximation to calculate the differential cross-section of plane wave scattering on a right, circular cylinder of length $l$ and radius $R$, for arbitrary incidence.
8.12. Formulate the quantitative condition of the Born approximation validity for a uniform linear-dielectric scatterer with all linear dimensions of the order of $a$.
8.13. Use the Huygens principle to calculate wave's intensity on the symmetry plane of the slit diffraction experiment (i.e. at $x=0$ in Fig. 11), for arbitrary ratio $z / k a^{2}$.
8.14. A plane wave with wavelength $\lambda$ is normally incident on an opaque, plane screen, with a round orifice of radius $R \gg \lambda$. Use the Huygens principle to calculate passed wave's intensity distribution along system's symmetry axis, at distances $z \gg R$ from the screen (see Fig. on the right), and analyze the result.

8.15. A plane monochromatic wave is normally incident on an opaque circular disk of radius $R \gg \lambda$. Use the Huygens principle to calculate wave's intensity at distance $z \gg R$ behind the disk center (see Fig. on the right). Discuss the result.

8.16. Use the Huygens principle to analyze the Fraunhofer diffraction of a plane wave normally incident on a square-shape hole, of size $a \times a$, in an opaque screen. Sketch the diffraction pattern you would observe at a sufficiently large distance, and quantify expression "sufficiently large" for this case.
8.17. Within the Fraunhofer approximation, analyze the pattern produced by a 1 D diffraction grating with the periodic transparency profile shown in Fig. on the right, for the normal incidence of a plane, monochromatic wave.

8.18. $N$ equal point charges are attached, at equal intervals, to a circle rotating with a constant angular velocity about its center - see Fig. on the right. For what values of $N$ does the system emit:
(i) the electric dipole radiation?
(ii) the magnetic dipole radiation?
(iii) the electric quadrupole radiation?

8.19. The orientation of a magnetic dipole $\mathbf{m}$, of a fixed magnitude, is rotating about a certain axis with angular velocity $\omega$, with angle $\theta$ between them staying constant. Calculate the angular distribution and the average power of its radiation (into free space).
8.20. Complete the solution of the problem started in Sec. 9, by calculating the full power of radiation of the system of two charges oscillating in antiphase along the same straight line - see Fig. 6. Also, calculate the average radiation power for the case of harmonic oscillations, $d(t)=a \cos \omega t$, compare it with the case of a single charge performing similar oscillations, and interpret the difference.

## This page is

## Chapter 9. Special Relativity

This chapter starts with a brief review of the special relativity's basics. This background is used, later in the chapter, for the analysis of the relation between electromagnetic field values measured in different reference frames moving relative to each other, and discussions of relativistic particle dynamics in the electric and magnetic fields, and of analytical mechanics of electromagnetism.

### 9.1. Einstein postulates and the Lorentz transform

As was emphasized at the derivation of expressions for the dipole and quadrupole radiation in the last chapter, they are only valid for systems of non-relativistic particles. Thus, these results cannot be used for description of such important phenomena as the Cherenkov radiation or synchrotron radiation, in which relativistic effects are essential. Moreover, analysis of motion of charged relativistic particles in electric and magnetic fields is also a natural part of electrodynamics. This is why I will follow the tradition of using this course for a (by necessity, brief) introduction to special relativity theory. This theory is based on the idea that measurements of all physical variables (including spatial and even temporal intervals between two events) may give different results in different reference frames, in particular two frames moving relative to each other translationally (i.e. without rotation), with a certain constant velocity $\mathbf{v}$ (Fig. 1).

Fig. 9.1. Translational, uniform motion of two reference frames.

In the non-relativistic (Newtonian) mechanics the problem of transfer between such reference frames has a simple solution at least in the limit $v \ll c$, because the basic equation of particle dynamics (the $2^{\text {nd }}$ Newton law) ${ }^{1}$

$$
\begin{equation*}
m_{k} \ddot{\mathbf{r}}_{k}=-\nabla_{k} \sum_{k^{\prime}} U\left(\mathbf{r}_{k}-\mathbf{r}_{k^{\prime}}\right), \tag{9.1}
\end{equation*}
$$

where $U$, the potential energy of inter-particle interactions, is invariant with respect to the so-called Galilean transform (or "transformation"). ${ }^{2}$ Choosing the coordinate axes of both frames so that axes $x$ and $x^{\prime}$ are parallel to vector $\mathbf{v}$ (Fig. 1), the transform ${ }^{3}$ may be presented as

Galilean transform

$$
\begin{equation*}
x=x^{\prime}+v t^{\prime}, \quad y=y^{\prime}, \quad z=z^{\prime}, \quad t=t^{\prime} \tag{9.2a}
\end{equation*}
$$

[^381]and plugging Eq. (2a) into Eq. (1), we get an absolutely similarly looking equation of motion in the "moving" reference frame 0'. Since the reciprocal transform,
\[

$$
\begin{equation*}
x^{\prime}=x-v t, \quad y=y^{\prime}, \quad z^{\prime}=z, \quad t^{\prime}=t \tag{9.2b}
\end{equation*}
$$

\]

is similar to the direct one, with the replacement of $(+v)$ with $(-v)$, we may say that the Galilean invariance means that there is no any "master" (absolute) spatial reference frame in classical mechanics, although the spatial and temporal intervals between different events are absolute (reference-frame invariant).

However, it is straightforward to use Eq. (2) to check that the form of the wave equation

$$
\begin{equation*}
\left(\frac{\partial^{2}}{\partial x^{2}}+\frac{\partial^{2}}{\partial y^{2}}+\frac{\partial^{2}}{\partial z^{2}}-\frac{1}{c^{2}} \frac{\partial^{2}}{\partial t^{2}}\right) f=0 \tag{9.3}
\end{equation*}
$$

describing in particular the electromagnetic wave propagation in free space, ${ }^{4}$ is not Galilean-invariant. ${ }^{5}$ For the "usual" (say, elastic) waves, which obey a similar equation albeit with a different speed, ${ }^{6}$ this lack of Galilean invariance is natural and is compatible with the invariance of Eq. (1), from which the wave equation originates. This is because the elastic waves are essentially the oscillations of interacting particles of a certain medium (e.g., an elastic solid), which makes the reference frame connected to this medium, special. So, if the electromagnetic waves were oscillations of a certain special medium (that was first called the "luminiferous aether" ${ }^{7}$ and later just ether), similar arguments might be applicable to reconcile Eqs. (2) and (3).

The detection of such a medium was the goal of the Michelson-Morley measurements (carried out between 1881 and 1887 with better and better precision), that are sometimes called "the most famous failed experiment in physics". Figure 2 shows a crude scheme of their experiments.

[^382]A nearly-monochromatic wave is split in two parts (nominally, of equal intensity), using a semitransparent mirror tilted by $45^{\circ}$ to the incident wave direction. These two partial waves are reflected back by two genuine mirrors, and arrive at the same semi-transparent mirror again. Here a half of each wave is returned to the light source area (where they vanish without affecting the source), but another half passes toward the detector, forming, with its counterpart, an interference pattern similar to that in the Young experiment. Thus each of the interfering waves has traveled twice (back and forth) each of two mutually perpendicular "arms" of the interferometer. Assuming that the ether, in which light propagates with speed $c$, moves with speed $v<c$ along one of the arms, of length $l_{l}$, it is straightforward (and hence left for reader's exercise :-) to get the following expression for the difference between light roundtrip times:

$$
\begin{equation*}
\Delta t=\frac{2}{c}\left(\frac{l_{t}}{\left(1-v^{2} / c^{2}\right)^{1 / 2}}-\frac{l_{l}}{1-v^{2} / c^{2}}\right) \approx \frac{l}{c}\left(\frac{v}{c}\right)^{2} \tag{9.4}
\end{equation*}
$$

where $l_{t}$ is the length of the second, "transverse" arm of the interferometer (perpendicular to $\mathbf{v}$ ), and the last, approximate expression is valid at $l_{t} \approx l_{l}$ and $v \ll c$.

Since Earth moves around the Sun with speed $v_{\mathrm{E}} \approx 30 \mathrm{~km} / \mathrm{s} \approx 10^{-4} c$, the arm positions relative to this motion alternate, due to Earth rotation about its axis, each 6 hours - see the right panel of Fig. 2. Hence if we assume that the ether rests in Sun's reference frame, $\Delta t$ (and the corresponding shift of interference fringes), has to alternate with this half-period as well. The same alternation may be achieved, at a smaller time scale, by a deliberate rotation of the instrument by $\pi / 2$. In the most precise version of the Michelson-Morley experiment (1887), this shift was expected to be close to 0.4 of the fringe pattern period. The result was negative, with the error bar about 0.01 of the fringe period. ${ }^{8}$

The most prominent immediate explanation of this zero result ${ }^{9}$ was suggested in 1889 by G. FitzGerald and (independently and more qualitatively) by H. Lorentz in 1892: as evident from Eq. (4), if the longitudinal arm of the interferometer itself experiences the so-called length contraction,

$$
\begin{equation*}
l_{l}(v)=l_{l}(0)\left(1-\frac{v^{2}}{c^{2}}\right)^{1 / 2} \tag{9.5}
\end{equation*}
$$

while the transverse arm's length is not affected by the motion relative to the ether, this kills $\Delta t$. This, extremely radical, idea received a strong support from the proof, in 1887-1905, that the Maxwell equations, and hence the wave equation (3), are form-invariant under the so-called Lorentz transform. ${ }^{10}$ For the choice of coordinates shown in Fig. 1, the transform reads

[^383]\[

$$
\begin{equation*}
x=\frac{x^{\prime}+v t^{\prime}}{\left(1-v^{2} / c^{2}\right)^{1 / 2}}, \quad y=y^{\prime}, \quad z=z^{\prime}, \quad t=\frac{t^{\prime}+\left(v / c^{2}\right) x^{\prime}}{\left(1-v^{2} / c^{2}\right)^{1 / 2}} . \tag{9.6a}
\end{equation*}
$$

\]

It is elementary to solve these equations for the primed coordinates to get the reciprocal transform

$$
\begin{equation*}
x^{\prime}=\frac{x-v t}{\left(1-v^{2} / c^{2}\right)^{1 / 2}}, \quad y^{\prime}=y, \quad z^{\prime}=z, \quad t^{\prime}=\frac{t-\left(v / c^{2}\right) x}{\left(1-v^{2} / c^{2}\right)^{1 / 2}} . \tag{9.6b}
\end{equation*}
$$

(I will soon present Eqs. (6) in a more elegant form.)
The Lorentz transform relations (6) are evidently reduced to the Galilean transform formulas (2) at $v^{2} \ll c^{2}$. As will be proved in the next section, Eqs. (6) also yield the Lorentz length contraction (5). However, all attempts to give a reasonable interpretation of these equations while keeping the notion of the ether have failed, in particular because of the restrictions imposed by results of earlier experiments carried out in 1851 and 1853 by H. Fizeau - that were repeated with higher accuracy by the same Michelson and Morley in 1886. These experiments have shown that if one sticks to the ether concept, this hypothetical medium should be partially "dragged" by any moving dielectric media with a speed proportional to $\left(\varepsilon_{r}-1\right)$. Careful reasoning shows that such local drag is irreconcilable with the assumed continuity of the ether.

In his famous 1905 paper, Albert Einstein has suggested a bold resolution of this contradiction, essentially removing the concept of the ether altogether. Moreover, he argued that the Lorentz transform is the general property of time and space, rather than of the electromagnetic field alone. He has started with two postulates, the first one essentially repeating the principle of relativity, formulated earlier (1904) by H. Poincaré in the following form:
"...the laws of physical phenomena should be the same, whether for an observer fixed, or for an observer carried along in a uniform movement of translation; so that we have not and could not have any means of discerning whether or not we are carried along in such a motion." ${ }^{11}$

The second Einstein's postulate was that the speed of light $c$, in free space, should be constant in all reference frames. (This is essentially a denial of ether's existence.)

Then, Einstein showed how naturally do the Lorenz transform relations (6) follow from his postulates, with a few (very natural) additional assumptions. Let a point source emit a short flash of light, at the moment $t=t^{\prime}=0$ when origins of the reference frames shown in Fig. 1 coincide. Then, according to the second of Einstein's postulates, in each of the frames the spherical wave propagates with the same speed $c$, i.e. coordinates of points of its front, measured in the two frames, have to obey equations

$$
\begin{align*}
& (c t)^{2}-\left(x^{2}+y^{2}+z^{2}\right)=0, \\
& \left(c t^{\prime}\right)^{2}-\left(x^{\prime 2}+y^{\prime 2}+z^{\prime 2}\right)=0 . \tag{9.7}
\end{align*}
$$

What may be the general relation between the combinations in the left-hand side of these equations - not for this selected pair of events, the light flash and its detection, but in general? A very natural (essentially, the only justifiable) choice is

[^384]\[

$$
\begin{equation*}
\left[(c t)^{2}-\left(x^{2}+y^{2}+z^{2}\right)\right]=f\left(v^{2}\right)\left[\left(c t^{\prime}\right)^{2}-\left(x^{\prime 2}+y^{\prime 2}+z^{\prime 2}\right)\right] . \tag{9.8}
\end{equation*}
$$

\]

Now, according to the first postulate, the same relation should be valid if we swap the reference frames ( $x \leftrightarrow x^{\prime}$, etc.) and replace $v$ with $(-v)$. This is only possible if $f^{2}=1$, so that excluding option $f=-1$ (which is incompatible with the Galilean transform in the limit $v / c \rightarrow 0$ ), we get

$$
\begin{equation*}
(c t)^{2}-\left(x^{2}+y^{2}+z^{2}\right)=\left(c t^{\prime}\right)^{2}-\left(x^{\prime 2}+y^{\prime 2}+z^{\prime 2}\right) . \tag{9.9}
\end{equation*}
$$

For the line $y=y^{\prime}=0, z=z^{\prime}=0$, Eq. (9) is reduced to

$$
\begin{equation*}
(c t)^{2}-x^{2}=\left(c t^{\prime}\right)^{2}-x^{\prime 2} . \tag{9.10}
\end{equation*}
$$

It is very illuminating to interpret this relation as the one resulting from a mutual rotation of the reference frames (that now have to include clocks to measure time) on the plane of coordinate $x$ and the so-called Euclidian time $\tau \equiv i c t-$ see Fig. 3.

Fig. 9.3. The Lorentz transform as a mutual rotation of reference frames on the $[x, \tau]$ plane.

Indeed, rewriting Eq. (10) as

$$
\begin{equation*}
\tau^{2}+x^{2}=\tau^{\prime 2}+x^{\prime 2} \tag{9.11}
\end{equation*}
$$

we may consider it as the invariance of the squared radius at the rotation that is shown in Fig. 3 and described by the evident geometric relations

$$
\begin{align*}
& x=x^{\prime} \cos \psi-\tau^{\prime} \sin \psi,  \tag{9.12a}\\
& \tau=x^{\prime} \sin \psi+\tau^{\prime} \cos \psi,
\end{align*}
$$

with the reciprocal relations

$$
\begin{align*}
& x^{\prime}=x \cos \psi+\tau \sin \psi, \\
& \tau^{\prime}=-x \sin \psi+\tau \cos \psi . \tag{9.12b}
\end{align*}
$$

So far, angle $\psi$ has been arbitrary. In the spirit of Eq. (8), a natural choice is $\psi=\psi(v)$, with the requirement $\psi(0)=0$. In order to find this function, let us write the definition of velocity $v$ of frame $0^{\prime}$, as measured in reference frame 0 : for $x^{\prime}=0, x=v t$. In variables $x$ and $\tau$, this means

$$
\begin{equation*}
\left.\left.\frac{x}{\tau}\right|_{x^{\prime}=0} \equiv \frac{x}{i c t}\right|_{x^{\prime}=0}=\frac{v}{i c} . \tag{9.13}
\end{equation*}
$$

On the other hand, for the same point $x^{\prime}=0$, Eqs. (12a) yield

$$
\begin{equation*}
\left.\frac{x}{\tau}\right|_{x^{\prime}=0}=-\tan \psi \tag{9.14}
\end{equation*}
$$

These two expressions are compatible only if

$$
\begin{equation*}
\tan \psi=\frac{i v}{c} \tag{9.15}
\end{equation*}
$$

so that

$$
\begin{equation*}
\sin \psi \equiv \frac{\tan \psi}{\left(1+\tan ^{2} \psi\right)^{1 / 2}}=\frac{i v / c}{\left(1-v^{2} / c^{2}\right)^{1 / 2}} \equiv i \beta \gamma, \quad \cos \psi \equiv \frac{1}{\left(1+\tan ^{2} \psi\right)^{1 / 2}}=\frac{1}{\left(1-v^{2} / c^{2}\right)^{1 / 2}} \equiv \gamma \tag{9.16}
\end{equation*}
$$

where $\beta$ and $\gamma$ are two very convenient and commonly used dimensionless parameters defined as

$$
\begin{equation*}
\boldsymbol{\beta} \equiv \frac{\mathbf{v}}{c}, \quad \gamma \equiv \frac{1}{\left(1-v^{2} / c^{2}\right)^{1 / 2}}=\frac{1}{\left(1-\beta^{2}\right)^{1 / 2}} . \tag{9.17}
\end{equation*}
$$

(Vector $\beta$ is called the normalized velocity, while scalar $\gamma$, the Lorentz factor.) ${ }^{12}$
Using the relations for $\psi$, Eqs. (12) become

$$
\begin{array}{ll}
x=\gamma\left(x^{\prime}-i \beta \tau^{\prime}\right), & \tau=\gamma\left(i \beta x^{\prime}+\tau^{\prime}\right), \\
x^{\prime}=\gamma(x+i \beta \tau), & \tau^{\prime}=\gamma(-i \beta x+\tau) . \tag{9.18b}
\end{array}
$$

Now returning to the real variables $[x, c t]$, we get the Lorentz transform relations (6) in a more compact form: ${ }^{13}$

$$
\begin{array}{llll}
x=\gamma\left(x^{\prime}+\beta c t^{\prime}\right), & y=y^{\prime}, & z=z^{\prime}, & c t=\gamma\left(c t^{\prime}+\beta x^{\prime}\right), \\
x^{\prime}=\gamma(x-\beta c t), & y^{\prime}=y, & z^{\prime}=z, & c t^{\prime}=\gamma(c t-\beta x) . \tag{9.19b}
\end{array}
$$

An immediate corollary of Eqs. (6) is that for $\gamma$ to stay real, we need $v^{2} \leq c^{2}$, i.e. that the speed of any physical body (to which we could connect a reference frame) cannot exceed the speed of light, as measured in any physically meaningful reference frame. ${ }^{14}$

### 9.2. Relativistic kinematic effects

In order to discuss other corollaries of Eqs. (19), we need to spend a few minutes to discuss what do these relations actually mean. Evidently, they are trying to tell us that the spatial and temporal intervals are not absolute (as they are in the Newtonian space), but do depend on the reference frame they are measured in. So, we have to understand very clearly what exactly may be measured - and thus may be discussed in a physics theory. Recognizing this necessity, A. Einstein has introduced the notion of numerous imaginary observers that may be distributed all over each reference frame. Each observer has a clock and may use it to measure the instants of local events. He also conjectured that:
(i) all observers within the same reference frame may agree on a common length measure ("a scale"), i.e. on their relative positions in that frame, and synchronize their clocks, ${ }^{15}$ and

[^385](ii) observers belonging to different reference frames may agree on the nomenclature of world events (e.g., short flashes of light) to which their respective measurements belong.

Actually, these additional postulates have been already implied in our "derivation" of the Lorentz transform in Sec. 1. For example, by $\{x, y, z$, and $t\}$ we mean the results of space and time measurements of a certain world event, about that all observers belonging to frame 0 agree. Similarly, all observers of frame 0 ' have to agree about results $\left\{x^{\prime}, y^{\prime}, z^{\prime}, t^{\prime}\right\}$. Finally, when the origin of frame $0^{\prime}$ passes by some sequential points $x_{k}$ of frame 0 , observers in that frame may measure its passage times $t_{k}$ without a fundamental error, and know that all these times belong to $x^{\prime}=0$.

Now we can analyze the major corollaries of the Lorentz transform, which are rather striking from the point of view of our everyday (rather non-relativistic :-) experience.
(i) Length contraction. Let us consider a rigid rod, stretched along axis $x$, with length $l=x_{2}-x_{1}$, where $x_{1,2}$ are the coordinates of rod's ends, as measured in its rest frame 0 , at any instant $t$ (Fig. 4). What would be the rod's length $l$ ' measured by the Einstein observers in the moving frame 0 '?

Fig. 9.4. Relativistic length contraction.

At a time instant $t$ ' agreed upon in advance, the observers who find themselves exactly at the rod's ends, may register that fact, and then subtract their coordinates $x^{\prime}{ }_{1,2}$ to calculate the apparent rod length $l^{\prime}=x_{2}{ }^{\prime}-x_{1}{ }^{\prime}$ in the moving frame. According to Eq. (19a), $l$ may be expressed via $l^{\prime}$ as

$$
\begin{equation*}
l \equiv x_{2}-x_{1}=\gamma\left(x_{2}^{\prime}+\beta c t^{\prime}\right)-\gamma\left(x_{1}^{\prime}+\beta c t^{\prime}\right)=\gamma\left(x_{2}^{\prime}-x_{1}^{\prime}\right)=\gamma l^{\prime}>l^{\prime} . \tag{9.20a}
\end{equation*}
$$

Hence, the rod's length, as measured in the moving reference frame is

Length contraction

$$
\begin{equation*}
l^{\prime}=\frac{l}{\gamma}=l\left(1-\frac{v^{2}}{c^{2}}\right)^{1 / 2} \leq l \tag{9.20b}
\end{equation*}
$$

in accordance with the FitzGerald-Lorentz hypothesis (5). This is the relativistic length contraction effect: an object is always the longest (has the so-called proper length l) if measured in its rest frame. Note that according to Eq. (19), the length contraction takes place only in the direction of the relative motion of two reference frames. As has been noted in Sec. 1, this result immediately explains the zero result of the Michelson-Morley-type experiments, so that they give a convincing evidence (if not an irrefutable proof) of Eq. (20).

[^386](ii) Time dilation. Now let us use Eqs. (19a) to find the time interval $\Delta t$, as measured in frame 0, between two world events - say, two ticks of a clock moving with frame 0 ' (Fig. 5), i.e. having constant values of $x^{\prime}, y^{\prime}$, and $z^{\prime}$.

Fig. 9.5. Relativistic time dilation.

Let the time interval between these two events, measured in clock's rest frame $0^{\prime}$, be $\Delta t^{\prime} \equiv t_{2}{ }^{\prime}-$ $t_{1}$ '. At these two moments, the clock would fly by certain two Einstein's observers at rest in frame 0 , so that they can record the corresponding moments $t_{1,2}$ shown by their clocks, and then calculate $\Delta t$ as their difference. According to the second of Eqs. (19a),

$$
\begin{equation*}
\Delta t \equiv t_{2}-t_{1}=\frac{\gamma}{c}\left[\left(c t_{2}^{\prime}+\beta x^{\prime}\right)-\left(c t_{1}^{\prime}+\beta x^{\prime}\right)\right]=\gamma \Delta t^{\prime} \tag{9.21a}
\end{equation*}
$$

so that, finally,

$$
\begin{equation*}
\Delta t=\gamma \Delta t^{\prime} \equiv \frac{\Delta t^{\prime}}{\left(1-v^{2} / c^{2}\right)^{1 / 2}} \geq \Delta t^{\prime} \tag{9.21b}
\end{equation*}
$$

This is the famous relativistic time dilation (or "dilatation") effect: a time interval is longer if measured in a frame (in our case, frame 0) moving relatively to the clock, while that in the rest frame is the shortest - the so-called proper time interval.

This counter-intuitive effect is the everyday reality at experiments with high-energy elementary particles. For example, in a typical (by no means record-breaking) experiment carried out in Fermilab, a beam of charged 200 GeV pions with $\gamma \approx 1,400$ passed distance $l=300 \mathrm{~m}$ distance with the measured loss of only $3 \%$ of the initial beam intensity due to the pion decay (mostly, into muon-neutrino pairs) with proper lifetime $t_{0} \approx 2.56 \times 10^{-8} \mathrm{~s}$. Without the time dilation, only an $\exp \left\{-1 / c t_{0}\right\} \sim 10^{-17}$ part of the initial pions would survive, while the relativity-corrected number $\exp \{-l / c t\}=\exp \left\{-l / c \gamma t_{0}\right\} \approx 0.97$ was in a full accordance with experimental measurements. As another example, the global positioning system (GPS) is designed with the account of the time dilation due to the velocity of its satellites (and also some gravity-induced, i.e. general-relativity corrections that I do not have time to discuss) and would give large errors without such corrections. So, there is no doubt that time dilation (21) is a reality, though the precision of its experimental tests I am aware of has been limited by a few percent, because of almost unavoidable involvement of gravity effects. ${ }^{16}$

Before the first reliable observation of the time dilation (by B. Rossi and D. Hall in 1940), there had been serious doubts in the reality of this effect, the most famous being the twin paradox first posed (together with an immediate suggestion of its resolution) by P. Langevin in 1911. Let us send one of two twins on a long star journey with a speed $v$ approaching $c$. Upon his return to Earth, who of the twins

[^387]would be older? The naïve approach is to say that due to the relativity principle, not one can be (and hence there is no time dilation), because each twin could claim that his counterpart, rather than himself, was moving, with the same speed $v$, just in the opposite direction. The resolution of the paradox in the general theory of relativity (which can handle gravity and acceleration effects) is that one of the twins had to be accelerated to be brought back, and hence the reference frames have to be dissimilar: only one of them may stay inertial all the time. Because of that, the twin who had been accelerated ("actually traveling") would be younger than his sibling when they meet.
(iii) Velocity transformation. Now let us calculate velocity $\mathbf{u}$ of a particle, as observed in reference frame 0, provided that its velocity, as measured in frame 0 ', is u' (Fig. 6).

Fig. 9.6. Relativistic velocity addition.

Keeping the usual definition of velocity, but with due attention to the relativity of not only spatial but also temporal intervals, we may write

$$
\begin{equation*}
\mathbf{u} \equiv \frac{d \mathbf{r}}{d t}, \quad \mathbf{u}^{\prime} \equiv \frac{d \mathbf{r}^{\prime}}{d t^{\prime}} . \tag{9.21}
\end{equation*}
$$

Plugging in the differentials of the Lorentz transform relations (6a), we get

$$
\begin{equation*}
u_{x}=\frac{d x}{d t}=\frac{d x^{\prime}+v d t^{\prime}}{d t^{\prime}+v d x^{\prime} / c^{2}}=\frac{u_{x}^{\prime}+v}{1+u_{x}^{\prime} v / c^{2}}, \quad u_{y}=\frac{d y}{d t}=\frac{1}{\gamma} \frac{d y^{\prime}}{d t^{\prime}+v d x^{\prime} / c^{2}}=\frac{1}{\gamma} \frac{u_{y}^{\prime}}{1+u_{x}^{\prime} v / c^{2}}, \tag{9.22}
\end{equation*}
$$

and the similar formula for $u_{z}$. In the classical limit $v / c \rightarrow 0$, these relations are reduced to

$$
\begin{equation*}
u_{x}=u_{x}^{\prime}+v, \quad u_{y}=u_{y}^{\prime}, \quad u_{z}=u_{z}^{\prime} \tag{9.23}
\end{equation*}
$$

and may be merged into the familiar Galilean vector form

$$
\begin{equation*}
\mathbf{u}=\mathbf{u}^{\prime}+\mathbf{v}, \text { for } v \ll c \tag{9.24}
\end{equation*}
$$

In order to see how strange the full relativistic rules (22) are, let us first consider a purely longitudinal motion, $u_{y}=u_{z}=0$; then ${ }^{17}$

$$
\begin{equation*}
u=\frac{u^{\prime}+v}{1+u^{\prime} v / c^{2}} \tag{9.25}
\end{equation*}
$$

where $u \equiv u_{x}$ and $u^{\prime} \equiv u^{\prime}{ }_{x}$. Figure 7 shows $u$ as the function of $u^{\prime}$, given by this formula, for several values of the reference frames' relative velocity $v$.

[^388]

Fig. 9.7. Longitudinal velocity addition.

The first sanity check is that if $v=0$, i.e. the reference frames are at rest relative to each other, then $u=u^{\prime}$, as it should be - see the diagonal straight line. Next, if magnitudes of $u$ ' and $v$ are both below $c$, so is the magnitude of $u$. (Also good, because otherwise ordinary particles in one frame would be tachyons in the other one, and the theory would be in a big trouble.) Now strange things start: even as $u$ ' and $v$ are both approaching $c$, then $u$ is also close to $c$, but does not exceed it. As an example, if we fired ahead a bullet with speed $0.9 c$ from a spaceship moving from the Earth also at $0.9 c$, Eq. (25) predicts the speed of the bullet relative to Earth to be just $[(0.9+0.9) /(1+0.9 \times 0.9)] c \approx 0.994 c<c$, rather than $(0.9+0.9) c=1.8 c>c$ as in the Galilean kinematics. We certainly should accept this strangeness of relativity, because it is necessary to fulfill the $2^{\text {nd }}$ Einstein's postulate: the independence of the speed of light in any reference frame. Indeed, for $u^{\prime}= \pm c$, Eq. (25) yields $u= \pm c$, regardless of $v$.

In the opposite case of transverse motion, when a particle moves across the relative motion of the frames (for example, at our choice of coordinates, $u^{\prime}{ }_{x}=u^{\prime}{ }_{z}=0$ ), Eqs. (22) yield a less spectacular result

$$
\begin{equation*}
u_{y}=\frac{u_{y}^{\prime}}{\gamma} \leq u_{y}^{\prime} . \tag{9.26}
\end{equation*}
$$

This effect comes purely from the time dilation, because the transverse coordinates are Lorentzinvariant.

In the case when both $u_{x}$ ' and $u_{y}$ ' are substantial (but $u_{z}{ }^{\prime}$ is still zero), we may divide expressions (22) by each other to relate angles $\theta$ of particle propagation, as observed in the two reference frames:

$$
\begin{equation*}
\tan \theta \equiv \frac{u_{y}}{u_{x}}=\frac{u^{\prime}{ }_{y}}{\gamma\left(u_{x}^{\prime}+v\right)}=\frac{\sin \theta^{\prime}}{\gamma\left(\cos \theta^{\prime}+v / u^{\prime}\right)} . \tag{9.27}
\end{equation*}
$$

This expression describes, in particular, the so-called stellar aberration effect, the dependence of the observed direction $\theta$ toward a star on the speed $v$ of the telescope motion relative to the star - see Fig. 8. (The effect is readily observable experimentally as the annual aberration due to the periodic change of speed $v$ by $2 \nu_{\mathrm{E}} \approx 60 \mathrm{~km} / \mathrm{s}$ because of Earth's rotation about the Sun. Since the aberration's main part
is of the first order in $v_{\mathrm{E}} / C \sim 10^{-4}$, the effect is very significant and has been known since the early 1700s.)

Fig. 9.8. Stellar aberration.

For the analysis of this effect, it is sufficient to take, in Eq. (27), $u^{\prime}=c$, i.e. $v / u^{\prime}=\beta$, and interpret $\theta$ ' as the "proper" direction to the star, that would be measured at $v=0 .{ }^{18}$ At $\beta \ll 1$, both Eq. (27) and the Galilean result (which the reader is invited to derive directly from Fig. 8),

$$
\begin{equation*}
\tan \theta=\frac{\sin \theta^{\prime}}{\cos \theta^{\prime}+\beta}, \tag{9.28}
\end{equation*}
$$

may be well approximated by the first-order term

$$
\begin{equation*}
\Delta \theta \equiv \theta^{\prime}-\theta \approx \beta \sin \theta \tag{9.29}
\end{equation*}
$$

Unfortunately, it is not easy to use the difference between Eqs. (27) and (28), of the second order in $\beta$, for the special relativity confirmation, because other components of Earth's motion, such as its rotation, nutation and torque-induced precession, ${ }^{19}$ give masking first-order contributions to the aberration.

Finally, at a completely arbitrary direction of vector u', Eqs. (22) may be readily used to calculate the velocity magnitude. The most popular form of the resulting expression is for the square of relative velocity (or rather relative reduced velocity $\boldsymbol{\beta}$ ) of two particles,

$$
\begin{equation*}
\beta^{2}=\frac{\left(\boldsymbol{\beta}_{1}-\boldsymbol{\beta}_{2}\right)^{2}-\left|\boldsymbol{\beta}_{1} \cdot \boldsymbol{\beta}_{2}\right|}{\left(1-\boldsymbol{\beta}_{1} \cdot \boldsymbol{\beta}_{2}\right)^{2}} \leq 1 \tag{9.30}
\end{equation*}
$$

where $\boldsymbol{\beta}_{1,2} \equiv \mathbf{v}_{1,2} / c$ are their normalized velocities as measured in the same reference frame.
(iv) The Doppler effect. Now let us consider a plane, monochromatic wave moving along axis $x$ :

$$
\begin{equation*}
f=\operatorname{Re}\left[f_{\omega} \exp \{i(k x-\omega t\}]=\left|f_{\omega}\right| \cos \left(k x-\omega t+\arg f_{\omega}\right) .\right. \tag{9.31}
\end{equation*}
$$

[^389]Its total phase, $\Psi \equiv k x-\omega t+\arg f_{\omega}$ (in contrast to amplitude $\left|f_{\omega}\right|$ !) cannot depend on the observer's reference frame, because all fields of a traveling wave vanish simultaneously at $\Psi=2 \pi n$, (for all integer $n$ ) and such "world events" should take place in all reference frames. The only way to keep $\Psi=\Psi$ ' at all times is to have ${ }^{20}$

$$
\begin{equation*}
k x-\omega t=k^{\prime} x^{\prime}-\omega^{\prime} t^{\prime} . \tag{9.32}
\end{equation*}
$$

First, let us consider the Doppler effect describing usual non-relativistic waves, e.g., oscillations of particles of a certain medium. Using the Galilean transform (2), we may rewrite Eq. (32) as

$$
\begin{equation*}
k\left(x^{\prime}+v t\right)-\omega t=k^{\prime} x^{\prime}-\omega^{\prime} t . \tag{9.33}
\end{equation*}
$$

Since this transform leaves all space intervals (including wavelength $\lambda=2 \pi / k$ ) intact, we can take $k=k$, so that Eq. (33) yields

$$
\begin{equation*}
\omega^{\prime}=\omega-k v . \tag{9.34}
\end{equation*}
$$

For a dispersion-free medium, the wave number $k$ is the ratio of its frequency $\omega$, as measured in the reference frame bound to the medium, and the wave velocity $v_{w}$. In particular, if the wave source rests in the medium, we can bind frame 0 to the medium as well, and frame 0 ' to wave's receiver (so that $v=v_{r}$ ), so that

$$
\begin{equation*}
k=\frac{\omega}{v_{w}}, \tag{9.35}
\end{equation*}
$$

and for the frequency perceived by the receiver, Eq. (34) yields

$$
\begin{equation*}
\omega^{\prime}=\omega \frac{v_{w}-v_{r}}{v_{w}} \tag{9.36}
\end{equation*}
$$

On the other hand, if the receiver and the medium are at rest in reference frame 0 ', while the wave source is bound to frame 0 (so that $v=-v_{s}$ ), Eq. (35) should be replaced with

$$
\begin{equation*}
k=k^{\prime}=\frac{\omega^{\prime}}{v_{w}} \tag{9.37}
\end{equation*}
$$

and Eq. (34) yields a different result:

$$
\begin{equation*}
\omega^{\prime}=\omega \frac{v_{w}}{v_{w}-v_{s}} \tag{9.38}
\end{equation*}
$$

Finally, if both the source and detector are moving, it is straightforward to combine these two results to get the general relation

$$
\begin{equation*}
\omega^{\prime}=\omega \frac{v_{w}-v_{r}}{v_{w}-v_{s}} . \tag{9.39}
\end{equation*}
$$

At low speeds of both the source and receiver, this result simplifies,

[^390]\[

$$
\begin{equation*}
\omega^{\prime} \approx \omega(1-\beta), \quad \beta \equiv \frac{v_{r}-v_{s}}{v_{w}}, \tag{9.40}
\end{equation*}
$$

\]

but at speeds comparable to $v_{w}$ we have to use the more general Eq. (39). Thus, the usual Doppler effect is affected not only by the relative speed ( $v_{r}-v_{s}$ ) of wave's source and detector, but also of their speeds relative to the medium in which waves propagate.

Somewhat counter-intuitively, for the electromagnetic waves the calculations are simpler, because for them the propagation medium (ether) does not exist, wave velocity equals $\pm c$ in any reference frame, and there are no two separate cases: we can always take $k= \pm \omega / c, k^{\prime}= \pm \omega^{\prime} / c$. Plugging these relations, together with the Lorentz transform (19a), into the phase-invariance equation (32), we get

$$
\begin{equation*}
\pm \frac{\omega}{c} \gamma\left(x^{\prime}+\beta c t^{\prime}\right)-\omega \gamma \frac{c t^{\prime}+\beta x^{\prime}}{c}= \pm \frac{\omega^{\prime}}{c} x^{\prime}-\omega^{\prime} t^{\prime} . \tag{9.41}
\end{equation*}
$$

This relation has to hold for any $x^{\prime}$ and $t^{\prime}$, so we may require the net coefficients before these variables to vanish. These two requirements yield the same condition:

$$
\begin{equation*}
\omega^{\prime}=\omega \gamma(1 \mp \beta) \tag{9.42}
\end{equation*}
$$

This result is already quite simple, but may be transformed further to be even more illuminating:

$$
\begin{equation*}
\omega^{\prime}=\omega \frac{1 \mp \beta}{\left(1-\beta^{2}\right)^{1 / 2}}=\omega\left[\frac{(1 \mp \beta)(1 \mp \beta)}{(1+\beta)(1-\beta)}\right]^{1 / 2} . \tag{9.43}
\end{equation*}
$$

At any sign before $\beta$, one pair of parentheses cancel, so that

$$
\begin{equation*}
\omega^{\prime}=\omega\left(\frac{1 \mp \beta}{1 \pm \beta}\right)^{1 / 2} \tag{9.44}
\end{equation*}
$$

(It may look like the reciprocal expression of $\omega$ via $\omega^{\prime}$ is different, violating the relativity principle. However, in this case we have to change the sign of $\beta$, because the relative velocity of the system is opposite, so we come down to Eq. (44) again.)

Thus the Doppler effect for electromagnetic waves depends only on the relative velocity $v=\beta c$ between the wave source and detector - as it should be, given the absence of the ether. At velocities much below $c$, Eq. (43) may be crudely approximated as

$$
\begin{equation*}
\omega^{\prime} \approx \omega \frac{1 \mp \beta / 2}{1 \pm \beta / 2} \approx \omega(1 \mp \beta) \tag{9.45}
\end{equation*}
$$

i.e. in the first approximation in $\beta \equiv v / c$ it coincides with the corresponding limit (38) of the usual Doppler effect. However, even at $v \ll c$ there is still a difference of the order of $(v / c)^{2}$ between the Galilean and Lorentzian relations.

If the wave vector $\mathbf{k}$ is tilted by angle $\theta$ to vector $\mathbf{v}$ (as measured in frame 0 ), then we have to repeat the calculations, with $k$ replaced by $k_{x}$, and components $k_{y}$ and $k_{z}$ left intact at the Lorentz transform. As a result, Eq. (42) is generalized as

$$
\begin{equation*}
\omega^{\prime}=\omega \gamma(1-\beta \cos \theta) . \tag{9.46}
\end{equation*}
$$

For the cases $\cos \theta= \pm 1$, Eq. (44) reduces to our previous result. However, at $\theta=\pi / 2$ (i.e. $\cos \theta=0$ ), the relation is rather different:

$$
\begin{equation*}
\omega^{\prime}=\gamma \omega=\frac{\omega}{\left(1-\beta^{2}\right)^{1 / 2}} . \tag{9.47}
\end{equation*}
$$

This is the transverse Doppler effect - which is completely absent in the non-relativistic physics. Its first experimental evidence was obtained using electron beams (as suggested in 1906 by J. Stark), by H. Ives and G. Stilwell in 1938 and 1941. Later, similar experiments were repeated several times, but the first unambiguous measurement were performed only in 1979 by D. Hasselkamp et al. who confirmed Eq. (47) with a relative accuracy about $10 \%$. This precision may not look too spectacular, but besides the special tests discussed above, the Lorentz transform formulas have been also confirmed, less directly, by a huge body of other experimental data, especially in high energy physics, being in agreement with calculations incorporating the transform as their part. This is why, with every respect to the challenging authority spirit, I should warn the reader: you decide to challenge the relativity theory (that is called "theory" by tradition only), you would also need to explain all these data. ${ }^{21}$ Best luck with that!

### 9.3. 4-vectors, momentum, mass, and energy

Before proceeding to relativistic dynamics, let us discuss a mathematical language that makes all the calculations more compact - and more beautiful. We have already seen that spatial coordinates $\{x, y$, $z\}$ and product $c t$ are Lorentz-transformed similarly - see Eqs. (19). So it is natural to consider them as components of a 4-component vector (or, for short, 4-vector),

$$
\begin{equation*}
\left\{x_{0}, x_{1}, x_{2}, x_{3}\right\}=\{c t, \mathbf{r}\}, \tag{9.48}
\end{equation*}
$$

with components

$$
\begin{equation*}
x_{0}=c t, \quad x_{1}=x, \quad x_{2}=y, \quad x_{3}=z . \tag{9.49}
\end{equation*}
$$

According to Eqs. (19), its components are Lorentz-transformed as

$$
\begin{equation*}
x_{j}=\sum_{j^{\prime}=0}^{3} L_{j j^{\prime}, X^{\prime}}{ }_{j^{\prime}}, \tag{9.50}
\end{equation*}
$$

[^391]mentioned in Sec. 8.9, the usual (3D) vector is not just any ordered set (string) of three scalars $\left\{A_{x}, A_{y}\right.$, $\left.A_{z}\right\}$; if we want it to represent a reference-frame-independent physical variable, vector components have to obey certain rules at transfer from one reference frame to another. In particular, vector's 3D norm (magnitude squared),
\[

$$
\begin{equation*}
A^{2}=A_{x}^{2}+A_{y}^{2}+A_{z}^{2}, \tag{9.52}
\end{equation*}
$$

\]

should be an invariant at the Galilean transform (2). However, a naïve extension of this formula to 4vectors would not work, because, according to the calculations of Sec. 1, the Lorentz transform keeps intact combinations of the type (7), with one sign negative, rather than the sum of all components squared. Hence for the 4 -vector all the rules of the game have to be reviewed and adjusted - or rather redefined from the very beginning.

Arbitrary 4 -vector is a string of 4 scalars,

General 4 -vector

$$
\begin{equation*}
\left\{A_{0}, A_{1}, A_{2}, A_{3}\right\} \tag{9.53}
\end{equation*}
$$

defined in 4D Minkowski space, ${ }^{22}$ whose components $A_{j}$, as measured in systems 0 and 0 ', shown in Fig. 1, obey the Lorentz transform similar to Eq. (50):

General 4-vector's Lorentz transform

Lorentz invariance

$$
\begin{equation*}
A_{j}=\sum_{j^{\prime}=0}^{3} L_{i j^{\prime}} A_{j^{\prime}}^{\prime} \tag{9.54}
\end{equation*}
$$

As we have already seen on the example of the space-time 4-vector (48), this means in particular that
$\square$

$$
\begin{equation*}
A_{0}^{2}-\sum_{j=1}^{3} A_{j}^{2}=\left(A_{0}^{\prime}\right)^{2}-\sum_{j=1}^{3}\left(A_{j}^{\prime}\right)^{2} \tag{9.55}
\end{equation*}
$$

This is the so-called Lorentz invariance condition of the norm of the 4 -vector. (The difference between this relation and Eq. (52), pertaining to the Euclidian geometry, is the reason why the Minkowski space is called pseudo-Euclidian.) It is also straightforward to use Eqs. (51) and (54) to check that an evident generalization of the norm, the scalar product of two arbitrary 4 -vectors,

Scalar 4-product

$$
\begin{equation*}
A_{0} B_{0}-\sum_{j=1}^{3} A_{j} B_{j} \tag{9.56}
\end{equation*}
$$

is also Lorentz-invariant.
Now consider the 4 -vector corresponding to a infinitesimal interval between two close world events:

$$
\begin{equation*}
\left\{d x_{0}, d x_{1}, d x_{2}, d x_{3}\right\}=\{c d t, d \mathbf{r}\} \tag{9.57}
\end{equation*}
$$

its norm,

Interval between two close events

$$
\begin{equation*}
(d s)^{2} \equiv d x_{0}^{2}-\sum_{j=1}^{3} d x_{j}^{2}=c^{2}(d t)^{2}-(d r)^{2} \tag{9.58}
\end{equation*}
$$

[^392]is of course also Lorentz-invariant. Since the speed of any particle (or signal) cannot be larger than $c$, for any pair of world events that are in a causal relation with each other, $d r$ cannot be larger than $c d t$, i.e. such time-like interval $(d s)^{2}$ cannot be negative. The 4D surface separating such intervals from spacelike intervals (ds) ${ }^{2}<0$ is called the light cone (Fig. 9).

Fig. 9.9. $2+1$ dimensional image of the light cone (which is actually $3+1$ dimensional).

Now let us assume that these two close world events happen with the same particle that moves with velocity $\mathbf{u}$. Then in the frame moving with a particle $(\mathbf{v}=\mathbf{u})$, the last term in the right-hand part of Eq. (58) equals zero, so that

$$
\begin{equation*}
d s=c d \tau \tag{9.59}
\end{equation*}
$$

where $d \tau$ is the proper time interval. But according to Eq. (21), this means that we can write

$$
\begin{equation*}
d \tau=\frac{d t}{\gamma} \tag{9.60}
\end{equation*}
$$

where $d t$ is the time interval in an arbitrary (besides being inertial) reference frame, while

$$
\begin{equation*}
\boldsymbol{\beta} \equiv \frac{\mathbf{u}}{c} \quad \text { and } \gamma \equiv \frac{1}{\left(1-\beta^{2}\right)^{1 / 2}}=\frac{1}{\left(1-u^{2} / c^{2}\right)^{1 / 2}} \tag{9.61}
\end{equation*}
$$

are the parameters (17) corresponding to particle's velocity ( $\mathbf{u}$ ) in that frame, so that $d s=c d t / \gamma^{23}$
Now, let us explore whether a 4 -vector can be formed using spatial components of particle's velocity

$$
\begin{equation*}
\mathbf{u}=\left\{\frac{d x}{d t}, \frac{d y}{d t}, \frac{d z}{d t}\right\} . \tag{9.62}
\end{equation*}
$$

Here we have a slight problem: as Eqs. (22) show, these components do not obey the Lorentz transform. However, let us use $d \tau \equiv d t / \gamma$, the proper time interval of the particle, to form the following string:

[^393]\[

$$
\begin{equation*}
\left\{\frac{d x_{0}}{d \tau}, \frac{d x_{1}}{d \tau}, \frac{d x_{2}}{d \tau}, \frac{d x_{3}}{d \tau}\right\}=\gamma\left\{c, \frac{d x}{d t}, \frac{d y}{d t}, \frac{d z}{d t}\right\}=\gamma\{c, \mathbf{u}\} . \tag{9.63}
\end{equation*}
$$

\]

As follows from comparison of the first form of this expression with Eq. (48), since the time-space vector obeys the Lorentz transform, and $\tau$ is Lorentz-invariant, string (63) is a legitimate 4 -vector. It is called the 4-velocity of the particle.

Now we are properly equipped to proceed to dynamics. Let us start with such basic notions of momentum $\mathbf{p}$ and energy $\varepsilon$ - so far, for a free particle. ${ }^{24}$ Perhaps the most elegant way to "derive" (or rather guess ${ }^{25}$ ) expressions for $\mathbf{p}$ and $\varepsilon$ as functions of particle's velocity $\mathbf{u}$ is based on analytical mechanics. Due to the conservation of $\mathbf{v}$, the trajectory of a free particle in the 4D Minkowski space is always a straight line. Hence, from the Hamilton principle of minimum action, ${ }^{26}$ we may expect its action $S$, between points 1 and 2 , to be a linear function of the space-time interval (59):

Free
particle's action

$$
\begin{equation*}
\mathcal{S}=\alpha \int_{1}^{2} d s=\alpha c \int_{1}^{2} d \tau=\alpha c \int_{t_{1}}^{t_{2}} \frac{d t}{\gamma} \tag{9.64}
\end{equation*}
$$

where $\alpha$ is some constant. On the other hand, in analytical mechanics the action is defined as

$$
\begin{equation*}
\mathcal{S}=\int_{t_{1}}^{t_{2}} \mathcal{L} d t \tag{9.65}
\end{equation*}
$$

where $\mathcal{L}$ is particle's Lagrangian function. ${ }^{27}$ Comparing these two expressions, we get

$$
\begin{equation*}
\mathcal{L}=\frac{\alpha c}{\gamma}=\alpha c\left(1-\frac{u^{2}}{c^{2}}\right)^{1 / 2} . \tag{9.66}
\end{equation*}
$$

In the non-relativistic limit $(u \ll c)$, this function tends to

$$
\begin{equation*}
\mathcal{L} \approx \alpha c\left(1-\frac{u^{2}}{2 c^{2}}\right)=\alpha c-\frac{\alpha u^{2}}{2 c} . \tag{9.67}
\end{equation*}
$$

In order to correspond to the Newtonian mechanics, the last (velocity-dependent) term should equal $m u^{2} / 2$. From here we find $\alpha=-m c$, so that, finally,

Free particle's Lagrangian function

$$
\begin{equation*}
\mathcal{L}=-m c^{2}\left(1-\frac{u^{2}}{c^{2}}\right)^{1 / 2} \tag{9.68}
\end{equation*}
$$

[^394]Now we can find Cartesian components $p_{j}$ of particle's momentum, as the generalized momenta corresponding to components $r_{j}(j=1,2,3)$ of the 3D radius-vector $\mathbf{r}$ : ${ }^{28}$

$$
\begin{equation*}
p_{j}=\frac{\partial \mathcal{L}}{\partial \dot{r}_{j}}=\frac{\partial \mathscr{L}}{\partial u_{j}}=-m c^{2} \frac{\partial}{\partial u_{j}}\left(1-\frac{u_{1}^{2}+u_{2}^{2}+u_{3}^{2}}{c^{2}}\right)^{1 / 2}=\frac{m u_{j}}{\left(1-u^{2} / c^{2}\right)^{1 / 2}}=m \gamma u_{j} . \tag{9.69}
\end{equation*}
$$

Thus for the 3D vector of momentum, we can write the result in the same form as in non-relativistic mechanics,

$$
\begin{equation*}
\mathbf{p}=m \gamma \mathbf{u}=M \mathbf{u} \tag{9.70}
\end{equation*}
$$

if we introduce the reference-frame-dependent scalar $M$ (called the relativistic mass) defined as

$$
\begin{equation*}
M \equiv m \gamma=\frac{m}{\left(1-u^{2} / c^{2}\right)^{1 / 2}} \geq m \tag{9.71}
\end{equation*}
$$

$m$ being the non-relativistic mass of the particle. (It is also called the rest mass, because in the reference frame in that the particle rests, Eq. (71) yields $M=m$.)

Next, let us return to analytical mechanics to calculate particle's energy $\varepsilon$ (which for a free particle coincides with the Hamiltonian function $\not \not F):{ }^{27}$

$$
\begin{equation*}
\varepsilon=\not \mathcal{H}=\sum_{j=1}^{3} p_{j} u_{j}-\mathcal{L}=\mathbf{p} \cdot \mathbf{u}-\mathcal{L}=\frac{m u^{2}}{\left(1-u^{2} / c^{2}\right)^{1 / 2}}+m c^{2}\left(1-\frac{u^{2}}{c^{2}}\right)=\frac{m c^{2}}{\left(1-u^{2} / c^{2}\right)^{1 / 2}} . \tag{9.72}
\end{equation*}
$$

Thus, we have arrived at the most famous of Einstein's formulas (and probably the most famous formula of physics as a whole),

$$
\begin{equation*}
\varepsilon=m \gamma c^{2}=M c^{2} \tag{9.73}
\end{equation*}
$$

that expresses the relation between particle's mass and energy. ${ }^{29}$ In the non-relativistic limit, it reduces to

$$
\begin{equation*}
\varepsilon=\frac{m c^{2}}{\left(1-u^{2} / c^{2}\right)^{1 / 2}} \approx m c^{2}\left(1+\frac{u^{2}}{2 c^{2}}\right)=m c^{2}+\frac{m u^{2}}{2} \tag{9.74}
\end{equation*}
$$

the first term $m c^{2}$ being called the rest energy of a particle.
Now let us consider the following string of 4 scalars:

$$
\begin{equation*}
\left\{\frac{\varepsilon}{c}, p_{1}, p_{2}, p_{3}\right\}=\left\{\frac{\varepsilon}{c}, \mathbf{p}\right\} . \tag{9.75}
\end{equation*}
$$

Using Eqs. (70) and (73) to present this expression as

[^395]\[

$$
\begin{equation*}
\left\{\frac{\varepsilon}{c}, \mathbf{p}\right\}=m \gamma\{c, \mathbf{u}\} \tag{9.76}
\end{equation*}
$$

\]

and comparing the result with Eq. (63), we immediately see that, since $m$ is Lorentz-invariant, this string is a legitimate 4 -vector of energy-momentum. As a result, its norm,

$$
\begin{equation*}
\left(\frac{\varepsilon}{c}\right)^{2}-p^{2} \tag{9.77}
\end{equation*}
$$

is Lorentz-invariant, and in particular has to be equal to the norm in the particle rest frame. But in that frame, $p=0$, and $\varepsilon=m c^{2}$, so that in an arbitrary frame

$$
\begin{equation*}
\left(\frac{\varepsilon}{c}\right)^{2}-p^{2}=(m c)^{2} \tag{9.78a}
\end{equation*}
$$

This very important relation ${ }^{30}$ between the relativistic energy and momentum (valid for free particles only!) is usually presented in the form ${ }^{31}$

$$
\begin{equation*}
\varepsilon^{2}=\left(m c^{2}\right)^{2}+(p c)^{2} \tag{9.78b}
\end{equation*}
$$

According to Eq. (70), in the ultra-relativistic limit $u \rightarrow c, p$ tends to infinity while $m c^{2}$ stays constant, so that $p c \gg m c^{2}$. As follows from Eq. (78), in this limit $\varepsilon \approx p c$. Though the above discussion was for particles with finite $m$, the 4 -vector formalism allows us to consider particles with zero rest mass as ultra-relativistic particles for which the above energy-to-moment relation,

$$
\begin{equation*}
\varepsilon=p c, \quad \text { for } m=0 \tag{9.79}
\end{equation*}
$$

is exact. Quantum electrodynamics ${ }^{32}$ tells us that under certain conditions, electromagnetic field quanta (photons) may be also considered as such massless particles, with momentum $\mathbf{p}=\hbar \mathbf{k}$. Plugging (the modulus of) the last relation into Eq. (78), for photon's energy we get $\varepsilon=p c=\hbar k c=\hbar \omega$. Please note that according to Eq. (73), the relativistic mass of a photon is finite: $M=\varepsilon / c^{2}=\hbar \omega / c^{2}$, so that the term "massless particle" has a limited meaning: $m=0$. For example, the mass of an optical phonon is of the order of $10^{-36} \mathrm{~kg}$. This is not too much, but still a noticeable (approximately one-millionth) part of the rest mass $m_{e}$ of an electron.

The fundamental relations (70) and (73) have been repeatedly verified in numerous particle collision experiments, in which the total energy and momentum of a system of particles are conserved at the same conditions at in the non-relativistic dynamics. (For momentum, this is the absence of external forces, and for energy, the elasticity of particle interactions - in other words, the absence of alternative channels of energy escape.) Of course, generally, the total energy of the system is conserved, including the potential energy of particle interactions. However, at typical particle collisions, the

[^396]potential energy vanishes so rapidly with the distance between them that we can use the momentum and energy conservation using Eq. (73).

As an example, let us calculate the minimum energy $\mathcal{\varepsilon}_{\text {min }}$ of a proton $\left(\mathrm{p}_{a}\right)$, necessary for the well-known high-energy reaction that generates a new proton-antiproton pair, $\mathrm{p}_{a}+\mathrm{p}_{b} \rightarrow \mathrm{p}+\mathrm{p}+\mathrm{p}+\bar{p}$, provided that before the collision, proton $\mathrm{p}_{b}$ has been at rest in the lab frame. This minimum evidently corresponds to the vanishing relative velocity of the reaction products, i.e. their motion with virtually the same velocity $\left(\mathbf{u}_{\text {fin }}\right)$, as seen from the lab frame - see Fig. 10.

Fig. 9.10. High-energy proton reaction at $\varepsilon \approx \varepsilon_{\text {min }}$ - schematically.

Due to the momentum conservation, this velocity should have the same direction as the initial velocity ( $\mathbf{u}_{\text {min }}$ ) of proton $p_{a}$. This is why two scalar equations: of for the energy conservation,

$$
\begin{equation*}
\frac{m c^{2}}{\left(1-u_{\min }^{2} / c^{2}\right)^{1 / 2}}+m c^{2}=\frac{4 m c^{2}}{\left(1-u_{\mathrm{fin}}^{2} / c^{2}\right)^{1 / 2}}, \tag{9.80a}
\end{equation*}
$$

and momentum conservation,

$$
\begin{equation*}
\frac{m u}{\left(1-u_{\min }^{2} / c^{2}\right)^{1 / 2}}+0=\frac{4 m u_{\mathrm{fin}}}{\left(1-u_{\mathrm{fin}}^{2} / c^{2}\right)^{1 / 2}}, \tag{9.80b}
\end{equation*}
$$

are sufficient to find both $u_{\text {min }}$ and $u_{\text {fin }}$. After a conceptually simple but rather tedious solution of this system of two nonlinear equations, we get

$$
\begin{equation*}
u_{\min }=\frac{4 \sqrt{3}}{7} c, \quad u_{\text {fin }}=\frac{\sqrt{3}}{2} c . \tag{9.81}
\end{equation*}
$$

Finally, we can use Eq. (73) to calculate the required energy: $\varepsilon_{\min }=7 \mathrm{mc}^{2}$. (Note that of the acceleration energy $6 m c^{2}$, only $2 m c^{2}$ go into the "useful" proton-antiproton pair production.) Proton's rest mass, $m_{p} \approx$ $1.67 \times 10^{-27} \mathrm{~kg}$, corresponds to the rest energy $m c^{2} \approx 1.502 \times 10^{-10} \mathrm{~J} \approx 0.938 \mathrm{GeV}$, so that $\varepsilon_{\min } \approx 6.57 \mathrm{GeV}$.

The second, more intelligent way to solve the same problem is to use the center-of-mass (c.o.m.) reference frame that, in relativity, is defined as the frame in which the total momentum of the system vanishes. ${ }^{33}$ In this frame, at $\varepsilon=\varepsilon_{\text {min }}$, the velocity and momenta of all reaction products are equal to zero, while velocities of protons $\mathrm{p}_{a}$ and $\mathrm{p}_{b}$ before the collision are equal and opposite, with some magnitude $u$ '. Hence the energy conservation law becomes

$$
\begin{equation*}
\frac{2 m c^{2}}{\left(1-u^{\prime 2} / c^{2}\right)^{1 / 2}}=4 m c^{2} \tag{9.82}
\end{equation*}
$$

[^397]readily giving $u^{\prime}=(\sqrt{3} / 2) c$. This is of course the same result as Eq. (81) gives for $u_{\text {fin }}$. Now we can use the fact that the velocity of proton $\mathrm{p}_{b}$ in the c.o.m. frame is $\left(-u^{\prime}\right)$, and hence the speed of proton $\mathrm{p}_{a}$ is $(+u ')$. Hence we may find the lab-frame speed of proton $p_{a}$ using the velocity transform formula (25):
\[

$$
\begin{equation*}
u_{\min }=\frac{2 u^{\prime}}{1+u^{\prime 2} / c^{2}} \tag{9.83}
\end{equation*}
$$

\]

This relation gives the same result as the first method, $u_{\min }=(4 \sqrt{ } 3 / 7) c$, but in a much simpler way.

### 9.4. More on 4-vectors and 4-tensors

This is a good moment to describe a formalism that will allow us, in particular, to solve the same proton collision problem in one more (and arguably, the most elegant) way. More importantly, this formalism will be virtually necessary for the description of the Lorentz transform of the electromagnetic field, and its interaction with relativistic particles - otherwise the formulas would be too cumbersome. Let us call the 4 -vectors we have used before,

$$
\begin{equation*}
A^{\alpha} \equiv\left\{A_{0}, \mathbf{A}\right\}, \tag{9.84}
\end{equation*}
$$

contravariant, and denote them with the top index, and introduce also covariant vectors,

$$
\begin{equation*}
A_{\alpha} \equiv\left\{A_{0},-\mathbf{A}\right\} \tag{9.85}
\end{equation*}
$$

marked by the lower index. Now if we form a scalar product of these vectors using the standard (3Dlike) rule, just as a sum of the products of the corresponding components, we immediately get

$$
\begin{equation*}
A_{\alpha} A^{\alpha} \equiv A^{\alpha} A_{\alpha} \equiv A_{0}^{2}-A^{2} \tag{9.86}
\end{equation*}
$$

Here and below the sign of sum of four components of the product has been dropped. ${ }^{34}$
The scalar product (86) is just the norm of the 4 -vector in our former definition, and as we already know, is Lorentz-invariant. Moreover, the scalar product of two different vectors (also a Lorentz invariant), may be written in any of two similar forms: ${ }^{35}$

## Scalar product <br> forms

$$
\begin{equation*}
A_{0} B_{0}-\mathbf{A} \cdot \mathbf{B} \equiv A_{\alpha} B^{\alpha}=A^{\alpha} B_{\alpha} \tag{9.87}
\end{equation*}
$$

again, the only caveat is to take one vector in the covariant, and another in the contravariant form.
Now let us return to our sample problem (Fig. 10). Since all components ( $\mathcal{L} / \mathrm{c}$ and $\mathbf{p}$ ) of the total 4-momentum of our system are conserved at the collision, its norm is conserved as well:

$$
\begin{equation*}
\left(p_{a}+p_{b}\right)_{\alpha}\left(p_{a}+p_{b}\right)^{\alpha}=(4 p)_{\alpha}(4 p)^{\alpha} . \tag{9.88}
\end{equation*}
$$

Since now the vector product is the usual math construct, we know that the parentheses in the left-hand part of this equation may be multiplied as usual. We may also swap the operands and move constant factors around as convenient. As a result, we get

[^398]\[

$$
\begin{equation*}
\left(p_{a}\right)_{\alpha}\left(p_{a}\right)^{\alpha}+\left(p_{b}\right)_{\alpha}\left(p_{b}\right)^{\alpha}+2\left(p_{a}\right)_{\alpha}\left(p_{b}\right)^{\alpha}=16 p_{\alpha} p^{\alpha} . \tag{9.89}
\end{equation*}
$$

\]

Thanks to the Lorentz-invariance of each of the terms, we can calculate each of them in the reference frame we like. For the first two terms in left-hand part, as well as for the right-hand part term, it is beneficial to use the frames in which that particular proton is at rest; as a result, each of the lefthand part terms equals $(m c)^{2}$, while the right-hand part equals $16(m c)^{2}$. On the contrary, the last term of the left-hand part is better evaluated in the lab frame, because in that frame the three spatial components of the 4 -momentum $p_{b}$ vanish, and the scalar product is the just the product of scalars $\varepsilon / c$ for protons $a$ and $b$. For the latter proton this is just $m c$, so that we get a simple equation,

$$
\begin{equation*}
(m c)^{2}+(m c)^{2}+2 \frac{\varepsilon_{\min }}{c} m c=16(m c)^{2}, \tag{9.90}
\end{equation*}
$$

immediately giving the final result: $\varepsilon_{\min }=7 m c^{2}$ we have already had.
Let me hope that this example was a convincing demonstration of the convenience of presenting 4 -vectors in the contravariant (84) and covariant (85) forms, ${ }^{36}$ with Lorentz-invariant norms (86). To be useful for more complex tasks, the formalism should be developed a little bit further. In particular, it is crucial to know how do the 4 -vectors change under the Lorentz transform. For contravariant vectors, we already know the answer (54), but let us rewrite it in the new notation:

$$
\begin{equation*}
A^{\alpha}=L_{\beta}^{\alpha} A^{\prime \beta} \tag{9.91}
\end{equation*}
$$

where $L_{\beta}^{\alpha}$ is the mixed Lorentz tensor (51):37

$$
L_{\beta}^{\alpha}=\left(\begin{array}{cccc}
\gamma & \beta \gamma & 0 & 0  \tag{9.92}\\
\beta \gamma & \gamma & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{array}\right)
$$

Note that though the position of indices $\alpha$ and $\beta$ in the Lorentz tensor notation is not crucial, because it is symmetric, it is convenient to place them using the general index balance rule: the difference of the numbers of the upper and lower indices should be the same in both parts of any 4 -vector/tensor equality, with the top index in the denominator of a fraction counted as a bottom index in the numerator, and vice versa. (Check yourself that all our formulas above do satisfy this rule.)

In order to rewrite Eq. (91) in a more general form that would not depend on the particular orientation of the coordinate axes (Fig. 1), let us use the contravariant and covariant forms of the 4vector of the time-space interval (57),

[^399]\[

$$
\begin{equation*}
d x^{\alpha}=\{c d t, d \mathbf{r}\}, \quad d x_{\alpha}=\{c d t,-d \mathbf{r}\} ; \tag{9.93}
\end{equation*}
$$

\]

then its norm (58) may be presented as ${ }^{38}$

$$
\begin{equation*}
(d s)^{2} \equiv(c d t)^{2}-(d r)^{2}=d x^{\alpha} d x_{\alpha}=d x_{\alpha} d x^{\alpha} \tag{9.94}
\end{equation*}
$$

Applying Eq. (91) to the contravariant form of vector (93), we get

$$
\begin{equation*}
d x^{\alpha}=L_{\beta}^{\alpha} d x^{\prime \beta} . \tag{9.95}
\end{equation*}
$$

But, with our new shorthand notation, we can also write the usual rule of differentiation of each component $x^{\alpha}$, considering it as a (in our case, linear) function of $4 \operatorname{arguments} x^{, \beta}$, as follows:

$$
\begin{equation*}
d x^{\alpha}=\frac{\partial x^{\alpha}}{\partial x^{\prime \beta}} d x^{\prime \beta} . \tag{9.96}
\end{equation*}
$$

Comparing Eqs. (95) and (96), we can rewrite the general Lorentz transform rule (92) in the new form,

$$
\begin{equation*}
A^{\alpha}=\frac{\partial x^{\alpha}}{\partial x^{\prime \beta}} A^{\prime \beta} \tag{9.97a}
\end{equation*}
$$

which evidently does not depend on the coordinate axes orientation.
It is straightforward to verify that the reciprocal transform may be presented as

Reciprocal
Lorentz transform

$$
\begin{equation*}
A^{\prime \alpha}=\frac{\partial x^{\prime \alpha}}{\partial x^{\beta}} A^{\beta} \tag{9.97b}
\end{equation*}
$$

However, the reciprocal transform differs from the direct one only by the sign of the relative velocity of the frames, so that for the coordinate choice shown in Fig. 1, the matrix is

$$
\frac{\partial x^{\prime \alpha}}{\partial x^{\beta}}=\left(\begin{array}{cccc}
\gamma & -\beta \gamma & 0 & 0  \tag{9.98}\\
-\beta \gamma & \gamma & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{array}\right),
$$

Since, according to Eqs. (84)-(85), covariant 4-vectors differ from the contravariant ones by the sign of the spatial components, their direct transform is given by matrix (98). Hence their direct and reciprocal transforms may be represented, respectively, as
${ }^{38}$ Another way to write this relation is $(d s)^{2}=g_{\alpha \beta} d x^{\alpha} d x^{\beta}=g^{\alpha \beta} d x_{\alpha} d x_{\beta}$, where double summation over indices $\alpha$ and $\beta$ is implied, and $g$ is the so-called metric tensor,

$$
g^{\alpha \beta} \equiv g_{\alpha \beta} \equiv\left(\begin{array}{cccc}
1 & 0 & 0 & 0 \\
0 & -1 & 0 & 0 \\
0 & 0 & -1 & 0 \\
0 & 0 & 0 & -1
\end{array}\right)
$$

that may be used, in particular, to a transfer a covariant vector into the corresponding contravariant one and back: $A^{\alpha}=g^{\alpha \beta} A_{\beta}, A_{\alpha}=g_{\alpha \beta} A^{\beta}$. The metric tensor plays a key role in general relativity, in which it is affected by gravity - "curved" by particle masses.

$$
\begin{equation*}
A_{\alpha}=\frac{\partial x^{\prime \beta}}{\partial x^{\alpha}} A_{\beta}^{\prime}, \quad A_{\alpha}^{\prime}=\frac{\partial x^{\beta}}{\partial x^{\prime \alpha}} A_{\beta} \tag{9.99}
\end{equation*}
$$

evidently satisfying the index balance rule. (Note that primed quantities are now multiplied, rather than divided as in the contravariant case.) As a sanity check, let us apply this formalism to the scalar product $A_{\alpha} A^{\alpha}$. As Eq. (96) shows, the implicit summation notation allows us to multiply and divide any equality by the same partial differential of a coordinate, so that we can write:

$$
\begin{equation*}
A_{\alpha} A^{\alpha}=\frac{\partial x^{\prime \beta}}{\partial x^{\alpha}} \frac{\partial x^{\alpha}}{\partial x^{\prime \gamma}} A_{\beta}^{\prime} A^{\prime \gamma}=\frac{\partial x^{\beta}}{\partial x^{\prime \gamma}} A_{\beta}^{\prime} A^{\prime \gamma}=\delta_{\beta \gamma} A_{\beta}^{\prime} A^{\prime \gamma}=A_{\gamma}^{\prime} A^{\prime \gamma}, \tag{9.100}
\end{equation*}
$$

i.e. the scalar product $A_{\alpha} A^{\alpha}$ (as well as $A^{\alpha} A_{\alpha}$ ) is Lorentz-invariant, as it should be.

Now, let us consider the 4 -vectors of derivatives. Here we should be very careful. Consider, for example, the following vector operator

$$
\begin{equation*}
\frac{\partial}{\partial x^{\alpha}} \equiv\left\{\frac{\partial}{\partial(c t)}, \nabla\right\} \tag{9.101}
\end{equation*}
$$

As was discussed above, the operator is not changed by its multiplication and division by another differential, e.g., $\partial x^{, \beta}$ (with the corresponding implied summation over $\beta$ ), so that

$$
\begin{equation*}
\frac{\partial}{\partial x^{\alpha}}=\frac{\partial x^{\prime \beta}}{\partial x^{\alpha}} \frac{\partial}{\partial x^{\prime \beta}} . \tag{9.102}
\end{equation*}
$$

But, according to the first of Eqs. (99), this is exactly how the covariant vectors are Lorentztransformed! Hence, we have to consider the derivative over a contravariant space-time interval as a covariant 4 -vector, and vice versa. ${ }^{39}$ (This result might be also expected from the index balance rule.) In particular, this means that the scalar product

$$
\begin{equation*}
\frac{\partial}{\partial x^{\alpha}} A^{\alpha} \equiv \frac{\partial A_{0}}{\partial(c t)}+\nabla \cdot \mathbf{A} \tag{9.103}
\end{equation*}
$$

should be Lorentz-invariant for any legitimate 4 -vector. A convenient shorthand for the covariant derivative, which complies with the index balance rule, is

$$
\begin{equation*}
\frac{\partial}{\partial x^{\alpha}} \equiv \partial_{\alpha} \tag{9.104}
\end{equation*}
$$

so that the invariant scalar product may be written just as $\partial_{a} A^{\alpha}$. A similar definition of the contravariant derivative,

$$
\begin{equation*}
\partial^{\alpha} \equiv \frac{\partial}{\partial x_{\alpha}}=\left\{\frac{\partial}{\partial(c t)},-\nabla\right\}, \tag{9.105}
\end{equation*}
$$

allows us to write the Lorentz-invariant scalar product (103) in any of two forms:

$$
\begin{equation*}
\frac{\partial A_{0}}{\partial(c t)}+\nabla \cdot \mathbf{A}=\partial^{\alpha} A_{\alpha}=\partial_{\alpha} A^{\alpha} . \tag{9.106}
\end{equation*}
$$

[^400]Finally, let us see how does the general Lorentz transform changes 4 -tensors. A second-rank $4 \times 4$ matrix is a legitimate 4 -tensor if both 4 -vectors it relates obey the Lorentz transform. For example, if two legitimate 4 -vectors are related as

$$
\begin{equation*}
A^{\alpha}=T^{\alpha \beta} B_{\beta} \tag{9.107}
\end{equation*}
$$

we should require that

$$
\begin{equation*}
A^{\prime \alpha}=T^{\prime \alpha \beta} B_{\beta}^{\prime}, \tag{9.108}
\end{equation*}
$$

where $A^{\alpha}$ and $A^{\prime \alpha}$ are related by Eqs. (97), while $B_{\beta}$ and $B^{\prime}{ }_{\beta}$, by Eqs. (99). This requirement immediately yields

Lorentz transform of 4-tensors

$$
\begin{equation*}
T^{\alpha \beta}=\frac{\partial x^{\alpha}}{\partial x^{\prime \gamma}} \frac{\partial x^{\beta}}{\partial x^{\prime \delta}} T^{\gamma \delta}, \quad T^{\prime \alpha \beta}=\frac{\partial x^{\prime \alpha}}{\partial x^{\gamma}} \frac{\partial x^{\prime \beta}}{\partial x^{\delta}} T^{\gamma \delta} \tag{9.109}
\end{equation*}
$$

with the implied summation over two indices, $\gamma$ and $\delta$. The rules for covariant and mixed tensors are similar. ${ }^{40}$

### 9.5. Maxwell equations in the 4 -form

This 4-vector formalism background is already sufficient to analyze the Lorentz transform of the electromagnetic field. Just to warm up, let us consider the continuity equation (4.5),

$$
\begin{equation*}
\frac{\partial \rho}{\partial t}+\nabla \cdot \mathbf{j}=0 \tag{9.110}
\end{equation*}
$$

which expresses the electric charge conservation, and, as we already know, is compatible with the Maxwell equations. If we now define the contravariant and covariant 4-vectors of electric current as

4-vector of electric current

Continuity equation in 4-form

$$
\begin{equation*}
j^{\alpha}=\{\rho c, \mathbf{j}\}, \quad j_{\alpha}=\{\rho c,-\mathbf{j}\} \tag{9.111}
\end{equation*}
$$

then Eq. (110) may be presented in the form

$$
\begin{equation*}
\partial^{\alpha} j_{\alpha}=\partial_{\alpha} j^{\alpha}=0 \tag{9.112}
\end{equation*}
$$

showing that the continuity equation is form-invariant ${ }^{41}$ with respect to the Lorentz transform.
Of course, such equation form invariance does not mean that all component values of the 4vectors participating in the equation are the same in both frames! For example, let us have some static charge density $\rho$ in frame 0 ; then Eq. (97b), applied to the contravariant form of 4 -vector (111), reads

$$
\begin{equation*}
j^{\prime \alpha}=\frac{\partial x^{\prime \alpha}}{\partial x^{\beta}} j^{\beta}, \quad j^{\beta}=\{\rho c, 0,0,0\} . \tag{9.113}
\end{equation*}
$$

[^401]Using the explicit form (98) of the reciprocal Lorentz matrix for the coordinate choice shown in Fig. 1, we see that this relation yields

$$
\begin{equation*}
\rho^{\prime}=\gamma \rho, \quad j_{x}^{\prime}=-\gamma \beta \rho c=-\gamma \rho \rho, \quad j_{y}^{\prime}=j_{z}^{\prime}=0 . \tag{9.114}
\end{equation*}
$$

Since the charge velocity, as observed from frame 0 ', is $(-\mathbf{v})$, the non-relativistic result would be $\mathbf{j}=-\mathbf{v} \rho$. The additional $\gamma$ factor in the relativistic results for both charge density and current is caused by the length contraction: $d x^{\prime}=d x / \gamma$, so that in order to keep the total charge $d Q=\rho d^{3} r=\rho d x d y d z$ inside the elementary volume $d^{3} r=d x d y d z$ intact, $\rho$ (and hence $j_{x}$ ) should increase proportionally.

Next, in the end of Chapter 6 we have seen that Maxwell equations for potentials $\phi$ and $\mathbf{A}$ may be presented in a similar form (6.109), under the Lorenz (again, not "Lorentz" please!) gauge condition (6.108). For the free space, this condition takes the form

$$
\begin{equation*}
\nabla \cdot \mathbf{A}+\frac{1}{c^{2}} \frac{\partial \phi}{\partial t}=0 \tag{9.115}
\end{equation*}
$$

This expression gives us a hint how to form the 4-vector of potentials: 42

$$
\begin{equation*}
A^{\alpha}=\left\{\frac{\phi}{c}, \mathbf{A}\right\}, \quad A_{\alpha}=\left\{\frac{\phi}{c},-\mathbf{A}\right\} ; \tag{9.116}
\end{equation*}
$$

indeed, these vectors satisfy Eq. (115) in its 4-vector form:

$$
\begin{equation*}
\partial^{\alpha} A_{\alpha}=\partial_{\alpha} A^{\alpha}=0 . \tag{9.117}
\end{equation*}
$$

Since this scalar product is Lorentz-invariant, and derivatives (104)-(105) are legitimate 4vectors, this implies that 4 -vector (116) is also legitimate, i.e. obeys the Lorentz transform formulas (97), (99). A more convincing evidence of this fact may be obtained from Maxwell equations (6.109) for the potentials. In free space, they may be rewritten as

$$
\begin{equation*}
\left[\frac{\partial^{2}}{\partial(c t)^{2}}-\nabla^{2}\right] \frac{\phi}{c}=\frac{(\rho c)}{\varepsilon_{0} c^{2}} \equiv \mu_{0}(\rho c), \quad\left[\frac{\partial^{2}}{\partial(c t)^{2}}-\nabla^{2}\right] \mathbf{A}=\mu_{0} \mathbf{j} . \tag{9.118}
\end{equation*}
$$

Using definition (116), these equations may be merged to one: ${ }^{43}$

$$
\begin{equation*}
\square A^{\alpha}=\mu_{0} j^{\alpha}, \tag{9.119}
\end{equation*}
$$

where $\square$ is the d'Alembert operator ${ }^{44}$ that may be presented as either of two scalar products,

$$
\begin{equation*}
\square \equiv \frac{\partial^{2}}{\partial(c t)^{2}}-\nabla^{2}=\partial^{\beta} \partial_{\beta}=\partial_{\beta} \partial^{\beta} \tag{9.120}
\end{equation*}
$$

and hence is Lorentz-invariant. Because of that, and the fact that the Lorentz transform changes both 4vectors $A^{\alpha}$ and $j^{\alpha}$ in a similar way, Eq. (119) does not depend on the reference frame choice. Thus we

[^402]have arrived at a key point of this chapter: we see that Maxwell equations are indeed form-invariant with respect to the Lorentz transform. As a by-product, the 4 -vector form (119) of these equations (for potentials) is extremely simple - and beautiful.

However, as we have seen in Chapter 7, for many applications the Maxwell equations for field vectors are more convenient; so let us present them in the 4 -form. For that, we may express the Cartesian components of the usual (3D) field vector vectors

$$
\begin{equation*}
\mathbf{E}=-\nabla \phi-\frac{\partial \mathbf{A}}{\partial t}, \quad \mathbf{B}=\nabla \times \mathbf{A} \tag{9.121}
\end{equation*}
$$

via those of the potential 4-vector $A^{\alpha}$. For example,

$$
\begin{gather*}
E_{x}=-\frac{\partial \phi}{\partial x}-\frac{\partial A_{x}}{\partial t}=-c\left(\frac{\partial}{\partial x} \frac{\phi}{c}+\frac{\partial A_{x}}{\partial(c t)}\right) \equiv-c\left(\partial^{0} A^{1}-\partial^{1} A^{0}\right),  \tag{9.122}\\
B_{x}=\frac{\partial A_{z}}{\partial y}-\frac{\partial A_{y}}{\partial z} \equiv-\left(\partial^{2} A^{3}-\partial^{3} A^{2}\right) . \tag{9.123}
\end{gather*}
$$

Completing similar calculations for other field components, we find that the following asymmetric, contravariant field-strength tensor,

$$
\begin{equation*}
F^{\alpha \beta} \equiv \partial^{\alpha} A^{\beta}-\partial^{\beta} A^{\alpha}, \tag{9.124}
\end{equation*}
$$

may be expressed via the field components as follows: ${ }^{45}$

Fieldstrength tensors

$$
F^{\alpha \beta}=\left(\begin{array}{cccc}
0 & -E_{x} / c & -E_{y} / c & -E_{z} / c  \tag{9.125a}\\
E_{x} / c & 0 & -B_{z} & B_{y} \\
E_{y} / c & B_{z} & 0 & -B_{x} \\
E_{z} / c & -B_{y} & B_{x} & 0
\end{array}\right),
$$

so that the covariant form of the tensor is

$$
F_{\alpha \beta} \equiv g_{\alpha \gamma} F^{\gamma \delta} g_{\delta \beta}=\left(\begin{array}{cccc}
0 & E_{x} / c & E_{y} / c & E_{z} / c  \tag{9.125b}\\
-E_{x} / c & 0 & -B_{z} & B_{y} \\
-E_{y} / c & B_{z} & 0 & -B_{x} \\
-E_{z} / c & -B_{y} & B_{x} & 0
\end{array}\right) .
$$

If this expression looks a bit too bulky, note that as a reward, the pair of inhomogeneous Maxwell equations, i.e. the two first equations of the system (6.93), which in free space ( $\mathbf{D}=\varepsilon_{0} \mathbf{E}, \mathbf{B}=$ $\left.\mu_{0} \mathbf{H}\right)$ may be rewritten as

$$
\begin{equation*}
\nabla \cdot \frac{\mathbf{E}}{c}=\mu_{0} c \rho, \quad \nabla \times \mathbf{B}-\frac{\partial}{\partial(c t)} \frac{\mathbf{E}}{c}=\mu_{0} \mathbf{j}, \tag{9.126}
\end{equation*}
$$

may be now rewritten in a very simple (and manifestly form-invariant) way,
${ }^{45}$ In Gaussian units, this formula, as well as Eq. (131) for $G^{\alpha \beta}$, does not have factors $c$ in all the denominators.

$$
\begin{equation*}
\partial_{\alpha} F^{\alpha \beta}=\mu_{0} j^{\beta} \tag{9.127}
\end{equation*}
$$

which is comparable with Eq. (119) in its beauty and simplicity. Somewhat counter-intuitively, the pair of homogeneous Maxwell equations,

$$
\begin{equation*}
\nabla \times \mathbf{E}+\frac{\partial \mathbf{B}}{\partial t}=0, \quad \nabla \cdot \mathbf{B}=0 \tag{9.128}
\end{equation*}
$$

look, in the 4-vector notation, a bit more complicated:46

$$
\begin{equation*}
\partial_{\alpha} F_{\beta \gamma}+\partial_{\beta} F_{\gamma \alpha}+\partial_{\gamma} F_{\alpha \beta}=0 . \tag{9.129}
\end{equation*}
$$

Note, however, that Eq. (128) may be also represented in a much simpler form,

$$
\begin{equation*}
\partial_{\alpha} G^{\alpha \beta}=0 \tag{9.130}
\end{equation*}
$$

using the so-called dual (and also asymmetric) tensor

$$
G^{\alpha \beta}=\left(\begin{array}{cccc}
0 & B_{x} & B_{y} & B_{z}  \tag{9.131}\\
-B_{x} & 0 & -E_{z} / c & E_{y} / c \\
-B_{y} & E_{z} / c & 0 & -E_{x} / c \\
-B_{z} & -E_{y} / c & E_{x} / c & 0
\end{array}\right)
$$

which may be obtained from $F^{\alpha \beta}$, given by Eq. (125), by the following replacements:

$$
\begin{equation*}
\frac{\mathbf{E}}{c} \rightarrow-\mathbf{B}, \quad \mathbf{B} \rightarrow \frac{\mathbf{E}}{c} \tag{9.132}
\end{equation*}
$$

Besides the proof of the form-invariance of the Maxwell equations, the 4 -vector formalism allows us to achieve our initial goal: find out how do the electric and magnetic field component change at the transfer between reference frames. Let us apply to tensor $F^{\alpha \beta}$ the reciprocal Lorentz transform given by the second of Eqs. (109). Generally, it gives, for each field component, a sum of 16 terms, but since (for our choice of coordinates, shown in Fig. 1) there are many zeros in the Lorentz transform matrix, and diagonal components of $F^{\gamma \delta}$ equal zero as well, the calculations are rather doable. Let us calculate, for example, $E_{x}^{\prime} \equiv-c F^{, 01}$. The only nonvanishing terms in the right-hand part are

$$
\begin{equation*}
E_{x}^{\prime}=-c F^{01}=-c\left(\frac{\partial x^{\prime 0}}{\partial x^{1}} \frac{\partial x^{\prime 1}}{\partial x^{0}} F^{10}+\frac{\partial x^{\prime 0}}{\partial x^{0}} \frac{\partial x^{\prime 1}}{\partial x^{1}} F^{01}\right)=-c \gamma^{2}\left(\beta^{2}-1\right) \frac{E_{x}}{c}=E_{x} . \tag{9.133}
\end{equation*}
$$

Repeating the calculation for other 5 components of the fields, we get very important relations

$$
\begin{array}{ll}
E_{x}^{\prime}=E_{x}, & B_{x}^{\prime}=B_{x}, \\
E_{y}^{\prime}=\gamma\left(E_{y}-v B_{z}\right), & B_{y}^{\prime}=\gamma\left(B_{y}+v E_{z} / c^{2}\right),  \tag{9.134}\\
E_{z}^{\prime}=\gamma\left(E_{z}+v B_{y}\right), & B_{z}^{\prime}=\gamma\left(B_{z}-v E_{y} / c^{2}\right),
\end{array}
$$

whose more compact "semi-vector" form is

[^403]Lorentz transform of components

$$
\begin{array}{ll}
\mathbf{E}_{\|}^{\prime}=\mathbf{E}_{\|}, & \mathbf{B}_{\|}^{\prime}=\mathbf{B}_{\|},  \tag{9.135}\\
\mathbf{E}_{\perp}^{\prime}=\gamma(\mathbf{E}+\mathbf{v} \times \mathbf{B})_{\perp}, & \mathbf{B}_{\perp}^{\prime}=\gamma\left(\mathbf{B}-\mathbf{v} \times \mathbf{E} / c^{2}\right)_{\perp},
\end{array}
$$

where indices $\|$ and $\perp$ stand, respectively, for the field components parallel and perpendicular to the relative velocity $\mathbf{v}$ of the two reference frames. In the non-relativistic limit, the Lorentz factor $\gamma$ tends to 1, and Eqs. (135) acquire an even simpler form

$$
\begin{equation*}
\mathbf{E}^{\prime} \rightarrow \mathbf{E}+\mathbf{v} \times \mathbf{B}, \quad \mathbf{B}^{\prime} \rightarrow \mathbf{B}-\frac{1}{c^{2}} \mathbf{v} \times \mathbf{E} . \tag{9.136}
\end{equation*}
$$

Thus we see that the electric and magnetic fields actually transform to each other even in the first order of the $v / c$ ratio. For example, if we fly across the field lines of a uniform, static, purely electric field $\mathbf{E}$ (e.g., the one in a plane capacitor) we will see not only the electric field re-normalization (in the second order of the $v / c$ ratio), but also a nonvanishing dc magnetic field $\mathbf{B}$ ' perpendicular to both vector $\mathbf{E}$ and vector $\mathbf{v}$, the direction of our motion. This is of course what might be expected from the relativity principle: from the point of view of the moving observer (which is as legitimate as that of a stationary observer), the surface charges of capacitor plates, that create field $\mathbf{E}$, move back creating dc currents (114) which induce the apparent magnetic field. Similarly, motion across a magnetic field creates, from the point of view of the moving observer, an electric field.

This fact is very important philosophically. One can say there is no such thing in Mother Nature as an electric field (or a magnetic field) all by itself. Not only can the electric field induce the magnetic field (and vice versa) in dynamics, but even in an apparently static configuration, what exactly we measure depends on our speed relative to the field sources - hence the very appropriate term for the whole field we are studying: the electromagnetism.

Another simple but very important application of Eqs. (134)-(135) is the calculation of the fields created by a charged particle moving in free space by inertia, i.e. along a straight line with constant velocity $\mathbf{u}$, at the impact parameter ${ }^{47}$ (the closest distance) $b$ from the observer. Selecting frame 0 ' to move with the particle in its origin, and frame 0 to reside in the "lab" (in that fields $\mathbf{E}$ and $\mathbf{B}$ are measured), we can take $\mathbf{v}=\mathbf{u}$. In this case fields $\mathbf{E}^{\prime}$ and $\mathbf{B}$ ' may be calculated from, respectively, electro- and magnetostatics, because in frame 0 ' the particle does not move:

$$
\begin{equation*}
\mathbf{E}^{\prime}=\frac{q}{4 \pi \varepsilon_{0}} \frac{\mathbf{r}^{\prime}}{r^{\prime 3}}, \quad \mathbf{B}^{\prime}=0 . \tag{9.137}
\end{equation*}
$$

Selecting the coordinate axes so that at the measurement point $x=0, y=b, z=0$ (Fig. 11a), we may write $x^{\prime}=-u t^{\prime}, y^{\prime}=b, z^{\prime}=0$, so that $r^{\prime}=\left(u^{2} t^{\prime 2}+b^{2}\right)^{1 / 2}$, and the field components are as follows:

$$
\begin{equation*}
E_{x}^{\prime}=-\frac{q}{4 \pi \varepsilon_{0}} \frac{u t^{\prime}}{\left(u^{2} t^{\prime 2}+b^{2}\right)^{3 / 2}}, \quad E_{y}^{\prime}=\frac{q}{4 \pi \varepsilon_{0}} \frac{b}{\left(u^{2} t^{\prime 2}+b^{2}\right)^{3 / 2}}, \quad E_{z}^{\prime}=0, \quad B_{x}^{\prime}=B_{y}^{\prime}=B_{z}^{\prime}=0 . \tag{9.138}
\end{equation*}
$$

Now using the last of Eq. (19b), with $x=0$, for the time transform, and the equations reciprocal to Eqs. (134) for the field transform (it is evident that they are similar to the direct transform with $v$ replaced with $-v=-u$ ), in the lab frame we get

[^404]\[

$$
\begin{gather*}
E_{x}=E_{x}^{\prime}=-\frac{q}{4 \pi \varepsilon_{0}} \frac{u \gamma t}{\left(u^{2} \gamma^{2} t^{2}+b^{2}\right)^{3 / 2}}, \quad E_{y}=\gamma E_{y}^{\prime}=\frac{q}{4 \pi \varepsilon_{0}} \frac{\gamma b}{\left(u^{2} \gamma^{2} t^{2}+b^{2}\right)^{3 / 2}}, \quad E_{z}=0,  \tag{9.139}\\
B_{x}=0, \quad B_{y}=0, \quad B_{z}=\frac{\gamma u}{c^{2}} E_{y}^{\prime}=\frac{u}{c^{2}} \frac{q}{4 \pi \varepsilon_{0}} \frac{\gamma b}{\left(u^{2} \gamma^{2} t^{2}+b^{2}\right)^{3 / 2}}=\frac{u}{c^{2}} E_{y} . \tag{9.140}
\end{gather*}
$$
\]

(b)

Fig. 9.11. Field pulses induced by a uniformly moving charge.

These results, ${ }^{48}$ plotted in Fig. 11b, reveal two major effects. First, the charge passage by the observer generates not only an electric field pulse, but also a magnetic field pulse. This is natural, because, as was repeatedly discussed in Chapter 5, charge motion is essentially an electric current. ${ }^{49}$ Second, Eqs. (139)-(140) show that the pulse duration scale is

$$
\begin{equation*}
\Delta t=\frac{b}{\gamma u}=\frac{b}{u}\left(1-\frac{u^{2}}{c^{2}}\right)^{1 / 2}, \tag{9.141}
\end{equation*}
$$

i.e. shrinks to zero as the charge velocity $u$ approaches the speed of light. This is of course a direct corollary of the relativistic length contraction: in the frame 0 ' moving with the charge, the longitudinal spread of its electric field at distance $b$ from the motion line is of the order of $\Delta x^{\prime}=b$. When observed from the lab frame 0, this interval, in accordance with Eq. (20), shrinks to $\Delta x=\Delta x^{\prime} / \gamma=b / \gamma$, and so does the pulse duration scale $\Delta t=\Delta x / u=b / \gamma u$.

### 9.6. Relativistic particles in electric and magnetic fields

Now let us analyze dynamics of charged particles in electric and magnetic fields. Inspired by "our" success of forming the 4 -vector (75) of energy-momentum,

$$
\begin{equation*}
p^{\alpha}=\left\{\frac{\varepsilon}{c}, \mathbf{p}\right\}=\gamma\{m c, \mathbf{p}\}=m \frac{d x^{\alpha}}{d \tau} \equiv m u^{\alpha} \tag{9.142}
\end{equation*}
$$

where $u^{\alpha}$ is the contravariant form of the 4-velocity (63) of the particle,

[^405]\[

$$
\begin{equation*}
u^{\alpha} \equiv \frac{d x^{\alpha}}{d \tau}, \quad u_{\alpha} \equiv \frac{d x_{\alpha}}{d \tau} \tag{9.143}
\end{equation*}
$$

\]

we may notice that the non-relativistic equation of motion, resulting from the Lorentz-force formula (5.10) for the three spatial components of $p^{\alpha}$, at charged particle's motion in electromagnetic field,

Particle's dynamics in 4-form
is fully consistent with the following 4-vector equality (which is evidently form-invariant):

$$
\begin{equation*}
\frac{d p^{\alpha}}{d \tau}=q F^{\alpha \beta} u_{\beta} \tag{9.145}
\end{equation*}
$$

For example, the $\alpha=1$ component of this equation reads

$$
\begin{equation*}
\frac{d p^{1}}{d \tau}=q F^{1 \beta} u_{\beta}=q\left[\frac{E_{x}}{c} \gamma c+0 \cdot\left(-\gamma u_{x}\right)+\left(-B_{z}\right)\left(-\gamma u_{y}\right)+B_{y}\left(-\gamma u_{z}\right)\right]=q \gamma[\mathbf{E}+\mathbf{u} \times \mathbf{B}]_{x}, \tag{9.146}
\end{equation*}
$$

and similarly for two other spatial components ( $\alpha=2$ and $\alpha=3$ ). We see that these expressions differ from the Newton law (144) by the extra factor $\gamma$. However, plugging into Eq. (146) the definition of the proper time interval, $d \tau=d t / \gamma$, and canceling $\gamma$ in both parts, we recover Eq. (144) exactly - for any velocity of the particle! The only caveat is that if $u$ is comparable with $c, \mathbf{p}$ in Eq. (144) has to be understood as the relativistic momentum (70) proportional to the velocity-dependent mass $M=\gamma m \geq m$ rather than to the rest mass $m$.

The only remaining task is to examine the meaning of the $0^{\text {th }}$ component of Eq. (145). Let us spell it out:

$$
\begin{equation*}
\frac{d p^{0}}{d \tau}=q F^{0 \beta} u_{\beta}=q\left[0 \cdot \gamma c+\left(-\frac{E_{x}}{c}\right)\left(-u_{x}\right)+\left(-\frac{E_{y}}{c}\right)\left(-\mu_{y}\right)+\left(-\frac{E_{z}}{c}\right)\left(-\gamma u_{z}\right)\right]=q \gamma \frac{\mathbf{E}}{c} \cdot \mathbf{u} . \tag{9.147}
\end{equation*}
$$

Recalling that $p^{0}=\varepsilon / c$, and using $d \tau=d t / \gamma$ again, we see that Eq. (147) looks exactly as the nonrelativistic relation for the kinetic energy change, ${ }^{50}$

Particle's energy evolution

$$
\begin{equation*}
\frac{d \varepsilon}{d t}=q \mathbf{E} \cdot \mathbf{u} \tag{9.148}
\end{equation*}
$$

besides that in the relativistic case the energy has to be taken in the general form (73).
No question, the 4 -component equation (145) of relativistic dynamics is beautiful in its simplicity. However, for the solution of particular problems, Eqs. (144) and (148) are frequently preferable. As an illustration of this point, let us now use these equations to explore the relativistic effects at charged particle motion in uniform, time-independent electric and magnetic fields. In doing that, we will, for the time being, neglect the contributions into the field by the particle itself. ${ }^{51}$

[^406](i) Uniform magnetic field. Let the magnetic field be constant and uniform in the "lab" reference frame 0. Then in this frame, Eqs. (144) and (148) yield
\[

$$
\begin{equation*}
\frac{d \mathbf{p}}{d t}=q \mathbf{u} \times \mathbf{B}, \quad \frac{d \varepsilon}{d t}=0 . \tag{9.149}
\end{equation*}
$$

\]

From the second equation, $\varepsilon=$ const, we get $u=$ const, $\beta \equiv u / c=$ const, $\gamma \equiv\left(1-\beta^{2}\right)^{-1 / 2}=$ const, and $M \equiv$ $\gamma m=$ const, so that the first of Eqs. (149) may be rewritten as

$$
\begin{equation*}
\frac{d \mathbf{u}}{d t}=\mathbf{u} \times \boldsymbol{\omega}_{c} \tag{9.150}
\end{equation*}
$$

where $\omega_{c}$ is the vector directed along the magnetic field $\mathbf{B}$, with the magnitude equal to the cyclotron frequency (sometimes called "gyrofrequency")

$$
\begin{equation*}
\omega_{c} \equiv \frac{q B}{M}=\frac{q B}{\gamma m}=\frac{q c^{2} B}{\varepsilon} . \tag{9.151}
\end{equation*}
$$

If particle's initial velocity $\mathbf{u}_{0}$ is perpendicular to the magnetic field, Eq. (150) describes its circular motion, with a constant speed $u=u_{0}$, in a plane perpendicular to $\mathbf{B}$, and frequency (151). In the non-relativistic limit $u \ll c$, when $\gamma \rightarrow 1$, i.e. $M \rightarrow m$, the cyclotron frequency is independent on the speed, but as the kinetic energy is increased to comparable to the rest energy of the particle, the frequency decreases, and in the ultra-relativistic limit,

$$
\begin{equation*}
\omega_{c} \approx q c \frac{B}{p}, \quad \text { at } u \approx c . \tag{9.152}
\end{equation*}
$$

The cyclotron motion radius may be calculated as $R=u / \omega_{c}$; in the non-relativistic limit it is proportional to particle's speed, i.e. to the square root of its kinetic energy. However, in the general case the radius is proportional to particle's relativistic momentum rather than its speed:

$$
\begin{equation*}
R=\frac{u}{\omega_{c}}=\frac{M u}{q B}=\frac{m \gamma u}{q B}=\frac{1}{q} \frac{p}{B}, \tag{9.153}
\end{equation*}
$$

Cyclotron radius
so that in the ultra-relativistic limit, when $p \approx \varepsilon / c, R$ is proportional to the kinetic energy.
This dependence of $\omega_{c}$ and $R$ on energy are the major factors in design of circular accelerators of charged particles. In the simplest of these machines (the cyclotron, invented in 1929 by E. Lawrence), frequency $\omega$ of the accelerating ac electric field is constant, so that even it is tuned to $\omega_{c}$ of the initially injected particles, the drop of the cyclotron frequency with energy eventually violates this tuning. Due to this reason, the maximum particle speed is limited to just $\sim 0.1 c$ (for protons, corresponding to the kinetic energy of just $\sim 15 \mathrm{MeV}$ ). This problem may be addressed in several ways. In particular, in synchrotrons (such as Fermilab's Tevatron and CERN's LHC) the magnetic field is gradually increased in time to compensate the momentum increase $(B \propto p)$, so that both $R(148)$ and $\omega_{c}(147)$ stay constant, enabling proton acceleration to energies as high as $\sim 7 \mathrm{TeV}$, i.e. $\sim 2,000 \mathrm{mc}^{2} .{ }^{52}$

[^407]Returning to our initial problem, if particle's initial velocity has a component $u_{\|}$along the magnetic field, it is conserved in time, so that the trajectory is a spiral around the magnetic field lines. As Eqs. (149) show, in this case Eq. (150) remains valid, but in Eqs. (151) and (153) the full speed and momentum have to be replaced with magnitudes of their (also time-conserved) components, $u_{\perp}$ and $p_{\perp}$, normal to $\mathbf{B}$, while the Lorentz factor $\gamma$ in those formulas still requires the full speed of the particle.

Finally, in the special case when particle's initial velocity is directed exactly along the magnetic field's direction, it continues to move by straight line along vector B. In this case, the cyclotron frequency (151) remains finite, but does not correspond to any real motion, because $R=0$.
(ii) Uniform electric field. This problem is (technically) more complex than the previous one, because in the electric field, particle's kinetic energy may change. Directing axis $z$ along the field, from Eq. (144) we get

$$
\begin{equation*}
\frac{d p_{z}}{d t}=q E, \quad \frac{d \mathbf{p}_{\perp}}{d t}=0 . \tag{9.154}
\end{equation*}
$$

If the field does not change in time, the first integration of these equations is trivial,

$$
\begin{equation*}
p_{z}(t)=p_{z}(0)+q E t, \quad \mathbf{p}_{\perp}(t)=\text { const }=\mathbf{p}_{\perp}(0), \tag{9.155}
\end{equation*}
$$

but the further integration requires care, because the effective mass $M=\gamma m$ of the particle depends on its full speed:

$$
\begin{equation*}
u^{2}=u_{z}^{2}+u_{\perp}^{2}, \tag{9.156}
\end{equation*}
$$

making the two motions, along and across the field, mutually dependent.
If the initial velocity is perpendicular to field $\mathbf{E}$, i.e. if $p_{z}(0)=0, p_{\perp}(0)=p(0) \equiv p_{0}$, the easiest way to proceed is to calculate the kinetic energy first:

$$
\begin{equation*}
\mathcal{\varepsilon}^{2}=\left(m c^{2}\right)^{2}+c^{2} p^{2}(t)=\varepsilon_{0}^{2}+c^{2}(q E t)^{2}, \quad \text { where } \varepsilon_{0} \equiv\left[\left(m c^{2}\right)^{2}+c^{2} p_{0}^{2}\right]^{1 / 2} \tag{9.157}
\end{equation*}
$$

On the other hand, we can calculate the same energy by integrating Eq. (148),

$$
\begin{equation*}
\frac{d \varepsilon}{d t}=q \mathbf{E} \cdot \mathbf{u}=q E \frac{d z}{d t}, \tag{9.158}
\end{equation*}
$$

over time, with a simple result:

$$
\begin{equation*}
\varepsilon=\varepsilon_{0}+q E z(t) \tag{9.159}
\end{equation*}
$$

where (for the notation simplicity) I took $z(0)=0$. Requiring Eq. (159) to give the same $\varepsilon^{2}$ as Eq. (157), we get a quadratic equation for $z(t)$,

$$
\begin{equation*}
\varepsilon_{0}^{2}+c^{2}(q E t)^{2}=\left[\varepsilon_{0}+q E z(t)\right]^{2}, \tag{9.160}
\end{equation*}
$$

whose solution (with the sign before the square root corresponding to $E>0$, i.e. $z \geq 0$ ) is

$$
\begin{equation*}
z(t)=\frac{\varepsilon_{0}}{q E}\left\{\left[1+\left(\frac{c q E t}{\varepsilon_{0}}\right)^{2}\right]^{1 / 2}-1\right\} . \tag{9.161}
\end{equation*}
$$

Now let us find particle's trajectory. Selecting axis $x$ so that the initial velocity vector (and hence the velocity vector at any further instant) is within the $[x, z]$ plane, i.e. $y(t) \equiv 0$, we may use Eqs. (155) to calculate trajectory's slope, at its arbitrary point, as

$$
\begin{equation*}
\frac{d z}{d x}=\frac{d z / d t}{d x / d t}=\frac{M u_{z}}{M u_{x}}=\frac{p_{z}}{p_{x}}=\frac{q E t}{p_{0}} . \tag{9.162}
\end{equation*}
$$

Now let us use Eq. (160) to express the numerator of this fraction, $q E t$, as a function of $z$ :

$$
\begin{equation*}
q E t=\frac{1}{c}\left[\left(\varepsilon_{0}+q E z\right)^{2}-\varepsilon_{0}^{2}\right]^{1 / 2} . \tag{9.163}
\end{equation*}
$$

Plugging this expression into Eq. (161), we get

$$
\begin{equation*}
\frac{d z}{d x}=\frac{1}{c p_{0}}\left[\left(\varepsilon_{0}+q E z\right)^{2}-\varepsilon_{0}^{2}\right]^{1 / 2} \tag{9.164}
\end{equation*}
$$

This differential equation may be readily integrated, separating variables $z$ and $x$, and using the following substitution: $\xi \equiv \cosh ^{-1}\left(q E z / \varepsilon_{0}+1\right)$. Selecting the origin of axis $x$ at the initial point, so that $x(0)=0$, we finally get the trajectory:

$$
\begin{equation*}
z=\frac{\varepsilon_{0}}{q E}\left(\cosh \frac{q E x}{c p_{0}}-1\right) \tag{9.165}
\end{equation*}
$$

At the initial part of the trajectory, where $q E x \ll c p_{0}(0)$, this expression may be approximated by the first nonvanishing term of the Taylor series, giving a parabola:

$$
\begin{equation*}
z=\frac{\varepsilon_{0} q E}{2}\left(\frac{x}{c p_{0}}\right)^{2}, \tag{9.166}
\end{equation*}
$$

so that if the initial velocity of the particle is much less than $c$ (i.e. $p_{0} \approx m u_{0}, \varepsilon_{0} \approx m c^{2}$ ), we get the familiar non-relativistic formula:

$$
\begin{equation*}
z=\frac{q E}{2 m u_{0}^{2}} x^{2}=\frac{a}{2} t^{2}, \quad a=\frac{F}{m}=\frac{q E}{m} . \tag{9.167}
\end{equation*}
$$

This solution may be readily generalized to the case of an arbitrary direction of particle's initial velocity; this generalization is left for reader's exercise.
(iii) Crossed uniform magnetic and electric fields $(\mathbf{E} \perp \mathbf{B})$. In the view of how bulky the solution of the previous problem (i.e. the particular case of the current problem for $\mathbf{B}=0$ ) was, one might think that this problem should be forbiddingly complex for an analytical solution. Counter-intuitively, it is not the case, due to the help from the field transform relations (135). Let us consider two possible cases.

Case I: $E / c<B$. Let us consider an inertial frame moving (relatively the "lab" reference frame 0 in which fields $\mathbf{E}$ and $\mathbf{B}$ are defined) with velocity

$$
\begin{equation*}
\mathbf{v}=\frac{\mathbf{E} \times \mathbf{B}}{B^{2}} \tag{9.168}
\end{equation*}
$$

whose magnitude $v=c \times(E / c) / B<c$. Selecting the coordinate axes as shown in Fig. 12, so that

$$
\begin{equation*}
E_{x}=0, \quad E_{y}=E, \quad E_{z}=0 ; \quad B_{x}=0, \quad B_{y}=0, \quad B_{z}=0, \tag{9.169}
\end{equation*}
$$

we see that the Cartesian components of this velocity are $v_{x}=v, v_{y}=v_{z}=0$.

Fig. 9.12. Particle's trajectory in crossed electric and magnetic fields (at $E / \mathrm{c}<B$ ).

Since this choice of coordinates complies with that used to derive Eqs. (134), we can readily use that simple form of the Lorentz transform to calculate field components in the moving reference frame:

$$
\begin{gather*}
E_{x}^{\prime}=0, \quad E_{y}^{\prime}=\gamma(E-v B)=\gamma\left(E-\frac{E}{B} B\right)=0, \quad E_{z}^{\prime}=0,  \tag{9.170}\\
B_{x}^{\prime}=0, \quad B_{y}^{\prime}=0, \quad B_{z}^{\prime}=\gamma\left(B-\frac{v E}{c^{2}}\right)=\gamma B\left(1-\frac{v E}{B c^{2}}\right)=\gamma B\left(1-\frac{v^{2}}{c^{2}}\right)=\frac{B}{\gamma} \leq B, \tag{9.171}
\end{gather*}
$$

where the Lorentz parameter $\gamma \equiv\left(1-v^{2} / c^{2}\right)^{-1 / 2}$ corresponds to velocity (168) rather than that of the particle.

Thus in this special reference frame the particle only sees a (re-normalized) uniform magnetic field $B^{\prime} \leq B$, parallel to the initial field, i.e. perpendicular to velocity (168). Using the result of the above example (i), we see that in this frame the particle will move along either a circle or a spiral winding about the direction of the magnetic field, with angular speed (151),

$$
\begin{equation*}
\omega_{c}^{\prime}=\frac{q B^{\prime}}{\varepsilon^{\prime} / c^{2}}, \tag{9.172}
\end{equation*}
$$

and radius (148):

$$
\begin{equation*}
R^{\prime}=\frac{p_{\perp}^{\prime}}{q B^{\prime}} . \tag{9.173}
\end{equation*}
$$

Hence in the lab frame, the particle will perform such orbital motion plus a "drift" with constant velocity $\mathbf{v}$ (Fig. 12). As the result, the lab-frame trajectory of the particle (or rater its projection onto the plane perpendicular to the magnetic field) is a trochoid-like curve ${ }^{53}$ that, depending on the initial velocity, may be either prolate (self-crossing), as in Fig. 12, or curtate (stretched so much that it is not selfcrossing).

[^408]Such looped motion of electrons (in practice, with $v \ll c$ ) is used, in particular, in magnetrons generators of microwave radiation. In these devices (Fig. 13a), the magnetic field, usually created by specially-shaped permanent magnets, is nearly uniform (in the region of electron motion) and directed along magnetron's axis, while the electric field of magnitude $E \ll c B$, created by the dc voltage applied between the anode and cathode, is virtually radial. As a result, the above simple theory is only approximately valid, and electron trajectories are close to epicycloids rather than trochoids. The applied electric field is adjusted so that these trajectories pass close to the gap openings to cylindrical microwave cavities drilled in magnetron's bulk anode (Fig. 13b). The fundamental mode of each cavity is quasi-lumped, with cylindrical walls working mostly as lumped inductances, and gaps as lumped capacitances, with the microwave electric field concentrated in the gap openings. This is why the mode is strongly coupled to the passing electrons, and their interaction creates large positive feedback (equivalent to negative damping) that results in intensive microwave self-oscillations at cavities' eigenfrequency. ${ }^{54}$ The oscillation energy, of course, is taken from the dc-field-accelerated electrons; due to the energy loss each electron gradually moves closer to the anode and finally lands on its surface. The wide use of such generators (in particular, in microwave ovens, which operate in a narrow frequency band around 2.45 GHz , allocated for these devices to avoid their interference with wireless communication systems) is due to their simplicity and high (up to 65\%) efficiency.

(b)

Fig. 9.13. Magnetron. (Adapted from http://microwavetubes.iwarp.com.)

Case II: $E / c>B$. In this case, the speed given by Eq. (168) would be above the speed of light, so let us introduce a reference frame moving with a different velocity,

$$
\begin{equation*}
\mathbf{v}=\frac{\mathbf{E} \times \mathbf{B}}{(E / c)^{2}} \tag{9.174}
\end{equation*}
$$

whose direction is the same as before (Fig. 12), and magnitude $v=c \times B /(E / c)$ is again below $c$. A calculation absolutely similar to the one performed above for Case I, yields

$$
\begin{equation*}
E_{x}^{\prime}=0, \quad E_{y}^{\prime}=\gamma(E-v B)=\gamma E\left(1-\frac{v B}{E}\right)=\gamma E\left(1-\frac{v^{2}}{c^{2}}\right)=\frac{E}{\gamma} \leq E, \quad E_{z}^{\prime}=0, \tag{9.175}
\end{equation*}
$$

[^409]\[

$$
\begin{equation*}
B_{x}^{\prime}=0, \quad B_{y}^{\prime}=0, \quad B_{z}^{\prime}=\gamma\left(B-\frac{v E}{c^{2}}\right)=\gamma\left(B-\frac{E B}{E}\right)=0 . \tag{9.176}
\end{equation*}
$$

\]

so that in the moving frame the particle sees only an electric field $E^{\prime} \leq E$. According to the solution of our previous problem (ii), the trajectory of the particle in the moving frame is hyperbolic, so that in the lab frame it has an "open", hyperbolic character as well.

To conclude this section, let me note that if the electric and magnetic fields are non-uniform, the particle motion is much more complex, and in most cases the integration of equations (144), (148) may be carried out only numerically. However, if the field nonuniformity is small, (approximate) analytical methods may be very effective. For example, if the magnetic field has a small transverse gradient $\nabla B$ in a direction perpendicular to the vector $\mathbf{B}$ itself, such that

$$
\begin{equation*}
\eta \equiv \frac{|\nabla B|}{B} \ll \frac{1}{R}, \tag{9.177}
\end{equation*}
$$

where $R$ is the cyclotron radius (153), then it is straightforward to use Eq. (150) to show ${ }^{55}$ that the cyclotron orbit drifts perpendicular to both $\mathbf{B}$ and $\nabla B$, with speed

$$
\begin{equation*}
v_{d} \approx \frac{\eta}{\omega_{c}}\left(\frac{1}{2} u_{\perp}^{2}+u_{\|}^{2}\right) \ll u . \tag{9.178}
\end{equation*}
$$

The physics of this drift is rather simple: according to Eq. (153), the instant curvature of the cyclotron orbit is proportional to the local value of the field. Hence if the field is nonuniform, the trajectory bends more on its parts passing through stronger field, thus acquiring a shape close to a curate trochoid.

For engineering and experimental practice, effects of longitudinal gradients of magnetic field on charged particle motion are much more important, but let me postpone their discussion until we have got a little bit more analytical tools in the next section.

### 9.7. Analytical mechanics of charged particles

Equation (145) gives a full description of relativistic particle dynamics in electric and magnetic fields, just as the $2^{\text {nd }}$ Newton law (1) does it in the non-relativistic limit. However, we know that in the latter case, the Lagrange formalism of analytical mechanics allows an easier solution of many problems. ${ }^{56}$ We can fully expect that to be true in relativistic mechanics as well, so let us expand the analysis of Sec. 3 to particles in the field.

Let recall that for a free particle, our main result was Eq. (68), which may be rewritten as

$$
\begin{equation*}
\gamma \mathcal{L}=-m c^{2}, \tag{9.179}
\end{equation*}
$$

showing that this product is Lorentz-invariant. How can the electromagnetic field affect this relation? In electrostatics, we could write

$$
\begin{equation*}
\mathcal{L}=T-U=T-q \phi . \tag{9.180}
\end{equation*}
$$

[^410]However, in relativity the scalar potential $\phi$ is just one component of the potential 4-vector (116). The only way to get a Lorentz-invariant contribution to $\gamma \mathcal{L}$ from the full 4 -vector, that would be also proportional to the Lorentz force, i.e. to the first power of particle's velocity (to account for the magnetic component of the Lorentz force), is evidently

$$
\begin{equation*}
\gamma \mathcal{L}=-m c^{2}+\text { const } \times u^{\alpha} A_{\alpha} \tag{9.181}
\end{equation*}
$$

where $u^{\alpha}$ is the 4 -velocity (63). In order to comply with Eq. (180) in electrostatics, the constant factor should be equal to ( $-q c$ ), so that Eq. (182) becomes

$$
\begin{equation*}
\gamma \mathcal{L}=-m c^{2}-q u^{\alpha} A_{\alpha}, \tag{9.182}
\end{equation*}
$$

and, finally,

$$
\begin{equation*}
\mathcal{L}=-\frac{m c^{2}}{\gamma}-q \phi+q \mathbf{u} \cdot \mathbf{A} \tag{9.183}
\end{equation*}
$$

i.e., in the Cartesian form,

$$
\begin{equation*}
\mathcal{L}=-m c^{2}\left(1-\frac{u_{x}^{2}+u_{y}^{2}+u_{z}^{2}}{c^{2}}\right)^{1 / 2}-q \phi+q\left(u_{x} A_{x}+u_{y} A_{y}+u_{z} A_{z}\right) \tag{9.184}
\end{equation*}
$$

Let us see whether this relation (that admittedly was obtained above by an educated guess rather than by a strict derivation) passes a natural sanity check. For the case of unconstrained motion of a particle, we can select its three Cartesian coordinates $r_{j}(j=1,2,3)$ as the generalized coordinates, and linear velocity components $u_{j}$ as the corresponding generalized velocities. In this case, the Lagrange equations of motion are ${ }^{57}$

$$
\begin{equation*}
\frac{d}{d t} \frac{\partial \mathcal{L}}{\partial u_{j}}-\frac{\partial \mathcal{L}}{\partial r_{j}}=0 \tag{9.185}
\end{equation*}
$$

For example, for $r_{1}=x$, Eq. (184) yields

$$
\begin{equation*}
\frac{\partial \mathcal{L}}{\partial u_{x}}=\frac{m u_{x}}{\left(1-u^{2} / c^{2}\right)^{1 / 2}}+q A_{x}=p_{x}+q A_{x}, \quad \frac{\partial \mathcal{L}}{\partial x}=-q \frac{\partial \phi}{\partial x}+q \mathbf{u} \cdot \frac{\partial \mathbf{A}}{\partial x} \tag{9.186}
\end{equation*}
$$

so that Eq. (185) takes the form

$$
\begin{equation*}
\frac{d p_{x}}{d t}=-q \frac{\partial \phi}{\partial x}+q \mathbf{u} \cdot \frac{\partial \mathbf{A}}{\partial x}-q \frac{d A_{x}}{d t} . \tag{9.187}
\end{equation*}
$$

In equations of motion, field values have to be taken at the instant position of the particle, so that the last (full) derivative has components due to both the actual field change (at a fixed point of space) and the particle's motion. Such addition is described by the so-called convective derivative ${ }^{58}$

$$
\begin{equation*}
\frac{d}{d t}=\frac{\partial}{\partial t}+\mathbf{u} \cdot \nabla \tag{9.188}
\end{equation*}
$$

Convective derivative

[^411]Spelling out both scalar products, we may group the terms remaining after cancellations as follows:

$$
\begin{equation*}
\frac{d p_{x}}{d t}=q\left[\left(-\frac{\partial \phi}{\partial x}-\frac{\partial A_{x}}{\partial t}\right)+u_{y}\left(\frac{\partial A_{y}}{\partial x}-\frac{\partial A_{x}}{\partial y}\right)-u_{z}\left(\frac{\partial A_{x}}{\partial z}-\frac{\partial A_{z}}{\partial x}\right)\right] . \tag{9.189}
\end{equation*}
$$

But taking into account relations (121) between the electric and magnetic fields and potentials, this expression is nothing more than

$$
\begin{equation*}
\frac{d p_{x}}{d t}=q\left(E_{x}+u_{y} B_{z}-u_{z} B_{y}\right)=q(\mathbf{E}+\mathbf{u} \times \mathbf{B})_{x}, \tag{9.190}
\end{equation*}
$$

i.e. the $x$-component of Eq. (144). Since other Cartesian coordinates participate in Eq. (184) in a similar way, it is evident that the Lagrangian equations of motion along other coordinates yield other components of the same vector equation of motion.

So, Eq. (183) does indeed give the correct Lagrangian function, and we can use it for the further analysis, in particular to discuss the first of Eqs. (186). This relation shows that in the electromagnetic field, the generalized momentum corresponding to particle's coordinate $x$ is not $p_{x}=m \gamma u_{x}$, but ${ }^{59}$

$$
\begin{equation*}
P_{x} \equiv \frac{\partial \mathscr{L}}{\partial u_{x}}=p_{x}+q A_{x} . \tag{9.191}
\end{equation*}
$$

Thus, as was already mentioned in brief in Sec. 6.3, particle's motion in a field may be is described by two momentum vectors: the kinetic momentum p, defined by Eq. (70), and the canonical (or "conjugate") momentum ${ }^{60}$

$$
\begin{equation*}
\mathbf{P}=\mathbf{p}+q \mathbf{A} \tag{9.192}
\end{equation*}
$$

In order to facilitate the discussion of this notion, let us generalize expression (72) for the Hamiltonian function $\not \subset$ of a free particle to the case of a particle in the field:

$$
\begin{equation*}
\mathcal{H}=\mathbf{P} \cdot \mathbf{u}-\mathcal{L}=(\mathbf{p}+q \mathbf{A}) \cdot \mathbf{u}-\left(-\frac{m c^{2}}{\gamma}+q \mathbf{u} \cdot \mathbf{A}-q \phi\right)=\mathbf{p} \cdot \mathbf{u}+\frac{m c^{2}}{\gamma}+q \phi . \tag{9.193}
\end{equation*}
$$

Merging the first two terms exactly as it was done in Eq. (72), we get an extremely simple result,

$$
\begin{equation*}
\nexists=\gamma m c^{2}+q \phi, \tag{9.194}
\end{equation*}
$$

that may leave us wondering: where is the vector-potential $\mathbf{A}$ here - and the field effects is has to describe? The resolution of this puzzle is easy: for a practical use (e.g., for the alternative derivation of the equations of motion), $\nexists$ has to be presented as a function of particle's generalized coordinates (in the case of unconstrained motion, these may be the Cartesian components of vector $\mathbf{r}$ that serves as an argument for potentials $\mathbf{A}$ and $\phi$ ), and the generalized momenta, i.e. the Cartesian components of vector $\mathbf{P}$ (plus, generally, time). Hence, velocity $u$ and factor $\gamma$ should be eliminated from Eq. (194). This may be done using relation (192), $\gamma m \mathbf{u}=\mathbf{P}-q \mathbf{A}$. For such elimination, it is sufficient to notice that according

[^412]to Eq. (193), difference ( $\not \boldsymbol{\nless}-q \phi$ ) is equal to the right-hand part of Eq. (72), so that the generalization of Eq. (78) is ${ }^{61}$
\[

$$
\begin{equation*}
(\not Z-q \phi)^{2}=\left(m c^{2}\right)^{2}+c^{2}(\mathbf{P}-q \mathbf{A})^{2} . \tag{9.195}
\end{equation*}
$$

\]

Particle's Hamiltonian

It is straightforward to verify that the Hamilton equations of motion for three Cartesian coordinates of the particle, obtained in the regular way ${ }^{62}$ from this $\mathcal{H}$, may be merged into the same vector equation (144). In the non-relativistic limit, the Taylor expansion of Eq. (195) to the first term in $p^{2}$ yields the following generalization of Eq. (74):

$$
\begin{equation*}
\nexists-m c^{2} \approx \frac{p^{2}}{2 m}+U=\frac{1}{2 m}(\mathbf{P}-q \mathbf{A})^{2}+U, \quad U=q \phi . \tag{9.196}
\end{equation*}
$$

This expression for $\mathcal{H}$, and Eq. (183) for $\mathcal{L}$, give a clear view of the electromagnetic field effect account in analytical mechanics. The electric part of the total Lorentz force $q(\mathbf{E}+\mathbf{u} \times \mathbf{B})$ can perform work on the particle, i.e. change its kinetic energy - see Eq. (148) and its discussion. As a result, the scalar potential $\phi$, whose gradient gives a contribution into $\mathbf{E}$, may be directly associated with potential energy $U=q \phi$. On the contrary, the magnetic component $q \mathbf{u} \times \mathbf{B}$ of the Lorentz force is always perpendicular to particle's velocity $\mathbf{u}$, and cannot work on it, and as a result cannot be described by a contribution to $U$. However, if A did not participate in functions $\mathcal{L}$ and/or $\not \subset$ at all, analytical mechanics would be unable to describe effects of magnetic field $\mathbf{B}=\nabla \times \mathbf{A}$ on particle's motion. Relations (183) and (197) show the wonderful way in which physics (or Mother Nature herself?) solves this problem: the vector-potential gives such contributions to both $\mathcal{L}$ and $\not \not \notin$ (if the latter is considered, as it should be, a function of $\mathbf{P}$ rather than $\mathbf{p}$ ) that cannot be uniquely attributed to either kinetic or potential energy, but ensure the correct equation of motion (144) in both the Lagrange and Hamilton formalisms.

I believe I still owe the reader a clear discussion of the physical sense of the canonical momentum $\mathbf{P}$. For that, let us consider a particle moving near a region of localized magnetic field $\mathbf{B}(\mathbf{r}, t)$, but not entering this region. If there is no electrostatic field (no other electric charges nearby), we can select such a local gauge that $\phi(\mathbf{r}, t)=0$ and $\mathbf{A}=\mathbf{A}(t)$, so that Eq. (144) is reduced to

$$
\begin{equation*}
\frac{d \mathbf{p}}{d t}=q \mathbf{E}=-q \frac{d \mathbf{A}}{d t}, \tag{9.197}
\end{equation*}
$$

immediately giving

$$
\begin{equation*}
\frac{d \mathbf{P}}{d t}=0 \tag{9.198}
\end{equation*}
$$

Hence, even if the magnetic field is changed in time, so that the induced electric field accelerates the particle, its conjugate momentum does not change. Hence $\mathbf{P}$ is a variable more stable to magnetic field changes than its kinetic counterpart $\mathbf{p}$. This conclusion may be criticized because it relies on a specific gauge, and generally $\mathbf{P} \equiv \mathbf{p}+q \mathbf{A}$ is not gauge-invariant, because vector-potential $\mathbf{A}$ isn't. ${ }^{63}$ However, as
${ }^{61}$ This relation may be also obtained from the expression for the Lorentz-invariant norm, $p^{\alpha} p_{\alpha}=(m c)^{2}$, of the 4momentum (75), $p^{\alpha}=\{\varepsilon / c, \mathbf{p}\}=\{(\nexists-q \phi) / c, \mathbf{P}-q \mathbf{A}\}$.
${ }^{62}$ See, e.g., CM Sec. 10.1.
${ }^{63}$ The kinetic momentum $\mathbf{p}=M \mathbf{u}$ is just the usual mu product modified for relativistic effects, so that this variable is evidently gauge- (though not Lorentz-) invariant.
was already discussed in Sec. 5.3, integral $\int \mathbf{A} \cdot d \mathbf{r}$ over a closed contour does not depend on the chosen gauge and equals to the magnetic flux $\Phi$ through the area limited by the contour - see Eq. (5.65). Integrating Eq. (197) over a closed trajectory of a particle (Fig. 14), and over the time of one orbit, we get

$$
\begin{equation*}
\Delta \oint_{C} \mathbf{p} \cdot d \mathbf{r}=-q \Delta \Phi, \quad \text { so that } \Delta \oint_{C} \mathbf{P} \cdot d \mathbf{r}=0, \tag{9.199}
\end{equation*}
$$

where $\Delta \Phi$ is the change of flux during that time. This gauge-invariant result confirms the above conclusion about the stability of the canonical momentum to magnetic field variations.

Fig. 9.14. Particle's motion around a localized magnetic flux.

Generally, Eq. (199) is invalid if a particle moves inside a magnetic field and/or changes its trajectory at the field variation. However, if the field is almost uniform, i.e. its gradient small in the sense of Eq. (177), this result is (approximately) applicable. Indeed, analytical mechanics ${ }^{64}$ tells us that for any canonical coordinate-momentum pair $\left\{q_{j}, p_{j}\right\}$, the corresponding action variable,

$$
\begin{equation*}
J_{j} \equiv \frac{1}{2 \pi} \oint p_{j} d q_{j} \tag{9.200}
\end{equation*}
$$

is asymptotically constant at slow variations of motion conditions. According to Eq. (191), for a particle in magnetic field, the generalized momentum corresponding to Cartesian coordinate $r_{j}$ is $P_{j}$ rather than $p_{j}$. Thus forming the net action variable $J \equiv J_{x}+J_{y}+J_{z}$, we may write

$$
\begin{equation*}
2 \pi J=\oint \mathbf{P} \cdot d \mathbf{r}=\oint \mathbf{p} \cdot d \mathbf{r}+q \Phi=\text { const } . \tag{9.201}
\end{equation*}
$$

Let us apply this relation to the motion of a non-relativistic particle in an almost uniform magnetic field, with a small longitudinal velocity, $\cdot u_{\|} / u_{\perp} \rightarrow 0$ (Fig. 15).

Fig. 9.15. Particle in a magnetic field with a small longitudinal gradient $\nabla B \|$ B .

In this case, $\Phi$ in Eq. (201) is the flux encircled by a cyclotron orbit, equal to $\left(-\pi R^{2} B\right)$, where $R$ is its radius given by Eq. (153), and the negative sign accounts for the fact that the "correct" direction of

[^413]the normal vector $\mathbf{n}$ in the definition of flux, $\Phi=\int \mathbf{B} \cdot \mathbf{n} d^{2} r$, is antiparallel to vector $\mathbf{B}$. At $u \ll c$, the kinetic momentum is just $p_{\perp}=m u_{\perp}$, while Eq. (153) yields
\[

$$
\begin{equation*}
m u_{\perp}=q B R . \tag{9.202}
\end{equation*}
$$

\]

Plugging these relations into Eq. (201), we get

$$
\begin{equation*}
2 \pi J=m u_{\perp} 2 \pi R-q \pi R^{2} B=m \frac{q R B}{m} 2 \pi R-q \pi R^{2} B=(2-1) q \pi R^{2} B=-q \Phi . \tag{9.203}
\end{equation*}
$$

This means that even if the circular orbit slowly moves in the magnetic field, the flux encircled by the cyclotron orbit should remain constant. One manifestation of this effect is the result already mentioned in the end of Sec. 6: if a small gradient of the magnetic field is perpendicular to the field itself, particle orbit's drift is perpendicular to $\nabla B$, so that $\Phi$ stays constant. Now let us analyze the case of a small longitudinal gradient, $\nabla B \| \mathbf{B}$ (Fig. 15). If the small initial longitudinal velocity $u \|$ is directed toward the higher field region, in order to keep $\Phi$ constant, the cyclotron orbit has to gradually shrink. Rewriting Eq. (202) as

$$
\begin{equation*}
m u_{\perp}=q \frac{\pi R^{2} B}{\pi R}=q \frac{|\Phi|}{\pi R} \tag{9.204}
\end{equation*}
$$

we see that this reduction of $R$ (at constant $\Phi$ ) should increase the orbiting speed $u_{\perp}$. But since the magnetic field cannot do work on the particle, its kinetic energy,

$$
\begin{equation*}
\varepsilon=\frac{m}{2}\left(u_{\|}^{2}+u_{\perp}^{2}\right) \tag{9.205}
\end{equation*}
$$

should stay constant, so that the longitudinal velocity $u_{\|}$has to decrease. Hence eventually orbit's drift has to stop, and then the orbit has to start moving back toward the region of lower fields, being essentially repulsed from the high-field region. This effect is very important, in particular, for plasma confinement: two coaxial magnetic coils, inducing magnetic fields of the same direction (Fig. 16), naturally form a "magnetic bottle" that traps charged particles injected, with sufficiently low longitudinal velocities, into the region between the coils. Such bottles are the core components of the (generally, very complex) systems used for plasma confinement, in particular in the context of the longterm efforts to achieve controllable nuclear fusion. ${ }^{65}$

Fig. 9.16. Magnetic bottle (VERY schematically).

Returning to the constancy of magnetic flux encircled by free particles, it reminds us of the Meissner-Ochsenfeld effect discussed in Sec. 6.3, and gives a motivation for a brief revisit of the electrodynamics of superconductivity. As was emphasized in that section, superconductivity is a

[^414]substantially quantum phenomenon; nevertheless the notion of the conjugate momentum $\mathbf{P}$ helps to understand its description. Indeed, the general rule of quantization of physical systems ${ }^{66}$ is that each canonical pair $\left\{q_{j}, p_{j}\right\}$ of a generalized coordinate and the corresponding momentum is described by quantum-mechanical operators that obey the following commutation relation
\[

$$
\begin{equation*}
\left[\hat{q}_{j}, \hat{p}_{j^{\prime}}\right]=i \hbar \delta_{j j^{\prime}} . \tag{9.206}
\end{equation*}
$$

\]

According to Eq. (191), for Cartesian coordinates $r_{j}$ of a particle in electromagnetic field, the corresponding generalized momenta are $P_{j}$, so that their operators should obey the following commutation relations:

$$
\begin{equation*}
\left[\hat{r}_{j}, \hat{P}_{j^{\prime}}\right]=i \hbar \delta_{j j^{\prime}} . \tag{9.207}
\end{equation*}
$$

In the coordinate representation of quantum mechanics, canonical momentum operators are described by Cartesian components of the vector operator -i $\hbar \nabla$. As a result, ignoring the rest energy $m c^{2}$ (which gives an inconsequential phase factor $\exp \left\{-i m c^{2} t / \hbar\right\}$ in the wave function), we can use Eq. (196) to rewrite the non-relativistic Schrödinger equation,

$$
\begin{equation*}
i \hbar \frac{\partial \psi}{\partial t}=\hat{\nexists} \psi \psi \tag{9.208}
\end{equation*}
$$

as follows:

$$
\begin{equation*}
i \hbar \frac{\partial \psi}{\partial t}=\left(\frac{\hat{p}^{2}}{2 m}+U\right) \psi=\left[\frac{1}{2 m}(-i \hbar \nabla-q \mathbf{A})^{2}+q \phi\right] \psi . \tag{9.209}
\end{equation*}
$$

Thus, I believe I have finally delivered on my promise to justify the replacement (6.44) which had been used in Chapter 6 to discuss electrodynamics of superconductors, including the MeissnerOchsenfeld effect. ${ }^{67}$

### 9.8. Analytical mechanics of electromagnetic field

We have just seen that analytical mechanics of a particle in an electromagnetic field may be used to get some important results. The same is true for the analytical mechanics of the field alone, and the field-particle system as a whole, which will be discussed in this section. For such a space-distributed system as the field, governed by local dynamics laws (Maxwell equations), we need to apply analytical mechanics to the local densities $\ell$ and $h$ of the Lagrangian and Hamiltonian functions, defined by relations

$$
\begin{equation*}
\mathcal{L}=\int \ell d^{3} r, \quad \nexists=\int h d^{3} r . \tag{9.210}
\end{equation*}
$$

Let us start, as usual, from the Lagrange formalism. Some clue on the possible structure of the Lagrangian density $\ell$ may be obtained from that of the description of the particle-field interaction in this

[^415]formalism, which was discussed in the last section. For the case of a single particle, the interaction is described by the last two terms of Eq. (183):
\[

$$
\begin{equation*}
\mathcal{L}_{\mathrm{int}}=-q \phi-q \mathbf{u} \cdot \mathbf{A} . \tag{9.211}
\end{equation*}
$$

\]

It is obvious that if charge $q$ is continuously distributed over some volume, we may present $\mathcal{L}$ as a volume integral of Lagrangian density

$$
\begin{equation*}
\ell_{\text {int }}=-\rho \phi+\mathbf{j} \cdot \mathbf{A}=-j_{\alpha} A^{\alpha} . \tag{9.212}
\end{equation*}
$$

## Interaction Lagrangian density

Notice that the density (in contrast to $\mathcal{L}_{\text {int }}$ itself) is Lorentz-invariant. (This is due to the contraction of the longitudinal coordinate, and hence volume, at the Lorentz transform.) Hence we may expect the density of field's Lagrangian to be Lorentz-invariant as well. Moreover, in the view of the simple, local structure of the Maxwell equations (containing only first spatial and temporal derivatives of the fields), $\ell$ should be a simple function of potential's 4 -vector and its 4 -derivative:

$$
\begin{equation*}
\ell=\ell\left(A^{\alpha}, \partial_{\alpha} A^{\beta}\right) . \tag{9.213}
\end{equation*}
$$

Also, the density should be selected in such a way that the 4-vector analog of the Lagrangian equations of motion,

$$
\begin{equation*}
\partial_{\alpha} \frac{\partial \ell}{\partial\left(\partial_{\alpha} A^{\beta}\right)}-\frac{\partial \ell}{\partial A^{\beta}}=0, \tag{9.214}
\end{equation*}
$$

gave us correct inhomogeneous Maxwell equations (127). ${ }^{68,69}$ It is clear that the field part $\ell_{\text {field }}$ of the total Lagrangian density $\ell$ should be a scalar, and a quadratic form of the field strength, i.e. of $F^{\alpha \beta}$, so that the natural choice is

$$
\begin{equation*}
\ell_{\text {field }}=\text { const } \times F_{\alpha \beta} F^{\alpha \beta} . \tag{9.215}
\end{equation*}
$$

with implied summation over both indices. Indeed, adding to this expression the interaction Lagrangian (212),

$$
\begin{equation*}
\ell=\ell_{\text {field }}+\ell_{\text {int }}=\operatorname{const} \times F_{\alpha \beta} F^{\alpha \beta}-j_{\alpha} A^{\alpha}, \tag{9.216}
\end{equation*}
$$

and performing differentiation, we may check that Eq. (214) indeed yields Eqs. (127), provided that the constant factor equals $\left(-1 / 4 \mu_{0}\right) \cdot{ }^{70}$ With that, the field Lagrangian

$$
\begin{equation*}
\ell_{\text {field }}=-\frac{1}{4 \mu_{0}} F_{\alpha \beta} F^{\alpha \beta}=\frac{1}{2 \mu_{0}}\left(\frac{E^{2}}{c^{2}}-B^{2}\right)=\frac{\varepsilon_{0}}{2} E^{2}-\frac{B^{2}}{2 \mu_{0}}=u_{e}-u_{m} \tag{9.217}
\end{equation*}
$$

Field's
Lagrangian density
where $u_{e}$ is the local density of the electric field energy density (1.67), and $u_{m}$ is the magnetic field energy density (5.57).

[^416]Let me hope the reader agrees that Eq. (217) is a wonderful result, because the Lagrangian function has the structure absolutely similar to the well-known expression $\mathcal{L}=T-U$ of the classical mechanics. So, for the field alone, the "potential" and "kinetic" energies are separable again. ${ }^{71}$

As a sanity check, let us explore whether we can calculate a 4 -vector analog of the Hamiltonian function $\mathcal{H}$. In the generic analytical mechanics,

$$
\begin{equation*}
\mathcal{H}=\sum_{j} \frac{\partial \mathscr{L}}{\partial \dot{q}_{j}} \dot{q}_{j}-\mathscr{L} \tag{9.218}
\end{equation*}
$$

However, just as for the Lagrangian function, for a field we should find the spatial density $h$ of the Hamiltonian, defined by the second of Eqs. (210), for which a natural 4-form of Eq. (218) is

$$
\begin{equation*}
h^{\alpha \beta}=\frac{\partial \ell}{\partial\left(\partial_{\alpha} A^{\gamma}\right)} \partial^{\beta} A^{\gamma}-g^{\alpha \beta} \ell . \tag{9.219}
\end{equation*}
$$

Calculated for the field alone, i.e. using Eq. (217) for $\ell$, this definition yields

$$
\begin{equation*}
h_{\text {field }}^{\alpha \beta}=\theta^{\alpha \beta}-\tau_{D}^{\alpha \beta}, \tag{9.220}
\end{equation*}
$$

where tensor

Symmetric energymomentum tensor

$$
\begin{equation*}
\theta^{\alpha \beta} \equiv \frac{1}{\mu_{0}}\left(g^{\alpha \gamma} F_{\gamma \delta} F^{\delta \beta}+\frac{1}{4} g^{\alpha \beta} F_{\gamma \delta} F^{\gamma \delta}\right), \tag{9.221}
\end{equation*}
$$

is gauge-invariant, while the remaining term,

$$
\begin{equation*}
\tau_{D}^{\alpha \beta} \equiv \frac{1}{\mu_{0}} g^{\alpha \gamma} F_{\gamma \delta} \partial^{\delta} A^{\beta} \tag{9.222}
\end{equation*}
$$

is not, so that it cannot correspond to any measurable variables. Fortunately, it is straightforward to verify that tensor $\tau_{D}$ may be presented in the form

$$
\begin{equation*}
\tau_{D}^{\alpha \beta}=\frac{1}{\mu_{0}} \partial_{\gamma}\left(F^{\gamma \alpha} A^{\beta}\right), \tag{9.223}
\end{equation*}
$$

and as a result obeys the following relations:

$$
\begin{equation*}
\partial_{\alpha} \tau_{D}^{\alpha \beta}=0, \quad \int \tau_{D}^{0 \beta} d^{3} r=0 \tag{9.224}
\end{equation*}
$$

so it does not interfere with the conservation properties of the gauge-invariant, symmetric energymomentum tensor (also called the symmetric stress tensor) $\theta^{\alpha \beta}$, to be discussed below.

Using Eqs. (125), components of the latter tensor may be expressed via the electric and magnetic fields. For $\alpha=\beta=0$,

$$
\begin{equation*}
\theta^{00}=h_{\text {field }}=\frac{\varepsilon_{0}}{2} E^{2}+\frac{B^{2}}{2 \mu_{0}}=u_{e}+u_{m}=u \tag{9.225}
\end{equation*}
$$

[^417]i.e. the expression for the total energy density $u$ - see Eq. (6.104b). The other 3 components of the same row/column turn out to be just the Cartesian components of the Poynting vector, divided by $c$ :
\[

$$
\begin{equation*}
\theta^{j 0}=\frac{1}{\mu_{0}}\left(\frac{\mathbf{E}}{c} \times \mathbf{B}\right)_{j}=\left(\frac{\mathbf{E}}{c} \times \mathbf{H}\right)_{j}=\frac{S_{j}}{c}, \quad \text { for } j=1,2,3 \tag{9.226}
\end{equation*}
$$

\]

The remaining 9 components $\theta_{j j^{\prime}}$ of the tensor, with $j^{\prime}=1,2,3$, are usually presented as

$$
\begin{equation*}
\theta^{j j^{\prime}}=-\tau_{j j^{\prime}}^{(M)} \tag{9.227}
\end{equation*}
$$

where $\tau^{(M)}$ is the so-called Maxwell stress tensor:

$$
\begin{equation*}
\tau_{j j^{\prime}}^{(M)}=\varepsilon_{0}\left(E_{j} E_{j^{\prime}}-\frac{\delta_{i j j^{\prime}}}{2} E^{2}\right)+\frac{1}{\mu_{0}}\left(B_{j} B_{j^{\prime}}-\frac{\delta_{i j^{\prime}}}{2} B^{2}\right), \tag{9.228}
\end{equation*}
$$

so that the whole symmetric energy-momentum tensor may be conveniently presented in the following symbolic way:

$$
\theta^{\alpha \beta}=\left(\begin{array}{c:cc}
u & \leftarrow & \mathbf{S} / c  \tag{9.229}\\
\hdashline \uparrow & & \rightarrow \\
\mathbf{S} & -\tau_{j j^{\prime}}^{(M)} \\
\hdashline c &
\end{array}\right) .
$$

The physical meaning of this tensor may be revealed in the following way. Considering Eq. (221) just as the definition of tensor $\theta^{\alpha \beta},{ }^{72}$ and using the 4 -vector form of Maxwell equations, given by Eqs. (127) and (129), it is straightforward to verify an extremely simple result for the 4-derivative of the symmetric tensor:

$$
\begin{equation*}
\partial_{\alpha} \theta^{\alpha \beta}=-F^{\beta \gamma} j_{\gamma} . \tag{9.230}
\end{equation*}
$$

Maxwell
stress
tensor

This expression is valid in the presence of the electromagnetic field sources, e.g., for any system of charged particles and the field they have created. Of these 4 equations (for 4 values of index $\beta$ ), the temporal one (with $\beta=0$ ) may be simply expressed via the energy density (225) and Poynting vector (226):

$$
\begin{equation*}
\frac{\partial u}{\partial t}+\nabla \cdot \mathbf{S}=-\mathbf{j} \cdot \mathbf{E} \tag{9.231}
\end{equation*}
$$

while 3 spatial equations (with $\beta=j=1,2,3$ ) may be presented in the form

$$
\begin{equation*}
\frac{\partial}{\partial t} \frac{S_{j}}{c^{2}}-\sum_{j^{\prime}=1}^{3} \frac{\partial}{\partial r_{j^{\prime}}} \tau_{j j^{\prime}}^{(M)}=-(\rho \mathbf{E}+\mathbf{j} \times \mathbf{B})_{j} \tag{9.232}
\end{equation*}
$$

Integrated over a volume $V$ limited by surface $S$, with the account of the divergence theorem, Eq. (231) returns us to the Poynting theorem (6.103):

[^418]\[

$$
\begin{equation*}
\int_{V}\left(\frac{\partial u}{\partial t}+\mathbf{j} \cdot \mathbf{E}\right) d^{3} r+\oint_{S} S_{n} d^{2} r=0 \tag{9.233}
\end{equation*}
$$

\]

while Eq. (232) yields: ${ }^{73}$

$$
\begin{equation*}
\int_{V}\left[\frac{\partial}{\partial t} \frac{\mathbf{S}}{c^{2}}+\mathbf{f}\right]_{j} d^{3} r=\sum_{j^{\prime}=1}^{3} \oint_{S} \tau_{j j^{\prime}}^{(M)} d A_{j^{\prime}}, \quad \text { with } \mathbf{f} \equiv \rho \mathbf{E}+\mathbf{j} \times \mathbf{B} \tag{9.234}
\end{equation*}
$$

where $d A_{j}=n_{j} d A=n_{j} d^{2} r$ is the $j^{\text {th }} \quad$ component of the elementary area vector $d \mathbf{A}=\mathbf{n} d A=\mathbf{n} d^{2} \mathbf{r}$ that is normal to volume's surface, and directed out of the volume - see Fig. 17.

Since, according to Eq. (5.10), vector $\mathbf{f}$ is nothing else than the density of volume-distributed forces applied from the field to the particles, we can use the $2^{\text {nd }}$ Newton law, in its relativistic form (144), to rewrite Eq. (234), for a stationary volume $V$, as

dynamics

$$
\begin{equation*}
\frac{d}{d t}\left[\int_{V} \frac{\mathbf{S}}{c^{2}} d^{3} r+\mathbf{p}_{\text {part }}\right]=\mathbf{F} \tag{9.235}
\end{equation*}
$$

where $\mathbf{p}_{\text {part }}$ is the total mechanical (relativistic) momentum of all particles in volume $V$, and vector $\mathbf{F}$ is defined by its Cartesian components:

Fig. 9.17. Force $d \mathbf{F}$ exerted on a boundary element $d \mathbf{A}$ of volume $V$ occupied by the field.

Force via the Maxwell tensor

Electromagnetic field's momentum um

discussion. As has been emphasized at this discussion, vector $\mathbf{S}=\mathbf{E} \times \mathbf{H}$ in this case does not correspond to any measurable energy flow. However, the corresponding momentum (237) of the field is not only real, but may be measured by the recoil impulse ${ }^{74}$ it gives to the field sources (say, to a magnetic coil inducing field $\mathbf{H}$ and to the capacitor plates creating field $\mathbf{E}$ ).

Now let us turn to our second result, Eq. (236). It tells us that the $3 \times 3$-element Maxwell stress tensor complies with the general definition of the stress tensor ${ }^{75}$ characterizing force $\mathbf{F}$ exerted by external forces on the boundary of a volume, in this case occupied by the electromagnetic field (Fig. 17). ${ }^{76}$ Let us use this important result to analyze two simple examples for static fields.
(i) Electrostatic field's effect on a perfect conductor. Since Eq. (235) has been derived for a free space region, we have to select volume $V$ outside the conductor, but we may align one of its faces with conductor's surface (Fig. 18).

Fig. 9.18. Electrostatic field near conductor's surface.

From Chapter 2, we know that the electrostatic field has to be perpendicular to the conductor's surface. Selecting axis $z$ in this direction, we have $E_{x}=E_{y}=0, E_{z}= \pm E$, so that only diagonal components of the tensor (228) are not equal to zero:

$$
\begin{equation*}
\tau_{x x}^{(M)}=\tau_{y y}^{(M)}=-\frac{\varepsilon_{0}}{2} E^{2}, \quad \tau_{z z}^{(M)}=\frac{\varepsilon_{0}}{2} E^{2}, \tag{9.238}
\end{equation*}
$$

Since the elementary surface area vector has just one nonvanishing component, $d A_{z}$, according to Eq. (236), only the last component (that is positive regardless of the sign of $E$ ) gives a contribution to the surface force $\mathbf{F}$. We see that the force exerted by the conductor (and eventually by external forces that hold the conductor in its equilibrium position) on the field is normal to the conductor and directed out of the field volume: $d F_{z} \geq 0$. Hence, by the $3^{\text {rd }}$ Newton law, the force exerted by the field on conductor's surface is directed toward the field-filled space:

$$
\begin{equation*}
d F_{\text {surface }}=-d F_{z}=-\frac{\varepsilon_{0}}{2} E^{2} d A \tag{9.239}
\end{equation*}
$$

[^419]This important result could be obtained by simpler means as well. For example, one could argue, quite convincingly, that the local relation between the force and field should not depend on the global

[^420]configuration creating the field, and consider a planar capacitor (Fig. 2.2) with surfaces of both plates charged by equal and opposite charges of density $\sigma= \pm \varepsilon_{0} E$. According to the Coulomb law, the charges should attract each other, pulling each plate toward the field region, so that Maxwell-tensor result gives the correct direction of the force. The force's magnitude (240) can be verified either by the direct integration of the Coulomb law, or by the following simple reasoning. In the plane capacitor, field $E_{z}=$ $\sigma / \varepsilon_{0}$ is equally contributed by two surface charges; hence the field created by the negative charge of the counterpart plate (not shown in Fig. 18) is $E_{-}=\sigma / 2 \varepsilon_{0}$, and the force it exerts of the elementary surface charge $d Q=\sigma d A$ of the positively charged plate is $d F=E_{-} d Q=\sigma^{2} d A / 2 \varepsilon_{0}=\varepsilon_{0} E^{2} d A / 2$, in accordance with Eq. (239). ${ }^{77}$

Quantitatively, even for such high electric field as $E=3 \mathrm{MV} / \mathrm{m}$ (close to the electric breakdown in air), the "negative pressure" ( $d F / d A$ ) given by Eq. (240) is of the order of $500 \mathrm{~Pa}\left(\mathrm{~N} / \mathrm{m}^{2}\right)$, i.e. below one thousandth of the ambient atmospheric pressure ( $1 \mathrm{bar} \approx 10^{5} \mathrm{~Pa}$ ). Still, these forces may be substantial in some cases, especially in good dielectrics (such as high-quality $\mathrm{SiO}_{2}$, grown at high temperature, which is broadly used in integrated circuits) that can withstand fields up to $\sim 10^{9} \mathrm{~V} / \mathrm{m}$.
(ii) Static magnetic field's effect on its source ${ }^{78}$ - say, solenoid's wall or superconductor's surface (Fig. 19).

Fig. 9.19. Static magnetic field near a current-carrying surface.

With the choice of coordinates shown in Fig. 19, we have $B_{x}= \pm B, B_{y}=B_{z}=0$, so that the Maxwell stress tensor (228) is diagonal again:

$$
\begin{equation*}
\tau_{x x}^{(M)}=\frac{1}{2 \mu_{0}} B^{2}, \quad \tau_{y y}^{(M)}=\tau_{z z}^{(M)}=-\frac{1}{2 \mu_{0}} B^{2} . \tag{9.240}
\end{equation*}
$$

However, but since for this geometry only $d A_{z}$ differs from 0 in Eq. (236), the sign of the resulting force is opposite to that in electrostatics: $d F_{z} \leq 0$, and the force exerted by the magnetic field upon the conductor's surface,

$$
\begin{equation*}
d F_{\text {surface }}=-d F_{z}=\frac{1}{2 \mu_{0}} B^{2} d A \tag{9.241}
\end{equation*}
$$

[^421]corresponds to a positive pressure. For good laboratory magnets ( $B \sim 10 \mathrm{~T}$ ), this pressure is of the order of $4 \times 10^{7} \mathrm{~Pa} \approx 400$ bars, i.e. is very substantial, so the magnets require solid mechanical design.

The direction of force (241) could be also readily predicted elementary magnetostatics arguments. Indeed, we can imagine the magnetic field volume limited by another, parallel wall with the opposite direction of surface current. According to the starting point of magnetostatics, Eq. (5.1), such surface currents of opposite directions have to repulse each other - doing that via the magnetic field.

Another explanation of the fundamental sign difference between the electric and magnetic field pressures may be provided on the electric circuit language. As we know from Chapter 2, the potential energy of the electric field stored in a capacitor may be presented in two equivalent forms,

$$
\begin{equation*}
U_{e}=\frac{C V^{2}}{2}=\frac{Q^{2}}{2 C} . \tag{9.242}
\end{equation*}
$$

Similarly, the magnetic field energy of in an inductive coil is

$$
\begin{equation*}
U_{m}=\frac{L I^{2}}{2}=\frac{\Phi^{2}}{2 L} \tag{9.243}
\end{equation*}
$$

If we do not want to consider the work of external sources on a virtual change of the system dimensions, we should use the latter forms of these relations, i.e. consider a galvanically detached capacitor ( $Q=$ const) and an externally-shorted inductance ( $\Phi=$ const). ${ }^{99}$ Now if we let the electric field forces (239) drag capacitor's plates in the direction they "want", i.e. toward each other, this would lead to a reduction of the capacitor thickness, and hence to an increase of capacitance $C$, and hence to a decrease of $U_{e}$. Similarly, for a solenoid, allowing pressure (242) to move its walls would lead to an increase of the solenoid volume, and hence of its inductance $L$, so that the potential energy $U_{m}$ would be also reduced as it should be. It is remarkable (actually, beautiful) how do the local field formulas (239) and (241) "know" about these global circumstances.

Finally, let us see whether the major results (237) and (241), obtained in this section, match each other. For that, let us return to the normal incidence of a plane, monochromatic wave from free space on the plane surface of a perfect conductor (see Fig. 7.8 and its discussion), and use those results to calculate the time average of pressure $d F_{\text {surface }} / d A$ imposed by the wave on the surface. At elastic reflection from conductor's surface, electromagnetic field's momentum retains its amplitude but changes its sign, so that the momentum transferred to a unit area of the surface (i.e. average pressure) is

$$
\begin{equation*}
\frac{\overline{d F_{\text {surface }}}}{d A}=2 c g_{\text {incident }}=2 c \frac{\overline{S_{\text {incident }}}}{c^{2}}=2 c \frac{1}{c^{2}} \frac{E_{\omega} H_{\omega}^{*}}{2}=\frac{E_{\omega} H_{\omega}^{*}}{c}, \tag{9.244}
\end{equation*}
$$

where $E_{\omega}$ and $H_{\omega}$ are complex amplitudes of the incident wave. Using relation (7.7) between these amplitudes (for $\varepsilon=\varepsilon_{0}$ and $\mu=\mu_{0}$ giving $E_{\omega}=c B_{\omega}$ ), we get

$$
\begin{equation*}
\frac{\overline{d F_{\text {surface }}}}{d A}=\frac{1}{c} c B_{\omega} \frac{B_{\omega}^{*}}{\mu_{0}}=\frac{\left|B_{\omega}\right|^{2}}{\mu_{0}} . \tag{9.245}
\end{equation*}
$$

[^422]On the other hand, as was discussed in Sec. 7.4, at the surface of the perfect mirror the electric field vanishes while the magnetic field doubles, so that we can use Eq. (241) with $B \rightarrow B(t)=2 \operatorname{Re}\left[B_{\omega} \mathrm{e}\{-\right.$ $i \omega t\}]$. Averaging the pressure over time, we get

$$
\begin{equation*}
\frac{\overline{d F_{\text {surface }}}}{d A}=\frac{1}{2 \mu_{0}} \overline{\left(2 \operatorname{Re}\left[B_{\omega} e^{-i \omega t}\right]\right)^{2}}=\frac{\left|B_{\omega}\right|^{2}}{\mu_{0}}, \tag{9.246}
\end{equation*}
$$

i.e. the same result as Eq. (245).

For the physics intuition development, it is useful to estimate the electromagnetic radiation pressure's magnitude. Even for a relatively high wave intensity $S_{n}$ of $1 \mathrm{~kW} / \mathrm{m}^{2}$ (close to that of the direct sunlight at Earth's orbit), the pressure $2 \mathrm{cg}_{n}=2 S_{n} / \mathrm{c}$ is somewhat below $10^{-5} \mathrm{~Pa} \sim 10^{-10}$ bar. Still, this extremely small effect was experimentally observed (by P. Lebedev) as early as in 1899, giving one more confirmation of the Maxwell's theory.

### 9.9. Exercise problems

9.1. Use the non-relativistic Doppler effect picture to derive Eq. (4).
9.2. Show that two successive Lorentz space/time transforms in the same direction, with velocities $u$ ' and $v$, are equivalent to a single transform with velocity $u$ given by Eq. (25).
9.3. $N+1$ reference frames, numbered by index $n$ (taking values $0,1, \ldots, N$ ), move in the same direction as a particle. Express the particle's velocity in frame $n=0$ via its velocity $u_{N}$ in frame number $N$ and the set of velocities $v_{n}$ of frame number $n$ relative to the frame number $(n-1)$.
9.4. A spaceship, moving with constant velocity $v$ directly from the Earth, sends back brief flashes of light with period $\Delta t_{s}$ - as measured by spaceship's clock. Calculate the period with which Earth's observers receive the signals - as measured by Earth's clock.
9.5. From the point of view of reference frame $0^{\prime}$, a straight rod, parallel to axis $x^{\prime}$, is moving, without rotation, with constant velocity $\mathbf{u}^{\prime}$ directed along axis $y^{\prime}$. The reference frame $0^{\prime}$ is itself moving relative to another ("lab") reference frame 0 , with similarly oriented axes, with a constant velocity $v$ along axis $x$, also without rotation - see Fig. on the right. Calculate:
(i) the direction of rod's velocity, and
(ii) the orientation of the rod on the $[x, y]$ plane,
as observed from the lab reference frame. Is the velocity perpendicular to the rod?
9.6. A relativistic particle moving with velocity $u$ decays into two particles with zero rest mass.
(i) Calculate the smallest possible angle between the decay product velocities (in the lab frame).
(ii) What is the largest possible energy of one product particle?
9.7. Starting from the rest at $t=0$, a spaceship moves with a constant acceleration, as measured in its instantaneous rest frame. Find its displacement $x(t)$ from the starting point, as measured from the lab frame, and interpret the result.
9.8. Calculate the first relativistic correction to the frequency of a harmonic oscillator as a function of its amplitude.
9.9. A particle with rest mass $m$ decays into two particles, with rest masses $m_{1}$ and $m_{2}$. Calculate the total energy of the first decay product, in the rest frame of the decayed particle.
9.10. A relativistic particle, propagating with velocity $\mathbf{v}$ outside of external fields, decays into two photons. ${ }^{80}$ Calculate the angular dependence of the probability of photon detection.
9.11. Photon with wavelength $\lambda$ is scattered by an electron, initially at rest. Considering the photon as an ultrarelativistic particle (with the rest mass $m=0$ ), find wavelength $\lambda$ ' of the scattered photon as a function of the scattering angle $\alpha$-see Fig. on the right. ${ }^{81}$

9.12. Calculate the threshold energy of a $\gamma$-photon for the reaction

$$
\gamma+\mathrm{p} \rightarrow \mathrm{p}+\pi^{0}
$$

if the proton was initially at rest.
Hint: For protons $m_{p} c^{2} \approx 938 \mathrm{MeV}$, while for neutral pions $m_{\pi} c^{2} \approx 135 \mathrm{MeV}$.
9.13. A relativistic particle with energy $\varepsilon$ and rest mass $m$ collides with a similar particle, initially at rest in the laboratory frame. Find:
(i) the final velocity of the center of mass of the system, in the lab frame,
(ii) the total energy of the system, in the center-of-mass frame, and
(iii) the final velocities of both particles (in the lab frame), if they move along the same direction.
9.14. A "primed" reference frame moves with the reduced velocity $\boldsymbol{\beta} \equiv \mathbf{v} / c=\mathbf{n}_{\chi} \beta$ relative to the "lab" frame. Use Eq. (109) to spell out components $T^{, 00}$ and $T^{, 0 j}$ (with $j=1,2,3$ ) of an arbitrary contravariant 4-tensor $T^{\gamma \delta}$.
9.15. Static fields $\mathbf{E}$ and $\mathbf{B}$ are uniform but arbitrary (both in magnitude and in direction). What should be the velocity of an inertial reference frame to have the vectors $\mathbf{E}$ ' and $\mathbf{B}$ ', observed from that frame, parallel? Is this solution unique?
9.16. Two charged particles, moving with the same constant velocity $\mathbf{u}$, are offset by distance $\mathbf{R}=\{a, b\}$ (see Fig. on the right), as measured in the lab frame. Calculate the forces between the particles - also in the lab frame.

[^423]9.17. Each of two very thin, long, parallel beams of electrons of the same velocity $\mathbf{u}$ carries electric charge of density $\lambda$ per unit length (as measured in the coordinate frame moving with electrons).
(i) Calculate the distribution of the electric and magnetic fields in the system (outside the beams), as measured in the lab frame.
(ii) Calculate the interaction force between the beams (per particle) and the resulting acceleration, both in the lab frame and in the system moving with the electrons. Compare the results and give a brief discussion of the comparison.
9.18. Spell out the Lorentz transform of the scalar potential and the vector potential components, and use the result to calculate the potentials of a point charge $q$, moving with a constant velocity $\mathbf{u}$, as measured in the lab reference frame.
9.19. Calculate the scalar and vector potentials created by a time-independent electric dipole $\mathbf{p}$, as measured in a reference frame which moves relatively to the dipole with a constant velocity $\mathbf{v}$, with the shortest distance ("impact parameter") equal to $b$.
9.20. Calculate the scalar and vector potentials created by a time-independent magnetic dipole $\mathbf{m}$, as measured in a reference frame which moves relatively to the dipole with a constant velocity $v \ll$ $c$, with the shortest distance ("impact parameter") equal to $b$.
9.21. Assuming that the magnetic monopole does exist and has magnetic charge $g$, calculate the change $\Delta \Phi$ of magnetic flux in a superconductor ring due to the passage of single monopole through it. Evaluate $\Delta \Phi$ for the monopole charge conjectured by Dirac, $g=n g_{0} \equiv n(2 \pi \hbar / e)$, where $n$ is an integer; compare the result with the magnetic flux quantum $\Phi_{0}$ (6.55) and discuss their relation.
9.22.* Calculate the trajectory of a relativistic particle in a uniform electrostatic field $\mathbf{E}$ for the case of arbitrary direction of its initial velocity $\mathbf{u}(0)$, using two different approaches - one of them different from the approach used in Sec. 6 for the case $\mathbf{u}(0) \perp \mathbf{E}$.
9.23. A charged relativistic particle with velocity $u$ performs planar cyclotron rotation in a uniform external magnetic field $B$. How much would the velocity and orbit radius change at a slow change of the field to a new magnitude $B^{\prime \prime}$ ?
9.24.* Analyze the motion of a relativistic particle in uniform, mutually perpendicular fields $\mathbf{E}$ and $\mathbf{B}$, for the particular case when $E$ is exactly equal to $c B$.
9.25.* Find the law of motion of a relativistic particle in uniform, parallel, static fields $\mathbf{E}$ and $\mathbf{B}$.
9.26. Neglecting relativistic effects, calculate the smallest voltage $V$ that has to be applied between the anode and cathode of a magnetron (see Fig. 13 and its discussion) to enable electrons to reach the anode in the absence of electron-electron interactions and collisions with the residual gas molecules. You may model the cathode and anode as two coaxial round cylinders, of radii $R_{1}$ and $R_{2}$, respectively, assume that the magnetic field $\mathbf{B}$, directed along their common axis, is uniform, and neglect the initial velocity of the electrons emitted by the cathode. (After the solution, estimate the validity of the last assumption for reasonable values of parameters.)
9.27. A charged, relativistic particle has been injected into a uniform electric field that oscillates in time with frequency $\omega$. Calculate the time dependence of the particle's velocity, as observed from a lab frame.
9.28. Analyze motion of a non-relativistic particle in a region where the electric and magnetic fields are both constant and uniform, but not necessarily parallel or perpendicular to each other.
9.29. A static distribution of electric charge in otherwise free space has created a timeindependent distribution $\mathbf{E}(\mathbf{r})$ of the electric field. Use two different approaches to express the energy density $u$ ' and the Poynting vector $\mathbf{S}^{\prime}$, as observed in a reference frame moving with constant velocity $\mathbf{v}$, via the components of vector $\mathbf{E}$. In particular, is $\mathbf{S}^{\prime}$ equal to ( $-\mathrm{v} \mathbf{u}^{\prime}$ )?
9.30. A plane wave, of frequency $\omega$ and intensity $S$, is normally incident on a perfect mirror, moving with velocity $v$ in the same direction as the wave.
(i) Calculate the reflected wave's frequency, as observed in the lab reference frame, and
(ii) use the Lorentz transform of the fields to calculate the reflected wave's intensity

- both as observed from the lab reference frame.
9.31. Carry out the second task of the previous problem by using the relations between wave's energy, power, and momentum.

Hint: As a byproduct, this approach should also give you the pressure exerted by the wave on the moving mirror.
9.32. Consider the simple model of plane capacitor charging by a lumped current source, shown in Fig. on the right, and prove that the momentum given by the constant, uniform external magnetic field $\mathbf{B}$ to the current-carrying conductor is equal and opposite to the momentum of the electromagnetic field that current $I(t)$ builds up in the capacitor. (You may let the capacitor be planar and very broad, and neglect the fringe field effects.)

9.33. Consider an electromagnetic plane wave packet propagating in free space, with the electric field represented as the Fourier integral

$$
\mathbf{E}(\mathbf{r}, t)=\operatorname{Re} \int_{-\infty}^{+\infty} \mathbf{E}_{k} e^{i \psi_{k}} d k, \quad \text { with } \psi_{k} \equiv k z-\omega_{k} t, \quad \text { and } \omega_{k} \equiv c|k| .
$$

Express the full linear momentum (per unit area of wave's front) of the packet via the complex amplitudes $\mathbf{E}_{k}$. Does the momentum depend on time? (In contrast with Problem 7.7, in this case the wave packet is not necessarily narrow.)
9.34. Calculate the pressure exerted on well-conducting walls of a waveguide with rectangular $(a \times b)$ cross-section by a wave propagating along it in the fundamental $\left(H_{10}\right)$ mode. Give an interpretation of the result.

## Chapter 10. Radiation by Relativistic Charges

In this chapter, we return to the electromagnetic wave radiation by moving charges, because the review of the special relativity background in the previous chapter enables an analysis of the radiation effects for arbitrary speed of the charged particle. After an analysis of such important particular cases as synchrotron radiation and "Bremsstrahlung" (brake radiation), we will discuss the apparently unrelated effect of Coulomb losses, which nevertheless will lead us to such important phenomena as the Cherenkov radiation and transitional radiation. In the end of the chapter, I will briefly review the effects of back action of the emitted radiation on the emitting particle, whose analysis reveals some limitations of classical electrodynamics.

### 10.1. Liénard-Wiechert potentials

A convenient starting point for the discussion of radiation by relativistic moving charges is provided by Eqs. (8.17) for retarded potentials. In free space these formulas are reduced to

$$
\begin{equation*}
\phi(\mathbf{r}, t)=\frac{1}{4 \pi \varepsilon_{0}} \int \frac{\rho\left(\mathbf{r}^{\prime}, t-R / c\right)}{R} d^{3} r^{\prime}, \quad \mathbf{A}(\mathbf{r}, t)=\frac{\mu_{0}}{4 \pi} \int \frac{\mathbf{j}\left(\mathbf{r}^{\prime}, t-R / c\right)}{R} d^{3} r^{\prime} . \tag{10.1}
\end{equation*}
$$

Here $R$ is the magnitude of the vector,

$$
\begin{equation*}
\mathbf{R}=\mathbf{r}-\mathbf{r}^{\prime}, \tag{10.2}
\end{equation*}
$$

that connects the source point $\mathbf{r}$ ' to the observation point $\mathbf{r}$. As a reminder, Eqs. (1) were derived from the Maxwell equations without any restrictions, and are very convenient for situations with continuous distribution of charge and current. On the other hand, for point charges, with delta-functional $\rho$ and $\mathbf{j}$, it is more convenient to recast these relations into a simpler form that would not require the integration over the $\mathbf{r}$ 'space.

This reduction, however, requires care. Indeed, for a single point charge $q$ moving with velocity $\mathbf{u}$, such integration of Eqs. (1), if carried out naïvely, would yield the following apparent result:

$$
\begin{equation*}
\phi(\mathbf{r}, t)=\frac{1}{4 \pi \varepsilon_{0}} \frac{q}{R_{r}}, \quad \text { i.e. } \frac{\phi(\mathbf{r}, t)}{c}=\frac{\mu_{0}}{4 \pi} \frac{q c}{R_{r}} ; \quad \mathbf{A}(\mathbf{r}, t)=\frac{\mu_{0}}{4 \pi} \frac{q \mathbf{u}_{r}}{R_{r}}, \quad[\mathrm{WRONG}!] \tag{10.3}
\end{equation*}
$$

where index $r$ marks the variables to be calculated at time $t-R_{r} / c$. This is a good example how the science of relativity (even the special one :-) cannot be taken too lightly. Indeed, 4-vectors (9.84)-(9.85), formed from potentials (3), would not obey the Lorentz transform rule (9.91), because distance $R_{r}$ also depends on the reference frame it is measured in.

In order to correct the error, we need, first of all, to specify what exactly is $R_{r}$ for a point charge. Evidently, in this case, only one space-time point $\left\{\mathbf{r}^{\prime}, t^{\prime}\right\}$ may contribute to integrals (1) for any observation point $\{\mathbf{r}, \mathrm{t}\}$. The point should be found from the retardation condition $t^{\prime}=t-R_{r} / c$, i.e.

$$
\begin{equation*}
c\left(t-t^{\prime}\right)=\left|\mathbf{r}(t)-\mathbf{r}^{\prime}\left(t^{\prime}\right)\right| . \tag{10.4}
\end{equation*}
$$

Figure 1 depicts the graphical solution of this self-consistency equation as the point of intersection of the light cone of the observation point (see Fig. 9.9 and its discussion) and the trajectory of the charged
particle. ${ }^{1}$ As in Eq. (3), I will use index $r$ to mark all variables corresponding to the retarded point $\{\mathbf{r}$,, $\left.t^{\prime}\right\}$ that satisfies Eq. (4); for example, $t^{\prime} \equiv t_{r}, c\left(t-t_{r}\right) \equiv R_{r}$ (see Fig. 1), $\mathbf{u}\left\{\mathbf{r}^{\prime}, t_{r}\right) \equiv \mathbf{u}_{r}$, etc, as measured in the "lab" reference frame - generally, any inertial frame that moves with the same velocity as the observation point at the moment $t$ we are considering.

Fig. 10.1. Graphical solution of Eq. (4).

Now let us write Eqs. (1) for a point charge in another inertial reference frame 0 ', whose velocity (as measured in the lab frame) coincides, at moment $t_{r}$, with the same velocity ( $\mathbf{u}_{r}$ ) of the point charge. In that frame the charge rests, so that

$$
\begin{equation*}
\phi^{\prime}=\frac{q}{4 \pi \varepsilon_{0} R^{\prime}}, \quad \mathbf{A}^{\prime}=0 \tag{10.5}
\end{equation*}
$$

but let us remember that this $R$ ' may not be equal to $R$, because the latter distance is measured in the "lab" reference frame. Let us use the identity $1 / \varepsilon_{0} \equiv \mu_{0} c^{2}$ to rewrite Eq. (5) in the form of components of a 4-vector similar in structure to Eq. (3):

$$
\begin{equation*}
\frac{\phi^{\prime}}{c}=\frac{\mu_{0}}{4 \pi} q \frac{c}{R^{\prime}}, \quad \mathbf{A}^{\prime}=0 \tag{10.6}
\end{equation*}
$$

Now it is easy to guess the correct answer for the whole 4-potential:

$$
\begin{equation*}
A^{\alpha}=\frac{\mu_{0}}{4 \pi} q \frac{c u^{\alpha}}{u_{\beta} R^{\beta}} \tag{10.7}
\end{equation*}
$$

where (just as a reminder), $A^{\alpha} \equiv\{\phi / c, \mathbf{A}\}, u^{\alpha} \equiv \gamma\{c, \mathbf{u}\}$, and $R^{\alpha}$ is a 4-vector of the event distance, formed similarly to that of a single event - cf. Eq. (9.48):

$$
\begin{equation*}
R^{\alpha} \equiv\left\{c\left(t-t^{\prime}\right), \mathbf{R}\right\} \equiv\left\{c\left(t-t^{\prime}\right), \mathbf{r}-\mathbf{r}^{\prime}\right\} \tag{10.8}
\end{equation*}
$$

Indeed, we need the 4 -vector $A^{\alpha}$ that would:
(i) obey the Lorentz transform,
(ii) have its spatial components $A_{j}$ scaling as $u_{j}$, and
(iii) be reduced to the correct result (5) in the reference frame moving with the charge.

[^424]Formula (7) evidently satisfies all these requirements, because the scalar product in its denominator is just

$$
\begin{equation*}
u_{\beta} R^{\beta}=\gamma\{c,-\mathbf{u}\} \cdot\left\{c\left(t-t^{\prime}\right), \mathbf{R}\right\}=\gamma\left[c^{2}\left(t-t^{\prime}\right)-\mathbf{u} \cdot \mathbf{R}\right]=\gamma c(R-\boldsymbol{\beta} \cdot \mathbf{R})=\gamma c R(1-\boldsymbol{\beta} \cdot \mathbf{n}), \tag{10.9}
\end{equation*}
$$

where $\mathbf{n} \equiv \mathbf{R} / R$ is a unit vector in the observer's direction, $\boldsymbol{\beta} \equiv \mathbf{u} / c$ is the normalized velocity of the particle, and $\gamma \equiv 1 /\left(1-u^{2} / c^{2}\right)^{1 / 2} .^{2}$ In the reference frame of the charge (in which $\beta=0$ and $\gamma=1$ ), expression (9) is reduced to $c R$, so that Eq. (7) is correctly reduced to Eq. (6). Now let us spell out components of Eq. (7) in the lab frame (in which $t^{\prime}=t_{r}$ and $R=R_{r}$ ):

LiénardWiechert potentials

$$
\begin{gather*}
\phi(\mathbf{r}, t)=\frac{1}{4 \pi \varepsilon_{0}} \frac{q}{(R-\boldsymbol{\beta} \cdot \mathbf{R})_{r}}=\frac{1}{4 \pi \varepsilon_{0}} q\left[\frac{1}{R(1-\boldsymbol{\beta} \cdot \mathbf{n})}\right]_{r},  \tag{10.10a}\\
\mathbf{A}(\mathbf{r}, t)=\frac{\mu_{0}}{4 \pi} q\left(\frac{\mathbf{u}}{R-\boldsymbol{\beta} \cdot \mathbf{R}}\right)_{r}=\frac{\mu_{0}}{4 \pi} q c\left[\frac{\boldsymbol{\beta}}{R(1-\boldsymbol{\beta} \cdot \mathbf{n})}\right] r=\phi(\mathbf{r}, t) \frac{\mathbf{u}_{r}}{c^{2}} . \tag{10.10b}
\end{gather*}
$$

These formulas are called the Liénard-Wiechert potentials. ${ }^{3}$ In the non-relativistic limit, they coincide with the naïve guess (3), but in the general case include the additional factor (1- $\boldsymbol{\beta} \cdot \mathbf{n}$ ) in the denominator, which describes the apparent increase of the effective charge density of the source due to the apparent change of distance $R$, at $\beta \sim 1$. In order to understand its origin, let us consider a simple 1D model of the radiation: a uniformly charged rod, of length $l$, moving directly toward an observer located at point $\mathbf{r}$, with a constant speed $u$ (Fig. 2). As a result of this motion, the observer may measure the field (1) induced by the rod, within a certain time interval $\left[t_{\text {start }}, t_{\text {stop }}\right]$.

Fig. 10.2. Geometric effect behind factor (1- $\boldsymbol{\beta} \cdot \mathbf{n}$ ) in the Liénard-Wiechert potentials.

That trailing end of this field pulse, observed at $t=t_{\text {stop }}$, is emitted by the far (in Fig. 2, leftmost) end of the rod at moment $t$ 'stop. Due to the limited speed of the rod, $u<c$, the moment $t^{\prime}$ stop comes earlier than the moment $t_{\text {start, }}^{\prime}$, at which the front end of the rod emits the field that starts the observed pulse. During the positive time interval ( $t^{\prime}$ start $-t^{\prime}$ stop $)$, the rod passes an additional distance $u\left(t^{\prime}\right.$ start $\left.-t_{\text {stop }}^{\prime}\right)-$ see the bottom panel of Fig. 2. Using the evident relations shown on each of the two panels of Fig. 2 to express $r$, and requiring them to give the same result, we get the following relation

$$
\begin{equation*}
c\left(t_{\text {stop }}-t_{\text {stop }}^{\prime}\right)=u\left(t_{\text {start }}^{\prime}-t_{\text {stop }}^{\prime}\right)+l+c\left(t_{\text {start }}-t_{\text {start }}^{\prime}\right) \tag{10.11}
\end{equation*}
$$

[^425]Using it to express the difference $\Delta t^{\prime}(u) \equiv t_{\text {start }}^{\prime}-t_{\text {start }}>0$ in the limit when $t_{\text {stop }} \rightarrow t_{\text {start, }}$, i.e. when the observed radiation pulse is short, we get

$$
\begin{equation*}
\Delta t^{\prime}(u)=\frac{l}{c-u}=\frac{l / c}{1-\beta} \equiv \frac{\Delta t(0)}{1-\beta}, \quad \text { where } \Delta t^{\prime}(0) \equiv \frac{l}{c}, \tag{10.12}
\end{equation*}
$$

is a factor of $1 /(1-\beta)$ smaller than what is would be at negligible source speed. Hence the time interval between the retarded moments $t_{r}$ for two ends of the rod is compressed as $u$ is increased. Since the total charge of the rod does not depend on $u$, its linear charge density is increased, and the field in the observation point is increased accordingly. Somewhat counter-intuitively, Eq. (12) shows that this field re-normalization is independent of the source size $l$, and hence takes place even in the limit $l \rightarrow 0$, e.g., for a point source. ${ }^{4}$

So, the 4 -vector formalism has provided a big help for the calculation of field potentials. Now, the electric and magnetic field corresponding to the potentials may be found by the plugging Eqs. (10) into the general formulas (6.106). This operation should be also performed very carefully, because Eqs. (6.106) require the differentiation over the coordinates $\{\mathbf{r}, t\}$ of the observation point, while we want the fields to be expressed via particle's velocity $\mathbf{u}_{\mathrm{r}} \equiv\left(d \mathbf{r}^{\prime} / d t^{\prime}\right)_{r}$ that participates in Eqs. (10). In order to find the relation between derivatives over $t$ and $t^{\prime}$, let us differentiate Eq. (4), rewritten as

$$
\begin{equation*}
R_{r}=c\left(t-t_{r}\right) \tag{10.13}
\end{equation*}
$$

over $t$ and $t_{r}$. In order to calculate derivative $\partial R_{r} / \partial t_{r}$, let us first differentiate identity $R^{2}=\mathbf{R} \cdot \mathbf{R}$ :

$$
\begin{equation*}
2 R_{r} \frac{\partial R_{r}}{\partial t_{r}}=2 \mathbf{R}_{r} \cdot \frac{\partial \mathbf{R}_{r}}{\partial t_{r}} \tag{10.14}
\end{equation*}
$$

Since $\partial \mathbf{R}_{r} / \partial t_{r}=\partial\left(\mathbf{r}-\mathbf{r}^{\prime}\right) / \partial t_{r}=-\partial \mathbf{r}^{\prime} / \partial t_{r}=-\mathbf{u}$, Eq. (14) yields

$$
\begin{equation*}
\frac{\partial R_{r}}{\partial t_{r}}=\frac{\mathbf{R}_{r}}{R_{r}} \cdot \frac{\partial \mathbf{R}_{r}}{\partial t_{r}}=-(\mathbf{n} \cdot \mathbf{u})_{r} . \tag{10.15}
\end{equation*}
$$

Now let us differentiate the same function $R_{r}$ over $t$, keeping $\mathbf{r}$ fixed. On one hand, Eq. (13) yields

$$
\begin{equation*}
\frac{\partial R_{r}}{\partial t}=c-c \frac{\partial t_{r}}{\partial t} . \tag{10.16}
\end{equation*}
$$

On the other hand, according to Eq. (4), if $\mathbf{r}$ is fixed, $t^{\prime}$ is a function of $t$ alone, so that, using Eq. (15), we may write

$$
\begin{equation*}
\frac{\partial R}{\partial t}=\frac{\partial R_{r}}{\partial t_{r}} \frac{\partial t_{r}}{\partial t}=-(\mathbf{n} \cdot \mathbf{u})_{r} \frac{\partial t_{r}}{\partial t} . \tag{10.17}
\end{equation*}
$$

Requiring Eqs. (16) and (17) to give the same result, we get the same factor that participates in the Liénard-Wiechert potentials (10) and Eq. (12):

[^426]\[

$$
\begin{equation*}
\frac{\partial t_{r}}{\partial t}=\frac{c}{c-(\mathbf{n} \cdot \mathbf{u})_{r}}=\left(\frac{1}{1-\boldsymbol{\beta} \cdot \mathbf{n})_{r}}\right)_{r} \tag{10.18}
\end{equation*}
$$

\]

This relation may be readily interpreted - at least semi-quantitatively. At fixed $\mathbf{r}$, variation $\partial t$ of the observation time corresponds to a small vertical shift of the light cone in Fig. 2, while $\partial t_{r}$ is the corresponding shift of the retarded time $t_{r}$, i.e. of the point where the world line $\mathbf{r}^{\prime}\left(t^{\prime}\right)$ crosses the light cone at the observation point $\mathbf{r}(t)$. It is evident from that figure that if the particle does not move (i.e. its world trajectory in a vertical straight line), then $\partial t_{r}=\partial t$. On the other hand, if the particles moves fast (with speed $u \approx \mathrm{c}$ ) toward the observation point, its world line crosses the light cone at a small ("grazing") angle, so that $\partial t_{r} \gg \partial t$, in accordance with Eq. (18).

Since the retarded time $t_{r}$, as the solution of Eq. (3), depends not only on the observation time $t$, but also the observation point $\mathbf{r}$, so we also need to calculate its spatial derivative - the gradient in $\mathbf{r}$ space. A calculation, absolutely similar to that carried above, yields

$$
\begin{equation*}
\nabla t_{r}=-\left[\frac{\mathbf{n}}{c(1-\boldsymbol{\beta} \cdot \mathbf{n})}\right]_{r} . \tag{10.19}
\end{equation*}
$$

Using Eqs. (6.106), (18) and (19), the calculation of fields from Eqs. (10) is straightforward but tedious, and is left for reader's exercise. For the electric field, the result is:

Electric magnetic fields of relativistic particle

$$
\begin{equation*}
\mathbf{E}=\frac{q}{4 \pi \varepsilon_{0}}\left[\frac{\mathbf{n}-\boldsymbol{\beta}}{\gamma^{2}(1-\boldsymbol{\beta} \cdot \mathbf{n})^{3} R^{2}}+\frac{\mathbf{n} \times\{(\mathbf{n}-\boldsymbol{\beta}) \times \dot{\boldsymbol{\beta}}\}}{(1-\boldsymbol{\beta} \cdot \mathbf{n})^{3} c R}\right]_{r} . \tag{10.20a}
\end{equation*}
$$

The only good news about this uncomfortably bulky result is that a similar differentiation gives essentially the same formula for the magnetic field, which may be expressed via Eq. (20a): ${ }^{5}$

$$
\begin{equation*}
\mathbf{B}=\mathbf{n}_{r} \times \frac{\mathbf{E}}{c}, \quad \text { i.e. } \mathbf{H}=\frac{1}{Z_{0}} \mathbf{n}_{r} \times \mathbf{E} . \tag{10.20b}
\end{equation*}
$$

Thus the magnetic and electric fields are always perpendicular to each other, and related just as in a plane wave - cf. Eq. (7.6), ${ }^{6}$ with the only difference that now vector $\mathbf{n}_{r}$ may be a function of time.

As a sanity check, let us use Eq. (20a) as an alternative way to find the electric field of a charge moving without acceleration, i.e. uniformly, along a straight line - see Fig. 9.11 (reproduced in Fig. 3) and its discussion in Sec. 5. (This example will also exhibit the challenges of practical application of the Liénard-Wiechert formulas.) In this case vector $\beta$ does not change in time, so that the second term in Eq. (20a) vanishes, and all we need to do is to spell out the Cartesian components of the first term. Let us select the coordinate axes and time origin in the same way as shown in Fig. 3, and make a clear distinction between the actual position, $\mathbf{r}^{\prime}(t)=\{u t, 0,0\}$ of the charged particle at the instant $t$ we are
${ }^{5}$ An alternative way to derive Eqs. (20) is to plug the 4 -vector of potentials, given by Eq. (7), into Eq. (9.124) to calculate the field strength tensor. This calculation yields

$$
F^{\alpha \beta}=\frac{\mu_{0} q}{4 \pi} \frac{1}{u_{\gamma} R^{\gamma}} \frac{d}{d \tau}\left[\frac{R^{\alpha} u^{\beta}-R^{\beta} u^{\alpha}}{u_{\delta} R^{\delta}}\right] .
$$

Now the elements of this tensor may be identified with fields components in accordance with Eq. (9.125).
${ }^{6}$ Superficially, Eq. (20b) contradicts the electrostatics where B should vanish while E stays finite. However, note that according to the Coulomb law for a point charge, in this case $\mathbf{E}=E \mathbf{n}=E \mathbf{n}_{r}$, so that $\mathbf{B} \propto \mathbf{n}_{r} \times \mathbf{E} \propto \mathbf{n}_{r} \times \mathbf{n}_{r}=0$.
considering, and its retarded position $\mathbf{r}$ ' $\left(t_{r}\right)$, where $t_{r}$ is the solution of Eq. (4), i.e. the moment when the particle's field, moving with the speed of light, reaches the observation point $\mathbf{r}$. In these coordinates

$$
\begin{equation*}
\boldsymbol{\beta}=\{\beta, 0,0\}, \quad \mathbf{r}=\{0,0, b\}, \quad \mathbf{r}^{\prime}\left(t_{r}\right)=\left\{u t_{r}, 0,0\right\}, \quad \mathbf{n}_{r}=\{\cos \theta, 0, \sin \theta\} \tag{10.21}
\end{equation*}
$$

with $\cos \theta=-u t^{\prime} / R_{r}$, so that $\left[(\mathbf{n}-\boldsymbol{\beta})_{x}\right]_{r}=-u t^{\prime} / R_{r}-\beta$, and for the longitudinal component of the electric field, Eq. (20a) yields

$$
\begin{equation*}
E_{x}=\frac{q}{4 \pi \varepsilon_{0}}\left[\frac{-u t_{r} / R-\beta}{\gamma^{2}(1-\boldsymbol{\beta} \cdot \mathbf{n})^{3} R^{2}}\right]_{r}=\frac{q}{4 \pi \varepsilon_{0}}\left[\frac{-u t_{r}-\beta R}{\gamma^{2}(1-\boldsymbol{\beta} \cdot \mathbf{n})^{3} R^{3}}\right]_{r} . \tag{10.22}
\end{equation*}
$$

Fig. 10.3. Geometry of the linearly moving charge problem.

But according to Eq. (13), product $\beta R_{r}$ may be presented as $\beta c\left(t-t_{r}\right)=u\left(t-t_{r}\right)$. Plugging this expression into Eq. (22), we may eliminate the explicit dependence of $E_{x}$ on time $t^{\prime}$ :

$$
\begin{equation*}
E_{x}=\frac{q}{4 \pi \varepsilon_{0}} \frac{-u t}{\gamma^{2}[(1-\boldsymbol{\beta} \cdot \mathbf{n}) R]_{r}^{3}} . \tag{10.23}
\end{equation*}
$$

The nonvanishing transverse component of the field also has a similar form:

$$
\begin{equation*}
E_{y}=\frac{q}{4 \pi \varepsilon_{0}}\left[\frac{\sin \theta}{\gamma^{2}(1-\boldsymbol{\beta} \cdot \mathbf{n})^{3} R^{2}}\right]_{r}=\frac{q}{4 \pi \varepsilon_{0}} \frac{b}{\gamma^{2}[(1-\boldsymbol{\beta} \cdot \mathbf{n}) R]_{r}^{3}}, \tag{10.24}
\end{equation*}
$$

while $E_{z}=0$. Hence, the only combination of $t_{r}$ and $R_{r}$ we still need to calculate is $[(1-\boldsymbol{\beta} \cdot \mathbf{n}) R]_{r}$. From Fig. 3, $\boldsymbol{\beta} \cdot \mathbf{n}_{r}=\beta \cos \theta=-\beta u t^{\prime} / R_{r}$, so that $(1-\beta \cdot \mathbf{n}) R_{r}=R_{r}+\beta u t_{r}=c\left(t-t_{r}\right)+c \beta^{2} t_{r}=c t-c t_{r} / \gamma^{2}$. What remains is to find time $t_{r}$ from the self-consistency equation (13) that in our case (Fig. 3) takes the form

$$
\begin{equation*}
R_{r}^{2} \equiv c^{2}\left(t-t_{r}\right)^{2}=b^{2}+\left(u t_{r}\right)^{2} . \tag{10.25}
\end{equation*}
$$

After solving this quadratic equation (with the appropriate negative sign before the square root, in order to get $t_{r}<t$ ),

$$
\begin{equation*}
t_{r}=\gamma^{2} t-\left[\left(\gamma^{2} t\right)^{2}-\gamma^{2}\left(t^{2}-b^{2} / c^{2}\right)\right]^{1 / 2}=\gamma^{2} t-\frac{\gamma}{c}\left(u^{2} \gamma^{2} t^{2}+b^{2}\right)^{1 / 2} \tag{10.26}
\end{equation*}
$$

we obtain a simple result:

$$
\begin{equation*}
[(1-\boldsymbol{\beta} \cdot \mathbf{n}) R]_{\mathrm{r}}=\frac{c}{\gamma^{2}}\left(u^{2} \gamma^{2} t^{2}+b^{2}\right)^{1 / 2} \tag{10.27}
\end{equation*}
$$

so that the electric field components are

$$
\begin{equation*}
E_{x}=-\frac{q}{4 \pi \varepsilon_{0}} \frac{\gamma u t}{\left(b^{2}+\gamma^{2} u^{2} t^{2}\right)^{3 / 2}}, \quad E_{y}=\frac{q}{4 \pi \varepsilon_{0}} \frac{\gamma b}{\left(b^{2}+\gamma^{2} u^{2} t^{2}\right)^{3 / 2}}, \quad E_{z}=0 . \tag{10.28}
\end{equation*}
$$

These are exactly Eqs. (9.139), ${ }^{7}$ which had been obtained in Sec. 9.5 by simpler means, without the necessity to solve the self-consistency equation for $t_{r}$. However, that alternative approach was essentially based on the inertial motion of the particle, and cannot be used in problems in which particle moves with acceleration. In those problems, the second term in Eq. (20a), describing wave radiation, is essential and most important.

### 10.2. Radiation power

Let us calculate the angular distribution of particle's radiation. For that, we need to return to use Eqs. (20) to find the Poynting vector $\mathbf{S}=\mathbf{E} \times \mathbf{H}$, and in particular its component $S_{n}=\mathbf{S} \cdot \mathbf{n}_{r}$, at large distances $R$ from the particle. Following tradition, let us express the result as the radiated energy per unit solid angle per unit time interval $d t_{r}$ of the radiation (rather than its measurement), using Eq. (18):

$$
\begin{equation*}
\frac{d \mathcal{P}}{d \Omega} \equiv-\frac{d \varepsilon}{d \Omega d t_{r}}=\left[R^{2} S_{n} \frac{\partial t}{\partial t_{r}}\right]_{r}=\left[R^{2}(\mathbf{E} \times \mathbf{H}) \cdot \mathbf{n}(1-\boldsymbol{\beta} \cdot \mathbf{n})\right]_{r} . \tag{10.29}
\end{equation*}
$$

At sufficiently large distances from the particle, i.e. in the limit $R \rightarrow \infty$, the contribution of the first (essentially, the Coulomb field) term in the square brackets of Eq. (20a) vanishes as $1 / R^{2}$, so that we get a key formula valid for an arbitrary law of particle motion: ${ }^{8}$

$$
\begin{equation*}
\frac{d \mathcal{P}}{d \Omega}=\frac{Z_{0} q^{2}}{(4 \pi)^{2}} \frac{|\mathbf{n} \times[(\mathbf{n}-\boldsymbol{\beta}) \times \dot{\boldsymbol{\beta}}]|^{2}}{(1-\mathbf{n} \cdot \boldsymbol{\beta})^{5}} \tag{10.30}
\end{equation*}
$$

Now, let us apply this important result to some simple cases. First of all, Eq. (30) says that a charge moving with constant velocity $\beta$ does not radiate at all. This might be expected from our analysis of this case in Sec. 9.5, because in the reference frame moving with the charge it produces only the Coulomb electrostatic field, i.e. no radiation.

Next, let us consider a linear motion of a point charge with a nonvanishing acceleration evidently directed along the motion line. With the coordinate axes directed as shown in Fig. 4a, each of the vectors involved in Eq. (30) has at most two nonvanishing Cartesian components:

$$
\begin{equation*}
\mathbf{n}=\{\sin \theta, 0, \cos \theta\}, \quad \boldsymbol{\beta}=\{0,0, \beta\}, \quad \dot{\boldsymbol{\beta}}=\{0,0, \dot{\beta}\} . \tag{10.31}
\end{equation*}
$$

where $\theta$ is the angle between the directions of particle's motion and radiation propagation. Plugging these expressions into Eq. (30) and performing the vector multiplications, we get

$$
\begin{equation*}
\frac{d P}{d \Omega}=\frac{Z_{0} q^{2}}{(4 \pi)^{2}} \dot{\beta}^{2} \frac{\sin ^{2} \theta}{(1-\beta \cos \theta)^{5}} \tag{10.32}
\end{equation*}
$$

[^427]

Fig. 10.4. Radiation at linear acceleration: (a) geometry of the problem, and (b) the last fraction in Eq. (32) as a function of angle $\theta$.

Figure 4 b shows the angular distribution of this radiation, for three values of particle's speed. If it is relatively low ( $\beta \ll 1$ ), the denominator in Eq. (32) is close to 1 for all observation angles $\theta$, so that the angular distribution of the radiation power is close to $\sin ^{2} \theta$ - just as it follows from the general nonrelativistic formula (8.26). However, as the velocity is increased, the denominator is less than 1 for $\theta<$ $\pi / 2$, i.e. for the forward-looking directions, and is larger than 1 for back directions. As a result, the radiation toward particle's velocity is increased (somewhat counter-intuitively, regardless of the acceleration sign!), while that in the back direction is suppressed. For ultra-relativistic particles ( $\beta \rightarrow 1$ ), this trend is enormously exacerbated, and radiation to very small forward angles dominates. In order to describe this main part of the distribution, we may expand the trigonometric functions of $\theta$, participating in Eq. (32), into the Taylor series in small $\theta$, and keep only their leading terms: $\sin \theta \approx \theta, \cos \theta \approx 1-\theta$ ${ }^{2} / 2$, so that $(1-\beta \cos \theta) \approx\left(1+\gamma^{2} \theta^{2}\right) / 2 \gamma^{2}$. The resulting expression,

$$
\begin{equation*}
\frac{d P}{d \Omega} \approx \frac{2 Z_{0} q^{2}}{\pi^{2}} \dot{\beta}^{2} \gamma^{8} \frac{(\gamma \theta)^{2}}{\left(1+\gamma^{2} \theta^{2}\right)^{5}}, \text { for } \gamma \gg 1 \tag{10.33}
\end{equation*}
$$

describes a narrow distribution of radiation, with a maximum at angle

$$
\begin{equation*}
\theta_{0}=\frac{1}{2 \gamma} \ll 1 \tag{10.34}
\end{equation*}
$$

Note that due to the axial symmetry of the result, and the fact that according to Eq. (33), $d \mathcal{P} / d \Omega=0$ in the exact direction of particle's propagation $(\theta=0)$, Eq. (40) describes a narrow circular "hollow cone" of radiation. Another important aspect of this result is how fast does the maximum radiation brightness grows with the Lorentz factor $\gamma$, i.e. with particle's energy $\varepsilon=\gamma m c^{2}$.

Still, the total radiated power $P$ (into all observation angles) at linear acceleration is not too high for any practicable values of parameters. In order to show this, it is convenient to calculate $P$ for an arbitrary motion of the particle first. It is possible to do this by a straightforward integration of Eq. (30) over the full solid angle, but let me demonstrate how $\mathcal{P}$ may be found (or rather guessed) from the general relativistic arguments. In Sec. 8.2, we have derived Eq. (8.27) for the electric dipole radiation for non-relativistic particle motion. That result is valid, in particular, for one charged particle whose electric dipole moment's derivative over time may be expressed as $d(q \mathbf{r}) / d t=(q / m) \mathbf{p}$, where $\mathbf{p}$ is
particle's mechanical momentum (not its electric dipole moment). As the result, the Larmor formula (8.27) in free space, i.e. with $v=c$, reduces to

$$
\begin{equation*}
\mathcal{P}=\frac{Z_{0}}{6 \pi c^{2}}\left(\frac{q}{m} \frac{d p}{d t}\right)^{2}=\frac{Z_{0} q^{2}}{6 \pi m^{2} c^{2}}\left(\frac{d \mathbf{p}}{d t} \cdot \frac{d \mathbf{p}}{d t}\right) \tag{10.35}
\end{equation*}
$$

This is evidently not a Lorentz-invariant result, but it gives a clear hint how such an invariant, that is reduced to Eq. (35) in the non-relativistic limit, may be formed:

$$
\begin{equation*}
\mathcal{P}=-\frac{Z_{0} q^{2}}{6 \pi m^{2} c^{2}}\left(\frac{d p_{\alpha}}{d \tau} \cdot \frac{d p^{\alpha}}{d \tau}\right)=\frac{Z_{0} q^{2}}{6 \pi m^{2} c^{2}}\left[\left(\frac{d \mathbf{p}}{d \tau}\right)^{2}-\frac{1}{c^{2}}\left(\frac{d \varepsilon}{d \tau}\right)^{2}\right] . \tag{10.36}
\end{equation*}
$$

Plugging in the relativistic expressions, $\mathbf{p}=\gamma m c \boldsymbol{\beta}, \varepsilon=\gamma m c^{2}$, and $d \tau=d t / \gamma$, the last formula may be recast into the Liénard extension of the Larmor formula: ${ }^{9}$

Total
radiation power via $\beta$

$$
\begin{equation*}
\mathcal{P}=\frac{Z_{0} q^{2}}{6 \pi} \gamma^{6}\left[(\dot{\boldsymbol{\beta}})^{2}-(\boldsymbol{\beta} \times \dot{\boldsymbol{\beta}})^{2}\right] \equiv \frac{Z_{0} q^{2}}{6 \pi} \gamma^{4}\left[(\dot{\boldsymbol{\beta}})^{2}+\gamma^{2}(\boldsymbol{\beta} \cdot \dot{\boldsymbol{\beta}})^{2}\right], \tag{10.37}
\end{equation*}
$$

which may be also obtained by a direct integration of Eq. (30) over the full solid angle, thus confirming our guess. However, for some applications, it is beneficial to express $P$ the via the time evolution of particle's momentum alone. For that, we may differentiate the fundamental relativistic relation (9.78), $\varepsilon^{2}=\left(m c^{2}\right)^{2}+(p c)^{2}$, over the proper time $\tau$ to get

$$
\begin{equation*}
2 \varepsilon \frac{d \varepsilon}{d \tau}=2 c^{2} p \frac{d p}{d \tau}, \text { i.e. } \frac{d \varepsilon}{d \tau}=\frac{c^{2} p}{\varepsilon} \frac{d p}{d \tau}=u \frac{d p}{d \tau} \tag{10.38}
\end{equation*}
$$

where, at the last transition, the magnitude of the relativistic vector relation mentioned in Chapter 9, $c^{2} \mathbf{p} / \mathcal{E}=\mathbf{u}$, has been used. Plugging this relation into Eq. (36), we may rewrite it as

Total radiation power via $\mathbf{p}$

$$
\begin{equation*}
\mathcal{P}=\frac{Z_{0} q^{2}}{6 \pi m^{2} c^{2}}\left[\left(\frac{d \mathbf{p}}{d \tau}\right)^{2}-\beta^{2}\left(\frac{d p}{d \tau}\right)^{2}\right] \tag{10.39}
\end{equation*}
$$

Note the difference between the squared derivatives in this expression: in the first of them we have to differentiate the momentum vector $\mathbf{p}$, and only then form a scalar by squaring the resulting vector derivative, while in the second case, only the magnitude of the vector is differentiated. For example, for a circular motion with constant speed (to be analyzed in detail in the next section), the second term is zero, while the first one is not.

However, if we return to the simplest case of linear acceleration (Fig. 4), then $(d \mathbf{p} / d \tau)^{2}=$ $(d p / d \tau)^{2}$, and Eq. (39) is reduced to

$$
\begin{equation*}
\mathcal{P}=\frac{Z_{0} q^{2}}{6 \pi m^{2} c^{2}}\left(\frac{d p}{d \tau}\right)^{2}\left(1-\beta^{2}\right)=\frac{Z_{0} q^{2}}{6 \pi m^{2} c^{2}}\left(\frac{d p}{d \tau}\right)^{2} \frac{1}{\gamma^{2}}=\frac{Z_{0} q^{2}}{6 \pi m^{2} c^{2}}\left(\frac{d p}{d t^{\prime}}\right)^{2}, \tag{10.40}
\end{equation*}
$$

[^428](where $t^{\prime} \equiv t_{r}$ is the time of emitting radiation as measured as in the lab frame), i.e. formally coincides with non-relativistic Eq. (35). In order to get a better feeling of the magnitude of this radiation, we may use the fact that $d p / d t=d \varepsilon / d z^{\prime}$. This allows us to rewrite Eq. (40) in the following form:
\[

$$
\begin{equation*}
\mathcal{P}=\frac{Z_{0} q^{2}}{6 \pi m^{2} c^{2}}\left(\frac{d \varepsilon}{d z}\right)^{2}=\frac{Z_{0} q^{2}}{6 \pi m^{2} c^{2}} \frac{d \varepsilon}{d z^{\prime}} \frac{d \varepsilon}{d t^{\prime}} \frac{d t^{\prime}}{d z^{\prime}}=\frac{Z_{0} q^{2}}{6 \pi m^{2} c^{2} u} \frac{d \varepsilon}{d z^{\prime}} \frac{d \varepsilon}{d t^{\prime}} . \tag{10.41}
\end{equation*}
$$

\]

For the most important case of ultra-relativistic motion $(u \rightarrow c)$, this result may be presented as

$$
\begin{equation*}
\frac{P}{d \varepsilon / d t^{\prime}} \approx \frac{2}{3} \frac{d\left(\varepsilon / m c^{2}\right)}{d\left(z^{\prime} / r_{\mathrm{c}}\right)} \tag{10.42}
\end{equation*}
$$

where $r_{c}$ is the classical radius of the particle, given by Eq. (8.41). This formula shows that the radiated power, i.e. the change of particle's energy due to radiation, is much smaller than that due to the accelerating field, unless energy as large as $m c^{2}$ is gained on the classical radius of the particle. For example, for an electron, such acceleration would require the accelerating electric field of the order of $(0.5 \mathrm{MV}) /\left(3 \times 10^{-15} \mathrm{~m}\right) \sim 10^{14} \mathrm{MV} / \mathrm{m}$, while practicable accelerating fields are below $10^{3} \mathrm{MV} / \mathrm{m}$, limited by the electric breakdown effects. Such smallness of radiative losses of energy is actually a large advantage of linear electron accelerators - such as the famous 2-mile-long SLAC ${ }^{10}$ that can accelerate electrons or positrons to energies up to 50 GeV , i.e. to $\gamma \approx 10^{5}$.

### 10.3. Synchrotron radiation

Now let me show that in circular accelerators, the radiation is much larger. Consider a charged particle being accelerated in the direction perpendicular to its velocity $\mathbf{u}$ (for example by a the magnetic component of the Lorentz force), so that its speed $u$, and hence the magnitude $p$ of its momentum, do not change. In this case, the second term in Eq. (39) vanishes, and it yields

$$
\begin{equation*}
\mathcal{P}=\frac{Z_{0} q^{2}}{6 \pi m^{2} c^{2}}\left(\frac{d \mathbf{p}}{d \tau}\right)^{2}=\frac{Z_{0} q^{2}}{6 \pi m^{2} c^{2}}\left(\frac{d \mathbf{p}}{d t^{\prime}}\right)^{2} \gamma^{2} . \tag{10.43}
\end{equation*}
$$

Comparing this expression with Eq. (40), we see that for the same acceleration magnitude, the electromagnetic radiation is a factor of $\gamma^{2}$ larger. For modern accelerators, with $\gamma \sim 10^{4}-10^{5}$, such a factor creates an enormous difference. For example, if a particle is on a cyclotron orbit in a constant magnetic field (as was analyzed in Sec. 9.6), both $\mathbf{u}$ and $\mathbf{p}=\gamma m \mathbf{u}$ obey Eq. (9.150), so that

$$
\begin{equation*}
\left|\frac{d \boldsymbol{p}}{d t^{\prime}}\right|=\omega_{c} p=\frac{u}{R} p=\beta^{2} \gamma \frac{m c^{2}}{R} \tag{10.44}
\end{equation*}
$$

(where $R$ is orbit's radius), so that for the power of this synchrotron radiation, Eq. (43) yields

$$
\begin{equation*}
\mathcal{P}=\frac{Z_{0} q^{2}}{6 \pi} \beta^{4} \gamma^{4} \frac{c^{2}}{R^{2}} \tag{10.45}
\end{equation*}
$$

According to Eq. (9.153), at fixed magnetic field (in particle accelerators, limited to a few Tesla produced by the beam-bending magnets), the synchrotron orbit radius $R$ scales as $\gamma$, so that according to

[^429]Eq. (45), $\mathcal{P}_{\text {scales as }} \gamma^{2}$, i.e. grows fast with particle's energy $\varepsilon \propto \gamma$. For example, for typical parameters of the first electron cyclotrons (such as the General Electric machine in which the synchrotron radiation was first noticed in 1947), $R \sim 1 \mathrm{~m}, \varepsilon \sim 0.3 \mathrm{GeV}$ ( $\gamma \sim 600$ ), Eq. (45) gives a very modest electron energy loss per one revolution: $P \Delta t^{\prime} \approx 2 \pi P R / c \sim 1 \mathrm{keV}$. However, already by the mid-1970s, electron accelerators, with $R \sim 100 \mathrm{~m}$, have reached energies $\mathcal{E} \sim 10 \mathrm{GeV}$, and the energy loss per revolution has grown to $\sim 10 \mathrm{MeV}$, becoming the major energy loss mechanism. ${ }^{11}$ However, what is bad for particle accelerators and storage rings is good for the so-called synchrotron light sources - the electron accelerators designed specially for the generation of intensive synchrotron radiation - with the spectrum extending well beyond the visible light range. Let us now analyze the angular and spectral distributions of such radiation.

To calculate the angular distribution, let us select the coordinate axes as shown in Fig. 5, with the origin at the current location of the orbiting particle, axis $z$ along its instant velocity (i.e. vector $\beta$ ), and axis $x$ toward the orbit center.

Fig. 10.5. Geometry of the synchrotron radiation problem.

In the general case, the unit vector $\mathbf{n}$ toward the radiation observer is not within any of the coordinate planes, and hence should be described by two angles - the polar angle $\theta$ and the azimuthal angle $\varphi$ between the $x$ axis and projection 0 P of vector $\mathbf{n}$ on plane $[x, y]$. Since the length of segment 0 P is $\sin \theta$, the Cartesian coordinates of the relevant vectors are as follows:

$$
\begin{equation*}
\mathbf{n}=\{\sin \theta \cos \varphi, \sin \theta \sin \varphi, \cos \theta\}, \quad \boldsymbol{\beta}=\{0,0, \beta\}, \quad \dot{\boldsymbol{\beta}}=\{\dot{\beta}, 0,0\} . \tag{10.46}
\end{equation*}
$$

Plugging these coordinates into the general Eq. (30), we get

Synchrotron radiation's angular distribution

$$
\begin{equation*}
\frac{d \mathcal{P}}{d \Omega}=\frac{2 Z_{0} q^{2}}{\pi^{2}}|\dot{\boldsymbol{\beta}}|^{2} \gamma^{6} f(\theta, \varphi), \text { with } f(\theta, \varphi) \equiv \frac{1}{8 \gamma^{6}(1-\beta \cos \theta)^{3}}\left[1-\frac{\sin ^{2} \theta \cos ^{2} \varphi}{\gamma^{2}(1-\beta \cos \theta)^{2}}\right], \tag{10.47}
\end{equation*}
$$

According to this result, just as at the linear acceleration, in the ultra-relativistic limit, most radiation goes to a narrow cone (of width $\Delta \theta \sim \gamma^{-1} \ll 1$ ) around vector $\beta$, i.e. around the instant direction of particle's propagation. For such small angles, and $\gamma \gg 1$, the second of Eqs. (47) is reduced to

[^430]\[

$$
\begin{equation*}
f(\theta, \varphi) \approx \frac{1}{\left(1+\gamma^{2} \theta^{2}\right)^{3}}\left[1-\frac{4 \gamma^{2} \theta^{2} \cos ^{2} \varphi}{\left(1+\gamma^{2} \theta^{2}\right)^{2}}\right] . \tag{10.48}
\end{equation*}
$$

\]

Left panel of Fig. 6 shows the angular distribution $f(\theta, \varphi)$ color-coded, on the plane perpendicular to particle's instant velocity (in Fig. 5, plane $[x, y]$ ), while its right panel shows the intensity as a function of $\theta$ in two perpendicular directions: within the particle rotation plane (along axis $x$ ) and perpendicular to this plane (along axis $y$ ). The result shows, first of all, that, in contrast to the case of linear acceleration, the narrow radiation cone is now not hollow: the intensity maximum is reached exactly at $\theta=0$, i.e. in particle's motion direction. Second, the radiation cone is not axiallysymmetric: the intensity drops faster within the particle rotation plane (and even has nodes at $\theta= \pm 1 / \gamma$ ).

Fig. 10.6. Angular distribution of the synchrotron radiation at $\gamma \gg 1$.

Let us consider the time/frequency structure of the synchrotron radiation, now from the point of view of the observer rather than the particle itself. (In the latter picture, due to the axial symmetry of the problem, the total radiation power $\mathcal{P}$ is evidently constant.) Its semi-quantitative picture may be obtained from the angular distribution we have just analyzed. Indeed, if an ultra-relativistic particle's radiation is observed from a point in (or close to) the rotation plane, ${ }^{12}$ the observer is being "struck" by the narrow radiation cone once each rotation period, each "strike" giving a pulse of a short duration $\Delta t$ $\ll \omega_{c}-$ see Fig. 7.

[^431]

Fig. 10.7. (a) Synchrotron radiation cones at $\gamma \gg 1$, and (b) the in-plane component of their electric field, observed in the rotation plane, as a function of observation time $t$-schematically.

The evaluation of the time duration $\Delta t$ of each pulse requires some care: its estimate $\Delta t^{\prime} \sim 1 / \gamma \omega_{c}$ is correct for the duration of the time of particle's motion while its cone is aimed at the observer. However, due to the time compression effect, discussed in detail in Sec. 1 and described by Eqs. (12) and (18), the pulse duration as seen by observer is a factor of $1 /(1-\beta)$ shorter, so that

$$
\begin{equation*}
\Delta t=(1-\beta) \Delta t^{\prime} \sim \frac{1-\beta}{\gamma \omega_{c}} \sim \frac{1}{\gamma^{3} \omega_{c}} . \tag{10.49}
\end{equation*}
$$

From the Fourier theorem, we can expect that the frequency spectrum of the radiation consists of numerous $\left(N \sim \gamma^{3} \gg 1\right.$ ) harmonics of the rotation frequency $\omega_{\mathrm{c}}$, with comparable amplitudes. However, if the orbital frequency fluctuates even slightly $\left(\delta \omega_{c} / \omega_{c}>1 / N \sim 1 / \gamma^{3}\right)$, as it happens in most practical systems, the radiation pulses are not coherent, so that the average radiation power spectrum may be calculated as that of one pulse, multiplied by number of pulses per second. In this case, the spectrum is continuous, extending from low frequencies all the way to approximately

$$
\begin{equation*}
\omega_{\max } \sim 1 / \Delta t \sim \gamma^{3} \omega_{c} . \tag{10.50}
\end{equation*}
$$

In order to verify this estimate, let us calculate the spectrum of radiation, due to a single pulse. For that, we should first make the general notion of spectrum quantitative. Let us present an arbitrary electric field (say that of the synchrotron radiation we are studying now), considered as a function of the observation time $t$ (at fixed $\mathbf{r}$ ), as a Fourier integral: ${ }^{13}$

$$
\begin{equation*}
\mathbf{E}(t)=\int_{-\infty}^{+\infty} \mathbf{E}_{\omega} e^{-i \omega t} d t \tag{10.51}
\end{equation*}
$$

This expression may be plugged into the following formula for the total energy of the radiation pulse (i.e. of particle energy's loss) per unit solid angle: ${ }^{14}$

[^432]\[

$$
\begin{equation*}
-\frac{d \varepsilon}{d \Omega} \equiv \int_{-\infty}^{+\infty} S_{n}(t) R^{2} d t=\frac{R^{2}}{Z_{0}} \int_{-\infty}^{+\infty}|\mathbf{E}(t)|^{2} d t \tag{10.52}
\end{equation*}
$$

\]

This substitution, plus a natural change of integration order, yield

$$
\begin{equation*}
\frac{d \varepsilon}{d \Omega}=\frac{R^{2}}{Z_{0}} \int_{-\omega}^{+\omega} d \omega \int_{-\omega}^{+\omega} d \omega^{\prime} \mathbf{E}_{\omega} \cdot \mathbf{E}_{\omega^{\prime}} \int_{-\infty}^{+\infty} d t e^{-i\left(\omega+\omega^{\prime}\right) t} \tag{10.53}
\end{equation*}
$$

But the inner integral (over $t$ ) is just $2 \pi \delta\left(\omega+\omega^{\prime}\right) .{ }^{15}$ This delta-function kills one of the frequency integrals (say, one over $\omega^{\prime}$ ), and Eq. (53) gives a result which may be recast as

$$
\begin{equation*}
-\frac{d \varepsilon}{d \Omega}=\int_{0}^{+\infty} I(\omega) d \omega, \quad \text { with } I(\omega) \equiv \frac{4 \pi R^{2}}{Z_{0}} \mathbf{E}_{\omega} \cdot \mathbf{E}_{-\omega}=4 \pi Z_{0} \varepsilon_{0}^{2}(c R)^{2} \mathbf{E}_{\omega} \mathbf{E}_{\omega}^{*} \tag{10.54}
\end{equation*}
$$

where the evident frequency symmetry of the scalar product $\mathbf{E}_{\omega} \cdot \mathbf{E}_{-\omega}$ has been utilized to fold the integral of $I(\omega)$ to positive frequencies only. The first of Eqs. (51) and the first of Eqs. (54) make the physical sense of function $I(\omega)$ clear: this is the so-called spectral density of the electromagnetic radiation (per unit solid angle, per unit pulse). ${ }^{16}$

In order to calculate the spectral density, we need to express function $\mathbf{E}_{\omega}$ via $\mathbf{E}(t)$ using the Fourier transform reciprocal to Eq. (51):

$$
\begin{equation*}
\mathbf{E}_{\omega}=\frac{1}{2 \pi} \int_{-\infty}^{+\omega} \mathbf{E}(t) e^{i \omega t} d t \tag{10.55}
\end{equation*}
$$

In the particular case of radiation by a single point charge, we should use the second term of Eq. (20a):

$$
\begin{equation*}
\mathbf{E}_{\omega}=\frac{1}{2 \pi} \frac{q}{4 \pi \varepsilon_{0}} \frac{1}{c R} \int_{-\infty}^{+\infty} \frac{\mathbf{n} \times\{(\mathbf{n}-\boldsymbol{\beta}) \times \dot{\boldsymbol{\beta}}\}}{(1-\boldsymbol{\beta} \cdot \mathbf{n})^{3}} e^{i \omega t} d t \tag{10.56}
\end{equation*}
$$

Since vectors $\mathbf{n}$ and $\beta$ are natural functions of the radiation (retarded) time $t^{\prime}$, let us use Eqs. (18) to change integration in Eq. (52) from the observation time $t$ to time $t^{\prime}$ :

$$
\begin{equation*}
\mathbf{E}_{\omega}=\frac{q}{4 \pi \varepsilon_{0}} \frac{1}{2 \pi} \frac{1}{c R} \int_{-\infty}^{+\infty} \frac{\mathbf{n} \times\{(\mathbf{n}-\boldsymbol{\beta}) \times \dot{\boldsymbol{\beta}}\}}{(1-\boldsymbol{\beta} \cdot \mathbf{n})^{2}} \exp \left\{i \omega\left(t^{\prime}+\frac{R_{r}}{c}\right)\right\} d t^{\prime} \tag{10.57}
\end{equation*}
$$

The strong inequality $R_{r} \gg r$ ' that is implied from the beginning of this section allows us to consider the unit vector $\mathbf{n}$ as constant and, moreover, to use approximation (8.19) to reduce Eq. (57) to

$$
\begin{equation*}
\mathbf{E}_{\omega}=\frac{1}{2 \pi} \frac{q}{4 \pi \varepsilon_{0}} \frac{1}{c R} \exp \left\{\frac{i \omega r}{c}\right\} \int_{-\infty}^{+\infty} \frac{\mathbf{n} \times\{(\mathbf{n}-\boldsymbol{\beta}) \times \dot{\boldsymbol{\beta}}\}}{(1-\boldsymbol{\beta} \cdot \mathbf{n})^{2}} \exp \left\{i \omega\left(t^{\prime}-\frac{\mathbf{n} \cdot \mathbf{r}^{\prime}}{c}\right)\right\} d t^{\prime} \tag{10.58}
\end{equation*}
$$

Plugging this expression into Eq. (54), we get ${ }^{17}$

[^433]\[

$$
\begin{equation*}
I(\omega)=\frac{Z_{0} q^{2}}{16 \pi^{3}}\left|\int_{-\infty}^{+\infty} \frac{\mathbf{n} \times\{(\mathbf{n}-\boldsymbol{\beta}) \times \dot{\boldsymbol{\beta}}\}}{(1-\boldsymbol{\beta} \cdot \mathbf{n})^{2}} \exp \left\{i \omega\left(t^{\prime}-\frac{\mathbf{n} \cdot \mathbf{r}^{\prime}}{c}\right)\right\} d t^{\prime}\right|^{2} . \tag{10.59}
\end{equation*}
$$

\]

Let me remind the reader that $\beta$ inside this integral is supposed to be taken at the retarded point $\left\{\mathbf{r}^{\prime}, t^{\prime}\right\}$, so that Eq. (59) is fully sufficient for finding the spectral density from the law $\mathbf{r}^{\prime}\left(t^{\prime}\right)$ of particle's motion. However, this result may be further simplified by noticing that the fraction before the exponent may be presented as a full derivative over $t^{\prime}$,

$$
\begin{equation*}
\frac{\mathbf{n} \times\left\{(\mathbf{n}-\boldsymbol{\beta}) \times d \boldsymbol{\beta} / d t^{\prime}\right\}}{(1-\boldsymbol{\beta} \cdot \mathbf{n})^{2}}=\frac{d}{d t^{\prime}}\left[\frac{\mathbf{n} \times(\mathbf{n} \times \boldsymbol{\beta})}{1-\boldsymbol{\beta} \cdot \mathbf{n}}\right], \tag{10.60}
\end{equation*}
$$

and working out the resulting integral by parts. At this operation, the time differentiation of the parentheses in the exponent, $d\left(t^{\prime}-\mathbf{n} \cdot \mathbf{r}^{\prime} / c\right) / d t^{\prime}=1-\mathbf{n} \cdot \mathbf{u} / c=1-\boldsymbol{\beta} \cdot \mathbf{n}$, leads to the cancellation of denominator's remains and hence to a surprisingly simple result: ${ }^{18}$

$$
\begin{equation*}
I(\omega)=\frac{Z_{0} q^{2} \omega^{2}}{16 \pi^{3}} \int_{-\infty}^{+\infty} \mathbf{n} \times\left.(\mathbf{n} \times \boldsymbol{\beta}) \exp \left\{i \omega\left(t^{\prime}-\frac{\mathbf{n} \cdot \mathbf{r}^{\prime}}{c}\right)\right\} d t^{\prime}\right|^{2} \tag{10.61}
\end{equation*}
$$

Returning to the particular case of synchrotron radiation, it is beneficial to choose the origin of time $t^{\prime}$ so that at $t^{\prime}=0$, angle $\theta$ takes its smallest value $\theta_{0}$, i.e., in terms of Fig. 5, vector $\mathbf{n}$ is within plane $[y, z]$. Fixing this direction of axes in time, we can redraw that figure as shown in Fig. 8. In these coordinates,

$$
\begin{equation*}
\mathbf{n}=\left\{0, \sin \theta_{0}, \cos \theta_{0}\right\}, \quad \mathbf{r}^{\prime}=\{R(1-\cos \alpha), 0, R \sin \alpha\}, \quad \boldsymbol{\beta} \equiv\{\beta \sin \alpha, 0, \beta \cos \alpha\} \tag{10.62}
\end{equation*}
$$

where $\alpha \equiv \omega_{c} t^{\prime}$, and an easy multiplication yields

$$
\begin{align*}
& \mathbf{n} \times(\mathbf{n} \times \boldsymbol{\beta})=\beta\left\{\sin \alpha, \sin \theta_{0} \cos \theta_{0} \cos \alpha,-\sin ^{2} \theta_{0} \sin \alpha\right\},  \tag{10.63}\\
& \quad \exp \left\{i \omega\left(t^{\prime}-\frac{\mathbf{n} \cdot \mathbf{r}^{\prime}}{c}\right)\right\}=\exp \left\{i \omega\left(t^{\prime}-\frac{R}{c} \cos \theta_{0} \sin \alpha\right)\right\} . \tag{10.64}
\end{align*}
$$

Fig. 10.8. Deriving the spectral density of synchrotron radiation. Vector $\mathbf{n}$ is fixed in plane $[y, z]$, while vectors $\mathbf{r}^{\prime}\left(t^{\prime}\right)$ and $\beta\left(t^{\prime}\right)$ rotate in plane $[x, y]$ with angular velocity $\omega_{c}$.

[^434]As we already know, in the (most interesting) ultra-relativistic limit $\gamma \gg 1$, most radiation is confined to short pulses, so that only small angles $\alpha \sim \omega_{\mathrm{c}} \Delta t^{\prime} \sim \gamma^{-1}$ may contribute to the integral in Eq. (61). Moreover, since most radiation goes to small angles $\theta \sim \gamma^{-1}$, it makes sense to consider only small angles $\theta_{0} \sim \gamma^{-1} \ll 1$. Expanding both trigonometric functions of these small angles, participating in parentheses of Eq. (64), into Taylor series, and keeping only terms up to $O\left(\gamma^{-3}\right)$, we can present them as

$$
\begin{equation*}
\left(t^{\prime}-\frac{R}{c} \cos \theta_{0} \sin \alpha\right)=\left(t^{\prime}-\frac{R}{c} \omega_{c} t^{\prime}+\frac{R}{c} \frac{\theta_{0}^{2}}{2} \omega_{c} t^{\prime}+\frac{R}{c} \frac{\omega_{c}^{3} t^{\prime 3}}{6}\right) . \tag{10.65}
\end{equation*}
$$

Since $(R / c) \omega_{c}=u / c=\beta \approx 1$, in two last terms we may approximate this parameter by 1 . However, it is crucial to distinguish the difference of two first terms, proportional to $(1-\beta) t^{\prime}$, from zero, and as we have done before we may approximate it with $t^{\prime} / 2 \gamma^{2}$. In Eq. (63), which does not have such critical differences, we may be more bold, taking ${ }^{19}$

$$
\begin{equation*}
\mathbf{n} \times(\mathbf{n} \times \boldsymbol{\beta}) \approx\left\{\alpha, \theta_{0}, 0\right\}=\left\{\omega_{c} t^{\prime}, \theta_{0}, 0\right\} . . \tag{10.66}
\end{equation*}
$$

As a result, Eq. (61) is reduced to

$$
\begin{equation*}
I(\omega)=\frac{Z_{0} q^{2}}{16 \pi^{3}}\left|a_{x} \mathbf{n}_{x}+a_{y} \mathbf{n}_{y}\right|^{2}=\frac{Z_{0} q^{2}}{16 \pi^{3}}\left(\left|a_{x}\right|^{2}+\left|a_{y}\right|^{2}\right), \tag{10.67}
\end{equation*}
$$

where $a_{x}$ and $a_{y}$ are the dimensionless factors,

$$
\begin{align*}
& a_{x} \equiv \omega \int_{-\infty}^{+\infty} \omega_{c} t^{\prime} \exp \left\{\frac{i \omega}{2}\left(\left(\theta_{0}^{2}+\gamma^{-2}\right) t^{\prime}+\frac{\omega_{c}^{2}}{3} t^{\prime 3}\right)\right\} d t^{\prime},  \tag{10.68}\\
& a_{y} \equiv \omega \int_{-\infty}^{+\infty} \theta_{0} \exp \left\{\frac{i \omega}{2}\left(\left(\theta_{0}^{2}+\gamma^{-2}\right) t^{\prime}+\frac{\omega_{c}^{2}}{3} t^{\prime 3}\right)\right\} d t^{\prime}
\end{align*}
$$

which describe the frequency spectra of two components of the synchrotron radiation, with mutually perpendicular directions of polarization. Defining a dimensionless parameter

$$
\begin{equation*}
v \equiv \frac{\omega}{3 \omega_{c}}\left(\theta_{0}^{2}+\gamma^{-2}\right)^{3 / 2} \tag{10.69}
\end{equation*}
$$

proportional to the observation frequency, and changing the integration variable to $\xi \equiv \omega_{c} t^{\prime} /\left(\theta_{0}{ }^{2}+\gamma^{-2}\right)^{1 / 2}$, integrals (68) may be reduced to the modified Bessel functions of the second kind:

$$
\begin{align*}
& a_{x}=\frac{\omega}{\omega_{c}}\left(\theta_{0}^{2}+\gamma^{-2}\right) \int_{-\infty}^{+\infty} \xi \exp \left\{\frac{3}{2} i v\left(\xi+\frac{\xi^{3}}{3}\right)\right\} d \xi=\frac{2 \sqrt{3} i}{\left(\theta_{0}^{2}+\gamma^{-2}\right)^{1 / 2}} v K_{2 / 3}(v),  \tag{10.70}\\
& a_{y}=\frac{\omega}{\omega_{c}} \theta_{0}\left(\theta_{0}^{2}+\gamma^{-2}\right)^{1 / 2} \int_{-\infty}^{+\infty} \exp \left\{\frac{3}{2} i v\left(\xi+\frac{\xi^{3}}{3}\right)\right\} d \xi=\frac{2 \sqrt{3} \theta_{0}}{\theta_{0}^{2}+\gamma^{-2}} v K_{1 / 3}(v)
\end{align*}
$$

[^435]Figure 9a shows the dependence of amplitudes $a_{x}$ and $a_{y}$ of the normalized observation frequency $v$. It is clear that the in-plane component, proportional to $a_{x}$, is larger. (The off-plane component disappears altogether at $\theta_{0}=0$, i.e. at observation within the particle rotation plane $[x, y]$, due to the evident mirror symmetry of the problem about the plane.) It is also clear that the spectrum changes rather slowly (note the log-log scale of the plot!) until the normalized frequency, defined by Eq. (69), reaches $\sim 1$. For most important observation angles $\theta_{0} \sim \gamma$ this means that our estimate (50) is indeed correct, though theoretically the frequency spectrum extends to infinity. ${ }^{20}$

Fig. 10.9. Synchrotron radiation frequency spectra of: (a) two polarization amplitudes and (b) the total (polarization- and angle-averaged) radiation.

Naturally, a similar frequency behavior is valid for the spectral density integrated over the full solid angle. Without performing the integration, ${ }^{21}$ let me give the result (also valid for $\gamma \gg 1$ only) for reader's reference:

$$
\begin{equation*}
\oint_{4 \pi} I(\omega) d \Omega=\frac{\sqrt{3}}{4 \pi} q^{2} \gamma \zeta \int_{\zeta}^{\infty} K_{5 / 3}(\xi) d \xi, \quad \zeta \equiv \frac{2}{3} \frac{\omega}{\omega_{c} \gamma^{3}} . \tag{10.71}
\end{equation*}
$$

Figure 8 b shows the dependence of this integral on the normalized frequency $\zeta$. (This plot is sometimes called the "universal flux curve".) In accordance with estimate (50), it reaches maximum at

$$
\begin{equation*}
\zeta_{\max } \approx 0.3, \text { i.e. } \omega_{\max } \approx \frac{\omega_{c}}{2} \gamma^{3} . \tag{10.72}
\end{equation*}
$$

For the new National Synchrotron Light Source (NSLS-II), that is under construction in the Brookhaven National Laboratory very close to our campus, with the ring circumference of 792 m , the electron revolution period $T$ will be $2.64 \mu \mathrm{~s}$. Calculating $\omega_{c}$ as $2 \pi / T \approx 2.4 \times 10^{6} \mathrm{~s}^{-1}$, for the planned $\gamma \approx$

[^436]$6 \times 10^{3}(\varepsilon \approx 3 \mathrm{GeV}),{ }^{22}$ we get $\omega_{\max } \sim 3 \times 10^{17} \mathrm{~s}^{-1}$, corresponding to photon energy $\hbar \omega_{\max } \sim 200 \mathrm{eV}$, corresponding to soft X-rays. In the light of this estimate, the reader may be surprised by Fig. 10 that shows the projected spectra of radiation which this facility is designed to produce, with maximum photon energies up to a few keV.

Fig. 10.10. Design brightness of various synchrotron radiation sources of the NSLS-II facility. For bend magnets and wigglers, the "brightness" may be obtained by multiplication of the spectral density $I(\omega)$ from one electron pulse, calculated above, by the number of electrons passing the source per second. (Note the non-SI units, commonly used in the synchrotron radiation community.) However, for undulators, there is an additional factor due to the partial coherence of radiation - see below. (Data from document NSLS-II Source Properties and Floor Layout, available online at http://www.nsls.bnl.gov/.)

The reason of this discrepancy is that in NLLS-II, and in all modern synchrotron light sources, most radiation is produced not by the circular orbit itself, but rather using special devices inserted into the electron beam path. These devices include bend magnets with magnetic field stronger than the average

[^437]field on the orbit (which, according to Eq. (9.112), produce higher effective value of $\omega_{c}$ and hence of $\omega_{\max }$ ), and wigglers and undulators: strings of several strong magnets with alternating field direction (Fig. 11), that induce periodic bending of electron trajectory, with radiation emitted at each bend.

Fig. 10.11. The generic magnetic structure common for wigglers, undulators and freeelectron lasers. (Adapted from http://wwwxfel.spring8.or.jp/cband/e/Undulator.htm.)

The difference between wigglers and undulators is more quantitative than qualitative: the former devices have a larger spatial period $\lambda$ (distance between the adjacent magnets of the same polarity, see Fig. 11), giving enough space for the electron beam to bend by an angle larger than $\gamma^{-1}$, i.e. larger than the radiation cone angle. As a result, the pulses radiated at each period arrive to an in-plane observer as a periodic sequence of individual pulses (Fig. 12a). The shape of each pulse, and hence its frequency spectrum, are similar to those discussed above, ${ }^{23}$ but with much higher local values of $\omega_{c}$ and $\omega_{\max }$ - see Fig. 9. Another difference is a much higher frequency of the peaks. Indeed, the fundamental Eq. (18) allows us to calculate the time distance between them, for the observer, as

$$
\begin{equation*}
\Delta t \approx \frac{\partial t}{\partial t^{\prime}} \Delta t^{\prime} \approx(1-\beta) \frac{\lambda}{u} \approx \frac{1}{2 \gamma^{2}} \frac{\lambda}{c} \ll \frac{\lambda}{c}, \tag{10.73}
\end{equation*}
$$

where the first two relations are valid at $\lambda \ll R$ (the relation typically satisfied very well, see Fig. 10), and the last two relations also require the ultra-relativistic limit. As a result, the radiation intensity, that is proportional to the number of poles, is much higher than that from the bend magnets - in the NLSL-II case, more than by 2 orders of magnitude, clearly visible in Fig. 10.

(b)

Fig. 10.12. Radiation (with in-plane polarization) from (a) a wiggler and (b) an undulator - schematically.

[^438]The situation in different in undulators - similar structures with smaller spatial period $\lambda$, in which electron's velocity vector oscillates with angular amplitude smaller that $\gamma^{-1}$. As a result, the radiation pulses overlap (Fig. 12b) and the radiation waveform is closer to sinusoidal one. As a result, the radiation spectrum narrows to the central frequency ${ }^{24}$

$$
\begin{equation*}
\omega_{0}=\frac{2 \pi}{\Delta t} \approx 2 \gamma^{2} \frac{2 \pi c}{\lambda} . \tag{10.74}
\end{equation*}
$$

For example, for the LSNL-II undulators with $\lambda=20 \mathrm{~mm}$, this formula predicts the radiation peak at phonon energy $\hbar \omega_{0} \approx 4 \mathrm{keV}$, in a reasonable agreement with results of quantitative calculations, shown in Fig. 10. ${ }^{25}$ Due to the spectrum narrowing, the intensity of undulators radiation is higher that that of wigglers using the same electron beam.

This spectrum-narrowing trend is brought to its logical conclusion in the so-called free-electron lasers ${ }^{26}$ whose basic structure is the same as that of wigglers and undulators (Fig. 11), but the radiation at each beam bend is so intense and narrow-focused that it affects the electron motion downstream the radiation cone. As a result, the radiation of all bends becomes synchronized, so its spectrum is a narrow line at frequency (74), with electromagnetic wave amplitude proportional to the number $N$ of electrons in the structure, and hence its power proportional to $N^{2}$ (rather than to $N$ as in wigglers and undulators).

Finally, note that wigglers, undulators, and free-electron lasers may be also used at the end of a linear electron accelerator (such as SLAC) that, as was noted above, may provide extremely high values of $\gamma$, and hence radiation frequencies, due to the absence of the radiation energy losses at the electron acceleration stage.

### 10.4. Bremsstrahlung and Coulomb losses

Surprisingly, a very similar mechanism of radiation by charged particles works at much lower spatial scale, namely at their scattering by charged particles of the propagation medium, the so-called bremsstrahlung - German for "brake radiation". This effect responsible, in particular, for the continuous part of the frequency spectrum of the radiation produced by standard vacuum X-ray tubes, its incidence on a solid "anticathode". 27

The bremsstrahlung in condensed matter is generally a rather complicated phenomenon, because of simultaneous involvement of many particles, and some quantum electrodynamic effect involvement.

[^439]This is why I will give only a very brief glimpse at the theoretical description of this effect, for the simplest case when scattering of incoming, relatively light charged particles (such as electrons, protons, $\alpha$-particles, etc.) is produced by atomic nuclei that remain virtually immobile during the scattering event (Fig. 13a). This is a reasonable approximation if the energy of incoming particles is not too low, otherwise most scattering is produced by atomic electrons whose dynamics is substantially quantum see below.

(b)

Fig. 10.13. Basic geometry of the bremsstrahlung and Coulomb loss problems in (a) direct and (b) reciprocal space.

To calculate the frequency spectrum of radiation emitted during a single scattering event, it is convenient to use a byproduct of the last section's analysis, namely Eq. (59) with replacement (60):28

$$
\begin{equation*}
I(\omega)=\left.\frac{1}{4 \pi^{2} c} \frac{q^{2}}{4 \pi \varepsilon_{0}} \int_{-\infty}^{+\infty} \frac{d}{d t^{\prime}}\left[\frac{\mathbf{n} \times(\mathbf{n} \times \boldsymbol{\beta})}{1-\boldsymbol{\beta} \cdot \mathbf{n}}\right] \exp \left\{i \omega\left(t^{\prime}-\frac{\mathbf{n} \cdot \mathbf{r}^{\prime}}{c}\right)\right\} d t^{\prime}\right|^{2} . \tag{10.75}
\end{equation*}
$$

The typical duration $\tau$ of a single scattering event, that is described by this formula, is of the order of $a_{0} / c \sim\left(10^{-10} \mathrm{~m}\right) /\left(3 \times 10^{8} \mathrm{~m} / \mathrm{s}\right) \sim 10^{-18} \mathrm{~s}$ in solids, and only an order of magnitude longer in gases at ambient conditions. This is why for most frequencies of interest, from zero all the way up to at least soft X-rays, ${ }^{29}$ we can use the so-called low-frequency approximation, taking the exponent in Eq. (75) for 1 through the whole collision event, i.e. the integration interval. This approximation immediately yields

$$
\begin{equation*}
I(\omega)=\frac{1}{4 \pi^{2} c} \frac{q^{2}}{4 \pi \varepsilon_{0}}\left|\frac{\mathbf{n} \times\left(\mathbf{n} \times \boldsymbol{\beta}_{f i n}\right)}{1-\boldsymbol{\beta}_{\text {fin }} \cdot \mathbf{n}}-\frac{\mathbf{n} \times\left(\mathbf{n} \times \boldsymbol{\beta}_{i n i}\right)}{1-\boldsymbol{\beta}_{i n i} \cdot \mathbf{n}}\right|^{2} . \tag{10.76}
\end{equation*}
$$

In the non-relativistic limit $\left(\beta_{\text {ini }}, \beta_{\text {fin }} \ll 1\right)$, this formula in reduced to ${ }^{30}$

$$
\begin{equation*}
I(\omega)=\frac{1}{4 \pi c} \frac{q^{2}}{4 \pi^{2} \varepsilon_{0}} \frac{q^{2}}{m^{2} c^{3}} \sin ^{2} \theta \tag{10.77}
\end{equation*}
$$

where $g$ is the momentum transferred from the scattering center to the scattered charge (Fig. 13b):31

[^440]\[

$$
\begin{equation*}
\boldsymbol{q} \equiv \mathbf{p}_{f i n}-\mathbf{p}_{i n i}=m \Delta \mathbf{u}=m c \Delta \boldsymbol{\beta}=m c\left(\boldsymbol{\beta}_{f i n}-\boldsymbol{\beta}_{i n i}\right) \tag{10.78}
\end{equation*}
$$

\]

and $\theta$ is the angle between vector $g$ and the direction $\mathbf{n}$ toward the observer.
The most important feature of result (77) is the frequency-independent ("white") spectrum of the radiation, very typical for any rapid leaps, which may be approximated as theta-functions of time. (Note, however, that this is only valid for a fixed value of $g$, so that the statistics of this parameter, to be discussed in a minute, "colors" the radiation.) Note also the angular distribution of the radiation, forming the usual "doughnut" shape about the momentum transfer vector $\mathbf{g}$. In particular, this means that in typical cases when $q \sim p$, the bremsstrahlung produces a significant radiation flow in the direction back to the particle source - the fact significant for the operation of X-ray tubes.

Now integrating over all wave propagation angles, just as we did for the instant radiation power in Sec. 8.2, we get the spectral density of the full energy loss,

$$
\begin{equation*}
-\frac{d \varepsilon}{d \omega}=\oint_{4 \pi} I(\omega) d \Omega=\frac{2}{3 \pi c} \frac{q^{2}}{4 \pi^{2} \varepsilon_{0}} \frac{q^{2}}{m^{2} c^{3}} . \tag{10.79}
\end{equation*}
$$

The main new feature of bremsstrahlung (as of most scattering problems ${ }^{32}$ ), is the necessity to take into account the randomness of the impact parameter $b$ (Fig. 13a). For elastic ( $\beta_{\text {ini }}=\beta_{f i n} \equiv \beta$ ) Coulomb collisions we can use the so-called Rutherford formula for the differential cross-section of scattering ${ }^{33}$

$$
\begin{equation*}
\frac{d \sigma}{d \Omega^{\prime}}=\left(\frac{q q^{\prime}}{4 \pi \varepsilon_{0}}\right)^{2}\left(\frac{1}{2 p c \beta}\right)^{2} \frac{1}{\sin ^{4}\left(\theta^{\prime} / 2\right)} \tag{10.80}
\end{equation*}
$$

Here $d \sigma=2 \pi b d b$ is the elementary area of the sample cross-section (as visible from the direction of incident particles) corresponding to particle scattering into an elementary body angle ${ }^{34}$

$$
\begin{equation*}
d \Omega^{\prime}=2 \pi \sin \theta^{\prime} d \theta^{\prime} \tag{10.81}
\end{equation*}
$$

Differentiating the geometric relation that is evident from Fig. 13b,

$$
\begin{equation*}
q=2 p \sin \frac{\theta^{\prime}}{2} \tag{10.82}
\end{equation*}
$$

we may present Eq. (80) in a more convenient form

$$
\begin{equation*}
\frac{d \sigma}{d q}=8 \pi\left(\frac{q q^{\prime}}{4 \pi \varepsilon_{0}}\right)^{2} \frac{1}{u^{2} q^{3}} \tag{10.83}
\end{equation*}
$$

[^441]Now combining Eqs. (79) and (83), we get

$$
\begin{equation*}
-\frac{d \varepsilon}{d \omega} \frac{d \sigma}{d q}=\frac{16}{3} \frac{q^{2}}{4 \pi \varepsilon_{0}}\left(\frac{q q^{\prime}}{4 \pi \varepsilon_{0} m c^{2}}\right)^{2} \frac{1}{c \beta^{2}} \frac{1}{q} . \tag{10.84}
\end{equation*}
$$

This product is called the differential radiation cross-section. When averaged it over all values $g$ (which is equivalent to averaging over all values of the impact parameter), it gives a convenient measure of radiation intensity. Indeed, after the multiplication by the volume density $n$ of independent scattering centers, the integral gives particle's energy loss by unit bandwidth of radiation by unit path length $d^{2} \varepsilon / d \omega d x$. A technical problem here is that the integral of $1 / g$ formally diverges at both infinite and zero values of $\mathfrak{g}$. However, these divergences are very weak (logarithmic), and the integral converges due to virtually any reason unaccounted for by our simple analysis. The standard simple way to account for these effects is to write

$$
\begin{equation*}
-\frac{d^{2} \varepsilon}{d \omega d x} \approx \frac{16}{3} n \frac{q^{2}}{4 \pi \varepsilon_{0}}\left(\frac{q q^{\prime}}{4 \pi \varepsilon_{0} m c^{2}}\right)^{2} \frac{1}{c \beta^{2}} \ln \frac{q_{\max }}{g_{\min }}, \tag{10.85}
\end{equation*}
$$

and then plug, instead of $g_{\max }$ and $g_{\min }$, scales of the most important effects limiting the small momentum range. At classical analysis, according to Eq. (82), $g_{\max }=2 p$. To estimate $q_{\min }$, let us note that very small momentum transfer takes place when the impact parameter $b$ is very large and hence the effective scattering time $\tau \sim b / v$ is very long. Recalling the condition of the low-frequency approximation, we may associate $g_{\min }$ with $\tau \sim 1 / \omega$ and hence with $b \sim u \tau \sim v / \omega$. Since for the small scattering angles, $g$ may be estimated as the impulse $F \tau \sim\left(q q^{\prime} / 4 \pi \varepsilon_{0} b^{2}\right) \tau$ of the Coulomb force, so that $g_{\min } \sim\left(q q^{\prime} / 4 \pi \varepsilon_{0}\right) \omega / u^{2}$, and Eq. (85) becomes

$$
\begin{equation*}
-\frac{d^{2} \varepsilon}{d \omega d x} \approx \frac{16}{3} n \frac{q^{2}}{4 \pi \varepsilon_{0}}\left(\frac{q q^{\prime}}{4 \pi \varepsilon_{0} m c^{2}}\right)^{2} \frac{1}{c \beta^{2}} \ln \left(\frac{4 \pi \varepsilon_{0} 2 m u^{3}}{q q^{\prime} \omega}\right) . \tag{10.86}
\end{equation*}
$$

This is Bohr's formula for what is called the classical bremsstrahlung. We see that the low momentum cutoff indeed makes the spectrum colored, with more energy going to lower frequencies. There is even a formal divergence at $\omega \rightarrow 0$; however, this divergence is integrable, so it does not present a problem in finding the total energy radiative losses $(-d \mathcal{L} / d x)$ as an integral of Eq. (86) over all radiated frequencies $\omega$. A larger problem for this procedure is the upper integration limit, $\omega \rightarrow \infty$, at which the integral diverges. This means that our approximate description, which considers the collision as an elastic process, becomes wrong, and needs to be amended by taking into account the difference between the initial and final kinetic energies of the particle due to radiation of the energy quantum $\hbar \omega$ of the emitted photon:

$$
\begin{equation*}
\frac{p_{i n i}^{2}}{2 m}-\frac{p_{f i n}^{2}}{2 m}=\hbar \omega . \tag{10.87}
\end{equation*}
$$

As a result, taking into account that the minimum and maximum values of $\mathfrak{q}$ correspond to, respectively, the parallel and antiparallel alignments of vectors $\mathbf{p}_{i n i}$ and $\mathbf{p}_{f i n}$, we get

$$
\ln \frac{\boldsymbol{q}_{\max }}{\boldsymbol{q}_{\text {min }}}=\ln \frac{p_{i n i}+p_{\text {fin }}}{p_{\text {ini }}-p_{\text {fin }}}=\ln \frac{\left(p_{i n i}+p_{f i n}\right)^{2}}{p_{i n i}^{2}-p_{f i n}^{2}}=\ln \frac{\left[\varepsilon^{1 / 2}+(\varepsilon-\hbar \omega)^{1 / 2}\right]^{2}}{\hbar \omega} .
$$

Quantum bremsstrahlung

Plugged into Eq. (85), this expression yields the so-called Bethe-Heitler formula for quantum bremsstrahlung. ${ }^{35}$ Note that at this approach, $g_{\max }$ is close to that of the classical approximation, but $g_{\min }$ $\sim \hbar \omega / u$, so that

$$
\begin{equation*}
\frac{\left.\boldsymbol{q}_{\min }\right|_{\text {classical }}}{\left.\boldsymbol{q}_{\min }\right|_{\text {quantum }}} \sim \frac{\alpha z z^{\prime}}{\beta} \tag{10.89}
\end{equation*}
$$

where $z$ and $z$ ' are particles' charges in units of $e$, and $\alpha$ is the fine structure ("Sommerfeld") constant,

$$
\begin{equation*}
\left.\alpha \equiv \frac{e^{2}}{4 \pi \varepsilon_{0} \hbar c}\right|_{\mathrm{SI}}=\left.\frac{e^{2}}{\hbar c}\right|_{\text {Gaussian }} \approx \frac{1}{137} \ll 1, \tag{10.90}
\end{equation*}
$$

which is one of the basic notions of quantum mechanics. ${ }^{36}$ For most cases of practical interest, ratio (89) is smaller that 1 , and since we have to keep the highest value of $q_{\text {min }}$, the Bethe-Heitler formula should be used.

Now nothing prevents us from calculating the total radiative losses of energy per unit length:

$$
\begin{equation*}
-\frac{d \varepsilon}{d x}=\int_{0}^{\infty}\left(-\frac{d^{2} \varepsilon}{d \omega d z}\right) d \omega=\frac{16}{3} n \frac{q^{2}}{4 \pi \varepsilon_{0} c}\left(\frac{q q^{\prime}}{4 \pi \varepsilon_{0} m c^{2}}\right)^{2} \frac{1}{\beta^{2}} 2 \int_{0}^{\omega_{\max }} \ln \frac{\varepsilon^{1 / 2}-(\varepsilon-\hbar \omega)^{1 / 2}}{(\hbar \omega)^{1 / 2}} d \omega \tag{10.91}
\end{equation*}
$$

where $\hbar \omega_{\max }=\varepsilon$ is the maximum energy of the radiation quantum. By introducing the dimensionless integration variable $\xi \equiv \hbar \omega / \varepsilon=2 \hbar \omega /\left(m u^{2} / 2\right)$ this integral is reduced to the table one, ${ }^{37}$ and we get

$$
\begin{equation*}
-\frac{d \varepsilon}{d x}=\frac{16}{3} n \frac{q^{2}}{4 \pi \varepsilon_{0} c}\left(\frac{q q^{\prime}}{4 \pi \varepsilon_{0} m c^{2}}\right)^{2} \frac{1}{\beta^{2}} \frac{u^{2}}{\hbar}=\frac{16}{3} n\left(\frac{q^{\prime 2}}{4 \pi \varepsilon_{0} \hbar c}\right)\left(\frac{q^{2}}{4 \pi \varepsilon_{0}}\right)^{2} \frac{1}{m c^{2}} \tag{10.92}
\end{equation*}
$$

In my usual style, I would give you an estimate of the losses for a typical case; however, let me compare them to a parallel energy loss mechanism, the so-called Coulomb losses, due to the transfer of mechanical impulse from the scattered particle to the scattering center. (This energy eventually goes into an increase of the thermal energy of the scattering medium.) Using Eqs. (9.139) for the electric field of a linearly moving charge, we can readily find the momentum it transfers to charge $q^{\prime}: 3^{38}$

$$
\begin{equation*}
\Delta p^{\prime}=\left|\left(\Delta p^{\prime}\right)_{y}\right|=\left|\int_{-\infty}^{+\infty}\left(\dot{p}^{\prime}\right)_{y} d t\right|=\left|\int_{-\infty}^{+\infty} q^{\prime} E_{y} d t\right|=\frac{q q^{\prime}}{4 \pi \varepsilon_{0}} \int_{-\infty}^{+\infty} \frac{\gamma b}{\left(b^{2}+\gamma^{2} u^{2} t^{2}\right)^{3 / 2}} d t=\frac{q q^{\prime}}{4 \pi \varepsilon_{0}} \frac{2}{b u} . \tag{10.93}
\end{equation*}
$$

[^442]Hence, the kinetic energy acquired by the scattering center (equal to the loss of energy of the incident particle) is

$$
\begin{equation*}
-\Delta \varepsilon=\frac{\left(\Delta p^{\prime}\right)^{2}}{2 m^{\prime}}=\left(\frac{q q^{\prime}}{4 \pi \varepsilon_{0}}\right)^{2} \frac{2}{m^{\prime} u^{2} b^{2}} . \tag{10.94}
\end{equation*}
$$

Such energy losses have to be summed up over all collisions, with random values of the impact parameter $b$. At the scattering center density $n$, the number of collisions per small path length $d z$ per small range $d b$ is $d N=n 2 \pi b d b d x$, so that

$$
\begin{equation*}
-\frac{d \varepsilon}{d x}=\int(-\Delta \varepsilon) d N=n\left(\frac{q q^{\prime}}{4 \pi \varepsilon_{0}}\right)^{2} \frac{2}{m^{\prime} u^{2}} 2 \pi \int_{b_{\min }}^{b_{\max }} \frac{d b}{b}=4 \pi n\left(\frac{q q^{\prime}}{4 \pi \varepsilon_{0}}\right)^{2} \frac{\ln B}{m^{\prime} u^{2}}, \quad \text { where } B \equiv \frac{b_{\max }}{b_{\min }} . \tag{10.95}
\end{equation*}
$$

Here the logarithmic integral over $b$ was treated similarly to that over $g$ in the bremsstrahlung theory. This approach is adequate, because the ratio $b_{\text {max }} / b_{\text {min }}$ is much larger than 1 . Indeed, $b_{\text {min }}$ may be estimated from $\left(\Delta p^{\prime}\right)_{\max } \sim p=r m u$. For this value, Eq. (93) with $q^{\prime} \sim q$ gives $b_{\min } \sim r_{c}$ (see Eq. (8.41) and its discussion), which is, for elementary particles, of the order of $10^{-15} \mathrm{~m}$. On the other hand, for the most important case when charges $q$ ' belong to electrons (which, according to Eq. (94) are the most efficient Coulomb energy absorbers, due to their extremely low mass $m^{\prime}$ ), $b_{\text {max }}$ may be estimated from condition $\tau=b / \gamma u \sim 1 / \omega_{\max }$, where $\omega_{\max } \sim 10^{16} \mathrm{~s}^{-1}$ is the characteristic frequency of electron transitions in atoms. (Below this frequency, our classical analysis of scatterer's motion is invalid.) From here, we have the estimate $b_{\max } \sim \mu u / \omega_{\max }$, so that

$$
\begin{equation*}
B \equiv \frac{b_{\max }}{b_{\min }} \sim \frac{r u}{r_{c} \omega_{0}} \tag{10.96}
\end{equation*}
$$

for $\gamma \sim 1$ and $u \sim c \approx 3 \times 10^{8} \mathrm{~m} / \mathrm{s}$ giving $b_{\max } \sim 3 \times 10^{-8} \mathrm{~m}$, and $B \sim 10^{9}$ (give or take a couple orders of magnitude - this does not change the estimate $\ln B \sim 20$ too much). ${ }^{39}$

Now we can compare the Coulomb losses (95) with those due to the bremsstrahlung, given by Eq. (92):

$$
\begin{equation*}
\frac{-\left.d \varepsilon\right|_{\text {radiation }}}{-\left.d \varepsilon\right|_{\text {Coulomb }}} \sim \alpha \mathcal{F}^{\prime} \frac{m^{\prime}}{m} \beta^{2} \frac{1}{\ln B} \tag{10.97}
\end{equation*}
$$

Since $\alpha \sim 10^{-2} \ll 1$, for non-relativistic particles $(\beta \ll 1)$ the Coulomb losses of energy are much higher, and only for ultra-relativistic particles, the relation may be opposite.

According to Eq. (95), for electron-electron scattering ( $q=q^{\prime}=-e, m^{\prime}=m_{e}$ ), ${ }^{40}$ at the value $n$ $6 \times 10^{26} \mathrm{~m}^{-3}$ typical for air at ambient conditions, the characteristic length of energy loss,

[^443]\[

$$
\begin{equation*}
l_{c} \equiv \frac{\varepsilon}{(-d \varepsilon / d x)} \tag{10.98}
\end{equation*}
$$

\]

for electrons with kinetic energy $\varepsilon=6 \mathrm{keV}$ is close to $2 \times 10^{-4} \mathrm{~m}=0.2 \mathrm{~mm}$. (This is why you need vacuum in CRT monitors and electron microscope columns!) Since $l_{c} \propto \varepsilon^{2}$, more energetic particles penetrate deeper, until the bremsstrahlung steps in at very high energies.

### 10.5. Density effects and the Cherenkov radiation

For condensed matter, the Coulomb loss estimate made in the last section is not quite suitable, because it is based on the upper cutoff $b_{\max } \sim \mu u / \omega_{\max }$. For the example given above, incoming electron velocity $u$ is close to $5 \times 10^{7} \mathrm{~m} / \mathrm{s}$, and for the typical value $\omega_{\max } \sim 10^{16} \mathrm{~s}-1\left(\hbar \omega_{\max } \sim 10 \mathrm{eV}\right)$, this cutoff $b_{\max } \sim 5 \times 10^{-9} \mathrm{~m}=5 \mathrm{~nm}$. Even for air at ambient conditions, this is larger than the average distance ( $\sim 2$ nm ) between the molecules, so that at the high end of the impact parameter range, at $b \sim b_{\text {max }}$, the Coulomb loss events in adjacent molecules are not quite independent, and the theory needs corrections. For condensed matter, with much higher particle density $n$, most collisions satisfy condition

$$
\begin{equation*}
n b^{3} \gg 1, \tag{10.99}
\end{equation*}
$$

and the treatment of Coulomb collisions as independent events is completely inadequate. However, condition (99) enables the opposite approach: treating the medium as a continuum. In the time domain formulation, used in the previous sections of this chapter, this would be a very complex problem, because it would require an explicit description of medium dynamics. Here the frequency-domain approach, based on the Fourier transform in both time and space, helps a lot, provided that functions $\varepsilon(\omega)$ and $\mu(\omega)$ are considered known - either calculated or taken from experiment. Let us have a good look at such approach, because it gives some interesting (and practically important) results.

In Chapter 6, we have used the macroscopic Maxwell equations to derive Eqs. (6.109), which describe the time evolution of potentials in a medium with frequency-independent $\varepsilon$ and $\mu$. Looking for all functions participating in Eqs. (6.109) in the form of plane-wave expansion ${ }^{41}$

$$
\begin{equation*}
f(\mathbf{r}, t)=\int d^{3} k \int d \omega f_{\mathbf{k}, \omega} e^{i(\mathbf{k} \cdot \mathbf{r}-\omega t)} \tag{10.100}
\end{equation*}
$$

and requiring all coefficients at similar exponents to be balanced, we get their Fourier image: ${ }^{42}$

$$
\begin{equation*}
\left[k^{2}-\omega^{2} \varepsilon \mu\right] \phi_{\mathbf{k}, \omega}=\frac{\rho_{\mathbf{k}, \omega}}{\varepsilon}, \quad\left[k^{2}-\omega^{2} \varepsilon \mu\right] \mathbf{A}_{\mathbf{k}, \omega}=\mu \mathbf{j}_{\mathbf{k}, \omega} . \tag{10.101}
\end{equation*}
$$

[^444]As was discussed in Chapter 7, in such a Fourier form, the Maxwell theory remain valid even for the dispersive media, so that Eq. (101) is generalized as

$$
\begin{equation*}
\left[k^{2}-\omega^{2} \varepsilon(\omega) \mu(\omega)\right] \phi_{\mathbf{k}, \omega}=\frac{\rho_{\mathbf{k}, \omega}}{\varepsilon(\omega)}, \quad\left[k^{2}-\omega^{2} \varepsilon(\omega) \mu(\omega)\right] \mathbf{A}_{\mathbf{k}, \omega}=\mu(\omega) \mathbf{j}_{\mathbf{k}, \omega} \tag{10.102}
\end{equation*}
$$

The evident advantage of these equations is that their formal solution is trivial:
potentials in a linear medium

$$
\begin{equation*}
\phi_{\mathbf{k}, \omega}=\frac{\rho_{\mathbf{k}, \omega}}{\varepsilon(\omega)\left[k^{2}-\omega^{2} \varepsilon(\omega) \mu(\omega)\right]}, \quad \mathbf{A}_{\mathbf{k}, \omega}=\frac{\mu(\omega) \mathbf{j}_{\mathbf{k}, \omega}}{\left[k^{2}-\omega^{2} \varepsilon(\omega) \mu(\omega)\right]} \tag{10.103}
\end{equation*}
$$

so that the "only" remaining things to do is to calculate the Fourier transforms of functions $\rho(\mathbf{r}, t)$ and $\mathbf{j}(\mathbf{r}, t)$, describing stand-alone charges and currents, using the transform reciprocal to Eq. (100), with one factor $1 / 2 \pi$ per each scalar dimension,

$$
\begin{equation*}
f_{\mathbf{k}, \omega}=\frac{1}{(2 \pi)^{4}} \int d^{3} r \int d t f(\mathbf{r}, t) e^{-i(\mathbf{k} \cdot \mathbf{r}-\omega t)} \tag{10.104}
\end{equation*}
$$

and than carry out the integration (100).
For our current problem of a single charge $q$, uniformly moving in the medium with velocity $\mathbf{u}$,

$$
\begin{equation*}
\rho(\mathbf{r}, t)=q \delta(\mathbf{r}-\mathbf{u} t), \quad \mathbf{j}(\mathbf{r}, t)=q \mathbf{u} \delta(\mathbf{r}-\mathbf{u} t), \tag{10.105}
\end{equation*}
$$

the first task is easy:

$$
\begin{equation*}
\rho_{\mathbf{k}, \omega}=\frac{q}{(2 \pi)^{4}} \int d^{3} r \int d t q \delta(\mathbf{r}-\mathbf{u} t) e^{-i(\mathbf{k} \cdot \mathbf{r}-\omega t)}=\frac{q}{(2 \pi)^{4}} \int e^{i(\omega t-\mathbf{k} \cdot \mathbf{u} t)} d t=\frac{q}{(2 \pi)^{3}} \delta(\omega-\mathbf{k} \cdot \mathbf{u}) . \tag{10.106}
\end{equation*}
$$

Since expressions (105) for $\rho(\mathbf{r}, t)$ and $\mathbf{j}(\mathbf{r}, t)$ differ only by a constant factor $\mathbf{u}$, it is clear that the absolutely similar calculation for current would give

$$
\begin{equation*}
\mathbf{j}_{\mathbf{k}, \omega}=\frac{q \mathbf{u}}{(2 \pi)^{3}} \delta(\omega-\mathbf{k} \cdot \mathbf{u}) . \tag{10.107}
\end{equation*}
$$

Let us summarize what we have got by now, plugging Eqs. (106) and (107) into Eqs. (103):

$$
\begin{equation*}
\phi_{\mathbf{k}, \omega}=\frac{1}{(2 \pi)^{3}} \frac{q \delta(\omega-\mathbf{k} \cdot \mathbf{u})}{\varepsilon(\omega)\left[k^{2}-\omega^{2} \varepsilon(\omega) \mu(\omega)\right]}, \quad \mathbf{A}_{\mathbf{k}, \omega}=\frac{1}{(2 \pi)^{3}} \frac{\mu(\omega) q \mathbf{u} \delta(\omega-\mathbf{k} \cdot \mathbf{u})}{\left[k^{2}-\omega^{2} \varepsilon(\omega) \mu(\omega)\right]}=\varepsilon(\omega) \mu(\omega) \mathbf{u} \phi_{\mathbf{k}, \omega} . \tag{10.108}
\end{equation*}
$$

Now, at the last step of calculations, namely integration (100), we are starting to pay a heavy price for the easiness of the first steps. This is why let us think well what exactly do we need from it. First of all, for the calculation of power losses, the electric field is more convenient to use than the potentials, so let us calculate the Fourier images of $\mathbf{E}$ and B. Plugging expansion (100) into the fundamental relations (6.106), and again requiring the balance of exponent's coefficients, we get

$$
\begin{equation*}
\mathbf{E}_{\mathbf{k}, \omega}=-i \mathbf{k} \phi_{k, \omega}+i \omega \mathbf{A}_{\mathbf{k}, \omega}=i[\omega \varepsilon(\omega) \mu(\omega) \mathbf{u}-\mathbf{k}] \phi_{\mathbf{k}, \omega}, \quad \mathbf{B}_{\mathbf{k}, \omega}=i \mathbf{k} \times \mathbf{A}_{\mathbf{k}, \omega}=i \varepsilon(\omega) \mu(\omega) \mathbf{k} \times \mathbf{u} \phi_{\mathbf{k}, \omega}, \tag{10.109}
\end{equation*}
$$

so that Eqs. (100) and (108) yield

$$
\begin{equation*}
\mathbf{E}(\mathbf{r}, t)=\int d^{3} k \int d \omega \mathbf{E}_{\mathbf{k}, \omega} e^{i(\mathbf{k} \cdot \mathbf{r}-\omega t)}=\frac{i q}{(2 \pi)^{3}} \int d^{3} k \int d \omega \frac{[\omega \varepsilon(\omega) \mu(\omega) \mathbf{u}-\mathbf{k}] \delta(\omega-\mathbf{k} \cdot \mathbf{u})}{\varepsilon(\omega)\left[k^{2}-\omega^{2} \varepsilon(\omega) \mu(\omega)\right]} e^{i(\mathbf{k} \cdot \mathbf{r}-\omega t)} \tag{10.110}
\end{equation*}
$$

With the notation used in Eq. (51), this integral may be partitioned as

$$
\begin{equation*}
\mathbf{E}(\mathbf{r}, t)=\int \mathbf{E}_{\omega} e^{-i \omega t} d \omega, \quad \mathbf{E}_{\omega}=\int \mathbf{E}_{\mathbf{k}, \omega} e^{i \mathbf{k} \cdot \mathbf{r}} d^{3} k=\frac{i q}{(2 \pi)^{3}} \int \frac{[\omega \varepsilon(\omega) \mu(\omega) \mathbf{u}-\mathbf{k}] \delta(\omega-\mathbf{k} \cdot \mathbf{u})}{\varepsilon(\omega)\left[k^{2}-\omega^{2} \varepsilon(\omega) \mu(\omega)\right]} e^{i \mathbf{k} \cdot \mathbf{r}} d^{3} k .( \tag{10.111}
\end{equation*}
$$

Let us calculate the Cartesian components of the partial Fourier image $\mathbf{E}_{\omega}$, at a point separated by distance $b$ from particle's trajectory. Selecting the coordinates and time origin as shown in Fig. 9.11a, we have $\mathbf{r}=\{0, b, 0\}$, so that only $E_{x}$ and $E_{y}$ are not vanishing. In particular, according to Eq. (111),

$$
\begin{equation*}
\left(E_{x}\right)_{\omega}=\frac{i q}{(2 \pi)^{3} \varepsilon(\omega)} \int d k_{x} \int d k_{y} \int d k_{z} \frac{\omega \varepsilon(\omega) \mu(\omega) u-k_{x}}{k^{2}-\omega^{2} \varepsilon(\omega) \mu(\omega)} \delta\left(\omega-k_{x} u\right) e^{i k_{y} b} \tag{10.112}
\end{equation*}
$$

The delta-function kills one integral (over $k_{x}$ ) of three, and we get:

$$
\begin{equation*}
\left(E_{x}\right)_{\omega}=\frac{i q}{(2 \pi)^{3} \varepsilon(\omega) u}\left[\omega \varepsilon(\omega) \mu(\omega) u-\frac{\omega}{u}\right] \int e^{i k_{y} b} d k_{y} \int \frac{d k_{z}}{\omega^{2} / u^{2}+k_{y}^{2}+k_{z}^{2}-\omega^{2} \varepsilon(\omega) \mu(\omega)} . \tag{10.113}
\end{equation*}
$$

The last integral (over $k_{y}$ ) may be readily reduced to the table integral $\int d \xi /\left(1+\xi^{2}\right)$, in infinite limits, equal to $\pi .{ }^{43}$ The result may be presented as

$$
\begin{equation*}
\left(E_{x}\right)_{\omega}=-\frac{i \pi q \kappa^{2}}{(2 \pi)^{3} \omega \varepsilon(\omega)} \int \frac{e^{i k_{y} b}}{\left(k_{y}^{2}+\kappa^{2}\right)^{1 / 2}} d k_{y} \tag{10.114}
\end{equation*}
$$

where parameter $\kappa$ (generally, a complex function of frequency) is defined as

$$
\begin{equation*}
\kappa^{2} \equiv \omega^{2}\left(\frac{1}{u^{2}}-\varepsilon(\omega) \mu(\omega)\right) . \tag{10.115}
\end{equation*}
$$

The last integral may be expressed via the modified Bessel function of the second kind:44

$$
\begin{equation*}
\left(E_{x}\right)_{\omega}=-\frac{i q u \kappa^{2}}{(2 \pi)^{2} \omega \varepsilon(\omega)} K_{0}(\kappa b) . \tag{10.116}
\end{equation*}
$$

A similar calculation yields

$$
\begin{equation*}
\left(E_{y}\right)_{\omega}=\frac{q \kappa}{(2 \pi)^{2} \varepsilon(\omega)} K_{1}(\kappa b) . \tag{10.117}
\end{equation*}
$$

Now, instead of rushing to make the final integration (111) over frequency to calculate $\mathbf{E}(t)$, let us realize that what we need for power losses is only the total energy loss through the whole time of particle passage. Energy loss per unit volume is

$$
\begin{equation*}
-\frac{d \varepsilon}{d V}=\int \mathbf{j} \cdot \mathbf{E} d t \tag{10.118}
\end{equation*}
$$

[^445]where $\mathbf{j}$ is the current of bound charges in the medium, and should not be confused with the free particle's current (105). This integral may be readily expressed via the partial Fourier image $\mathbf{E}_{\omega}$ and the similarly defined image $\mathbf{j}_{\omega}$, just as it was done at the derivation of Eq. (54):
\[

$$
\begin{equation*}
-\frac{d \varepsilon}{d V}=\int d t \int d \omega e^{-i \omega t} \int d \omega^{\prime} e^{-i \omega^{\prime} t} \mathbf{j}_{\omega} \cdot \mathbf{E}_{\omega^{\prime}}=2 \pi \int d \omega \int d \omega^{\prime} \mathbf{j}_{\omega} \cdot \mathbf{E}_{\omega^{\prime}} \delta\left(\omega+\omega^{\prime}\right)=2 \pi \int \mathbf{j}_{\omega} \cdot \mathbf{E}_{-\omega} d \omega \tag{10.119}
\end{equation*}
$$

\]

In our approach, the Ohmic conductance is incorporated into the complex permittivity $\varepsilon(\omega)$, so that, according to the discussion in the end of Sec. 7.2, current's Fourier image is

$$
\begin{equation*}
\mathbf{j}_{\omega}=\sigma_{\mathrm{ef}}(\omega) \mathbf{E}_{\omega}=-i \omega \varepsilon(\omega) \mathbf{E}_{\omega} . \tag{10.120}
\end{equation*}
$$

As a result, Eq. (119) yields

$$
\begin{equation*}
-\frac{d \varepsilon}{d V}=-2 \pi i \int \varepsilon(\omega) \mathbf{E}_{\omega} \cdot \mathbf{E}_{-\omega} \omega d \omega=4 \pi \operatorname{Im} \int_{0}^{\infty} \varepsilon(\omega)\left|E_{\omega}\right|^{2} \omega d \omega \tag{10.121}
\end{equation*}
$$

(The last transition is possible due to the property $\delta(-\omega)=\varepsilon^{*}(\omega)$, which was discussed in Sec. 7.2.)
Finally, just as in the last section, we have to calculate the energy loss rate averaged over random values of the impact parameter $b$ :

$$
\begin{equation*}
\left.-\frac{d \varepsilon}{d x}=\int\left(-\frac{d \varepsilon}{d V}\right) d^{2} b=2 \pi \int_{b_{\text {min }}}^{\infty}\left(-\frac{d \varepsilon}{d V}\right) b d b=8 \pi^{2} \int_{b_{\text {min }}}^{\infty} b d b \int_{0}^{\infty}\left(\left|E_{x}\right|_{\omega}^{2}+\left|E_{y}\right|_{\omega}^{2}\right) \operatorname{Im} \varepsilon(\omega)\right) \omega d \omega . \tag{10.122}
\end{equation*}
$$

Note that we are cutting the resulting integral over $b$ from below at some $b_{\text {min }}$ where our theory looses legitimacy. (On that limit, we are not doing much better than in the past section). Plugging in the calculated expressions (116) and (117) for field components, swapping the integrals, and using recurrence relations (2.142), which are valid for any Bessel functions, we finally get:

$$
\begin{equation*}
-\frac{d \varepsilon}{d x}=\frac{2}{\pi} q^{2} \operatorname{Im} \int_{0}^{\infty}\left(\kappa^{*} b_{\min }\right) K_{1}\left(\kappa^{*} b_{\min }\right) K_{0}\left(\kappa^{*} b_{\min }\right) \frac{d \omega}{\omega \varepsilon(\omega)} \tag{10.123}
\end{equation*}
$$

This general result is valid for an arbitrary linear medium, with arbitrary dispersion relations $\varepsilon(\omega)$ and $\mu(\omega)$. (The last function participates in Eq. (123) only via Eq. (115) which defines parameter $\kappa$.) To get more concrete results, some particular model of the medium should be used. Let us explore the Lorentz oscillator model, which was discussed in Sec. 7.2, in its form (7.33) suitable for transition to quantum-mechanical description of atoms:

$$
\begin{equation*}
\varepsilon(\omega)=\varepsilon_{0}+\frac{n q^{\prime 2}}{m} \sum_{j} \frac{f_{j}}{\left(\omega_{j}^{2}-\omega^{2}\right)-2 i \omega \delta_{j}}, \quad \sum_{j} f_{j}=1, \quad \mu(\omega)=\mu_{0} . \tag{10.124}
\end{equation*}
$$

If the damping of the effective atomic oscillators is low, $\delta_{j} \ll \omega_{j}$, and particle's speed $u$ is much lower than the typical wave's phase velocity $v$ (and hence $c!$ ), then for most frequencies Eq. (115) gives

$$
\begin{equation*}
\kappa^{2} \equiv \omega^{2}\left(\frac{1}{u^{2}}-\frac{1}{v^{2}(\omega)}\right) \approx \frac{\omega^{2}}{u^{2}} \tag{10.125}
\end{equation*}
$$

i.e. $\kappa=\kappa^{*} \approx \omega / u$ is real. In this case, Eq. (123) may be shown to give Eq. (95) with

$$
\begin{equation*}
b_{\max }=\frac{1.123 u}{\langle\omega\rangle} . \tag{10.126}
\end{equation*}
$$

Good news here is that both approaches (the microscopic analysis of Sec. 4 and the macroscopic analysis of this section) give essentially the same result. This fact may be also perceived as bad news: the treatment of the medium as a continuum does not give any new results here. The situation somewhat changes at relativistic velocities at which such treatment provides noticeable corrections (called density effects), in particular reducing the energy loss estimates.

Let me, however, skip these details and focus on a much more important effect described by our formulas. Consider the dependence of the electric field components on the impact parameter $b$, i.e. on the closest distance between particle's trajectory and the field observation point. If $\kappa^{2}>0$, then $\kappa$ is real, and we can use, in Eqs. (116)-(117), the asymptotic formula (2.158),

$$
\begin{equation*}
K_{n}(\xi) \rightarrow\left(\frac{\pi}{2 \xi}\right)^{1 / 2} e^{-\xi}, \text { at } \xi \rightarrow \infty \tag{10.127}
\end{equation*}
$$

to conclude that the complex amplitudes $E_{\omega}$ of both components $E_{x}$ and $E_{y}$ of the electric field decrease exponentially, starting from $b \sim u /\langle\omega\rangle$. However, let us consider what happens at frequencies where $\kappa^{2}<$ 0 , i.e.

$$
\begin{equation*}
\varepsilon(\omega) \mu(\omega) \equiv \frac{1}{v^{2}(\omega)}<\frac{1}{u^{2}}<\frac{1}{c^{2}}=\varepsilon_{0} \mu_{0} . \tag{10.128}
\end{equation*}
$$

(This condition means that particle's velocity is larger than the phase velocity of waves, at this particular frequency.) In these intervals, $\kappa$ is purely imaginary, ${ }^{45}$ functions $\exp \{\kappa b\}$ become just phase factors, and

$$
\begin{equation*}
\left|E_{x}(\omega)\right| \propto\left|E_{y}(\omega)\right| \propto \frac{1}{b^{1 / 2}} . \tag{10.129}
\end{equation*}
$$

This means that the Poynting vector drops as $1 / b$, so that its flux through a surface of a round cylinder of radius $b$, with the axis on the particle trajectory (i.e. power flow), does not depend on $b$. Hence, this is wave emission - the famous Cherenkov radiation. ${ }^{46}$

The direction of its propagation may be readily found taking into account that at large distances from particle's trajectory the emitted wave has to be locally planar, so that the Cherenkov angle $\theta$ may be found from the ratio of the field components (Fig. 14a):

$$
\begin{equation*}
\tan \theta=-\frac{E_{x}}{E_{y}} \tag{10.130}
\end{equation*}
$$

[^446]

Fig. 10.14. (a) Cherenkov radiation's propagation angle $\theta$, and (b) its interpretation.
This ratio may be calculated by plugging the asymptotic formula (127) into Eqs. (116) and (117) and calculating their ratio:

$$
\begin{equation*}
\tan \theta=-\frac{E_{x}}{E_{y}}=\frac{i \kappa u}{\omega}=\left[\varepsilon(\omega) \mu(\omega) u^{2}-1\right]^{1 / 2}=\left(\frac{u^{2}}{v^{2}(\omega)}-1\right)^{1 / 2}, \tag{10.131a}
\end{equation*}
$$

so that

Cherenkov angle

$$
\begin{equation*}
\cos \theta=\frac{v(\omega)}{u}<1 \tag{10.131b}
\end{equation*}
$$

Remarkably, this direction does not depend on the emission time $t$, so that radiation of frequency $\omega$, at each instant, forms a hollow cone led by the particle. This simple result allows an evident interpretation (Fig. 14b): the cone is just the set of all observation points that may be reached by "signals" propagating with speed $v(\omega)<u$ from all previous points of particle's trajectory.

This phenomenon is closely related to the so-called Mach cone in fluid dynamics, ${ }^{47}$ besides that in the Cherenkov radiation there is a separate cone for each frequency (of the range in which $v(\omega)<u$ ): the smaller is the $\delta(\omega) \mu(\omega)$ product, i.e. the larger is wave velocity $v(\omega)=1 /[\varepsilon(\omega) \mu(\omega)]^{1 / 2}$, and the broader is the cone, i.e. the earlier the corresponding "shock wave" arrives to an observer. Please note that the Cherenkov radiation is a unique radiative phenomenon: it takes place even if a particle moves without acceleration, and (in agreement with our analysis in Sec. 2), is impossible in free space where $v$ $=c$ is always larger than $u$.

The intensity of the Cherenkov radiation intensity may be also readily found by plugging the asymptotic expression (127), with imaginary $\kappa$, into Eq. (123). The result is

Cherenkov radiation intensity

$$
\begin{equation*}
-\frac{d \varepsilon}{d x} \approx\left(\frac{\mathfrak{Y}}{4 \pi}\right)^{2} \int_{v(\omega)<u} \omega\left(1-\frac{v^{2}(\omega)}{u^{2}}\right) d \omega . \tag{10.132}
\end{equation*}
$$

For non-relativistic particles $(u \ll c)$, the Cherenkov radiation condition $u>v(\omega)$ may be fulfilled only in relatively narrow frequency intervals where the product $\varepsilon(\omega) \mu(\omega)$ is very large (usually, due to optical resonance peaks of the electric permittivity - see Fig. 7.5 and its discussion). In this case the emitted light consists of a few nearly monochromatic components. On the contrary, if the condition $u>v(\omega)$, i.e. $u^{2} / \varepsilon(\omega) \mu(\omega)>1$ is fulfilled in a broad frequency range (as it is for ultra-relativistic particles in

[^447]condensed media), the radiated power is clearly dominated by higher frequency of the range - hence the famous bluish color of the Cherenkov radiation glow in water nuclear reactors- see Fig. 15.

Fig. 10.15. The Cherenkov radiation glow coming from the Advanced Test Reactor of the Idaho National Laboratory. Adapted from http://en.wikipedia.org/wiki/Cherenkov radiation.

The Cherenkov radiation is broadly used for the detection of radiation in high energy experiments for particle identification and speed measurement (since it is easy to pass particles through media of various density and hence of the dielectric constant) - for example, in the so-called Ring Imaging Cherenkov (RICH) detectors that have been designed for the DELPHI experiment ${ }^{48}$ at the Large Electron-Positron Collider (LEP) in CERN.

A little bit counter-intuitively, the formalism described in this section is also very useful for the description of an apparently rather different effect - the so-called transition radiation that takes place when a charged particle crosses a border between two media. ${ }^{49}$ The effect may be understood as result of the time dependence of the electric dipole formed by the moving charge and its mirror image in the counterpart medium - see Fig. 16. In the non-relativistic limit, the effect allows a straightforward description combining the electrostatics picture of Sec. 3.4 (see Fig. 3.9 and its discussion), and Eq. (8.27) - slightly corrected for polarization effects of the media. However, if particle's velocity $u$ is comparable with the phase velocity of waves in either medium, the adequate theory of the transition radiation becomes very close to that of the Cherenkov radiation.

Fig. 10.16. Physics of the transition radiation.

[^448]In comparison with the Cherenkov radiation, the transition radiation is rather weak, and its practical use (mostly for the measurement of the relativistic factor $\gamma$, to which the radiation intensity is proportional) requires multi-layered stacks. ${ }^{50}$ In these systems, the radiation emitted at sequential borders may be coherent, and the system's physics becomes close to that of the undulators discussed in Sec. 4.

### 10.6. Radiation's back-action

An attentive reader could notice that so far our treatment of charged particle dynamics has never been fully self-consistent. Indeed, in Sec. 9.6 we have analyzed particle's motion in various external fields, ignoring the fields radiated by particle itself, while in Sec. 8.2 and earlier in this chapter these fields have been calculated (admittedly, just for a few simple cases), but, again, their back-action on the emitting particle have been ignored. Only in few cases we have taken the back effects of the radiation implicitly, via the energy conservation. However, even in these cases, the near-field components of the fields (such as the first term in Eq. (20a), that affect the moving particle most, have been ignored.

At the same time, it is clear that generally the interaction of a point charge with its own field cannot be always ignored. As the simplest example, if an electron is made to fly through a resonant cavity, thus inducing oscillations in it, and then is forced to return to it before the oscillations have decayed, its motion will be certainly affected by the oscillating fields, just as if they had been induced by another source. There is no conceptual problem with applying the Maxwell theory to such "fieldparticle rendezvous" effects; moreover, it is the basis of the engineering design of such electron devices as klystrons, magnetrons, and undulators.

A problem arises only when no finite "rendezvous" point is enforced by boundary conditions, so that the most important self-field effects are at $R \equiv|\mathbf{r}-\mathbf{r}| \rightarrow 0$, the most evident example being the radiation of particle in free space, described earlier in this chapter. We already know that radiation takes away a part of charge's kinetic energy, i.e. has to cause its deceleration. One should wonder, however, whether such self-action effects might be described in a more direct, non-perturbative way.

As the first attempt, let us try a phenomenological approach based on the already derived formulas for radiation power $P$. For the sake of simplicity, let us consider a non-relativistic point charge $q$ in free space, so that $P$ is described by Eq. (8.27), with electric dipole moment's derivative over time equal to $q \mathbf{u}$ :

$$
\begin{equation*}
\mathcal{P}=\frac{Z_{0} q^{2}}{6 \pi c^{2}} \dot{u}^{2}=\frac{2}{3 c^{3}} \frac{q^{2}}{4 \pi \varepsilon_{0}} \dot{u}^{2} . \tag{10.133}
\end{equation*}
$$

The most naïve approach would be to write the equation of particle's motion in the form

$$
\begin{equation*}
m \dot{\mathbf{u}}=\mathbf{F}_{e x t}+\mathbf{F}_{\text {self }}, \tag{10.134}
\end{equation*}
$$

[^449]and try to calculate the radiation back-action force by requiring its instant power, $-\mathbf{F}_{\text {self }} \mathbf{u}$, to be equal to P. However, with Eq. (133), this approach (say, for 1D motion) would give a very unnatural result,
\[

$$
\begin{equation*}
F_{\text {self }} \propto \frac{\dot{u}^{2}}{u} \tag{10.135}
\end{equation*}
$$

\]

that might diverge at some points of particle's trajectory. This failure is clearly due to the retardation effect: as the reader may recall, Eq. (133) results from the analysis of radiation fields at large distances from the particle, e.g., from the second term in Eq. (20a), i.e. when the non-radiative first term (which is much larger at small distances, $R \rightarrow 0$ ) is ignored.

Before exploring the effects of this term, let us, however, make one more try with Eq. (133), considering its average effect on some periodic motion of the particle. To calculate the average, let us write

$$
\begin{equation*}
\overline{\dot{u}^{2}} \equiv \frac{1}{T} \int_{0}^{T} \dot{\mathbf{u}} \cdot \dot{\mathbf{u}} d t \tag{10.136}
\end{equation*}
$$

and integrate this identity, over the motion period, by parts:

$$
\begin{equation*}
\overline{\mathcal{P}}=\frac{2}{3 c^{3}} \frac{q^{2}}{4 \pi \varepsilon_{0}} \overline{(\dot{\mathbf{u}})^{2}}=\frac{2}{3 c^{3}} \frac{q^{2}}{4 \pi \varepsilon_{0}} \frac{1}{T}\left(\left.\dot{\mathbf{u}} \cdot \mathbf{u}\right|_{0} ^{T}-\int_{0}^{T} \ddot{\mathbf{u}} \cdot \mathbf{u} d t\right)=-\frac{1}{T} \int_{0}^{T} \frac{2}{3 c^{3}} \frac{q^{2}}{4 \pi \varepsilon_{0}} \ddot{\mathbf{u}} \cdot \mathbf{u} d t . \tag{10.137}
\end{equation*}
$$

One the other hand, the back-action force would give

$$
\begin{equation*}
\overline{\mathcal{P}}=-\frac{1}{T} \int_{0}^{T} \mathbf{F}_{\text {self }} \cdot \mathbf{u} d t \tag{10.138}
\end{equation*}
$$

These two averages coincide if ${ }^{51}$

$$
\begin{equation*}
\mathbf{F}_{\text {self }}=\frac{2}{3 c^{3}} \frac{q^{2}}{4 \pi \varepsilon_{0}} \ddot{\mathbf{u}} \tag{10.139}
\end{equation*}
$$

This is the so-called Abraham-Lorentz force for self-action. Before going after a more serious derivation of this formula, let us estimate its scale, presenting Eq. (139) as

$$
\begin{equation*}
\mathbf{F}_{\text {self }}=m \tau \ddot{\mathbf{u}}, \quad \text { with } \tau \equiv \frac{2}{3 m c^{3}} \frac{q^{2}}{4 \pi \varepsilon_{0}} \tag{10.140}
\end{equation*}
$$

where constant $\tau$ evidently has the dimension of time. Recalling definition (8.41) of the classical radius $r_{c}$ of the particle, Eq. (140) for $\tau$ may be rewritten as

$$
\begin{equation*}
\tau=\frac{2}{3} \frac{r_{c}}{c} . \tag{10.141}
\end{equation*}
$$

[^450]- the so-called Abraham-Lorentz-Dirac force.

For the electron, $\tau$ is of the order of $10^{-23} \mathrm{~s}$. This means that in most cases the Abrahams-Lorentz force is either negligible or leads to the same results as the perturbative treatments of energy loss we have used earlier in this chapter.

However, Eq. (140) brings some unpleasant surprises. For example, let us consider a 1D oscillator of eigenfrequency $\omega_{0}$. For it, Eq. (134), with the back-action force given by Eq. (140), is

$$
\begin{equation*}
m \ddot{x}+m \omega_{0}^{2} x=m \tau \dddot{x} \tag{10.142}
\end{equation*}
$$

Looking for the solution to this linear differential equation in the usual exponential form, $x(t) \propto$ $\exp \{\lambda t\}$, we get the following characteristic equation,

$$
\begin{equation*}
\lambda^{2}+\omega_{0}^{2}=\tau \lambda^{3} . \tag{10.143}
\end{equation*}
$$

It may look like that for any "reasonable" value of $\omega_{0} \ll 1 / \tau \sim 10^{23} \mathrm{~s}^{-1}$, the right-hand side of this nonlinear algebraic equation may be treated as a perturbation. Indeed, looking for its solutions in the natural form $\lambda_{ \pm}= \pm i \omega_{0}+\lambda^{\prime}$, with $\left|\lambda^{\prime}\right| \ll \omega_{0}$, expanding both parts of Eq. (143) in the Taylor series in small parameter $\lambda^{\prime}$, and keeping only linear terms, we get

$$
\begin{equation*}
\lambda^{\prime} \approx-\frac{\omega_{0}^{2} \tau}{2} \tag{10.144}
\end{equation*}
$$

This means that the energy of free oscillations decreases in time as $\exp \left\{2 \lambda^{\prime} t\right\}=\exp \left\{-\omega_{0}{ }^{2} \tau t\right\}$; this is exactly the radiative damping analyzed earlier. However, Eq. (143) is deceiving; it has the third root corresponding to unphysical, exponentially growing (so-called run-away) solutions. It is easiest to see for a free particle, with $\omega_{0}=0$. Then Eq. (143) becomes very simple,

$$
\begin{equation*}
\lambda^{2}=\tau \lambda^{3} \tag{10.145}
\end{equation*}
$$

and it is easy to find all its 3 roots explicitly: $\lambda_{1}=\lambda_{2}=0$ and $\lambda_{3}=1 / \tau$. While the first 2 roots correspond the values $\lambda_{ \pm}$found earlier, the last one describes exponential (and extremely fast!) acceleration..

In order to remove this artifact, let us try to develop a self-consistent approach to back action, taking into account the near-field terms of particle fields. For that, we need somehow overcome the divergence of Eqs. (10) and (20) at $R \rightarrow 0$. The most reasonable way to do this is to spread particle charge over a ball of radius $a$, with a spherically-symmetric (but not necessarily constant) density $\rho(r)$, and in the end of calculations trace the limit $a \rightarrow 0 .{ }^{52}$ Again sticking to the non-relativistic case (so that the magnetic component of the Lorentz force is not important), we should calculate

$$
\begin{equation*}
\mathbf{F}_{r a d}=\int_{V} \rho(\mathbf{r}) \mathbf{E}(\mathbf{r}, t) d^{3} r, \tag{10.146}
\end{equation*}
$$

where the electric field is that of the charge itself, with field of any elementary charge $d q=\rho(r) d^{3} r$, described by Eqs. (20a).

[^451]In order to make analytical calculations doable, we need to make assumption $a \ll r_{c}$, treat ratio $R / r_{c} \sim a / r_{c}$ as a small parameter, and expand the result in the Taylor series in small $R$. This procedure yields

$$
\begin{equation*}
\mathbf{F}_{\text {self }}=-\frac{2}{3} \frac{1}{4 \pi \varepsilon_{0}} \sum_{n=0}^{\infty} \frac{(-1)^{n}}{c^{n+2} n!} \frac{d^{n+1} \mathbf{u}}{d t^{n+1}} \int_{V} d^{3} r \int_{V} d^{3} r^{\prime} \rho(r) R^{n-1} \rho\left(r^{\prime}\right) . \tag{10.147}
\end{equation*}
$$

Distance $R$ cancels only in the term with $n=1$,

$$
\begin{equation*}
\mathbf{F}_{1}=\frac{2}{3 c^{3}} \frac{\ddot{\mathbf{u}}}{4 \pi \varepsilon_{0}} \int_{V} d^{3} r \int_{V} d^{3} r^{\prime} \rho(r) \rho\left(r^{\prime}\right)=\frac{q^{2}}{6 \pi \varepsilon_{0} c^{3}} \ddot{\mathbf{u}}, \tag{10.148}
\end{equation*}
$$

showing that we have recovered (now in an apparently legitimate fashion) Eq. (139) for the AbrahamsLorentz force. One could argue that in the limit $a \rightarrow 0$ the terms higher in $R \sim a$ (with $n>1$ ) could be ignored. However, we have to notice that the main contribution to into series (147) is not described by Eq. (148) for $n=1$, but is given by the larger term with $n=0$ :

$$
\begin{equation*}
\mathbf{F}_{0}=-\frac{2}{3} \frac{1}{4 \pi \varepsilon_{0}} \frac{\dot{\mathbf{u}}}{c^{2}} \int_{V} d^{3} r \int_{V} d^{3} r^{\prime} \frac{\rho(r) \rho\left(r^{\prime}\right)}{R}=-\frac{4}{3} \frac{\dot{\mathbf{u}}}{c^{2}} \frac{1}{8 \pi \varepsilon_{0}} \int_{V} d^{3} r \int_{V} d^{3} r^{\prime} \frac{\rho(r) \rho\left(r^{\prime}\right)}{R}=-\frac{4}{3 c^{2}} \dot{\mathbf{u}} U, \tag{10.149}
\end{equation*}
$$

This term may be interpreted as the inertial "force" $-m_{\mathrm{e} f} \mathbf{a}^{53}$ with the effective electromagnetic mass

$$
\begin{equation*}
m_{\mathrm{ef}}=\frac{4}{3} \frac{U}{c^{2}} \tag{10.150}
\end{equation*}
$$

This is the famous (or rather infamous :-) $4 / 3$ problem that does not allow to interpret the electron's mass as that of its electric field. The (admittedly, rather formal) resolution of this paradox is possible only in quantum electrodynamics with its renormalization techniques - beyond the framework of this course. Note that these issues are only important for motions with frequencies of the order of $1 / \tau$ $\sim 10^{23} \mathrm{~s}^{-1}$, i.e. at energies $\varepsilon \sim \hbar / \tau \sim 10^{-11} \mathrm{~J} \sim 10^{8} \mathrm{eV}$, while other quantum electrodynamics effects may be observed at much lower frequencies, starting from $\sim 10^{10} \mathrm{~s}^{-1}$. Hence the $4 / 3$ problem is by no means the only motivation for the transfer from classical to quantum electrodynamics.

However, the reader should not think that his or her time spent on this course has been lost: quantum electrodynamics incorporates virtually all classical electrodynamics results, and transition between them is surprisingly straightforward. ${ }^{54}$

### 10.6. Exercise problems

10.1. A point charge $q$ that had been in a stationary position on a circle of radius $R$, is carried over, along the circle, to the opposite position on the same diameter (see Fig. on the right) as fast as only physically possible, and then is kept steady at this new position. Calculate and sketch the time dependence of the
 electric field $\mathbf{E}$ at the center of the circle.

[^452]10.2. Express the total radiation power by a relativistic particle with the electric charge $q$ and the rest mass $m$, moving with velocity $\mathbf{u}$, via the external Lorentz force $\mathbf{F}$ exerted on the particle.
10.3. A relativistic particle with electric charge $q$, initially at rest, is accelerated by a constant force $\mathbf{F}$ until it reaches certain velocity $u$, and then moves by inertia. Calculate the total energy radiated during the acceleration.
10.4. ${ }^{*}$ Calculate the power spectrum of the radiation emitted by a relativistic particle with charge $q$, performing 1D harmonic oscillations with frequency $\omega$ and displacement amplitude $a$.
10.5. Analyze the polarization and the spectral contents of the synchrotron radiation in the direction propagating perpendicular to particle's rotation plane. How do the results change if not one, but $N>1$ similar particles move around the circle, at equal angular distances?
10.6. Calculate the time dependence of the kinetic energy of a charged relativistic particle performing synchrotron motion in a constant and uniform magnetic field $\mathbf{B}$, and hence emitting the synchrotron radiation. Sketch particle's trajectory.

Hint: You may assume that the energy loss is relatively slow $\left(-d \mathcal{E} / d t \ll \omega_{c} \mathcal{E}\right)$, but should spell out the condition of validity of this assumption.
10.7. Find the polarization of the synchrotron radiation propagating within particle's rotation plane.
10.8. The basic quantum theory of radiation shows ${ }^{55}$ that the electric dipole radiation by a particle is allowed only if its angular momentum change at the transition equals $\pm \hbar$.
(i) Estimate the change $\Delta L$ of the orbital momentum of an ultra-relativistic particle due to its emission of a single photon of the synchrotron radiation.
(ii) Does the quantum mechanics forbid such radiation? If not, why?
10.9. A relativistic particle moves along axis $z$, with velocity $u_{z}$, through an undulator - a system of permanent magnets providing (in the simplest model) a perpendicular magnetic field, whose distribution near axis $z$ is sinusoidal: ${ }^{56}$

$$
\mathbf{B}=\mathbf{n}_{y} B_{0} \cos k_{0} z .
$$

Assuming that the field is so weak that it causes only relatively small deviations of particle's trajectory from the straight line, calculate the angular distribution of the resulting radiation. What condition does this assumption impose on system's parameters?

[^453]10.10. Discuss possible effects of the interference of the undulator radiation from different periods of its static field distribution, in particular, calculate the angular positions of maxima of the radiation power density.
10.11. An electron, launched directly toward a plane surface of a perfect conductor, is instantly absorbed by it at the collision. Find the angular distribution and frequency spectrum of the electromagnetic waves radiated at this collision, if the initial kinetic energy $T$ of the particle is much larger than conductor's workfunction $\phi$. Give a semi-quantitative discussion of the limitations of your result.
10.12. A relativistic particle, with the rest mass $m$ and electric charge $q$, flies with the velocity $u$ by an immobile point charge $q^{\prime}$, with the impact parameter $b$ so large that the deviations of its trajectory from the straight line are negligible. Calculate the total energy loss due to the electromagnetic radiation during the passage. Formulate the conditions of validity of your result.

# Part QM: Quantum Mechanics 

Last corrections: 2019/05/08

A revised version of this material is now published by the IOP under the title
"Quantum Mechanics: Lecture notes"
(Essential Advanced Physics - Volume 5, ISBN 978-0-7503-1411-4),
with the model solutions of the exercise problems published under the title
"Quantum Mechanics: Problems with solutions"
(Essential Advanced Physics - Volume 6, ISBN 978-0-7503-1414-5)

## Table of Contents

## Chapter 1. Introduction (26 pp.)

1.1. Experimental motivations
1.2. Wave mechanics postulates
1.3. Postulates' discussion
1.4. Continuity equation
1.5. Eigenstates and eigenvalues
1.6. Dimensionality reduction
1.7. Exercise problems (12)

Chapter 2. 1D Wave Mechanics (76 pp.)
2.1. Probability current and uncertainty relation
2.2. Free particle: Wave packets
2.3. Particle motion in simple potential profiles
2.4. The WKB approximation
2.5. Transfer matrix, resonant tunneling, and metastable states
2.6. Coupled quantum wells
2.7. 1D band theory
2.8. Effective mass and the Bloch oscillations
2.9. Landau-Zener tunneling
2.10. Harmonic oscillator: Brute force approach
2.11. Exercise problems (43)

Chapter 3. Higher Dimensionality Effects (56 pp.)
3.1. Quantum interference, the AB effect, and magnetic flux quantization
3.2. Landau levels and quantum Hall effect
3.3. Scattering and diffraction
3.4. Energy bands in higher dimensions
3.5. Axially-symmetric systems
3.6. Spherically-symmetric systems: The brute force approach
3.7. Atoms
3.8. Exercise problems (36)

## Chapter 4. Bra-ket Formalism (42 pp.)

4.1. Motivation
4.2. States, state vectors, and linear operators
4.3. State basis and matrix representation
4.4. Change of basis, unitary operators, and matrix diagonalization
4.5. Observables: Expectation values, uncertainties, and uncertainty relations
4.6. Quantum dynamics: Three pictures
4.7. Exercise problems (30)

## Chapter 1. Introduction

This introductory chapter briefly reviews the major motivations for quantum mechanics. Then its simplest formalism - Schrödinger's wave mechanics - is described, and its main features are discussed Much of this material (perhaps except for the last section) may be found in undergraduate textbooks. ${ }^{1}$

### 1.1. Experimental motivations

By the beginning of the 1900s, physics (which by that time included what we now know as nonrelativistic classical mechanics, classical statistics and thermodynamics, and classical electrodynamics including geometric and wave optics) looked as an almost completed discipline, with a lot of experimental observations explained, and just a couple of mysterious "dark clouds" ${ }^{2}$ on the horizon. However, the rapid technological progress and the resulting fast development of experimental techniques have led to a fast multiplication of observed phenomena that could not be explained on the classical basis. Let me list the most consequential of those experimental findings.
(i) Blackbody radiation measurements, started by G. Kirchhoff in 1859, have shown that the in the thermal equilibrium, the power of electromagnetic radiation by a fully absorbing ("black") surface per unit frequency interval drops exponentially at high frequencies. This is not what could be expected from the combination of the classical electrodynamics and statistics, which predicted an infinite growth of the radiation density with frequency. Indeed, the classical electrodynamics shows ${ }^{3}$ that electromagnetic field modes in free space evolve in time as harmonic oscillators, and that the density of these modes in a large volume $V \gg \lambda^{3}$ per small frequency interval is

$$
\begin{equation*}
d N=2 V \frac{d V_{k}}{(2 \pi)^{3}}=2 V \frac{4 \pi k^{2} d k}{(2 \pi)^{3}}=V \frac{\omega^{2}}{\pi^{2} c^{3}} d \omega \tag{1.1}
\end{equation*}
$$

where $c \approx 3 \times 10^{8} \mathrm{~m} / \mathrm{s}$ is the free-space speed of light, $\omega$ its frequency, $k=\omega / c$ the free-space wave number, and $\lambda=2 \pi / k$ is the radiation wavelength. On the other hand, classical statistics ${ }^{4}$ predicts that in the thermal equilibrium at temperature $T$, the average energy $E$ of each 1D harmonic oscillator should equal $k_{\mathrm{B}} T$, where $k_{\mathrm{B}}$ is the Boltzmann constant. ${ }^{5}$

Combining these two results, we readily get the so-called Rayleigh-Jeans formula for the average electromagnetic wave energy per unit volume:

[^454]\[

$$
\begin{equation*}
u \equiv \frac{1}{V} \frac{d E}{d \omega}=\frac{k_{B} T}{V} \frac{d N}{d \omega}=\frac{\omega^{2}}{\pi^{2} c^{3}} k_{\mathrm{B}} T \tag{1.2}
\end{equation*}
$$

\]

that diverges at $\omega \rightarrow \infty$. On the other hand, the blackbody radiation measurements, improved by O . Lummer and E. Pringsheim, and also H. Rubens and F. Kurlbaum to reach a $1 \%$-scale accuracy, were compatible with the phenomenological law suggested in 1900 by Max Planck:

$$
\begin{equation*}
u=\frac{\omega^{2}}{\pi^{2} c^{3}} \frac{\hbar \omega}{\exp \left(\hbar \omega / k_{\mathrm{B}} T\right)-1} \tag{1.3a}
\end{equation*}
$$

The law may be reconciled with the fundamental Eq. (1) if the following replacement is made for the average energy of each field oscillator:

$$
\begin{equation*}
k_{\mathrm{B}} T \rightarrow \frac{\hbar \omega}{\exp \left(\hbar \omega / k_{\mathrm{B}} T\right)-1}, \tag{1.3b}
\end{equation*}
$$

with a constant factor

$$
\begin{equation*}
\hbar \approx 1.055 \times 10^{-34} \mathrm{~J} \cdot \mathrm{~s}, \tag{1.4}
\end{equation*}
$$

Planck's constant
now called Planck's constant. ${ }^{6}$ At low frequencies $\left(\hbar \omega \ll k_{\mathrm{B}} T\right.$ ), the denominator in Eq. (3) may be approximated as $\hbar \omega / k_{\mathrm{B}} T$, so that the average energy (3b) tends to its classical value $k_{\mathrm{B}} T$, and the Planck law (3a) reduces to the Rayleigh-Jeans formula (2). However, at higher frequencies ( $\hbar \omega \gg k_{\mathrm{B}} T$ ), Eq. (3) describes the experimentally observed rapid decrease of the radiation density - see Fig. 1.

Fig. 1.1. Blackbody radiation density $u$, expressed in units of $u_{0} \equiv\left(k_{\mathrm{B}} T\right)^{3} / \pi^{2} \hbar^{2} c^{3}$, as a function of frequency, according to: the Rayleigh-Jeans formula (blue line) and the Planck law (red line).
(ii) The photoelectric effect, experimentally discovered in 1887 by H. Hertz, shows a sharp lower bound on the frequency of light that may kick electrons out from metallic surfaces, regardless of the light intensity. Albert Einstein, in the first of his three famous 1905 papers, noticed that this

[^455]threshold $\omega_{\min }$ could be readily explained assuming that light consisted of certain particles (now called photons) with energy

with the same Planck's constant that participates in Eq. (3). ${ }^{7}$ Indeed, with this assumption, at the photon absorption by the surface, its energy $E=\hbar \omega$ is divided between a fixed energy $W$ (now called the workfunction) of electron binding inside the metal, and the residual kinetic energy $m v^{2} / 2>0$ of the freed electron - see Fig. 2. In this picture, the frequency threshold finds a natural explanation as $\omega_{\min }=W / \hbar .{ }^{8}$ Moreover, as was shown by S. Bose in 1924, Eq. (5) readily explains ${ }^{9}$ Planck's law (3).

Fig. 1.2. Einstein's explanation of the photoelectric effect's frequency threshold.
(iii) The discrete frequency spectra of radiation by excited atomic gases, known since the 1600 s , could not be explained by classical physics. (Applied to the planetary model of atoms, proposed by E. Rutherford, it predicts the collapse of electrons on nuclei in $\sim 10^{-10}$ s due to electric dipole radiation of electromagnetic waves. ${ }^{10}$ ) Especially challenging was the observation by J. Balmer (in 1885) that the radiation frequencies of simple atoms may be described by simple formulas. For example, for the simplest atom, hydrogen, all radiation frequencies may be numbered with just two positive integers $n$ and $n^{\prime}$ :

$$
\begin{equation*}
\omega_{n, n^{\prime}}=\omega_{0}\left(\frac{1}{n^{2}}-\frac{1}{n^{\prime 2}}\right) \tag{1.6}
\end{equation*}
$$

with $\omega_{0} \equiv \omega_{1, \infty} \approx 2.07 \times 10^{16} \mathrm{~s}^{-1}$. The Balmer series, including the value of $\omega_{0}$, have found its first explanation in the famous 1913 theory by Niels Bohr, which was a semi-phenomenological precursor for quantum mechanics. In this theory, $\omega_{n, n}$, is interpreted as the frequency of a photon that obeys the Einstein's formula (5), with its energy $E_{n, n}$, being the difference between two quantized (discrete) energy levels of the atom (Fig. 3):

$$
\begin{equation*}
E_{n, n^{\prime}}=E_{n^{\prime}}-E_{n}>0 . \tag{1.7}
\end{equation*}
$$

[^456]

Fig. 1.3. Electromagnetic wave radiation at system's transition between its two quantized energy levels.

Bohr showed that the correct ${ }^{11}$ expression for the levels (relative to the free electron energy),

$$
\begin{equation*}
E_{n}=-\frac{E_{\mathrm{H}}}{2 n^{2}}<0 \tag{1.8}
\end{equation*}
$$

and the correct value of the so-called Hartree energy ${ }^{12}$

$$
\begin{equation*}
E_{\mathrm{H}} \equiv 2 \hbar \omega_{0}=\frac{m_{e}}{\hbar^{2}}\left(\frac{e^{2}}{4 \pi \varepsilon_{0}}\right)^{2} \approx 27.2 \mathrm{eV}, \tag{1.9}
\end{equation*}
$$

(where $e \approx 1.602 \times 10^{-19} \mathrm{C}$ is the fundamental electric charge, and $m_{e} \approx 0.911 \times 10^{-30} \mathrm{~kg}$ is electron's rest mass) could be obtained, with a virtually one-line calculation, from the classical mechanics plus just one additional postulate, equivalent to the assumption that the angular momentum $L=m_{e} v r$ of the electron moving on a circular trajectory of radius $r$ about hydrogen's nuclei (i.e. proton, assumed to stay at rest), is quantized as

$$
\begin{equation*}
L=\hbar n \tag{1.10}
\end{equation*}
$$

where $\hbar$ is again the same Planck's constant (4), and $n$ is an integer. Indeed, in order to derive Eq. (8), it is sufficient to solve Eq. (10) together with the $2^{\text {nd }}$ Newton's law for the rotating electron,

$$
\begin{equation*}
m_{e} \frac{v^{2}}{r}=\frac{e^{2}}{4 \pi \varepsilon_{0} r^{2}}, \tag{1.11}
\end{equation*}
$$

for the electron velocity $v$ and radius $r$, and then plug the results into the non-relativistic expression for the full electron's energy

$$
\begin{equation*}
E=\frac{m_{e} v^{2}}{2}-\frac{e^{2}}{4 \pi \varepsilon_{0} r} . \tag{1.12}
\end{equation*}
$$

(This non-relativistic approach to the problem is justified a posteriori by the fact the relevant energy scale $E_{\mathrm{H}}$ is much smaller than electron's rest energy, $m_{e} c^{2} \sim 0.5 \mathrm{MeV}$.) By the way, the value of $r$, corresponding to $n=1$, i.e. to the smallest possible electron orbit,

$$
\begin{equation*}
r_{\mathrm{B}} \equiv \frac{\hbar^{2}}{m_{e}\left(e^{2} / 4 \pi \varepsilon_{0}\right)} \approx 0.053 \mathrm{~nm} \tag{1.13}
\end{equation*}
$$

#### Abstract

Bohr radius

[^457]and called the Bohr radius, defines the most important spatial scale of phenomena in atomic, molecular and condensed matter physics - as well as in chemistry and biochemistry.

Now note that the quantization postulate (10) may be presented as the condition than an integer number $(n)$ of certain waves ${ }^{13}$ fits the circular orbit's perimeter $2 \pi r=n \lambda$. Dividing both parts of this relation by $\lambda$, we see that for this statement to be true, the wave number $k \equiv 2 \pi / \lambda$ of the (then hypothetic) de Broglie waves should be proportional to electron's momentum $p=m v$ :

$$
\begin{equation*}
p=\hbar k \tag{1.14}
\end{equation*}
$$

(iv) The Compton effect ${ }^{14}$ is the reduction of frequency of X-rays at their scattering on free (or nearly-free) electrons - see Fig. 4.

Fig. 1.4. Compton effect.

The effect may be explained assuming that the X-ray photon also has a momentum that obeys the vector-generalized version of Eq. (14):

$$
\begin{equation*}
\mathbf{p}_{\text {photon }}=\hbar \mathbf{k}=\frac{\hbar \omega}{c} \mathbf{n}, \tag{1.15}
\end{equation*}
$$

where $\mathbf{k}$ is the wavevector (whose magnitude is equal to the wave number $k$, and direction coincides with that, $\mathbf{n}$, of the wave propagation), and that momenta $\mathbf{p}$ of both the photon and the electron are related to their energies $E$ by the classical relativistic formula ${ }^{15}$

$$
\begin{equation*}
E^{2}=(c p)^{2}+\left(m c^{2}\right)^{2} \tag{1.16}
\end{equation*}
$$

(For a photon, the rest energy is zero, and this relation is reduced to Eq. (5): $E=c p=c \hbar k=\hbar \omega$.) Indeed, a straightforward solution of the following system of three equations,

$$
\begin{align*}
\hbar \omega+m_{e} c^{2} & =\hbar \omega^{\prime}+\left[(c p)^{2}+\left(m_{e} c^{2}\right)^{2}\right]^{1 / 2},  \tag{1.17}\\
\frac{\hbar \omega}{c} & =\frac{\hbar \omega^{\prime}}{c} \cos \theta+p \cos \varphi,  \tag{1.18}\\
0 & =\frac{\hbar \omega^{\prime}}{c} \sin \theta-p \sin \varphi, \tag{1.19}
\end{align*}
$$

[^458](which describe, respectively, the conservation of the full energy of the photon-electron system, and of two relevant Cartesian components of its full momentum, at the scattering event - see Fig. 4), yields the following result,
\[

$$
\begin{equation*}
\frac{1}{\hbar \omega^{\prime}}=\frac{1}{\hbar \omega}+\frac{1}{m_{e} c^{2}}(1-\cos \theta), \tag{1.20a}
\end{equation*}
$$

\]

which is traditionally represented as the relation between the initial and final values of photon's wavelength $\lambda=2 \pi / k=2 \pi /(\omega / c)$ :

$$
\begin{equation*}
\lambda^{\prime}=\lambda+\frac{2 \pi \hbar}{m_{e} c}(1-\cos \theta)=\lambda+\lambda_{c}(1-\cos \theta), \quad \text { with } \lambda_{c} \equiv \frac{2 \pi \hbar}{m_{e} c}, \tag{1.20b}
\end{equation*}
$$

and is in agreement with experiment. ${ }^{16}$
(v) De Broglie wave diffraction. In 1927, following the suggestion by W. Elassger (who was excited by de Broglie's conjecture of "matter waves"), C. Davisson and L. Germer, and independently G. Thomson succeeded to observe diffraction of electrons on crystals (Fig. 5). Specifically, they have found that the intensity of the elastic reflection from a crystal increases sharply when angle $\theta$ between the incident beam of electrons and crystal's atomic planes, separated by distance $d$, satisfies the following relation:

$$
\begin{equation*}
2 d \sin \theta=n \lambda \tag{1.21}
\end{equation*}
$$

where $\lambda=2 \pi / k=2 \pi \hbar / p$ is the de Broglie wavelength of electrons, and $n$ is an integer. As Fig. 5 shows, this is just the well-known condition ${ }^{17}$ that the optical path difference $\Delta l=2 d \sin \theta$ between the de Broglie waves reflected from two adjacent crystal planes coincides with an integer number of $\lambda$, i.e. of the constructive interference of the waves. ${ }^{18}$

Fig. 1.5. Electron scattering from a crystal lattice.
${ }^{16}$ The constant $\lambda_{c}$, which participates in this relation, is close to $2.46 \times 10^{-12} \mathrm{~m}$ and is called the Compton wavelength of the electron. This term is somewhat misleading: as the reader can see from Eqs. (17)-(19), no wave in the Compton problem has such a wavelength - either before or after the scattering.
${ }^{17}$ Frequently called the Bragg condition, due to the pioneering experiments by W. Bragg with X-ray scattering from crystals (that started in 1912).
${ }^{18}$ Later, spectacular experiments with diffraction and interference of heavier particles, e.g., neutrons and even $\mathrm{C}_{60}$ molecules, have also been performed - see, e.g., a review by A. Zeilinger et al., Rev. Mod. Phys. 60, 1067 (1988) and a later publication by O. Nairz et al., Am. J. Phys. 71, 319 (2003). Nowadays, such interference of heavy particles is used for ultrasensitive measurements of gravity - see, e.g., a popular review by M. Arndt, Phys. Today 67, 30 (May 2014), and recent advanced experiments by P. Hamilton et al., Phys. Rev. Lett. 114, 100405 (2015). Moreover, quantum interference between different parts and different quantum states of such macroscopic objects as superconducting condensates of millions Cooper pairs has been observed - see Sec. 3.1 below for details.

To summarize, all the listed effects may be explained starting from two very simple (and similarly looking) formulas: Eq. (5) for photons, and Eq. (15) for both photons and electrons - both relations involving the same Planck's constant. This might give an impression of sufficient experimental evidence to declare light consisting of discrete particles (photons), and, on the contrary, electrons being some "matter waves" rather than particles. However, by that time (the mid 1920s) physics has accumulated overwhelming evidence of wave properties of light, such as interference and diffraction. In addition, there was also a strong evidence for lumped-particle ("corpuscular") behavior of electrons. It is sufficient to mention the famous oil-drop experiments by R. Millikan and H. Fletcher (1909-1913) in that only single (and whole!) electrons could be added to an oil drop, changing its total electric charge by multiples of electron's charge ( $-e$ ) - and never its fraction. It was apparently impossible to reconcile these observations with a purely wave picture, in which an electron and hence its charge need to be spread over the wave, so that its arbitrary part of it could be cut out using appropriate experimental setups.

Thus the founding fathers of quantum mechanics faced a formidable task of reconciling the wave and corpuscular properties of electrons and photons - and other particles. The decisive breakthrough in that task has been achieved in 1926 by Ervin Schrödinger and Max Born who formulated what is now known as either the Schrödinger picture of non-relativistic quantum mechanics in the coordinate representation, or simply as wave mechanics. I will now formulate that picture, somewhat disregarding the actual history of its development.

### 1.2. Wave mechanics postulates

Let us consider a spinless, ${ }^{19}$ non-relativistic point-like particle whose classical dynamics may be described by a certain Hamiltonian function $H(\mathbf{r}, \mathbf{p}, t),{ }^{20}$ where $\mathbf{r}$ is particle's radius-vector and $\mathbf{p}$ is coordinate. ${ }^{21}$ Wave mechanics of such Hamiltonian particles may based on the following set of postulates ${ }^{22}$ that are comfortingly elegant - though their final justification is given only by the agreement of all their corollaries with experiment.
(i) Wavefunction and probability. Such variables as $\mathbf{r}$ or $\mathbf{p}$ cannot be always measured exactly, even at "perfect conditions" when all external uncertainties, including measurement instrument imperfection, macroscopic fluctuations of the initial state preparation, and unintended particle interactions with its environment, have been removed. ${ }^{23}$ Moreover, $\mathbf{r}$ and $\mathbf{p}$ of the same particle can

[^459]never be measured exactly simultaneously. Instead, even the most detailed description of the particle's state, allowed by Nature, ${ }^{24}$ is given by a certain complex function $\Psi(\mathbf{r}, t)$, called the wavefunction, that generally enables only probabilistic predictions of measured values of $\mathbf{r}, \mathbf{p}$, and other directly measurable variables (in quantum mechanics, called observables).

Specifically, the probability $d W$ of finding a particle inside an infinitesimal volume $d V \equiv d^{3} r$ is proportional to this volume and may be characterized by the probability density $w \equiv d W / d^{3} r$ that in turn is related to the wavefunction as

$$
\begin{equation*}
w=|\Psi(\mathbf{r}, t)|^{2} \equiv \Psi^{*}(\mathbf{r}, t) \Psi(\mathbf{r}, t) \tag{1.22a}
\end{equation*}
$$

where sign * means the complex conjugate. As a result, the total probability of finding the particle somewhere inside a volume $V$ may be calculated as

$$
\begin{equation*}
W=\int_{V} w d^{3} r=\int_{V} \Psi^{*} \Psi d^{3} r \tag{1.22b}
\end{equation*}
$$

In particular, if the volume $V$ contains the particle definitely (i.e. with the $100 \%$ probability, $W=1$ ), Eq. (22b) is reduced to the so-called normalization condition

$$
\begin{equation*}
\int_{V} \Psi^{*} \Psi d^{3} r=1 \tag{1.22c}
\end{equation*}
$$

(ii) Observables and operators. To each observable $A$, quantum mechanics associates a certain linear operator $\hat{A}$, such that, in the perfect conditions mentioned above, the average measured value (also called the expectation value) of $A$ is expressed as ${ }^{25}$

$$
\begin{equation*}
\langle A\rangle=\int_{V} \Psi^{*} \hat{A} \Psi d^{3} r, \tag{1.23}
\end{equation*}
$$

where $\langle\ldots\rangle$ means the statistical average, i.e. the result of averaging the measurement results over a large ensemble (set) of macroscopically similar experiments, and $\Psi$ is the normalized wavefunction - see Eq. (22c). For Eqs. (22) and (23) to be compatible, the identity ("unit") operator $\hat{I}$, defined by relation

$$
\begin{equation*}
\hat{I} \Psi=\Psi \tag{1.24}
\end{equation*}
$$

has to be associated with a particular type of measurement, namely with particle's detection.
(iii) Hamiltonian operator and the Schrödinger equation. Another particular operator, the Hamiltonian $\hat{H}$, whose observable is the particle's energy $E$, also plays in wave mechanics a very special role, because it participates in the Schrödinger equation,

$$
\begin{equation*}
i \hbar \frac{\partial \Psi}{\partial t}=\hat{H} \Psi \tag{1.25}
\end{equation*}
$$

[^460]that determines wavefunction's dynamics, i.e. its time evolution.
(iv) Radius-vector and momentum operators. In the coordinate representation accepted in wave mechanics, the (vector) operator of particle's radius-vector $\mathbf{r}$ just multiples the wavefunction by this

Operators of coordinate and momentum vector, while the operator of particle's momentum ${ }^{26}$ is represented by the spatial derivative:

$$
\begin{equation*}
\hat{\mathbf{p}}=-i \hbar \nabla, \tag{1.26a}
\end{equation*}
$$

where $\nabla$ is the del (or "nabla") vector operator. ${ }^{27}$ Thus in the Cartesian coordinates,

$$
\begin{equation*}
\hat{\mathbf{r}}=\mathbf{r}=\{x, y, z\}, \quad \hat{\mathbf{p}}=-i \hbar\left\{\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z}\right\} \tag{1.26b}
\end{equation*}
$$

(v) Correspondence principle. In the limit when quantum effects are insignificant, e.g., when the characteristic scale of action $S^{28}$ (i.e. the product of the relevant energy and time scales of the problem) is much larger than Planck's constant $\hbar$, all wave mechanics results have to tend to those given by classical mechanics. Mathematically, the correspondence is achieved by duplicating the classical relations between observables by similar relations between the corresponding operators. For example, for a free particle, the Hamiltonian (that in this case corresponds to the kinetic energy alone) has the form

$$
\begin{equation*}
\hat{H}=\frac{\hat{p}^{2}}{2 m}=-\frac{\hbar^{2}}{2 m} \nabla^{2}, \tag{1.27a}
\end{equation*}
$$

Free
particle's Hamiltonian
so that, taking into account Eq. (26b), in the Cartesian coordinates,

$$
\begin{equation*}
\hat{H}=-\frac{\hbar^{2}}{2 m}\left(\frac{\partial^{2}}{\partial x^{2}}+\frac{\partial^{2}}{\partial y^{2}}+\frac{\partial^{2}}{\partial z^{2}}\right) \tag{1.27b}
\end{equation*}
$$

Even before a discussion of physics of the postulates (offered in the next section), we may immediately see that they indeed provide a way toward the resolution of the apparent contradiction between the wave and corpuscular properties of particles. For a free particle, the Schrödinger equation (25), with the substitution of Eq. (27), takes the form

$$
\begin{equation*}
i \hbar \frac{\partial \Psi}{\partial t}=-\frac{\hbar^{2}}{2 m} \nabla^{2} \Psi \tag{1.28}
\end{equation*}
$$

whose particular (but most important) solution is a plane, monochromatic wave, ${ }^{29}$

$$
\begin{equation*}
\Psi(\mathbf{r}, t)=a e^{i(\mathbf{k} \cdot \mathbf{r}-\omega t)} \tag{1.29}
\end{equation*}
$$

[^461]where $a$, $\mathbf{k}$ and $\omega$ are constants. Indeed, plugging Eq. (29) into Eq. (28), we immediately see the plane wave, with an arbitrary amplitude $a$, is indeed a solution of the Schrödinger equation, provided a specific dispersion relation between wavevector $\mathbf{k}$ and frequency $\omega$ :
\[

$$
\begin{equation*}
\hbar \omega=\frac{(\hbar k)^{2}}{2 m} \tag{1.30}
\end{equation*}
$$

\]

Constant $a$ may be calculated, for example, assuming that solution (29) is extended over a certain volume $V$, while beyond it, $\Psi=0$. Then from the normalization condition (22c) and Eq. (29), we get ${ }^{30}$

$$
\begin{equation*}
|a|^{2} V=1 \tag{1.31}
\end{equation*}
$$

Now we can use Eqs. (23), (26) and (27) to calculate the expectation value of particle's momentum $\mathbf{p}$ and energy $E$ (which, for a free particle, coincides with its Hamiltonian function $H$ ), The result is

$$
\begin{equation*}
\langle\mathbf{p}\rangle=\hbar \mathbf{k}, \quad\langle E\rangle=\langle H\rangle=\frac{(\hbar k)^{2}}{2 m} \tag{1.32}
\end{equation*}
$$

according to Eq. (30), the last equality may be rewritten as $\langle E\rangle=\hbar \omega$.
Next, Eq. (23) enables one to calculate not only the statistical average (in the math speak, the first moment) of an observable, but also its higher moments, notably the second moment (in physics, usually called either the variance or dispersion):

$$
\begin{equation*}
\left\langle\widetilde{A}^{2}\right\rangle \equiv\left\langle(A-\langle A\rangle)^{2}\right\rangle=\left\langle A^{2}\right\rangle-\langle A\rangle^{2}, \tag{1.33}
\end{equation*}
$$

and hence its root mean square (r.m.s.) fluctuation,

$$
\begin{equation*}
\delta A \equiv\left\langle\tilde{A}^{2}\right\rangle^{1 / 2} \tag{1.34}
\end{equation*}
$$

Observable's variance
that characterizes the scale of deviations $\widetilde{A} \equiv A-\langle A\rangle$ of measurement results from the average, i.e. the uncertainty of observable $A$. In application to wavefunction (29), these relations yield $\delta E=0, \delta \mathbf{p}=0$, while the particle coordinate $\mathbf{r}($ at $V \rightarrow \infty)$ is completely uncertain. This means that in the plane-wave, monochromatic state (29), the energy and momentum of the particle are exactly defined, so that the signs of statistical average in Eqs. (32) might be removed. Thus, these relations are reduced to the experimentally-inferred Eqs. (5) and (15), though the relation of frequency $\omega$ of wavefunction's evolution in time to experimental observations still has to be clarified.

Hence the wave mechanics postulates may indeed explain the observed wave properties of nonrelativistic particles. (For photons, we would need a relativistic formalism - see Ch. 9 below.) On the other hand, due to the linearity of the Schrödinger equation (25), any sum of its solutions is also a solution - the so-called linear superposition principle. For a free particle, this means that a set of plane waves (29) is also a solution of this equation. Such sets, with close values of $\mathbf{k}$ and hence $\mathbf{p}=\hbar \mathbf{k}$ (and, according to Eq. (30), of $\omega$ as well), may be used to describe spatially localized "pulses", called wave packets - see Fig. 6. In Sec. 2.1, I will prove (or rather reproduce H. Weyl's proof :-) that the wave

[^462]packet extension $\delta x$ in any direction (say, $x$ ) is related to the width $\delta k_{x}$ of the corresponding component of its wave vector distribution as $\delta x \delta k_{x} \geq 1 / 2$, and hence, according to Eq. (15), to the width $\delta p_{x}$ of the momentum component distribution as
 relation
\[

$$
\begin{equation*}
\delta x \cdot \delta p_{x} \geq \frac{\hbar}{2} \tag{1.35}
\end{equation*}
$$

\]

(b)

Fig. 1.6. (a) Snapshot of a typical wave packet propagating along axis $x$, and (b) the corresponding distribution of wave numbers $k_{x}$, i.e. momenta $p_{x}$.

This is the famous the famous Heisenberg's uncertainty principle, which quantifies the first postulate's point that coordinate and momentum cannot be defined exactly simultaneously. However, since the Planck's constant is extremely small on the human scale of things, it still allows for the particle's localization in a very small volume even if the momentum spread in the wave packet is also small on that scale. For example, according to Eq. (35), a $0.1 \%$ spread of momentum of a 1 keV electron ( $p \sim 1.7 \times 10^{-24} \mathrm{~kg} \cdot \mathrm{~m} / \mathrm{s}$ ) allows a wave packet to be as small as $\sim 3 \times 10^{-10} \mathrm{~m}$. (For a heavier particle such as a proton, the packet would be even tighter.) As a result, wave packets may be used to describe particles that are point-like from the macroscopic point of view.

In a nutshell, this is the main idea of the wave mechanics, and the first part of this course (Chapters 1-3) will be essentially a discussion of various manifestations of this approach. During this discussion, we will not only evidence wave mechanics' many triumphs within its applicability domain, but will also gradually accumulate evidence for its handicaps, which force the eventual transfer to a more general formalism - to be discussed in Chapter 4 and beyond.

### 1.3. Postulates' discussion

The postulates listed in the previous section look very simple, and they are hopefully familiar to the reader from his or her undergraduate studies. However, the physics of these axioms are very deep, they lead to several counter-intuitive conclusions, and their in-depth discussion requires solutions of several key problems using these axioms. This is why in this section I will give only an initial, admittedly superficial discussion of the postulates, and will be repeatedly returning to the conceptual foundations of quantum mechanics throughout the course, especially in Secs. 7.7, 10.1, and 10.2.

First of all, the fundamental uncertainty of observables, which is in the core of postulate (i), is very foreign to the basic ideas of classical mechanics, and historically has made quantum mechanics so hard to swallow for many star physicists, notably including A. Einstein - despite his 1905 work which essentially launched the whole field! However, this fact has been confirmed by numerous experiments,
and (more importantly) there have not been a single confirmed experiment which would contradict to this postulate, so that quantum mechanics was long ago promoted from a theoretical hypothesis to the rank of a reliable scientific theory.

One more remark in this context is that Eq. (25) itself is deterministic, i.e. conceptually enables an exact calculation of wavefunction's distribution in space at any instant $t$, provided that its initial distribution, and particle's Hamiltonian, are known exactly. In classical kinetics, the probability density distribution $w(\mathbf{r}, t)$ may be also calculated from deterministic differential equations, e.g., the FokkerPlanck equation or the Boltzmann equation. ${ }^{31}$ The quantum-mechanical description differs from those situations in two important aspects. First, in the perfect conditions outlined above (exact initial state preparation, no irreversible interaction with environment, the best possible measurement), the FokkerPlanck equation reduces to the $2^{\text {nd }}$ Newton law, i.e. the statistical uncertainty disappears. In quantum mechanics this is not true: the quantum uncertainly, such as Eq. (35), persists even in this limit. Second, the wavefunction $\Psi(\mathbf{r}, t)$ gives more information than just $w(\mathbf{r}, t)$, because besides the modulus of $\Psi$, involved in Eq. (22), this complex function also has phase $\varphi \equiv \arg \Psi$, and may affect some observables, describing, in particular, the interference and diffraction of the de Broglie waves.

Next, it is very important to understand that the relation between the quantum mechanics to experiment, given by postulate (ii), necessarily involves another key notion: that of the corresponding statistical ensemble. Such ensemble may be defined as a set of many experiments carried out at apparently (macroscopically) similar conditions, which nevertheless may lead to different measurement results (outcomes). Indeed, the probability of a certain ( $n$-th) outcome of an experiment may be only defined for a certain ensemble, as the limit

$$
\begin{equation*}
W_{n} \equiv \lim _{M \rightarrow \infty} \frac{M_{n}}{M}, \quad \text { with } M \equiv \sum_{n=1}^{N} M_{n} \tag{1.36}
\end{equation*}
$$

where $M$ is the total number of experiments, $M_{n}$ is the number of outcomes of the $n$-th type, and $N$ is the number of different outcomes. It is clear that a particular choice of an ensemble may affect probabilities $W_{n}$ very significantly.

For example, if we pull out playing cards at random from a pack of 52 different cards of 4 suits, the probability $W_{n}$ of getting a certain card (e.g., the queen of spades) is $1 / 52$. However, if cards of a certain suit (say, hearts) had been taken out from the pack in advance, the probability of getting the queen of spades is higher, $1 / 39$. It is important that we would also get the last number for probability even if we had used the full 52 -card pack, but by some reason ignored results of all experiments giving us any rank of hearts.

Similarly, in quantum mechanics, the probability distributions (and hence expectation values of particle coordinate and other observables) depend not only on the experiment setup, but also on the set of outcomes we count. Because of the fundamental relation (22) between $w$ and $\Psi$, this means the wavefunction also depends on those factors, i.e. on both the experiment set preparation and the subset of outcomes taken into account. The insistence on the attribution of the wavefunction to a single experiment, both before and after the measurement, may lead to very unphysical interpretations of some experiments, including wavefunction's evolution not described by the Schrödinger equation (the socalled wave packet reduction), subluminal action on distance, etc. Later in the course we will see that minding the statistical nature of the quantum mechanics, and in particular the dependence of the

[^463]wavefunction on statistical ensemble's specification, may readily explain some apparent paradoxes of quantum measurements.

Let me also emphasize that statistics is intimately related to the information theory - and not only via their common mathematical background, the probability theory. For example, the question, "What subset of experimental results we will count?" may be replaced by the question, "What subset of results will we use information about?" As a result, the reader has to be prepared to the use of information theory notions for the discussion quantum mechanics, or at least its relation to experiment - i.e. to the "physical reality". This feature of quantum mechanics makes some physicists uncomfortable, because much of classical mechanics and electrodynamics may be discussed without any reference to information. In quantum mechanics (as in statistical mechanics), such an abstraction is impossible.

Proceeding to postulate (ii) and in particular Eq. (23), a better feeling of this definition may be obtained by its comparison with the general definition of the expectation value (i.e. the statistical average) in the probability theory. Namely, let each of $N$ possible outcomes in a set of $M$ macroscopically similar experiments give a certain value $A_{n}$ of observable $A$; then

Definition of statistical average

$$
\begin{equation*}
\langle A\rangle \equiv \lim _{M \rightarrow \infty} \frac{1}{M} \sum_{n=1}^{N} A_{n} M_{n}=\sum_{n=1}^{N} A_{n} W_{n} . \tag{1.37}
\end{equation*}
$$

Taking into account Eq. (22), which relates $W$ and $\Psi$, the structure of Eq. (23) and the final form of Eq. (37) is similar. Their exact relation will be further discussed in Sec. 4.1.

### 1.4. Continuity equation

The wave mechanics postulates survive one more sanity check: they satisfy the natural requirement that the particle does not appear or vanish in the course of the quantum evolution. ${ }^{32}$ Indeed, let us use Eq. (22) to calculate the rate of change of the probability $W$ to find the particle within a certain volume $V$ :

$$
\begin{equation*}
\frac{d W}{d t}=\frac{d}{d t} \int_{V} \Psi \Psi^{*} d^{3} r \tag{1.38}
\end{equation*}
$$

Assuming for simplicity that the boundaries of volume $V$ do not move, it is sufficient to carry out the partial differentiation of the product $\Psi \Psi^{*}$ inside the integral. Using the time-dependent Schrödinger equation (25), together with its complex conjugate,

$$
\begin{equation*}
-i \hbar \frac{\partial \Psi^{*}}{\partial t}=(\hat{H} \Psi)^{*} \tag{1.39}
\end{equation*}
$$

we get

$$
\begin{equation*}
\frac{d W}{d t}=\int_{V} \frac{\partial}{\partial t}\left(\Psi \Psi^{*}\right) d^{3} r=\int_{V}\left(\Psi^{*} \frac{\partial \Psi}{\partial t}+\Psi \frac{\partial \Psi^{*}}{\partial t}\right) d^{3} r=\frac{1}{i \hbar} \int_{V}\left[\Psi^{*}(\hat{H} \Psi)-\Psi(\hat{H} \Psi)^{*}\right] d^{3} r . \tag{1.40}
\end{equation*}
$$

[^464]Let the particle move in a field of external forces (not necessarily constant in time), so that its classical Hamiltonian function $H$ is a sum of particle's kinetic energy $p^{2} / 2 m$ and its potential energy $U(\mathbf{r}$, $t) .{ }^{33}$ According to the correspondence principle, the Hamiltonian operator may be presented as the sum ${ }^{34,}$

$$
\begin{equation*}
\hat{H}=\frac{\hat{p}^{2}}{2 m}+U(\mathbf{r}, t)=-\frac{\hbar^{2}}{2 m} \nabla^{2}+U(\mathbf{r}, t) \tag{1.41}
\end{equation*}
$$

At this stage we should notice that such operator, when acting on a real function, returns a real function. ${ }^{35}$ Hence, the result of its action on an arbitrary complex function $\Psi=a+i b$ (where $a$ and $b$ are real) is

$$
\begin{equation*}
\hat{H} \Psi=\hat{H}(a+i b)=\hat{H} a+i \hat{H} b \tag{1.42}
\end{equation*}
$$

where $\hat{H} a$ and $\hat{H} b$ are also real, while

$$
\begin{equation*}
(\hat{H} \Psi)^{*}=(\hat{H} a+i \hat{H} b)^{*}=\hat{H} a-i \hat{H} b=\hat{H}(a-i b)=\hat{H} \Psi^{*} . \tag{1.43}
\end{equation*}
$$

This means that Eq. (40) may be rewritten as

$$
\begin{equation*}
\frac{d W}{d t}=\frac{1}{i \hbar} \int_{V}\left[\Psi^{*} \hat{H} \Psi-\Psi \hat{H} \Psi^{*}\right] d^{3} r=-\frac{\hbar^{2}}{2 m} \frac{1}{i \hbar} \int_{V}\left[\Psi^{*} \nabla^{2} \Psi-\Psi \nabla^{2} \Psi^{*}\right] d^{3} r \tag{1.44}
\end{equation*}
$$

Now, let us use general rules of vector calculus ${ }^{36}$ to write the following identity:

$$
\begin{equation*}
\nabla \cdot\left(\Psi^{*} \nabla \Psi-\Psi \nabla \Psi^{*}\right)=\Psi^{*} \nabla^{2} \Psi-\Psi \nabla^{2} \Psi^{*} \tag{1.45}
\end{equation*}
$$

A comparison of Eqs. (44) and (45) shows that we may write

$$
\begin{equation*}
\frac{d W}{d t}=-\int_{V}(\nabla \cdot \mathbf{j}) d^{3} r \tag{1.46}
\end{equation*}
$$

where vector $\mathbf{j}$ is defined as

$$
\begin{equation*}
\mathbf{j} \equiv \frac{i \hbar}{2 m}\left(\Psi \nabla \Psi^{*}-\text { c.c. }\right)=\frac{\hbar}{m} \operatorname{Im}\left(\Psi^{*} \nabla \Psi\right), \tag{1.47}
\end{equation*}
$$

Probability
current density

[^465]Hamiltonian of a particle in a field
where $j_{n}$ is the projection of vector $\mathbf{j}$ on the outwardly directed normal to surface $S$ that limits volume $V$, i.e. the scalar product $\mathbf{j} \cdot \mathbf{n}$, where $\mathbf{n}$ is the unit vector along this normal.

Equations (47) and (48) show that if the wavefunction on the surface vanishes, the total probability $W$ of finding the particle within the volume does not change, providing the required sanity check. In the general case, Eq. (48) says that $d W / d t$ equals to flux $I$ of vector $\mathbf{j}$ through the surface, with the minus sign. It is clear that this vector may be interpreted as the probability current density - and $I$, as the total probability current through surface $S$. This interpretation may be further supported by rewriting Eq. (47) for a wavefunction presented in the polar form $\Psi=a e^{i \varphi}$, with real $a$ and $\varphi$ :

$$
\begin{equation*}
\mathbf{j}=a^{2} \frac{\hbar}{m} \nabla \varphi \tag{1.49}
\end{equation*}
$$

- evidently a real quantity. Note that for a real wavefunction, or even for that with an arbitrary but spaceconstant phase $\varphi$, the probability current density vanishes. On the contrary, for the traveling wave (29), with a constant probability density $w=a^{2}$, Eq. (49) yields a nonvanishing (and physically very transparent) result:

$$
\begin{equation*}
\mathbf{j}=w \frac{\hbar}{m} \mathbf{k}=w \frac{\mathbf{p}}{m}=w \mathbf{v} \tag{1.50}
\end{equation*}
$$

where $\mathbf{v}=\mathbf{p} / m$ is particle's velocity. If multiplied by the particle's mass $m$, the probability density $w$ turns into the (average) mass density $\rho$, and the probability current density into the mass flux density $\rho \mathbf{v}$, while if multiplied by the total electric charge $q$ of the particle, with $w$ turning into the charge density $\sigma$, j becomes the electric current density, both satisfying the classical continuity equations similar to Eq. (48). ${ }^{38}$

Finally, let us recast the continuity equation, rewriting Eq. (46) as

$$
\begin{equation*}
\int_{V}\left(\frac{\partial w}{\partial t}+\nabla \cdot \mathbf{j}\right) d^{3} r=0 \tag{1.51}
\end{equation*}
$$

Now we may argue that this equality may is true for any choice of volume $V$ only if the expression under the integral vanishes everywhere, i.e. if

$$
\begin{equation*}
\frac{\partial w}{\partial t}+\nabla \cdot \mathbf{j}=0 \tag{1.52}
\end{equation*}
$$

This differential form of the continuity equation is sometimes more convenient than its integral form (48).

### 1.5. Eigenstates and eigenvalues

Now let us discuss important corollaries of wave mechanics' linearity. First of all, it uses only linear operators. This term means that the operators must obey the following two rules: ${ }^{39}$

[^466]\[

$$
\begin{gather*}
\left(\hat{A}_{1}+\hat{A}_{2}\right) \Psi=\hat{A}_{1} \Psi+\hat{A}_{2} \Psi  \tag{1.53}\\
\hat{A}\left(c_{1} \Psi_{1}+c_{2} \Psi_{2}\right)=\hat{A}\left(c_{1} \Psi_{1}\right)+\hat{A}\left(c_{2} \Psi_{2}\right)=c_{1} \hat{A} \Psi_{1}+c_{2} \hat{A} \Psi_{2} \tag{1.54}
\end{gather*}
$$
\]

where $\Psi_{n}$ are arbitrary wavefunctions, while $c_{n}$ are arbitrary constants (in quantum mechanics, frequently called c-numbers, to distinguish them from operators and wavefunctions). Most important examples of linear operators are given by:
(i) the multiplication by a function, such as for operator $\hat{\mathbf{r}}$ in wave mechanics, and
(ii) the spatial or temporal differentiation of the wavefunction, such as in Eqs. (25)-(27).

Next, it is of key importance that the Schrödinger equation (25) is also linear. (We have already used this fact when we discussed wave packets in the last section.) This means that if each of functions $\Psi_{n}$ are (particular) solutions of Eq. (25) with a certain Hamiltonian, then an arbitrary linear combination

$$
\begin{equation*}
\Psi=\sum_{n} c_{n} \Psi_{n} \tag{1.55}
\end{equation*}
$$

is also a solution of the same equation. ${ }^{40}$
Now let us use the linearity of wave mechanics to accomplish an apparently impossible feat: immediately find the general solution to the Schrödinger equation for the most important case when system's Hamiltonian does not depend on time explicitly - for example, like in Eq. (27), or in Eq. (41) with time-independent $U=U(\mathbf{r})$. First of all, let us prove that the following product,

$$
\Psi_{n}=T_{n}(t) \psi_{n}(\mathbf{r}),
$$

qualifies as a (particular) solution to the Schrödinger equation. Indeed, plugging Eq. (56) into Eq. (25), using the fact that for a time-independent Hamiltonian

$$
\begin{equation*}
\hat{H} T_{n}(t) \psi_{n}(\mathbf{r})=T_{n}(t) \hat{H} \psi_{n}(\mathbf{r}), \tag{1.57}
\end{equation*}
$$

and dividing both parts of the equation by $\Psi_{n}=T_{n} \psi_{n}$, we get

$$
\begin{equation*}
\frac{i \hbar \dot{T}_{n}}{T_{n}}=\frac{\hat{H} \psi_{n}}{\psi_{n}} \tag{1.58}
\end{equation*}
$$

where (here and below) the dot denotes the differentiation over time. The left hand side of this equation may depend only on time, while the right hand one, only on coordinates. These facts may be only reconciled if we assume that each of these parts is equal to (the same) constant of the dimension of energy, which I will denote as $E_{n} .{ }^{41}$ As a result, we are getting two separate equations for the temporal and spatial parts of the wavefunction:

$$
\begin{equation*}
i \hbar \dot{T}_{n}=E_{n} T_{n} \tag{1.59}
\end{equation*}
$$

[^467]Stationary
Schrödinger equation

Stationary state:
evolution

$$
\begin{equation*}
\hat{H} \psi_{n}=E_{n} \psi_{n} \tag{1.60}
\end{equation*}
$$

The first of these equations is readily integrable, giving

$$
\begin{equation*}
T_{n}=\text { const } \times \exp \left\{-i \omega_{n} t\right\}, \quad \text { with } \omega_{n} \equiv \frac{E_{n}}{\hbar}, \tag{1.61}
\end{equation*}
$$

and thus substantiating the fundamental relation (5) between energy and frequency. Plugging Eqs. (56) and (61) into Eq. (22), we see that in such a state, the probability $w$ of finding the particle at a certain location does not depend on time. Doing the same with Eq. (23) shows that the same is true for the expectation value of any operator that does not depend on time explicitly:

$$
\begin{equation*}
\langle A\rangle_{n} \equiv \int \psi_{n}^{*} \hat{A} \psi_{n} d^{3} r=\text { const. } \tag{1.62}
\end{equation*}
$$

Due to this property, the states described by Eqs. (56), (60), and (61), are called stationary. In contrast to the simple and universal time dependence (61), the spatial distributions $\psi_{n}(\mathbf{r})$ of the stationary states are often hard to find, and the solution of the stationary (or "time-independent") Schrödinger equation (60), ${ }^{42}$ which describes the distributions, for various situations is a major focus of wave mechanics.

The stationary Schrödinger equation (60), with time-independent Hamiltonian (41),

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m} \nabla^{2} \psi_{n}+U(\mathbf{r}) \psi_{n}=E_{n} \psi_{n} \tag{1.63}
\end{equation*}
$$

falls into the mathematical category of linear eigenproblems, ${ }^{43}$ in which eigenfunctions $\psi_{n}$ and eigenvalues $E_{n}$ should be found simultaneously - self-consistently. ${ }^{44}$ Mathematics tells us that for the such problems with space-confined eigenfunctions $\psi_{n}$, tending to zero at $r \rightarrow \infty$, the spectrum of eigenvalues is discrete. It also proves that the eigenfunctions corresponding to different eigenvalues are orthogonal, i.e. that space integrals of the products $\psi_{n} \psi^{*}{ }_{n}$, vanish for all pairs with $n \neq n^{\prime}$. Moreover, due to the Schrödinger equation linearity, each of these functions may be multiplied by a constant coefficient to make this set orthonormal:

$$
\int \psi_{n}^{*} \psi_{n^{\prime}} d^{3} r=\delta_{n, n^{\prime}} \equiv \begin{cases}1, & \text { if } n=n^{\prime}  \tag{1.64}\\ 0, & \text { if } n \neq n^{\prime}\end{cases}
$$

Also, the eigenfunctions form a full set, meaning that an arbitrary function $\psi(\mathbf{r})$, in particular the actual wavefunction $\Psi$ of the system in the initial moment of its evolution (which I will take for $t=0$, with a few exceptions), may be presented as a unique expansion over the eigenfunction set:

$$
\begin{equation*}
\Psi(\mathbf{r}, 0)=\sum_{n} c_{n} \psi_{n}(\mathbf{r}) \tag{1.65}
\end{equation*}
$$

The expansion coefficients $c_{k}$ may be readily found by multiplying both parts of Eq. (65) by $\psi^{*}{ }_{n}$, integrating the result over the space, and using Eq. (64). The result is

[^468]\[

$$
\begin{equation*}
c_{n}=\int \psi_{n}^{*}(\mathbf{r}) \Psi(\mathbf{r}, 0) d^{3} r . \tag{1.66}
\end{equation*}
$$

\]

Now let us consider the following wavefunction

$$
\begin{equation*}
\Psi(\mathbf{r}, t)=\sum_{n} c_{n} a_{k}(t) \psi_{k}(\mathbf{r})=\sum_{n} c_{n} \psi_{n}(\mathbf{r}) \exp \left\{-i \frac{E_{n}}{\hbar} t\right\} \tag{1.67}
\end{equation*}
$$

Since each term of the sum has the form (56) and satisfies the Schrödinger equation, so does the sum as the whole. Moreover, if coefficients $c_{n}$ are derived in accordance with Eq. (66), then solution (67) satisfies the initial conditions as well. At this moment we can again use one more help by mathematicians who tell us that the partial differential equation of type (28) with the Hamiltonian operator (41) with fixed initial conditions, may have only one (unique) solution. This means that in our case of motion in a time-independent potential $U=U(\mathbf{r})$, Eq. (67) gives the general solution of the timedependent Schrödinger equation (25) for our case:

$$
\begin{equation*}
i \hbar \frac{\partial \Psi}{\partial t}=-\frac{\hbar^{2}}{2 m} \nabla^{2} \Psi+U(\mathbf{r}) \Psi . \tag{1.68}
\end{equation*}
$$

We will repeatedly use this key fact through the course, though in many cases, following the physical sense of particular problems, will be more interested in certain specific particular solutions of Eq. (68) rather in the whole linear superposition (67).

In order to get some feeling of functions $\psi_{n}$, let us consider perhaps the simplest example, which nevertheless will be the basis for discussion of many less trivial problems: a particle confined in a rectangular quantum well 45 with a flat "bottom" and sharp and infinitely high "hard walls":

The only way to keep the product $U \psi_{n}$ in Eq. (68) finite outside the well, is to have $\psi=0$ in these regions. Also, the function have to be continuous everywhere, to avoid the divergence of its Laplace operator. Hence, we may solve the stationary Schrödinger equation (63) only inside the well, where it takes a simple form ${ }^{46}$

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m} \nabla^{2} \psi_{n}=E_{n} \psi_{n}, \tag{1.70a}
\end{equation*}
$$

with zero boundary conditions on all the walls. For our particular geometry, it is natural to express the Laplace operator in the Cartesian coordinates $\{x, y, z\}$ aligned with the well sides, so that we get the following boundary problem:

[^469]\[

$$
\begin{gather*}
-\frac{\hbar^{2}}{2 m}\left(\frac{\partial^{2}}{\partial x^{2}}+\frac{\partial^{2}}{\partial y^{2}}+\frac{\partial^{2}}{\partial z^{2}}\right) \psi_{n}=E_{n} \psi_{n}, \quad \text { for } 0<x<a_{x}, 0<y<a_{y}, \text { and } 0<z<a_{z}  \tag{1.70b}\\
\psi_{n}=0, \quad \text { for } x=0 \text { and } a_{x} ; \quad y=0 \text { and } a_{y} ; \quad z=0 \text { and } a_{z} .
\end{gather*}
$$
\]

This problem may be readily solved using the same variable separation method which was used earlier in this section to separate the spatial and temporal variables, now to separate Cartesian spatial variables from each other. Let us look for a particular solution in the form

$$
\begin{equation*}
\psi(\mathbf{r})=X(x) Y(y) Z(z) . \tag{1.71}
\end{equation*}
$$

(It is convenient to postpone taking care of proper indices for a minute.) Plugging this expression into the Eq. (70b) and dividing by $\psi=X Y Z$, we get

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m}\left(\frac{1}{X} \frac{d^{2} X}{d x^{2}}+\frac{1}{Y} \frac{d^{2} Y}{d y^{2}}+\frac{1}{Z} \frac{d^{2} Z}{d z^{2}}\right)=E . \tag{1.72}
\end{equation*}
$$

Now let us repeat the standard argumentation of the variable separation method: since each term in the parentheses may be only a function of the corresponding argument, the equality is possible only if each term is a constant - with the dimensionality of energy. Calling them $E_{x}$, etc., we get three 1D equations

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m} \frac{1}{X} \frac{d^{2} X}{d x^{2}}=E_{x}, \quad-\frac{\hbar^{2}}{2 m} \frac{1}{Y} \frac{d^{2} Y}{d y^{2}}=E_{y}, \quad-\frac{\hbar^{2}}{2 m} \frac{1}{Z} \frac{d^{2} Z}{d x^{2}}=E_{z}, \tag{1.73}
\end{equation*}
$$

with Eq. (72) turning into the energy-matching condition

$$
\begin{equation*}
E_{x}+E_{y}+E_{z}=E . \tag{1.74}
\end{equation*}
$$

All three ordinary differential equations (73), and their solutions, are similar. For example, for $X(x)$, we have a 1D Helmholtz equation

$$
\begin{equation*}
\frac{d^{2} X}{d x^{2}}+k_{x}^{2} X=0, \quad \text { with } k_{x}^{2} \equiv \frac{2 m E_{x}}{\hbar^{2}}, \tag{1.75}
\end{equation*}
$$

and simple boundary conditions: $X(0)=X\left(a_{x}\right)=0$. Let me hope that the reader knows how to solve this well-known 1D boundary problem - describing, for example, usual mechanical waves on a guitar string, though with a very much different expression for $k_{x}$. The problem allows an infinite number of sinusoidal standing-wave solutions, ${ }^{47}$

Rectangular quantum well: partial eigenfunctions

$$
\begin{equation*}
X=\left(\frac{2}{a_{x}}\right)^{1 / 2} \sin k_{x} x=\left(\frac{2}{a_{x}}\right)^{1 / 2} \sin \frac{\pi n_{x} x}{a_{x}}, \text { with } n_{x}=1,2, \ldots \tag{1.76}
\end{equation*}
$$

corresponding to eigenenergies

$$
\begin{equation*}
E_{x}=\frac{\hbar^{2}}{2 m} k_{x}^{2}=\frac{\pi^{2} \hbar^{2}}{2 m a_{x}^{2}} n_{x}^{2} \equiv E_{x 1} n_{x}^{2} \tag{1.77}
\end{equation*}
$$

[^470]Figure 7 shows this result using a somewhat odd but very graphic and hence common way when the eigenenergy values (frequently called energy levels) are used as horizontal axes for plotting eigenfunctions, despite their different dimensionality.

Due to the similarity of all Eqs. (73), $Y(y)$ and $Z(z)$ are similar functions of their arguments, and may also be numbered by integers (say, $n_{y}$ and $n_{z}$ ) independent of $n_{x}$, so that the spectrum of the total energy (74) is

$$
\begin{equation*}
E_{n_{x}, n_{y}, n_{z}}=\frac{\pi^{2} \hbar^{2}}{2 m}\left(\frac{n_{x}^{2}}{a_{x}^{2}}+\frac{n_{y}^{2}}{a_{y}^{2}}+\frac{n_{z}^{2}}{a_{z}^{2}}\right) . \tag{1.78}
\end{equation*}
$$

Fig. 1.7. Eigenfunctions (solid lines) and eigenvalues (dashed lines) of the 1D wave equation (75) on a finitelength segment. Solid black lines show the potential energy profile of the problem.

Thus, in this 3D problem, the role of index $n$ in Eq. (67) is played by a set of 3 independent integers $\left\{n_{x}, n_{y}, n_{z}\right\}$. In quantum mechanics, such integers play a key role, and thus have a special name, quantum numbers. Now the general solution (67) of our simple problem may be presented as the sum

$$
\begin{equation*}
\Psi(\mathbf{r}, t)=\sum_{n_{x}, n_{y}, n_{z}=1}^{\infty} c_{n_{x}, n_{y}, n_{z}} \sin \frac{\pi n_{x} x}{a_{x}} \sin \frac{\pi n_{y} y}{a_{y}} \sin \frac{\pi n_{z} z}{a_{z}} \exp \left\{-i \frac{E_{n_{x}, n_{y}, n_{z}}^{\hbar}}{\hbar} t\right\} \tag{1.79}
\end{equation*}
$$

with the coefficients which may be readily calculated from the initial wavefunction $\Psi(\mathbf{r}, 0)$, using Eq. (66), again with the replacement $n \rightarrow\left\{n_{x}, n_{y}, n_{z}\right\}$. This simplest problem is a good illustration of the basic features of wave mechanics for a spatially-confined motion, including the discrete energy spectrum, and (in this case, evidently) orthogonal eigenfunctions.

An example of the opposite limit of a continuous spectrum for unconfined motion of a free particle is given by plane waves (29) which, with the account of relations $E=\hbar \omega$ and $\mathbf{p}=\hbar \mathbf{k}$, may be viewed as the product of the time-dependent factor (46) by eigenfunction

$$
\begin{equation*}
\psi_{\mathbf{k}}=a_{\mathbf{k}} \exp \{i \mathbf{k} \cdot \mathbf{r}\} \tag{1.80}
\end{equation*}
$$

Rectangular quantum well: general solution
I-2
that is the solution to the stationary Schrödinger equation (70a) if it is valid in the whole space. ${ }^{48}$
The reader should not be worried too much by the fact that the fundamental solution (80) in free space is a traveling wave (having, in particular, nonvanishing value (50) of the probability current $\mathbf{j}$ ),

[^471]while those inside a quantum well are standing waves, with $\mathbf{j}=0$, even though the free space may be legitimately considered as the ultimate limit of a quantum well with volume $V=a_{x} a_{y} a_{z} \rightarrow \infty$. Indeed, due to the linearity of wave mechanics, two traveling-wave solutions (80) with equal and opposite values of momentum (and hence with the same energy) may be readily combined to give a standingwave solution, for example $\exp \{i \mathbf{k} \cdot \mathbf{r}\}+\exp \{-i \mathbf{k} \cdot \mathbf{r}\}=2 \cos (\mathbf{k} \cdot \mathbf{r})$, with the net current $\mathbf{j}=0$. Thus, depending on convenience for solution of a particular problem, we can present the general solution as a sum of either traveling-wave or standing-wave eigenfunctions.

Since in the free space there are no boundary conditions to satisfy, Cartesian components of the wave vector $\mathbf{k}$ in Eq. (80) can take any real values. (This is why it is more convenient to label the wavefunctions and eigenenergies,
 eigenenergies
 of states

$$
\begin{equation*}
E_{\mathbf{k}}=\frac{\hbar^{2} k^{2}}{2 m} \geq 0 \tag{1.81}
\end{equation*}
$$

by their wave vector $\mathbf{k}$ rather than an integer index.) However, one aspect of systems with continuous spectrum requires a bit more math caution: summation (67) should be replaced by integration over a continuous index or indices (in this case, 3 components of vector $\mathbf{k}$ ). The main rule of such replacement may be readily extracted from Eq. (76): according to this relation, for standing-wave solutions, the eigenvalues of $k_{x}$ are equidistant, i.e. separated by equal intervals $\Delta k_{x}=\pi / a_{x}$ (with the similar relations for other two Cartesian components of vector $\mathbf{k}$ ). Hence the number of different eigenvalues of the standing wave vector $\mathbf{k}$ (with $k_{x}, k_{y}, k_{z} \geq 0$ ), within a volume $d^{3} k \gg 1 / V$ of the $\mathbf{k}$ space is just $d N=$ $d^{3} k /\left(\Delta k_{x} \Delta k_{x} \Delta k_{x}\right)=V / \pi^{3}$. Since in continuum it is more convenient to work with traveling waves, we should take into account that, as was just discussed, there are two different traveling wave vectors ( $\mathbf{k}$ and $\mathbf{k}^{\prime}=-\mathbf{k}$ ) corresponding to each standing wave vector $\mathbf{k}$. Hence the same number of physically different states corresponds to $2^{3}=8$-fold larger $\mathbf{k}$ space (which now is infinite in all directions) or, equivalently, to a smaller number of states per unit volume $d^{3} k$ :

$$
\begin{equation*}
d N=\frac{V}{(2 \pi)^{3}} d^{3} k \tag{1.82}
\end{equation*}
$$

For $d N \gg 1$, this expression is independent on the boundary conditions, ${ }^{49}$ and is frequently presented as the following summation rule

$$
\begin{equation*}
\lim _{k^{3} V \rightarrow \infty} \sum_{\mathbf{k}} f(\mathbf{k})=\int f(\mathbf{k}) d N=\frac{V}{(2 \pi)^{3}} \int f(\mathbf{k}) d^{3} k \tag{1.83}
\end{equation*}
$$

where $f(\mathbf{k})$ is an arbitrary function of $\mathbf{k}$. This rule is very important for statistical physics. Note also that if the same wave vector $\mathbf{k}$ corresponds to several internal quantum states (such as spin - see Chapter 4), the right-hand part of Eq. (83) requires multiplication by the corresponding degeneracy factor.

### 1.6. Dimensionality reduction

To conclude this introductory chapter, let me discuss the conditions when the spatial dimensionality of a wave mechanics problem may be reduced. ${ }^{50}$ For example, following our discussion

[^472]of the 3D rectangular, flat-bottom quantum well in Sec. 5, let us consider an infinitely deep quantum well whose bottom is flat only in one direction, say $z$ :
\[

U(\mathbf{r})=\left\{$$
\begin{array}{lr}
U(x, y), & \text { for } 0<z<a_{z}  \tag{1.84}\\
+\infty, & \text { otherwize }
\end{array}
$$\right.
\]

In this case, we can separate variables only partly, by presenting the eigenfunction as $\psi(x, y) Z(z)$. Plugging such solution into the corresponding form of the stationary Schrödinger equation (63), we see that functions $Z(z)$ are again similar to those given by Eq. (76), while function $\psi(x, y)$ satisfies the following 2D stationary Schrödinger equation:
$-\frac{\hbar^{2}}{2 m} \nabla_{x, y}^{2} \psi+U_{\text {ef }}(x, y) \psi=E_{x, y} \psi$,
where

$$
\begin{equation*}
U_{\mathrm{ef}}(x, y) \equiv U(x, y)+E_{z}=U(x, y)+\frac{\pi^{2} \hbar^{2} n_{z}^{2}}{2 m a_{z}^{2}} \tag{1.86}
\end{equation*}
$$

Thus, we have arrived at the boundary problem similar to the initial one, but with the spatial dimensionality reduced from 3 to 2 , due to what is called the partial confinement ${ }^{51}$ in direction $z$. If all partial functions $Z(z)$ are normalized to unity, the wavefunction normalization condition (22c) becomes

$$
\begin{equation*}
W=\int_{A} \psi(x, y) \psi^{*}(x, y) d x d y \tag{1.87}
\end{equation*}
$$

where $A$ is the total area of the system on the $[x, y]$ plane, and is formally similar to the initial 3D normalization condition. However, the effective 2D potential energy $U_{\text {ef }}(x, y)$ includes term $E_{z}$ depending on quantum number $n_{z},{ }^{52}$ making the physical relevance of such variable separation much less general than might be naively expected. There are three possible cases:
(i) If there is no strong relation between the energy scale $E_{x, y}$ of potential $U_{\text {ef }}(x, y)$ and $E_{z}$, the solution of a typical problem has to be presented as a (typically, large) sum of partial solutions $\psi(x, y) Z(z)$, each with its own $n_{z}, U_{\text {ef }}$, and $E_{z}$. In this general case, the variable separation may not provide much relief at all, because eigenenergies of solutions with different $n_{z}$ may be close, so that several of them would simultaneously participate in realistic processes.
(ii) $E_{z}$ is much smaller than $E_{x, y}$ and may be neglected. This may be the case, for example, if the potential profile is more steep along axes $x$ and $y$, than along direction $z$. Notice, however, that condition, $a_{z} \rightarrow \infty$, does not guarantee the smallness of $E_{z}$, because it may be compensated by large values of $n_{z}$. In this case (typical for solid state problems), either summation or integration over $n_{z}$ still

[^473]may be needed, though sometimes may be carried out analytically, because functions $Z(z)$ are simple sinusoidal waves.
(iii) Counter-intuitively, the most robust dimensionality reduction is possible in the opposite limit, when $a_{z}$ is much smaller than the characteristic scale of motion within the $[x, y]$ plane (Fig. 8a). Indeed, in this case the distance between adjacent levels of the confinement energy $E_{z}$ is much larger than the characteristic energy $E_{x, y}$ of motion within the plane. As a result, if the system was initially prepared to be on the lowest, ground level of $E_{z}$, , a "soft" motion along $x$ and $y$ cannot excite the system to higher levels of $E_{z} \cdot{ }^{53}$ Hence, the system keeps the fixed quantum number $n_{z}=1$, through the motion, so that the confinement energy $E_{z}$ is constant and, according to Eq. (86), may be treated just as a fixed potential energy offset.

The last conclusion is true even if the quantum well's profile in direction $z$ is not rectangular (provided that $E_{z}$ is still much larger than $E_{x, y}$ ). For example, many 2D quantum phenomena, such as the quantum Hall effect, ${ }^{54}$ have been studied experimentally using electrons confined at semiconductor heterojunctions (e.g., epitaxial interfaces $\mathrm{GaAs} / \mathrm{Al}_{\mathrm{x}} \mathrm{Ga}_{1-\mathrm{x}} \mathrm{As}$ ) where the potential well in the direction perpendicular to the interface has a nearly triangular shape, with the splitting of energies $E_{z}$ is the order of $10^{-2} \mathrm{eV} .{ }^{55}$ This splitting energy corresponds to $k_{\mathrm{B}} T$ at temperature $\sim 100 \mathrm{~K}$, so that careful experimentation at liquid helium temperatures ( 4 K and below) may keep the electrons performing purely 2 D motion in the "lowest subband" $\left(n_{z}=1\right)$.

(b)

Fig. 1.8. Partial confinement in: (a) one dimension, and (b) two dimensions.
Now, if a quantum well is formed in two dimensions (say, $y$ and $z$, see Fig. 8b), ${ }^{56}$

$$
U(\mathbf{r})=\left\{\begin{array}{lr}
U(x), & \text { for } 0<y<a_{y} \text { and } 0<z<a_{z}  \tag{1.88}\\
+\infty, & \text { otherwize }
\end{array}\right.
$$

then repeating the variable separation procedure we see that the 3D Schrödinger equation (68) may be satisfied with particular solutions of the type (71), again with sinusoidal standing waves $Y(y)$ and $Z(z)$, but generally a more complex function $X(x)$, which has to satisfy the following $1 D$ Schrödinger equation equation

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m} \frac{d^{2} X}{d x^{2}}+U_{\text {ef }}(x) X=E_{x} X \tag{1.89}
\end{equation*}
$$

[^474]with the effective potential energy
\[

$$
\begin{equation*}
U_{\mathrm{ef}}(x)=U(x)+E_{y}+E_{z} . \tag{1.90}
\end{equation*}
$$

\]

> Effective potential energy

Again, if the particle stays in the lowest subband, $n_{y}=n_{z}=1$, both $E_{y}$ and $E_{z}$ retain their constant values $E_{y 1}$ and $E_{z 1}$. Repeating the above discussion of the one-dimensional partial confinement, we can expect that a wave mechanics problem may be substantially simplified if $E_{y 1}$ and $E_{z 1}$ are much larger than the energy scale $E_{x}$ of the motion in direction $x$. Namely, if:
(i) the potential profile within the 2D partial confinement plane $[y, z]$ is arbitrary (provided that it provides partial confinement scales $a_{y}$ and $a_{z}$ much smaller the spatial scale of the motion in direction $x$ ), and
(ii) the potential energy $U$ is either constant in time or changes relatively slowly, at a time scale $\tau$ $\gg \hbar / E_{y z 1}$ (where $E_{y z 1}$ is the lowest eigenenergy of motion within the $[y, z]$ plane),
then a large range of experiments may be adequately described by looking for solution of the general (time-dependent, 3D) Schrödinger equation in the form of the following product

$$
\begin{equation*}
\Psi(x, t) Y Z_{1}(y, z) \exp \left\{-i \frac{E_{y z 1}}{\hbar} t\right\}, \tag{1.91}
\end{equation*}
$$

where $Y Z_{1}$ is the lowest (ground-state) eigenfunction of the 2D problem in the $[y, z]$ plane. Substituting this solution to the equation, and separating variables $\{y, z\}$ from $\{x, t\}$, we obtain the following timedependent, 1D equation

$$
\begin{equation*}
i \hbar \frac{\partial \Psi(x, t)}{\partial t}=-\frac{\hbar^{2}}{2 m} \frac{\partial^{2} \Psi(x, t)}{\partial x^{2}}+U(x, t) \Psi(x, t) \tag{1.92}
\end{equation*}
$$

The next chapter will be devoted to a detailed discussion of the wave mechanics described by this 1 D equation, because it allows to study most basic phenomena and concepts of wave mechanics without involving overly complex math. In that chapter, for the notation simplicity, energy $E_{x}$ 1D motion will be referred to just as $E$. However, one should always remember that each " 1 D problem" has two hidden degrees of freedom and that the genuine energy of the particle also includes a constant shift $E_{y z 1}$ which is typically much larger than $E_{x}$. The Universe is (at least :-) 3-dimensional, and it shows!

Finally, note that in systems with reduced dimensionality, Eq. (82) for the number of states at large $\mathbf{k}$ (i.e., for an essentially free particle motion) should be replaced accordingly: in a 2 D system of area $A \gg 1 / k^{2}$,

$$
\begin{equation*}
d N=\frac{A}{(2 \pi)^{2}} d^{2} k \tag{1.93}
\end{equation*}
$$

2D number of states

[^475]with the corresponding changes of the summation rule (83). This change has important implications for the density of states on the energy scale, $d N / d E$ : it is straightforward (and hence left for the reader :-) to use Eqs. (82), (93), and (94) to show that for free 3D particles the density increases with $E$
(proportionally to $E^{1 / 2}$ ), for free 2D particles it does not depend on energy, while for free 1D particles it scales as $E^{-1 / 2}$, i.e. decreases with energy.

### 1.7. Exercise problems

1.1. The actual postulate made by N. Bohr in his original 1913 paper was not directly Eq. (10), but an assumption that at quantum leaps between adjacent large (quasiclassical) orbits with $n \gg 1$, hydrogen atom either emits or absorbs energy $\Delta E=\hbar \omega$, where $\omega$ is its classical radiation frequency according to classical electrodynamics, equal to the angular velocity of electron's rotation. Prove that this postulate is indeed compatible with Eqs. (8)-(10).
1.2. Use Eq. (53) to prove that linear operators of quantum mechanics are commutative: $\hat{A}_{2}+\hat{A}_{1}=\hat{A}_{1}+\hat{A}_{2}$, and associative: $\left(\hat{A}_{1}+\hat{A}_{2}\right)+\hat{A}_{3}=\hat{A}_{1}+\left(\hat{A}_{2}+\hat{A}_{3}\right)$.
1.3. Prove that for any Hamiltonian operator $\hat{H}$ and two arbitrary complex functions $f(\mathbf{r})$ and $g(\mathbf{r})$,

$$
\int f(\mathbf{r}) \hat{H} g(\mathbf{r}) d^{3} r=\int \hat{H} f(\mathbf{r}) g(\mathbf{r}) d^{3} r
$$

1.4. Prove that the Schrödinger equation (1.25) with Hamiltonian (1.41) is Galilean-invariant, provided that the wave function is transformed as

$$
\Psi^{\prime}\left(\mathbf{r}^{\prime}, t^{\prime}\right)=\Psi(\mathbf{r}, t) \exp \left\{-i \frac{m \mathbf{v} \cdot \mathbf{r}}{\hbar}+i \frac{m v^{2} t}{2 \hbar}\right\},
$$

where the prime sign denotes the variables measured in the reference frame $O$ ' that moves, without rotation, with a constant velocity $\mathbf{v}$ relatively to the "lab" frame $O$. Give a physical interpretation of this transformation.
1.5.* Prove the so-called Hellmann-Feynman theorem: ${ }^{57}$

$$
\frac{\partial E_{n}}{\partial \lambda}=\left\langle\frac{\partial H}{\partial \lambda}\right\rangle_{n},
$$

where $\lambda$ is some parameter, on whom the Hamiltonian $\hat{H}$, and hence its eigenenergies $E_{n}$ depend.
1.6. Calculate $\langle x\rangle,\left\langle p_{x}\right\rangle, \delta x$, and $\delta p_{x}$ for eigenstate $\left\{n_{x}, n_{y}, n_{z}\right\}$ of a rectangular, infinitely deep quantum well (69). Compare product $\delta x \delta p_{x}$ with Heisenberg's uncertainty relation.

[^476]1.7. A particle, placed in a hard-wall, rectangular box with sides $a_{x}, a_{y}$, and $a_{z}$, is in its ground state. Calculate the average force acting on each face of the box. Can the forces be characterized by a certain pressure?
1.8. A 1 D quantum particle was initially in the ground state of a very deep, rectangular quantum well of width $a$ :
\[

U(x)=\left\{$$
\begin{array}{lr}
0, & \text { for }-a / 2<x<+a / 2 \\
+\infty, & \text { otherwise }
\end{array}
$$\right.
\]

At some instant, the well's width is abruptly increased to value $a^{\prime}>a$ (leaving the well symmetric about point $x=0$ ), and then left constant. Calculate the probability that after the change, the particle is still in the ground state of the system.
1.9. At $t=0$, a 1 D particle of mass $m$ is placed into a hard-wall, flat-bottom potential well

$$
U(x)=\left\{\begin{array}{lr}
0, & \text { for } 0<x<a \\
+\infty, & \text { otherwise }
\end{array}\right.
$$

in a $50 / 50$ linear superposition of the lowest (ground) and the first excited states, so that its wavefunction at that instant is

$$
\Psi(x, 0)=C\left[\psi_{g}(x)+\psi_{e}(x)\right]
$$

where $C$ is the normalization constant which ensures that the particle is (somewhere) in the well with probability $W=1$. Calculate:
(i) the normalized wavefunction $\Psi(x, t)$ for arbitrary time $t$, and
(ii) the time evolution of the expectation value $\langle x\rangle$ of particle's coordinate.
1.10. Find the potential profile $U(x)$ for which the following wavefunctions,

$$
\begin{align*}
& \Psi=c \exp \left\{-a x^{2}-i b t\right\}, \text { and }  \tag{i}\\
& \Psi=c \exp \{-a|x|-i b t\},
\end{align*}
$$

(with real coefficients $a>0$ and $b$ ), satisfy the Schrödinger equation for a particle with mass $m$. For each case, calculate $\langle x\rangle,\left\langle p_{x}\right\rangle, \delta x$, and $\delta p_{x}$, and compare the product $\delta x \delta p_{x}$ with Heisenberg's uncertainty relation.
1.11. Calculate the energy density $d N / d E$ of traveling wave states in large rectangular quantum wells of various dimensions: $d=1,2$, and 3 .
1.12.* Use the finite difference method with steps $a / 2$ and $a / 3$ to find as many eigenenergies as possible for a particle in the infinitely deep, hard-wall quantum well of width $a$. Compare the results with each other, with the exact formula. ${ }^{58}$

[^477]
## Chapter 2. 1D Wave Mechanics

The main goal of this chapter is the solution and discussion of a few conceptually most important problems of wave mechanics for the simplest, $1 D$ case. This lowest dimensionality, and a wide use of potential profiles' approximation by sets of Dirac's delta-functions, simplify the necessary calculations considerably without sacrificing the physical essence of the described phenomena. The reader is advised to pay special attention to Sections 6-9, which cover some important material not usually discussed in textbooks.

### 2.1. Probability current and uncertainty relations

As was discussed in the end of Chapter 1, in several cases (most importantly, at strong confinement within the $[y, z]$ plane), the general (3D) Schrödinger equation may be reduced to the 1D equation (1.92):

Schrödinger equation

Probability

Normalization

Expectation value

Probability
current

Continuity equation
耍

$$
\begin{equation*}
i \hbar \frac{\partial \Psi(x, t)}{\partial t}=-\frac{\hbar^{2}}{2 m} \frac{\partial^{2} \Psi(x, t)}{\partial x^{2}}+U(x, t) \Psi(x, t) \tag{2.1}
\end{equation*}
$$

If the transversal factor - say, the function $Y Z_{1}(y, z)$ that participates in Eq. (1.91), is normalized to unity, then the integration of Eq. (1.22a) over a segment $\left[x_{1}, x_{2}\right]$, gives the probability to find the particle on this segment:

$$
\begin{equation*}
W(t) \equiv \int_{x_{1}}^{x_{2}} \Psi(x, t) \Psi^{*}(x, t) d x \tag{2.2}
\end{equation*}
$$

If the particle under analysis is definitely inside the system, the normalization of its 1 D wavefunction $\Psi(x, t)$ is provided by extending integral (2) to the whole axis $x$ :

$$
\begin{equation*}
\int_{-\infty}^{+\infty} w(x, t) d x=1, \quad \text { where } w(x, t) \equiv \Psi(x, t) \Psi *(x, t) \tag{2.3}
\end{equation*}
$$

A similar integration of Eq. (1.23) shows that the expectation value of any operator depending only on coordinate $x$ (and possibly time), may be expressed as

It is also useful to introduce the probability current along the $x$-axis (a scalar):

$$
\begin{equation*}
I(x, t) \equiv \int j_{x} d y d z=\frac{\hbar}{m} \operatorname{Im}\left(\Psi^{*} \frac{\partial}{\partial x} \Psi\right)=\frac{\hbar}{m}|\Psi(x, t)|^{2} \frac{\partial \varphi}{\partial x} \tag{2.5}
\end{equation*}
$$

where $j_{x}$ is $x$-component of the probability current density vector $\mathbf{j}(\mathbf{r}, t)$. Then the continuity equation (1.48) for the segment $\left[x_{1}, x_{2}\right]$ takes the form

$$
\begin{equation*}
\frac{d W}{d t}+I\left(x_{2}\right)-I\left(x_{1}\right)=0 \tag{2.6}
\end{equation*}
$$

The above formulas are the basis for the analysis of 1D problems of wave mechanics, but before proceeding to particular cases, let me deliver on my earlier promise to prove that Heisenberg's uncertainty relation (1.35) is indeed valid for any wavefunction $\Psi(x, t)$. For that, let us consider an evidently positive (or at least non-negative) integral

$$
\begin{equation*}
J(\lambda) \equiv \int_{-\infty}^{+\infty}\left|x \Psi+\lambda \frac{\partial \Psi}{\partial x}\right|^{2} d x \geq 0 \tag{2.7}
\end{equation*}
$$

where $\lambda$ is an arbitrary real constant, and assume that at the at $x \rightarrow \pm \infty$ the wavefunction vanishes, together with its first derivative. The left-hand part of Eq. (7) may be recast as

$$
\begin{align*}
& \int_{-\infty}^{+\infty} x \Psi+\left.\lambda \frac{\partial \Psi}{\partial x}\right|^{2} d x=\int_{-\infty}^{+\infty}\left(x \Psi+\lambda \frac{\partial \Psi}{\partial x}\right)\left(x \Psi+\lambda \frac{\partial \Psi}{\partial x}\right)^{*} d x  \tag{2.8}\\
& =\int_{-\infty}^{+\infty} x^{2} \Psi \Psi^{*} d x+\lambda \int_{-\infty}^{+\infty} x\left(\Psi \frac{\partial \Psi *}{\partial x}+\frac{\partial \Psi}{\partial x} \Psi^{*}\right) d x+\lambda^{2} \int_{-\infty}^{+\infty} \frac{\partial \Psi}{\partial x} \frac{\partial \Psi^{*}}{\partial x} d x
\end{align*}
$$

According to Eq. (4), the first term in the last form of Eq. (8) is just $\left\langle x^{2}\right\rangle$. The second and the third integrals may be worked out by parts:

$$
\begin{align*}
& \int_{-\infty}^{+\infty} x\left(\Psi \frac{\partial \Psi^{*}}{\partial x}+\frac{\partial \Psi}{\partial x} \Psi^{*}\right) d x=\int_{-\infty}^{+\infty} x \frac{\partial}{\partial x}\left(\Psi \Psi^{*}\right) d x=\int_{x=-\infty}^{x=+\infty} x d\left(\Psi \Psi^{*}\right)=\left.\Psi \Psi^{*} x\right|_{x=-\infty} ^{x=+\infty}-\int_{-\infty}^{+\infty} \Psi \Psi^{*} d x=-1  \tag{2.9}\\
& \int_{-\infty}^{+\infty} \frac{\partial \Psi}{\partial x} \frac{\partial \Psi^{*}}{\partial x} d x=\int_{x=-\infty}^{x=+\infty} \frac{\partial \Psi}{\partial x} d \Psi^{*}=\frac{\partial \Psi}{\partial x} \Psi^{*} \left\lvert\, \begin{array}{l}
x=+\infty \\
x=-\infty \\
x-\int_{-\infty}^{+\infty} \Psi^{*} \frac{\partial^{2} \Psi}{\partial x^{2}} d x=\frac{1}{\hbar^{2}} \int_{-\infty}^{+\infty} \Psi^{*} \hat{p}_{x}^{2} \Psi d x=\frac{\left\langle p_{x}^{2}\right\rangle}{\hbar^{2}}
\end{array} .\right. \tag{2.10}
\end{align*}
$$

As a result, Eq. (7) takes the following form:

$$
\begin{equation*}
J(\lambda)=\left\langle x^{2}\right\rangle-\lambda+\lambda^{2} \frac{\left\langle p_{x}^{2}\right\rangle}{\hbar^{2}} \geq 0, \quad \text { i.e. } \lambda^{2}+a \lambda+b \geq 0, \quad \text { with } a \equiv-\frac{\hbar^{2}}{\left\langle p_{x}^{2}\right\rangle} \text { and } b \equiv \frac{\hbar^{2}\left\langle x^{2}\right\rangle}{\left\langle p_{x}^{2}\right\rangle} . \tag{2.11}
\end{equation*}
$$

This inequality should be valid for any real $\lambda$, i.e. the corresponding quadratic equation, $\lambda^{2}+a \lambda+b=0$, can have either one (degenerate) real root - or no real roots at all. This is only possible if its determinant, Det $=a^{2}-4 b$, is non-positive, leading to the following requirement:

$$
\begin{equation*}
\left\langle x^{2}\right\rangle\left\langle p_{x}^{2}\right\rangle \geq \frac{\hbar^{2}}{4} \tag{2.12}
\end{equation*}
$$

In particular, if $\langle x\rangle=0$ and $\left\langle p_{x}\right\rangle=0,{ }^{1}$ then according to Eq. (1.33), Eq. (12) takes the form

$$
\begin{equation*}
\left\langle\tilde{x}^{2}\right\rangle\left\langle\tilde{p}_{x}^{2}\right\rangle \geq \frac{\hbar^{2}}{4} \tag{2.13}
\end{equation*}
$$

which, according to the definition (1.34) of r.m.s. uncertainties, is equivalent to Eq. (1.35).

[^478]Now let us notice that the Heisenberg's uncertainty relation looks very similar to the commutation relation between the corresponding operators:

$$
\begin{equation*}
\left[\hat{x}, \hat{p}_{x}\right] \Psi \equiv\left(\hat{x} \hat{p}_{x}-\hat{p}_{x} \hat{x}\right) \Psi=-i \hbar x \frac{\partial \Psi}{\partial x}+i \hbar \frac{\partial}{\partial x}(x \Psi)=i \hbar \Psi . \tag{2.14a}
\end{equation*}
$$

Coordinate/ momentum operators' commutator

Since this relation is valid for arbitrary wavefunction $\Psi(x, \mathrm{t})$, we may present it as an operator equality:

$$
\begin{equation*}
\left[\hat{x}, \hat{p}_{x}\right]=i \hbar \neq 0 \tag{2.14b}
\end{equation*}
$$

In Sec. 4.5 we will see that the relation between Eqs. (13) and (14) is just a particular case of a general relation between the expectation values of non-commuting operators and their commutators.

### 2.2. Free particle: Wave packets

Let us start our discussion of particular problems with free the 1D motion, with $U(x, t)=0$. From our discussion of Eq. (1.29) in Chapter 1, it is clear that in the 1D case, a similar "fundamental" (i.e. a particular but the most important) solution of the Schrödinger equation (1) is a monochromatic wave

$$
\begin{equation*}
\Psi_{0}(x, t)=\mathrm{const} \times e^{i\left(k_{0} x-\omega_{0} t\right)} . \tag{2.15}
\end{equation*}
$$

According to Eqs. (1.32), it corresponds to a particle with an exactly defined momentum ${ }^{2} p_{0}=\hbar k_{0}$ and energy $E_{0}=\hbar \omega_{0}=\hbar^{2} k_{0}^{2} / 2 m$. However, for this wavefunction, product $\Psi * \Psi$ does not depend on either $x$ or $t$, so that the particle is completely delocalized, i.e. its probability is spread all over axis $x$, at all times. (As a result, such state is still compatible with Heisenberg's uncertainty relation (13), despite the exact value $p_{0}$ of momentum $p$.)

In order to describe a space-localized particle, let us form, at the initial moment of time $(t=0)$, a wave packet of the type shown in Fig. 1.6, by multiplying the sinusoidal waveform (15) by some smooth envelope function $A(x)$. As the most important particular example, consider a Gaussian packet

Initial Gaussian wave packet

$$
\begin{equation*}
\Psi(x, 0)=A(x) e^{i k_{0} x}, \quad \text { with } A(x)=\frac{1}{(2 \pi)^{1 / 4}(\delta x)^{1 / 2}} \exp \left\{-\frac{x^{2}}{(2 \delta x)^{2}}\right\} \tag{2.16}
\end{equation*}
$$

(By the way, Fig. 1.6 shows exactly such a packet.) The pre-exponential factor in this envelope function has been selected in the way to have the initial probability density,

$$
\begin{equation*}
w(x, 0)=\Psi^{*}(x, 0) \Psi(x, 0)=A^{*}(x) A(x)=\frac{1}{(2 \pi)^{1 / 2} \delta x} \exp \left\{-\frac{x^{2}}{2(\delta x)^{2}}\right\}, \tag{2.17}
\end{equation*}
$$

normalized according to Eq. (3), for any parameters $\delta x$ and $k_{0} \cdot{ }^{3}$
In order to explore the evolution of this packet in time, we could try to solve Eq. (1) with the initial condition (16) directly, but in the spirit of the discussion in Sec. 1.5, it is easier to proceed

[^479]differently. Let us first present the initial wavefunction (16) as a sum (1.65) of eigenfunctions $\psi_{k}(x)$ of the corresponding stationary 1D Schrödinger equation (1.60), in our current case
\[

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m} \frac{d^{2} \psi_{k}}{d x^{2}}=E_{k} \psi_{k}, \quad \text { with } E_{k} \equiv \frac{\hbar^{2} k^{2}}{2 m} \tag{2.18}
\end{equation*}
$$

\]

that are simply monochromatic waves,

$$
\begin{equation*}
\psi_{k}=a_{k} e^{i k x} \tag{2.19}
\end{equation*}
$$

with a continuum spectrum of possible wave numbers $k$. For that, sum (1.65) should be replaced with an integral: ${ }^{4}$

$$
\begin{equation*}
\Psi(x, 0)=\int a_{k} \psi_{k}(x) d p=\int a_{k} e^{i k x} d k \tag{2.20}
\end{equation*}
$$

Now let us notice that from the point of view of mathematics, Eq. (20) is just the usual Fourier transform from variable $k$ to the "conjugate" variable $x$, and we can use the well-known formula of the reciprocal Fourier transform to calculate

$$
\begin{equation*}
a_{k}=\frac{1}{2 \pi} \int \Psi(x, 0) e^{-i k x} d x=\frac{1}{2 \pi} \frac{1}{(2 \pi)^{1 / 4}(\delta x)^{1 / 2}} \int \exp \left\{-\frac{x^{2}}{(2 \delta x)^{2}}-i \widetilde{k} x\right\} d x, \quad \text { where } \tilde{k} \equiv k-k_{0} \tag{2.21}
\end{equation*}
$$

This Gaussian integral may be worked out by the following standard method. Let us complement the exponent to the full square of a linear combination of $x$ and $k$, plus a term independent of $x$ :

$$
\begin{equation*}
-\frac{x^{2}}{(2 \delta x)^{2}}-i \widetilde{k} x=-\frac{1}{(2 \delta x)^{2}}\left[x+2 i \widetilde{k}(\delta x)^{2}\right]^{2}-\widetilde{k}^{2}(\delta x)^{2} \tag{2.22}
\end{equation*}
$$

Since the integration in the right-hand part of Eq. (20) should be performed at constant $\widetilde{k}$, in the infinite limits, its result would not change if we replace $d x$ by $d x{ }^{\prime} \equiv d\left[x+2 i(\delta x)^{2} \widetilde{k}\right] .{ }^{5}$ As a result, we get,

$$
\begin{equation*}
a_{k}=\frac{1}{2 \pi} \frac{1}{(2 \pi)^{1 / 4}(\delta x)^{1 / 2}} \exp \left\{-\widetilde{k}^{2}(\delta x)^{2}\right\} \int \exp \left\{-\frac{x^{\prime 2}}{(2 \delta x)^{2}}\right\} d x^{\prime}=\left(\frac{1}{2 \pi}\right)^{1 / 2} \frac{1}{(2 \pi)^{1 / 4}(\delta k)^{1 / 2}} \exp \left\{-\frac{\widetilde{k}^{2}}{(2 \delta k)^{2}}\right\} \cdot( \tag{2.23}
\end{equation*}
$$

so that $a_{k}$ also has a Gaussian distribution, now along axis $k$, centered to value $k_{0}$ (Fig. 1.6b), with constant $\delta k$ defined as

$$
\begin{equation*}
\delta k \equiv 1 / 2 \delta x \tag{2.24}
\end{equation*}
$$

Thus we may present the initial wave packet (16) as

$$
\begin{equation*}
\Psi(x, 0)=\left(\frac{1}{2 \pi}\right)^{1 / 2} \frac{1}{(2 \pi)^{1 / 4}(\delta k)^{1 / 2}} \int \exp \left\{-\frac{\left(k-k_{0}\right)^{2}}{(2 \delta k)^{2}}\right\} e^{i k x} d k \tag{2.25}
\end{equation*}
$$

From comparison of this formula with Eq. (16), it is evident that the r.m.s. uncertainty of the wave number $k$ in this packet is indeed equal to $\delta k$ defined by Eq. (24), thus justifying the notation. The

[^480]comparison of that relation with Eq. (1.35) shows that the Gaussian packet presents the ultimate case in which the product $\delta x \delta p=\delta x(\hbar \delta k)$ has the lowest possible value ( $\hbar / 2$ ); for any other envelope's shape the uncertainty product may only be larger. We could of course get the same result for $\delta k$ from Eq. (16) using definitions (1.23), (1.33), and (1.34); the real advantage of Eq. (24) is that it can be readily generalized to $t>0$.

Indeed, we already know that the time evolution of the wavefunction is given by Eq. (1.67), for our case giving ${ }^{6}$

$$
\begin{equation*}
\Psi(x, t)=\left(\frac{1}{2 \pi}\right)^{1 / 2} \frac{1}{(2 \pi)^{1 / 4}(\delta k)^{1 / 2}} \int \exp \left\{-\frac{\left(k-k_{0}\right)^{2}}{(2 \delta k)^{2}}\right\} e^{i k x} \exp \left\{-i \frac{\hbar k^{2}}{2 m} t\right\} d k \tag{2.26}
\end{equation*}
$$

Fig. 1 shows several snapshots of the real part of wavefunction (26), for a particular case $\delta k=0.1 k_{0}$.

The plots clearly show the following effects:
(i) the wave packet as a whole (as characterized by its envelope) moves along the $x$ axis with a certain group velocity $\mathrm{v}_{\mathrm{gr}}$,

[^481](ii) the "carrier" wave inside the packet moves with a different, phase velocity $v_{\mathrm{ph}}$, which may be defined as the velocity the spatial points where wave's phase $\varphi(x, t) \equiv \arg \Psi$ takes a certain fixed value (say, $\varphi=\pi / 2$, where $\operatorname{Re} \Psi$ vanishes), and
(iii) the packet's spatial width gradually increases with time - the packet spreads.

All these effects are common for waves of any physical nature. ${ }^{7}$ Indeed, let us consider a 1D wave packet of the type (26),

$$
\begin{equation*}
\Psi(x, t)=\int a_{k} e^{i(k x-\omega t)} d k \tag{2.27}
\end{equation*}
$$

propagating in a media with an arbitrary (but smooth!) dispersion relation $\omega(k)$, and assume that the wave number distribution $a_{k}$ is arbitrary but narrow: $\delta k \ll\langle k\rangle \equiv k_{0}$ - see Fig. 1.6b. Then we may expand function $\omega(k)$ into the Taylor series near the central point $k_{0}$, and keep only two of its leading terms:

$$
\begin{equation*}
\omega(k) \approx \omega_{0}+\frac{d \omega}{d k} \widetilde{k}+\frac{1}{2} \frac{d^{2} \omega}{d k^{2}} \widetilde{k}^{2}, \quad \text { where } \widetilde{k} \equiv k-k_{0}, \omega_{0} \equiv \omega\left(k_{0}\right) \tag{2.28}
\end{equation*}
$$

and both derivatives are also evaluated at point $k=k_{0}$. In this approximation, ${ }^{8}$ the expression in parentheses in the right-hand part of Eq. (27) may be rewritten as

$$
\begin{equation*}
k x-\omega t=k_{0} x+\widetilde{k} x-\left(\omega_{0}+\frac{d \omega}{d k} \widetilde{k}+\frac{1}{2} \frac{d^{2} \omega}{d k^{2}} \widetilde{k}^{2}\right) t=\left(k_{0} x-\omega_{0} t\right)+\widetilde{k}\left(x-\frac{d \omega}{d k} t\right)-\frac{1}{2} \frac{d^{2} \omega}{d k^{2}} \widetilde{k}^{2} t \tag{2.29}
\end{equation*}
$$

so that Eq. (27) is reduced to integral

$$
\begin{equation*}
\Psi(x, t)=e^{i\left(k_{0} x-\omega_{0} t\right)} \int a_{k} \exp \left\{i\left[\widetilde{k}\left(x-\frac{d \omega}{d k} t\right)-\frac{1}{2} \frac{d^{2} \omega}{d k^{2}} \widetilde{k}^{2} t\right]\right\} d \widetilde{k} . \tag{2.30}
\end{equation*}
$$

First, let neglect the last term in square brackets (which is much smaller than the first term if the dispersion relation is smooth enough and/or the time interval $t$ is sufficiently small), and compare the result with the initial form of the wave packet (27)

$$
\begin{equation*}
\Psi(x, 0)=\int a_{k} e^{i k x} d k=A(x) e^{i k_{0} x}, \quad \text { with } A(x) \equiv \int a_{k} e^{i \tilde{k} x} d \tilde{k} \tag{2.31}
\end{equation*}
$$

The comparison shows that Eq. (30) is reduced to

$$
\begin{equation*}
\Psi(x, t)=A\left(x-v_{\mathrm{gr}} t\right) e^{i k_{0}\left(x-v_{\mathrm{ph}} t\right)} \tag{2.32}
\end{equation*}
$$

where $v_{\mathrm{gr}}$ and $v_{\mathrm{ph}}$ are two constants with the dimension of velocity:

$$
\begin{equation*}
\left.v_{\mathrm{gr}} \equiv \frac{d \omega}{d k}\right|_{k=k_{0}}, \quad \text { and }\left.\quad v_{\mathrm{ph}} \equiv \frac{\omega}{k}\right|_{k=k_{0}} \tag{2.33}
\end{equation*}
$$

It is clear that Eq. (32) describes effects (i) and (ii) listed above. Let us calculate the group and phase velocities for the particular case of de Broglie waves whose dispersion law is given by Eq. (1.30):

[^482]\[

$$
\begin{equation*}
\omega=\frac{\hbar k^{2}}{2 m},\left.\quad v_{\mathrm{gr}} \equiv \frac{d \omega}{d k}\right|_{k=k_{0}}=\frac{\hbar k_{0}}{m} \equiv v_{0},\left.\quad v_{\mathrm{ph}} \equiv \frac{\omega}{k}\right|_{k=k_{0}}=\frac{\hbar k_{0}}{2 m}=\frac{v_{g r}}{2} . \tag{2.34}
\end{equation*}
$$

\]

We see that (very fortunately!) the velocity of the wave packet envelope is constant and equals to that of the classical particle moving by inertia, in accordance with the correspondence principle.

The remaining term in the square brackets of Eq. (30) describes effect (iii), the wave packet's spread. It may be readily evaluated if the packet (27) is initially Gaussian, as in our example (25):

$$
\begin{equation*}
a_{k}=\text { const } \times \exp \left\{-\frac{\widetilde{k}^{2}}{(2 \delta k)^{2}}\right\} . \tag{2.34}
\end{equation*}
$$

In this case integral (30) is Gaussian, and may be worked out exactly as integral (20), i.e. merging the exponents under the integral, and presenting them as a full square of linear combination of $x$ and $k$ :

$$
\begin{equation*}
-\frac{\widetilde{k}^{2}}{(2 \delta k)^{2}}+i \widetilde{k}\left(x-v_{\mathrm{gr}} t\right)-\frac{i}{2} \frac{d^{2} \omega}{d k^{2}} \widetilde{k}^{2} t=-\Delta(t)\left(\widetilde{k}+i \frac{x-v_{\mathrm{gr}} t}{2 \Delta(t)}\right)^{2}-\frac{\left(x-v_{\mathrm{gr}} t\right)^{2}}{4 \Delta(t)}+i k_{0} x-\frac{i}{2} \frac{d^{2} \omega}{d k^{2}} k_{0}^{2} t \tag{2.35}
\end{equation*}
$$

where I have introduced the following complex function of time:

$$
\begin{equation*}
\Delta(t) \equiv \frac{1}{4(\delta k)^{2}}+\frac{i}{2} \frac{d^{2} \omega}{d k^{2}} t=(\delta x)^{2}+\frac{i}{2} \frac{d^{2} \omega}{d k^{2}} t \tag{2.36}
\end{equation*}
$$

and have used Eq. (24) in the second equality. Now integrating over $\widetilde{k}$, we get

$$
\begin{equation*}
\Psi(x, t) \propto \exp \left\{-\frac{\left(x-v_{\mathrm{gr}} t\right)^{2}}{4 \Delta(t)}+i\left(k_{0} x-\frac{1}{2} \frac{d^{2} \omega}{d k^{2}} k_{0}^{2} t\right)\right\} . \tag{2.37}
\end{equation*}
$$

The imaginary part of ratio $1 / \Delta(t)$ in the exponent gives just an additional contribution to wave's phase, and does not affect the resulting probability distribution

$$
\begin{equation*}
w(x, t)=\Psi^{*} \Psi \propto \exp \left\{-\frac{\left(x-v_{\mathrm{gr}} t\right)^{2}}{2} \operatorname{Re} \frac{1}{\Delta(t)}\right\} \tag{2.38}
\end{equation*}
$$

This is again a Gaussian bell curve spread over axis $x$, centered to point $\langle x\rangle=v_{\mathrm{gr}} t$, with the r.m.s. width

$$
\begin{equation*}
\left(\delta x^{\prime}\right)^{2} \equiv\left\{\operatorname{Re}\left[\frac{1}{\Delta(t)}\right]\right\}^{-1}=(\delta x)^{2}+\left(\frac{1}{2} \frac{d^{2} \omega}{d k^{2}} t\right)^{2} \frac{1}{(\delta x)^{2}} . \tag{2.39a}
\end{equation*}
$$

In the particular case of de Broglie waves, $d^{2} \omega / d k^{2}=\hbar / m$, so that

Wave packet's spread with time

$$
\begin{equation*}
\left(\delta x^{\prime}\right)^{2}=(\delta x)^{2}+\left(\frac{\hbar t}{2 m}\right)^{2} \frac{1}{(\delta x)^{2}} \tag{2.39b}
\end{equation*}
$$

The physics of the spreading is very simple: if $d^{2} \omega / d k^{2} \neq 0$, the group velocity $d \omega / d k$ of each small group $d k$ of monochromatic components of the wave packet is different, resulting in the gradual (eventually, linear) accumulation of the differences of the distances traveled by the groups. The most curious feature of Eq. (39) is that the packet width at $t>0$ depends on its initial width $\delta x{ }^{\prime}(0)=\delta x$ in a
non-monotonic way, tending to infinity at both $\delta x \rightarrow 0$ and $\delta x \rightarrow \infty$. Because of that, for a fixed $t$, there is an optimal value of $\delta x$ with minimizes $\delta x$ ':

$$
\begin{equation*}
\left(\delta x^{\prime}\right)_{\min }=\sqrt{2}(\delta x)_{\mathrm{opt}}=\left(\frac{\hbar t}{m}\right)^{1 / 2} \tag{2.40}
\end{equation*}
$$

This expression may be used for spreading effect estimates. Due to the smallness of the Planck constant $\hbar$ on the human scale of things, for macroscopic bodies this effect is extremely small even for very long time intervals; however, for light particles it may be very noticeable: for the electron ( $\mathrm{m}=\mathrm{m}_{e} \approx 10^{-30}$ kg ), and $t=1 \mathrm{~s}$, Eq. (40) yields ( $\left.\delta x^{\prime}\right)_{\min } \sim 1 \mathrm{~cm}$ !

Note also that for any $t \neq 0$, the wave packet retains its Gaussian envelope, but the ultimate relation (24) is not satisfied, $\delta x$ ' $\delta p>\hbar / 2$ - due to a gradually accumulated phase shift between the component monochromatic waves. The last remark on this topic: in quantum mechanics, the wave packet spreading is not an ubiquitous effect! For example, in Chapter 5 we will see that in a quantum oscillator, the spatial width of a Gaussian packet (for that system, called the Glauber state) does not grow monotonically but rather either stays constant or oscillates in time.

Now let us briefly discuss the case when the initial wave packet is not Gaussian, but is described by an arbitrary initial wavefunction. In order to make the forthcoming result more appealing, it is beneficial to generalize out calculations to an arbitrary initial time $t_{0}$; it is evident that if $U$ does not depend on time explicitly, it is sufficient to replace $t$ with $\left(t-t_{0}\right)$ in all above formulas. With this replacement, Eq. (27) becomes

$$
\begin{equation*}
\Psi(x, t)=\int a_{k} e^{i\left[k x-\omega\left(t-t_{0}\right)\right]} d k \tag{2.41}
\end{equation*}
$$

and the reciprocal transform (21) reads

$$
\begin{equation*}
a_{k}=\frac{1}{2 \pi} \int \Psi\left(x, t_{0}\right) e^{-i k x} d x \tag{2.42}
\end{equation*}
$$

If we want to express these two formulas with one relation, i.e. plug Eq. (42) into Eq. (41), we should give the integration variable $x$ some other name, e.g., $x_{0}$. The result is

$$
\begin{equation*}
\Psi(x, t)=\frac{1}{2 \pi} \int d k \int d x_{0} \Psi\left(x_{0}, t_{0}\right) e^{i\left[k\left(x-x_{0}\right)-\omega\left(t-t_{0}\right)\right]} . \tag{2.43}
\end{equation*}
$$

Changing the order of integration, this expression may be rewritten in the following general form:

$$
\begin{equation*}
\Psi(x, t)=\int G\left(x, t ; x_{0}, t_{0}\right) \Psi\left(x_{0}, t_{0}\right) d x_{0} \tag{2.44}
\end{equation*}
$$

where function $G$, usually called kernel in mathematics, in quantum mechanics is called the propagator. ${ }^{9}$ According to Eq. (43), in our particular case of a free particle the propagator is equal to

[^483]\[

$$
\begin{equation*}
G\left(x, t ; x_{0}, t_{0}\right)=\frac{1}{2 \pi} \int e^{i\left[k\left(x-x_{0}\right)-\omega\left(t-t_{0}\right)\right]} d k, \tag{2.45}
\end{equation*}
$$

\]

The physical sense of the propagator may be understood by considering the following special initial conditions: ${ }^{10}$

$$
\begin{equation*}
\Psi\left(x_{0}, t_{0}\right)=\delta\left(x_{0}-x^{\prime}\right), \tag{2.46}
\end{equation*}
$$

where $x$ ' is a certain point within the domain of particle's motion. In this particular case, Eq. (44) evidently gives

$$
\begin{equation*}
\Psi(x, t)=G\left(x, t ; x^{\prime}, t_{0}\right) . \tag{2.47}
\end{equation*}
$$

Hence, the propagator, considered as a function of $x$ and $t$ only, is just the solution of the linear differential equation with $\delta$-functional initial conditions. Thus while Eq. (41) may be understood as a mathematical expression of the linear superposition principle in the momentum (i.e., reciprocal) space domain, Eq. (44) is an expression of this principle in the direct space domain: the system's "response" $\Psi(x, t)$ to an arbitrary initial condition $\Psi\left(x_{0}, t_{0}\right)$ is just a sum of its responses to its thin spatial "slices", with propagator $G\left(x, t ; x_{0}, t_{0}\right)$ representing the weight of each slice in the final sum.

Calculating integral (45), one should remember that $\omega$ is not a constant but a function of $k$, given by the dispersion relation for particular waves. In particular, for the de Broglie waves

$$
\begin{equation*}
G\left(x, t ; x_{0}, t_{0}\right) \equiv \frac{1}{2 \pi} \int \exp \left\{i\left[k\left(x-x_{0}\right)-\frac{\hbar k^{2}}{2 m}\left(t-t_{0}\right)\right]\right\} d k \tag{2.48}
\end{equation*}
$$

This is a Gaussian integral again, and may be readily calculated just it was done (twice) above, by completing the exponent to the full square. The result is

Free
particle's propagator

$$
\begin{equation*}
G\left(x, t ; x_{0}, t_{0}\right)=\left(\frac{m}{2 \pi i \hbar\left(t-t_{0}\right)}\right)^{1 / 2} \exp \left\{-\frac{m\left(x-x_{0}\right)^{2}}{2 i \hbar\left(t-t_{0}\right)}\right\} \tag{2.49}
\end{equation*}
$$

Please note the following features of this complex function (plotted in Fig. 2):

[^484](i) It depends only on differences $\left(x-x_{0}\right)$ and $\left(t-t_{0}\right)$. This is natural, because the free-particle propagation problem is uniform (translation-invariant) both in space and time.
(ii) The function shape does not depend on its arguments - they just rescale the same function: its snapshot (Fig. 2), if plotted as a function of un-normalized $x$, just becomes broader and lower with time. It is curious that the spatial broadening scales as $\left(t-t_{0}\right)^{1 / 2}-$ just as at the classical diffusion, as a result of a deep analogy between quantum mechanics and classical statistics - to be discussed further in Chapter 7.
(iii) In accordance with the uncertainty relation, the ultimately compressed wave packet (46) has an infinite width of momentum distribution, and the quasi-sinusoidal tails of the free-particle propagator, clearly visible in Fig. 2, are the results of the free propagation of the fastest (highestmomentum) components of that distribution, in both directions from the packet center. In the following sections, we will mostly focus on the spatial distribution of stationary, monochromatic wavefunctions (that, for unconfined motion, may be interpreted as wave packets of very large spatial width $\delta x$ ), only rarely coming back to the wave packet discussion. Our excuse is the linear superposition principle, i.e. our conceptual ability to restore the general solution from that of monochromatic waves of all possible energies. However, the reader should not forget that, as the above discussion has illustrated, mathematically this restoration is not always trivial.

### 2.3. Particle motion in simple potential profiles

Now, let us proceed to the cases in which the potential energy $U(x, t)$ is not identically equal to zero. The easiest case is that of spatially-uniform but time-dependent potential: $U=U(t)=$ const. Indeed, the corresponding Schrödinger equation (1.25) with Hamiltonian

$$
\begin{equation*}
\hat{H}=\frac{\hat{p}^{2}}{2 m}+U(t)=-\frac{\hbar^{2}}{2 m} \nabla^{2}+U(t) \tag{2.50}
\end{equation*}
$$

allows the variable separation similar to that performed in Sec. 1.5, besides that the time-dependent function $T(t)$ obeys an equation of motion that is slightly more general than Eq. (1.59):

$$
\begin{equation*}
i \hbar \dot{T}=[E-U(t)] T \tag{2.51}
\end{equation*}
$$

whose solution may be expressed as an evident generalization of Eq. (1.61):

$$
\begin{equation*}
T(t)=T(0) e^{-i[\omega t+\varphi(t)]}, \quad \text { with } \omega=\frac{E}{\hbar} \text { and } \quad \frac{d \varphi}{d t}=-\frac{U(t)}{\hbar} . \tag{2.52}
\end{equation*}
$$

Looking at the basic relations (1.22) and (1.23) of wave mechanics, it seems that this additional phase factor does not affect the particle probability distribution, or even any observable (including energy it is referred to the instant value of $U$ ), and hence the phase increment $\varphi$, associated with $U(t)$, is just a mathematical artifact. This is certainly true for a single particle, however, the situation changes as soon as we recall that the Universe consists of more that one of them.

For example, consider two similar, independent particles, each in the same (say, ground) eigenstate, but with the potential energies (and hence eigenenergies $E_{1,2}$ ) different by a constant $\Delta U \equiv U_{1}$ $-U_{2}$. Then, the difference $\varphi \equiv \varphi_{1}-\varphi_{2}$ of their wavefunction phases evolves in time as

Quantum phase difference's evolution

$$
\begin{equation*}
\frac{d \varphi}{d t}=-\frac{\Delta U}{\hbar} \tag{2.53}
\end{equation*}
$$

If the particles are in different worlds (or at least in different laboratories :-), this evolution is unobservable; however, it should be intuitively clear that a very weak coupling of a certain detector to each particle may allow it to observe phase $\varphi$, while keeping the particle dynamics virtually unperturbed, i.e. Eq. (53) intact.

Perhaps the most dramatic demonstration of this phenomenon is the Josephson effect in superconductors. ${ }^{11}$ Experimentally, the easiest way to observe the effect is by connecting two bulk superconductor samples with a weak, short electric contact (called either the weak link or the Josephson junction) and bias them with a constant (dc) voltage $V$, typically in a few-microvolt range - see Fig. 3.

Fig. 2.3. Josephson effect in a weak link between two bulk superconductor electrodes.

Superconductivity may be explained by a specific coupling between its conduction electrons, that leads, at low temperatures, to formation of the so-called Cooper pairs. Such pairs, each consisting of two electrons with opposite spins and momenta, behave as Bose particles, and form coherent BoseEinstein condensate. ${ }^{12}$ Most properties of such a condensate may be described by a single wavefunction, evolving in time as that of a free particle with the effective potential energy $U=q \phi=-2 e \phi$, where $\phi$ is the electrochemical potential, ${ }^{13}$ and $q=-2 e$ is the total charge of the Cooper pair. As a result, for the situation shown in Fig. 3, Eq. (53) takes the form

$$
\begin{equation*}
\frac{d \varphi}{d t}=\frac{2 e}{\hbar} V, \tag{2.54}
\end{equation*}
$$

Josephson effect: basic equations
where $V=\phi_{1}-\phi_{2}$ is the applied voltage. B. Josephson has predicted that, in a particular case when a weal link is a tunnel junction, electric current $I$ of Cooper pairs through it should have a simple form: ${ }^{14}$

$$
\begin{equation*}
I=I_{c} \sin \varphi \tag{2.55}
\end{equation*}
$$

[^485]where $I_{c}$ is some constant (scaling as the weak link strength). Combining Eqs. (53) and (54), we see that if the applied voltage is constant in time, the current oscillates with the so-called Josephson frequency
\[

$$
\begin{equation*}
f_{J}=\frac{\omega_{J}}{2 \pi}, \quad \text { where } \omega_{J} \equiv \frac{2 e}{\hbar} \bar{V}, \tag{2.56}
\end{equation*}
$$

\]

as high as $\sim 484 \mathrm{MHz}$ per each microvolt of applied dc voltage. This effect is now well documented, though a direct detection of the Josephson radiation is tricky; it is much easier to observe the phase locking (synchronization) ${ }^{15}$ of the radiation by external microwave signal, which results in formation of nearly flat dc current steps at dc voltages

$$
\begin{equation*}
\bar{V}_{n}=n \frac{\hbar \omega}{2 e}, \tag{2.57}
\end{equation*}
$$

where $\omega$ is the external signal frequency and $n$ is an integer. ${ }^{16}$ This effect is now being used in highly accurate standards of dc voltage. ${ }^{17}$

Now, let us move on to a discussion of the opposite case, when a 1D particle modes in various potential profiles $U(x)$ that are constant in time. Conceptually, the simplest of such profiles is a potential step - see Fig. 4.

Fig. 2.4. Classical 1D motion in a potential profile $U(x)$.

As I am sure the reader knows, in classical mechanics, if a particle is incident on such a step (in Fig. 4, from the left), its kinetic energy $p^{2} / 2 m$ cannot be negative, so that it can only travel through the classically accessible region where its (conserved) full energy,

$$
\begin{equation*}
E=\frac{p^{2}}{2 m}+U(x) \tag{2.58}
\end{equation*}
$$

is larger than the local value $U(x)$. Let the initial velocity $v=p / m$ be positive, i.e. directed toward the step. Before it has reached the classical turning point $x_{c}$, defined by equation

$$
\begin{equation*}
U\left(x_{c}\right)=E, \tag{2.59}
\end{equation*}
$$

[^486]kinetic energy $p^{2} / 2 m$ never turns to zero, so that the particle continues to move in the initial direction. On the other hand, the particle cannot penetrate that classically forbidden region $x>x_{c}$, because there its kinetic energy would be negative there. At the point $x=x_{c}$, particle's velocity changes sign, i.e. it is reflected back from the classical turning point.

In order to see what the wave mechanics says about this situation, let us start from the simplest, sharp potential step shown with bold black lines in Fig. 5:

$$
U(x)=U_{0} \theta(x)= \begin{cases}0, & \text { at } x<0,  \tag{2.60}\\ U_{0}, & \text { at } 0<x .\end{cases}
$$

For this choice, and any energy within the interval $0<E<U_{0}$, the classical turning point is $x_{c}=0$.

Fig. 2.5. Reflection of a monochromatic wave from a potential step $U_{0}>E$. (This particular wavefunction's shape is for $U_{0}=5 E$.) The wavefunction is plotted with the same schematic vertical offset by $E$, as those in Fig. 1.7.

Let us represent an incident particle with a wave packet so long that the spread $\delta k \sim 1 / \delta x$ of its wave number spectrum, and hence the energy uncertainty $\delta E=\hbar \delta \omega=\hbar(d \omega / d k) \delta k$ is negligible in comparison with its average value $E<U_{0}$, as well as with ( $U_{0}-E$ ). In this case, $E$ may be considered a given constant, and the time dependence of the solution is given by Eq. (1.61), and we can limit ourselves to the solution of the 1D version of the stationary Schrödinger equation (1.63), in this case

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m} \frac{d^{2} \psi}{d x^{2}}+U(x) \psi=E \psi \tag{2.61}
\end{equation*}
$$

for the spatial part $\psi(x)$ of the wavefunction. ${ }^{18}$
At $x<0$, i.e. at $U=0$, the equation is reduced to the Helmholtz equation (1.75), and may be satisfied with two traveling waves, proportional to $\exp \{+i k x\}$ and $\exp \{-i k x\}$ correspondingly, with $k$ satisfying the dispersion equation (1.30):

$$
\begin{equation*}
k^{2} \equiv \frac{2 m E}{\hbar^{2}} . \tag{2.62}
\end{equation*}
$$

Thus the general solution of Eq. (61) in this region may be presented as

[^487]\[

$$
\begin{equation*}
\psi_{-}(x)=A e^{+i k x}+B e^{-i k x} \tag{2.63}
\end{equation*}
$$

\]

The second term in the right-hand part evidently describes an (infinitely long) wave packet traveling to the left, which represents particle's reflection from the potential step. If $B=-A$, this solution is reduced to Eq. (1.76) for the potential well with infinitely high walls, but as we will see in a minute, for our current case of finite step height $U_{0}$, the relation between coefficients $B$ and $A$ may be different.

To show this, let us solve Eq. (61) for $x>0$, where $U=U_{0}>E$. In this region the equation may be rewritten as

$$
\begin{equation*}
\frac{d^{2} \psi_{+}}{d x^{2}}=\kappa^{2} \psi_{+} \tag{2.64}
\end{equation*}
$$

where $\kappa$ is a real constant defined by the relation similar to Eq. (62):

$$
\begin{equation*}
\kappa^{2} \equiv \frac{2 m\left(U_{0}-E\right)}{\hbar^{2}}>0 \tag{2.65}
\end{equation*}
$$

The general solution of Eq. (64) is the sum of $\exp \{+\kappa x\}$ and $\exp \{-\kappa x\}$, with arbitrary coefficients. However, the wavefunction should be finite at $x \rightarrow \infty$, so only the latter exponent is acceptable:

$$
\begin{equation*}
\psi_{+}(x)=C e^{-\kappa x} \tag{2.66}
\end{equation*}
$$

This penetration of the wavefunction into the classically forbidden region, and hence a finite probability to find the particle there, is one of the most fascinating predictions of quantum mechanics, and has been repeatedly observed in experiment, e.g., via tunneling experiments - see below. From Eq. (66), it is evident that the constant $\kappa$, defined by Eqs. (65), may be interpreted as the reciprocal penetration depth. Even for the lightest particles this depth is usually very small. Indeed, for $E \ll U_{0}$ that equation yields

$$
\begin{equation*}
\left.\delta \equiv \frac{1}{\kappa}\right|_{E=0}=\frac{\hbar}{\left(2 m U_{0}\right)^{1 / 2}} . \tag{2.67}
\end{equation*}
$$

For example, for a conduction electron in a typical metal, that runs, at its surface, into a sharp potential step $U_{0}$, whose height equals to metal's workfunction $W \approx 5 \mathrm{eV}$ (see the discussion of the photoelectric effect in Sec. 1.1), $\delta$ is close to 0.1 nm , i.e. is close to a typical size of an atom. For heavier elementary particles (e.g., protons) the penetration depth is correspondingly lower, and for macroscopic bodies it is hardly measurable.

Returning to our problem, we still should find coefficients $A, B$, and $C$ from the boundary conditions at $x=0$. Since $E$ is a finite constant, and $U(x)$ is a finite function, Eq. (61) says that $d^{2} \psi / d x^{2}$ should be finite as well. This means that the first derivative should be continuous:

$$
\begin{equation*}
\lim _{\varepsilon \rightarrow 0}\left(\left.\frac{d \psi}{d x}\right|_{x=+\varepsilon}-\left.\frac{d \psi}{d x}\right|_{x=-\varepsilon}\right)=\lim _{\varepsilon \rightarrow 0} \int_{-\varepsilon}^{+\varepsilon} \frac{d^{2} \psi}{d x^{2}} d x=\frac{2 m}{\hbar^{2}} \lim _{\varepsilon \rightarrow 0} \int_{-\varepsilon}^{+\varepsilon}[U(x)-E] \psi d x=0 \tag{2.68}
\end{equation*}
$$

Repeating such calculation for function $\psi(x)$ itself, we see that it also should be continuous at all points, including $x=0$, so that

$$
\begin{equation*}
\psi_{-}(0)=\psi_{+}(0), \quad \frac{d \psi_{-}}{d x}(0)=\frac{d \psi_{+}}{d x}(0) . \tag{2.69}
\end{equation*}
$$

Plugging solutions (63) and (66) into these two boundary conditions, we get a system of two linear equations

$$
\begin{equation*}
A+B=C, \quad i k A-i k B=-\kappa C \tag{2.70}
\end{equation*}
$$

whose (elementary) solution enables us to express $B$ and $C$ via $A$ :

$$
\begin{equation*}
B=A \frac{k-i \kappa}{k+i \kappa}, \quad C=A \frac{2 k}{k+i \kappa} . \tag{2.71}
\end{equation*}
$$

We immediately see that since the numerator and denominator in the first of these formulas have equal moduli, so that $|B|=|A|$. This means that, as we could expect, a particle with energy $E<U_{0}$ is totally reflected from the step. As a result, at $x<0$ our solution (63) may be presented by a standing wave

$$
\begin{equation*}
\psi_{-}=2 i A e^{i \theta} \sin (k x-\theta), \quad \text { with } \theta \equiv \tan ^{-1} \frac{k}{\kappa} . \tag{2.72}
\end{equation*}
$$

Notice that the shift $\Delta x \equiv \theta / k=\left(\tan ^{-1} k / \kappa\right) / k$ of the standing wave to the right, due to the partial penetration of the wavefunction under the potential step, is commensurate with, but generally not equal to $\delta \equiv 1 / \kappa$. Figure 5 shows the full behavior of the wavefunction, for a particular case $E=U_{0} / 5$, at which $k / \kappa=\left[E /\left(U_{0}-E\right)\right]^{1 / 2}=1 / 2$.

According to Eq. (65), as the particle's energy $E$ is increased to approach $U_{0}$, the penetration depth $1 / \kappa$ diverges. This raises an important issue: what happens at $E>U_{0}$, i.e. if there is no classically forbidden region in the problem? Again, in classical mechanics the incident particle would continue to move to the right, though with a reduced velocity, corresponding to the new kinetic energy $E-U_{0}$, so there would be no reflection. In quantum mechanics, however, the situation is different. In order to analyze it, it is not necessary to re-solve the whole problem; it is sufficient to note that all our calculations, and hence Eqs. (71) are still valid if we take ${ }^{19}$

$$
\begin{equation*}
\kappa=-i k^{\prime}, \quad \text { with } \quad k^{\prime 2} \equiv \frac{2 m\left(E-U_{0}\right)}{\hbar^{2}}>0 . \tag{2.73}
\end{equation*}
$$

With this replacement, Eq. (71) becomes ${ }^{20}$

$$
\begin{equation*}
B=A \frac{k-k^{\prime}}{k+k^{\prime}}, \quad C=A \frac{2 k}{k+k^{\prime}} . \tag{2.74}
\end{equation*}
$$

The most important result of this change is that now the reflection is not complete: $|B|<|A|$. In order to evaluate this effect qualitatively, it is more fair to use not the $B / A$ or $C / A$ ratios, but rather that

[^488]of the probability currents (5) corresponding to traveling waves with amplitudes $C$ and $A$, in the corresponding regions (respectively, $x>0$ and $x<0$ ):
\[

$$
\begin{equation*}
T \equiv \frac{I_{C}}{I_{A}}=\frac{k^{\prime}|C|^{2}}{k|A|^{2}}=\frac{4 k k^{\prime}}{\left(k+k^{\prime}\right)^{2}}=\frac{4\left[E\left(E-U_{0}\right)\right]^{1 / 2}}{\left[E^{1 / 2}+\left(E-U_{0}\right)^{1 / 2}\right]^{2}} . \tag{2.75}
\end{equation*}
$$

\]

( $T$ so defined is called the transparency of the inhomogeneity, in our current case of the potential step.) The result given by Eq. (75) is plotted in Fig. 6a. Notice its most important features:
(i) At $U_{0}=0$, the transparency is full, $T=1$ - naturally, for having no step at all.
(ii) At $U_{0} \rightarrow E$, the transparency tends to zero - giving a proper connection with the case $E<U_{0}$.
(iii) We can use result (75) even for $U_{0}<0$, i.e. for the step-down (or "cliff") profile - see Fig. 6 b. Very counter-intuitively, the particle is (partly) reflected even from such a cliff, and the transmission diminishes (rather slowly) at $U_{0} \rightarrow-\infty$.

Fig. 2.6. (a) Transparency of a potential step with $U_{0}<E$ as a function of its height, according to Eq. (75), and (b) the potential profile at $U_{0}<0$.

The most important conceptual conclusion of our analysis is that the quantum particle is partly reflected from a potential step with $U_{0}<E$, in the sense that there is a nonvanishing probability $T<1$ to find it passed over the step, while there is also probability $(1-T)$ to have it reflected.

The same property is exhibited, for any relation between $E$ and $U_{0}$, by another simple potential profile $U(x)$, the famous tunnel barrier. Figure 7 shows its simple, "rectangular" version:

$$
U(x)=\left\{\begin{array}{lr}
0, & \text { for } x<-d / 2  \tag{2.76}\\
U_{0}, & \text { for }-d / 2<x<+d / 2 \\
0, & \text { for }+d / 2<x
\end{array}\right.
$$

Fig. 2.7. Rectangular tunnel barrier.

In order to analyze this problem, it is sufficient to look for the solution to the Schrödinger equation in the form (63) at $x \leq-d / 2$. At $x>+d / 2$, i.e., behind the barrier, we may use the arguments presented above (no wave packet source on the right!) to keep just one traveling wave,

$$
\begin{equation*}
\psi_{+}(x)=F e^{i k x} . \tag{2.77}
\end{equation*}
$$

However, under the barrier, i.e. at $-d / 2 \leq x \leq+d / 2$, we should generally keep both exponential terms,

$$
\begin{equation*}
\psi_{b}(x)=C e^{-\kappa x}+D e^{+\kappa x} \tag{2.78}
\end{equation*}
$$

because our previous argument, used in the potential step problem's solution, is no longer valid. (Here $k$ and $\kappa$ are still defined, respectively, by Eqs. (62) and (65).) In order to find the relation between coefficients $A, B, C, D$, and $F$, we need to plug in the solutions into the boundary conditions similar to Eqs. (69), but now at two boundary points, $x= \pm d / 2$.

Solving the resulting system of 4 linear equations for five amplitudes $(A, B, C, D$, and $F$ ), we can readily calculate four ratios $B / A, C / A$, etc., in particular,

$$
\begin{equation*}
\frac{F}{A}=\frac{\exp \{-i k d\}}{\cosh \kappa d+\frac{i}{2}\left(\frac{\kappa}{k}-\frac{k}{\kappa}\right) \sinh \kappa d} \tag{2.79a}
\end{equation*}
$$

and hence barrier's transparency

Rectangular tunnel barrier's transparency

$$
\begin{equation*}
T \equiv\left|\frac{F}{A}\right|^{2}=\left[\cosh ^{2} \kappa d+\left(\frac{\kappa^{2}-k^{2}}{2 \kappa k}\right)^{2} \sinh ^{2} \kappa d\right]^{-1} \tag{2.79b}
\end{equation*}
$$

Figure 8 a shows the transparency as a function of particle energy $E$, for several characteristic values of the barrier thickness $d$, or rather of the ratio $d / \delta$, where $\delta$ is defined by Eq. (67).

Fig. 2.8. Transparency of the rectangular tunnel barrier as a function of particle's energy $E$.

The plots show that for a thin barrier $(d<\delta)$ the transparency grows gradually with particle's energy. This growth is natural, because the penetration constant $\kappa$ decreases with the growth of $E$, i.e., the wavefunction penetrates more and more into the barrier, so that more and more of it is "picked up" at the second interface $(x=+d / 2)$ and transferred into the wave $F \exp \{i k x\}$ propagating behind the barrier. As Eq. (79b) shows, for thick barriers ( $d \gg \delta$ ), this dependence is dominated by an exponent,

$$
\begin{equation*}
T \approx\left(\frac{4 k \kappa}{k^{2}+\kappa^{2}}\right)^{2} e^{-2 \kappa d} \tag{2.80}
\end{equation*}
$$

Thick
tunnel
barrier's transparency
that may be clearly seen as a straight segments in semi-log plots (Fig. 8b) of $T$ as a function of the combination $\left(1-E / U_{0}\right)^{1 / 2}$ which is proportional to $\kappa$ - see Eq. (65).

Equation (80) also clearly shows the exponential dependence of the barrier transparency of its thickness at $d \gg \delta$. This dependence is the most important factor for various applications of the quantum-mechanical tunneling - from the field emission ${ }^{21}$ of electrons to scanning tunneling microscopy. ${ }^{22}$ Also noted should be substantial negative implications of the effect for modern electronic engineering, most importantly imposing a limit for scaling down of field effect transistors in semiconductor integrated circuits (and hence the circuit density increase according to the well-known Moore's law), due to increase of tunneling both through the gate oxide and along transistor's channel. ${ }^{23}$

Another interesting effect visible in Fig. 8a (for case $d=0.3 \delta$ ) are the oscillations of $T$ at $E>U_{0}$. This is our first glimpse at one more interesting quantum effect: resonant tunneling. I will discuss this effect in detail in Sec. 5 below.

### 2.4. The WKB approximation

Before moving on to exploring more complex potentials, let us see whether the results discussed in the previous section hold on in the opposite limit of so-called soft, gradual potential profiles, like that sketched in Fig. 4. (The quantitative conditions of the "softness" will be derived below). The most efficient analytical tool in this limit is the $W K B$ (or "quasiclassical") approximation developed by H. Jeffrey, G. Wentzel, A. Kramers, and L. Brillouin in 1926-27.

In order to derive its 1D version, let us rewrite the Schrödinger equation (61) as

$$
\begin{equation*}
\frac{d^{2} \psi}{d x^{2}}+k^{2}(x) \psi=0 \tag{2.81}
\end{equation*}
$$

where the local value of wave number $k(x)$ is defined similarly to Eq. (73),

$$
\begin{equation*}
k^{2}(x) \equiv \frac{2 m[E-U(x)]}{\hbar^{2}} \tag{2.82}
\end{equation*}
$$

Local wave
number
but now it may be a function of $x$. We already know that for $k(x)=$ const, the fundamental solutions of this equation have form $A \exp \{+i k x\}$ and $B \exp \{-i k x\}$. Any of them may be presented in a simple form

[^489]\[

$$
\begin{equation*}
\psi(x)=e^{i \Phi(x)} \tag{2.83}
\end{equation*}
$$

\]

where $\Phi(x)$ is a complex function, in this simplest case equal to either $(k x-i \ln A)$ or $(-k x-i \ln B)$. This is why we may try use Eq. (83) to look for solution of Eq. (81) even in the general case, $k(x) \neq$ const. Differentiating Eq. (83) twice, we get

$$
\begin{equation*}
\frac{d \psi}{d x}=i \frac{d \Phi}{d x} e^{i \Phi}, \quad \frac{d^{2} \psi}{d x^{2}}=\left[i \frac{d^{2} \Phi}{d x^{2}}-\left(\frac{d \Phi}{d x}\right)^{2}\right] e^{i \Phi} \tag{2.84}
\end{equation*}
$$

Plugging the last expression into Eq. (81) and requiring the factor before $\exp \{i \Phi(x)\}$ to vanish, we get

$$
\begin{equation*}
i \frac{d^{2} \Phi}{d x^{2}}-\left(\frac{d \Phi}{d x}\right)^{2}+k^{2}(x)=0 \tag{2.85}
\end{equation*}
$$

This is still an exact, general result. At the first sight, it looks worse than the initial equation (81), because Eq. (85) is nonlinear. However, it is more ready for simplification in the limit when the potential profile is very smooth, $d U / d x \rightarrow 0$. Indeed, we know that for a uniform potential, $\Phi$ " $=0$. Hence, in the " $0^{\text {th" }}$, approximation, $\Phi(x) \rightarrow \Phi_{0}(x)$, we may try to keep that result, so that Eq. (85) yields

$$
\begin{equation*}
\left(\frac{d \Phi_{0}}{d x}\right)^{2}=k^{2}(x) \tag{2.86a}
\end{equation*}
$$

Just as in the uniform case, this equation has two roots,

$$
\begin{equation*}
\frac{d \Phi_{0}}{d x}= \pm k(x) \tag{2.86b}
\end{equation*}
$$

so that its general solution is

$$
\begin{equation*}
\psi_{0}(x)=A \exp \left\{+i \int^{x} k\left(x^{\prime}\right) d x^{\prime}\right\}+B \exp \left\{-i \int^{x} k\left(x^{\prime}\right) d x^{\prime}\right\}, \tag{2.87}
\end{equation*}
$$

where $x$ ' is the lower limits of integration affect only constants $A$ and $B$. The physical sense of this result is simple: it is a sum of forward- and back-propagating waves, with the coordinate-dependent local wave number $k(x)$ that self-adjusts to the potential profile.

Let me emphasize the non-trivial nature of this approximation. ${ }^{24}$ First, any attempt to address the problem with a standard perturbation approach (say, $\psi=\psi_{0}+\psi_{1}+\ldots$, with $\psi_{n}$ proportional to $n^{\text {th }}$ power of some small parameter, ${ }^{25}$ in this case scaling $d^{2} U / d^{2} x$ ) would fail for most potentials, because even a slight but persisting deviation of $U(x)$ from a constant leads to a gradual accumulation of phase $\Phi_{0}$, impossible to describe by any small perturbation of $\psi$. Second, the dropping of term $d^{2} \Phi / d x^{2}$ in Eq. (85) is not too easy to justify. Indeed, since we are committed to the "soft potential limit" $d U / d x \rightarrow 0$, we should be ready to assume the characteristic length $a$ of spatial variation of $\Phi$ to be large, and neglect

[^490]the terms that are the smallest ones in the limit $a \rightarrow \infty$. However, both first terms in Eq. (85) are apparently of the same order in $a$, namely $O\left(a^{-2}\right)$; why have we neglected just one of them?

The price we have paid for such a "sloppy" treatment is high: Eq. (87) does not satisfy the fundamental property of the Schrödinger equation, the probability current conservation. Indeed, since Eq. (81) describes a fixed-energy (stationary) spatial part of the general Schrödinger equation, its probability density $w=\Psi \Psi^{*}=\psi \psi^{*}$, and should not depend on time. Hence, according to Eq. (6), we should have $I(x)=$ const. However, this is not true for each component of Eq. (87); for example for the forward-propagating component of its right-hand part, Eq. (5) yields

$$
\begin{equation*}
I_{0}(x)=\frac{\hbar}{m}|A|^{2} k(x), \tag{2.88}
\end{equation*}
$$

evidently not a constant if $k(x) \neq$ const.
The brilliance of the WKB theory is that the problem may be fixed without revising the $0^{\text {th }}$ approximation. Indeed, let us explore the next, $1^{\text {st }}$ approximation instead:

$$
\begin{equation*}
\Phi(x) \rightarrow \Phi_{\mathrm{WKB}}(x) \equiv \Phi_{0}(x)+\Phi_{1}(x) \tag{2.89}
\end{equation*}
$$

where $\Phi_{0}$ still obeys Eq. (85), while $\Phi_{1}$ describes a small correction to the $0^{\text {th }}$ approximation, in the following sense: ${ }^{26}$

$$
\begin{equation*}
\left|\frac{d \Phi_{1}}{d x}\right| \ll\left|\frac{d \Phi_{0}}{d x}\right|=k(x) . \tag{2.90}
\end{equation*}
$$

Plugging Eq. (89) into Eq. (85), with the account of the definition (86), we get

$$
\begin{equation*}
i\left(\frac{d^{2} \Phi_{0}}{d x^{2}}+\frac{d^{2} \Phi_{0}}{d x^{2}}\right)-\frac{d \Phi_{1}}{d x}\left(2 \frac{d \Phi_{0}}{d x}+\frac{d \Phi_{1}}{d x}\right)=0 \tag{2.91}
\end{equation*}
$$

Using condition (90), we may neglect $d^{2} \Phi_{1} / d x^{2}$ in comparison with $d^{2} \Phi_{0} / d x^{2}$ in the first parenthesis, and $d \Phi_{1} / d x$ in comparison with $2 d \Phi_{0} / d x$ in the second parenthesis. As a result, we get the following approximate result:

$$
\begin{gather*}
\frac{d \Phi_{1}}{d x}=\frac{i}{2} \frac{d^{2} \Phi_{0}}{d x^{2}} / \frac{d \Phi_{0}}{d x}=\frac{i}{2} \frac{d}{d x}\left(\ln \frac{d \Phi_{0}}{d x}\right)=\frac{i}{2} \frac{d}{d x}[\ln k(x)]=i \frac{d}{d x}\left[\ln k^{1 / 2}(x)\right],  \tag{2.92}\\
\left.i \Phi\right|_{\mathrm{WKB}} \equiv i \Phi_{0}+i \Phi_{1}= \pm i \int^{x} k\left(x^{\prime}\right) d x^{\prime}+\ln \frac{1}{k^{1 / 2}(x)},  \tag{2.93}\\
\psi_{\mathrm{WKB}}(x)=\frac{a}{k^{1 / 2}(x)} \exp \left\{i \int^{x} k\left(x^{\prime}\right) d x^{\prime}\right\}+\frac{b}{k^{1 / 2}(x)} \exp \left\{-i \int^{x} k\left(x^{\prime}\right) d x^{\prime}\right\}, \text { for } k^{2}(x)>0 . \tag{2.94}
\end{gather*}
$$

(Again, the lower integration limit is arbitrary, but its choice may be incorporated into complex constants $a$ and $b$.) This modification of the $0^{\text {th }}$ approximation (87) overcomes the problem of current continuity; for example, for the forward-propagating wave, Eq. (5) gives

[^491]\[

$$
\begin{equation*}
I_{\mathrm{WKB}}(x)=\frac{\hbar}{m}|a|^{2}=\mathrm{const} \tag{2.95}
\end{equation*}
$$

\]

Physically, factor $k^{1 / 2}$ in the denominator of the WKB wavefunction's pre-exponent is easy to understand. The smaller the local group velocity (34) of the wave packet, $v_{\mathrm{gr}}(x)=\hbar k(x) / m$, the "easier" (more probable) it should be to find the particle within a certain interval $d x$. This is exactly the result that WKB gives: $d W / d x=w(x)=\psi \psi^{*} \propto 1 / k(x) \propto 1 / v_{\mathrm{gr}}$.

Another value of the $1^{\text {st }}$ approximation is a clarification of WKB theory's validity condition: it is given by Eq. (90). Plugging into this relation the first form of Eq. (92), and estimating $\left|\Phi_{0}{ }^{\prime}\right|$ as $\left|\Phi_{0}{ }^{\prime}\right| / a$, where $a$ is the spatial scale of a substantial change of $\left|\Phi_{0}{ }^{\prime}\right|=k(x)$, we can rewrite the condition as

$$
\begin{equation*}
k a \gg 1 \tag{2.96}
\end{equation*}
$$

In plain English, this means that the region where $U(x)$, and hence $k(x)$, change substantially should contain many de Broglie wavelengths $\lambda=2 \pi / k$.

So far I have implied that $k^{2}(x) \propto E-U(x)$ is positive, i.e. particle moves in the classically accessible region. Now let us extend the WKB approximation to the situation where the difference $E$ $U(x)$ may change sign, for example to the reflection problem sketched in Fig. 4. Just as we did for the sharp potential step, we first need to find the appropriate solution for the classically forbidden region, in this case $x>x_{c}$. For that, there is no need to redo our calculations, because they are still valid if we, just as in the sharp step problem, take $k(x)=i \kappa(x)$, where

$$
\begin{equation*}
\kappa^{2}(x) \equiv \frac{2 m[U(x)-E]}{\hbar^{2}}>0, \quad \text { for } x>x_{c} \tag{2.97}
\end{equation*}
$$

and keep just one of two possible solutions (with $\kappa>0$ ), in analogy with Eq. (66). The result is

$$
\begin{equation*}
\psi_{\mathrm{WKB}}(x)=\frac{c}{\kappa^{1 / 2}(x)} \exp \left\{-\int^{x} \kappa\left(x^{\prime}\right) d x^{\prime}\right\}, \quad \text { for } k^{2}<0, \text { i.e. } \kappa^{2}>0, \tag{2.98}
\end{equation*}
$$

with the lower limit at some point with $\kappa^{2}>0$ as well. This is a really wonderful formula! It describes the quantum-mechanical penetration of the particle into the classically forbidden region, and provides a natural generalization of Eq. (66) - leaving intact, of course, our estimates of the depth $\delta \sim 1 / \kappa$ of such penetration.

Now we have to do what we have done for the sharp-step problem in Sec. 2: use the boundary conditions in the interface point $x=x_{c}$ to relate constants $a, b$, and $c$. However, now this operation is a tad more complex, because both WKB functions (94) and (98) diverge, albeit weakly, at the classical turning point, were both $k(x)$ and $\kappa(x)$ tend to zero. This connection problem may be however, solved in the following way. ${ }^{27}$ Let us use the commitment of potential "softness", assuming that it allows us to keep just two leading terms in the Taylor expansion of function $U(x)$ at point $x_{c}$ :

$$
\begin{equation*}
U(x) \approx U\left(x_{c}\right)+\left.\frac{d U}{d x}\right|_{x=x_{c}}\left(x-x_{c}\right)=E+\left.\frac{d U}{d x}\right|_{x=x_{c}}\left(x-x_{c}\right) . \tag{2.99}
\end{equation*}
$$

[^492]Using this truncated expansion, and introducing a dimensionless variable for coordinate's deviation from the classical turning point,

$$
\begin{equation*}
\zeta \equiv \frac{x-x_{c}}{x_{0}}, \quad x_{0} \equiv\left(\frac{\hbar^{2}}{2 m(d U / d x)}\right)^{1 / 3}, \tag{2.100}
\end{equation*}
$$

we reduce the Schrödinger equation (61) to the simple Airy equation

$$
\begin{equation*}
\frac{d^{2} \psi}{d \zeta^{2}}-\zeta \psi=0 \tag{2.101}
\end{equation*}
$$

Airy equation

As for all linear, ordinary differential equations of the second order, the general solution of Eq. (101) may be presented as a linear combination of two fundamental solutions, in this case called Airy functions $\operatorname{Ai}(\zeta)$ and $\operatorname{Bi}(\zeta)$, shown in Fig. 9a.
(a)

(b)

Fig. 2.9. (a) Airy functions Ai and Bi , and (b) the WKB approximation for function $\mathrm{Ai}(\varsigma)$.

The latter function diverges at $\zeta \rightarrow \infty$, and thus is not suitable for our current problem (Fig. 4), while the former function has the following asymptotic behaviors at $|\zeta| \gg 1: 28$

$$
\operatorname{Ai}(\zeta) \rightarrow \frac{1}{\pi^{1 / 2}|\zeta|^{1 / 4}} \times \begin{cases}\frac{1}{2} \exp \left\{-\frac{2}{3} \zeta^{3 / 2}\right\}, & \text { for } \zeta \rightarrow+\infty  \tag{2.102}\\ \sin \left\{\frac{2}{3}(-\zeta)^{3 / 2}+\frac{\pi}{4}\right\}, & \text { for } \zeta \rightarrow-\infty\end{cases}
$$

Now let us apply the WKB approximation to the Airy equation (101). Taking the classical turning point $(\zeta=0)$ for the lower limit, for $\zeta>0$ we get (in dimensionless units)

[^493]are often convenient for practical calculation of Airy functions at intermediate values of the argument, $\mid \varsigma \sim 1$.
\[

$$
\begin{equation*}
\kappa^{2}(\zeta)=\zeta, \quad \kappa(\zeta)=\zeta^{1 / 2}, \int_{0}^{\zeta} \kappa\left(\zeta^{2}\right) d \zeta^{\prime}=\frac{2}{3} \zeta^{3 / 2}, \tag{2.103}
\end{equation*}
$$

\]

i.e. exactly the exponent in the first line of Eq. (102). Making a similar calculation for $\zeta<0$, with the natural assumption $|b|=|a|$ (full reflection from the potential step), we arrive at the following result:

$$
\mathrm{Ai}_{\mathrm{WKB}}(\zeta)=\frac{1}{|\zeta|^{1 / 4}} \times \begin{cases}c \exp \left\{-\frac{2}{3} \zeta^{3 / 2}\right\}, & \text { for } \zeta>0  \tag{2.104}\\ a \sin \left\{\frac{2}{3}(-\zeta)^{3 / 2}+\varphi\right\}, & \text { for } \zeta<0\end{cases}
$$

This approximation differs from the exact solution at small values of $\zeta$, i.e. close to the classical turning point - see Fig. 9b. However, at $|\zeta| \gg 1$, Eqs. (104) describe the Airy function exactly if

$$
\begin{equation*}
\varphi=\frac{\pi}{4} \quad \text { and } \quad c=\frac{a}{2} . \tag{2.105}
\end{equation*}
$$

Hence we can use these connection formulas to express the relations between coefficients $a, b$, and $c$ of the general WKB solutions (94) and (98). In particular, the first of them yields $b=-a \exp \{i \pi / 2\}$, so that Eq. (94) becomes

$$
\begin{equation*}
\psi_{\mathrm{WKB}}\left(x<x_{c}\right)=\frac{a^{\prime}}{k^{1 / 2}(x)}\left[\exp \left\{+i \int_{x_{c}}^{x} k\left(x^{\prime}\right) d x^{\prime}\right\}-\exp \left\{-i \int_{x_{c}}^{x} k\left(x^{\prime}\right) d x^{\prime}+i \frac{\pi}{2}\right\}\right] . \tag{2.106}
\end{equation*}
$$

This result may be also described by a simple mnemonic rule: reflecting from a "soft" potential step, the wavefunction acquires an additional phase shift $\Delta \varphi=\pi / 2$, if compared with the reflection from a "hard" (vertical) potential wall located at $x=x_{c}$, for which, according to Eq. (1.76), we would have $b=-a$.

Let us quantify the condition of validity of the connection formulas (105) - in other words, the criterion of the step "softness". For that, within the region where the WKB approximation differs from for the exact Airy equation $\left(|\zeta| \sim 1\right.$, i.e. $\left|x-x_{c}\right| \sim x_{0}$ ), the deviation from the linear approximation (99) of the potential profile should be relatively small. This deviation may be estimated using the next term of the Taylor expansion, $d^{2} U /\left.d^{2} x\right|_{x=x c}\left(x-x_{c}\right)^{2} / 2$. As a result, the softness condition may be expressed as $\left|d^{2} U / d^{2} x\right|_{x=x c} x_{0} \ll|d U / d x|_{x=x c}$. With the account of Eq. (100) for $x_{0}$, the condition becomes

WKB:
second condition of validity

$$
\begin{equation*}
\left|\frac{d^{2} U}{d x^{2}}\right|_{x=x c}^{3} \ll \frac{2 m}{\hbar^{2}}\left(\frac{d U}{d x}\right)_{x=x c}^{4} \tag{2.107}
\end{equation*}
$$

As an example of a very useful application of the WKB approximation, let us use it to calculate the energy spectrum of 1D particle in a soft 1D quantum well (Fig. 10). As was discussed above, we may always consider the standing wave describing an eigenstate $\psi_{n}$ (corresponding to eigenenergy $E_{n}$ ) as a traveling wave going back and forth between the walls, being sequentially reflected by each of them. Let us apply the WKB approximation to such a traveling wave. First, according to Eq. (94), propagating from the left classical turning point $x_{L}$ to the right point $x_{R}$, it acquires phase change

$$
\begin{equation*}
\Delta \varphi_{\rightarrow}=\int_{x_{L}}^{x_{R}} k(x) d x \tag{2.108}
\end{equation*}
$$

At the reflection from the soft wall at $x_{R}$, according to the connection formula (106), the wave acquires an additional shift $\pi / 2$. Now, traveling back from $x_{R}$ to $x_{L}$ the wave gets a shift similar to one given by Eq. (108): $\Delta \varphi_{\leftarrow}=\Delta \varphi_{\rightarrow}$. Finally, at the reflection from $x_{L}$ it gets one more $\pi / 2$. Summing up all these contributions, we may write the self-consistency condition (that the wavefunction "catches its own tail with its teeth"), in the form

$$
\begin{equation*}
\Delta \varphi_{\text {total }} \equiv \Delta \varphi_{\rightarrow}+\frac{\pi}{2}+\Delta \varphi_{\leftarrow}+\frac{\pi}{2}=2 \int_{x_{L}}^{x_{R}} k(x) d x+\pi=2 \pi n, \quad \text { with } n=1,2, \ldots \tag{2.109}
\end{equation*}
$$

Rewriting this result in terms of particle's momentum $p(x)=\hbar k(x)$, we arrive at the famous 1D BohrSommerfeld quantization rule

$$
\begin{equation*}
\oint_{C} p(x) d x=2 \pi \hbar\left(n-\frac{1}{2}\right) \tag{2.110}
\end{equation*}
$$

Bohr-
Sommerfeld quantization rule
where the closed path $C$ means the full period of classical motion. ${ }^{29}$

Fig. 2.10. Quasiclassical treatment of eigenstates in a soft 1D potential well.

Let us see what does this rule give for the very important particular case of a quadratic potential profile of a harmonic oscillator of frequency $\omega_{0}$. In this case,

$$
\begin{equation*}
U(x)=\frac{m}{2} \omega_{0}^{2} x^{2}, \tag{2.111}
\end{equation*}
$$

and the classical turning points are the roots of a simple equation

$$
\begin{equation*}
\frac{m}{2} \omega_{0}^{2} x_{c}^{2}=E_{n} \tag{2.112}
\end{equation*}
$$

so that $x_{R}=x_{n} \equiv\left(2 E_{n} / m\right)^{1 / 2} / \omega_{0}>0, x_{L}=-x_{n}<0$. Due to potential's symmetry, the integration required by Eq. (110) is also simple:

$$
\begin{equation*}
\int_{x_{L}}^{x_{R}} p(x) d x=\int_{-x_{c}}^{+x_{c}}\left\{2 m\left[E_{n}-U(x)\right]\right\}^{1 / 2} d x=\left(2 m E_{n}\right)^{1 / 2} \int_{-x_{c}}^{+x_{c}}\left(1-\frac{x^{2}}{x_{n}^{2}}\right)^{1 / 2} d x=\left(2 m E_{n}\right)^{1 / 2} x_{n} \frac{\pi}{2}=\frac{2 E_{n}}{\omega_{0}} \frac{\pi}{2} \tag{2.113}
\end{equation*}
$$

[^494]so that Eq. (110) is satisfied if
\[

$$
\begin{equation*}
E_{n}=\hbar \omega_{0}\left(n^{\prime}+\frac{1}{2}\right), \quad \text { with } n^{\prime} \equiv n-1=0,1,2, \ldots \tag{2.114}
\end{equation*}
$$

\]

In order to estimate the validity of this result, we have to check condition (96) at all points of the classically allowed region, and Eq. (107) at the turning points. A straightforward calculation shows that both conditions are valid for $n \gg 1$. However, we will see below that Eq. (114) is actually exactly correct for all energy levels - thanks to special properties of potential profile (111).

Now, let us look at the second of connection formulas (105), $c=a / 2$. Again, it differs from the result (71) for a sharp potential step, that may be rewritten as

$$
\begin{equation*}
C=A \frac{2 k}{k+i \kappa}=A \frac{2}{\left[1+(\kappa / k)^{2}\right]^{1 / 2}} \exp \{-i 2 \theta\}, \tag{2.115}
\end{equation*}
$$

by both the modulus and phase factor. (In the WKB approximation, the latter factor always equals $\pi / 4$.) Hence, again, the WKB approximation's prediction is not exact for sharp potentials; nevertheless, it is broadly used for practical calculations. One of the most important of them is the transparency of an arbitrary but smooth potential barrier (Fig. 11).

Fig. 2.11. 1D potential barrier of an arbitrary (but smooth) shape.

Here, just as in the case of a rectangular barrier, we need to take unto consideration five partial "waves" (or rather fundamental solutions of the Schrödinger equation): ${ }^{30}$

$$
\psi_{\mathrm{WKB}}= \begin{cases}\frac{a}{k^{1 / 2}(x)} \exp \left\{i \int^{x} k\left(x^{\prime}\right) d x^{\prime}\right\}+\frac{b}{k^{1 / 2}(x)} \exp \left\{-i \int^{x} k\left(x^{\prime}\right) d x^{\prime}\right\}, & \text { for } x<x_{c},  \tag{2.116}\\ \frac{c}{\kappa^{1 / 2}(x)} \exp \left\{-\int^{x} \kappa\left(x^{\prime}\right) d x^{\prime}\right\}+\frac{d}{\kappa^{1 / 2}(x)} \exp \left\{\int^{x} \kappa\left(x^{\prime}\right) d x^{\prime}\right\}, & \text { for } x_{c}<x<x_{c}{ }^{\prime}, \\ \frac{f}{k^{1 / 2}(x)} \exp \left\{i \int^{x} k\left(x^{\prime}\right) d x^{\prime}\right\}, & \text { for } x_{c}{ }^{\prime}<x,\end{cases}
$$

where lower limits of integrals are arbitrary (each within the corresponding range of $x$ ). Since on the right of the left classical point we have two exponents rather than one, and on the right of the second

[^495]point, one traveling waves rather than two, the connection formulas (105) have to be generalized, using asymptotic formulas not only for $\operatorname{Ai}(\zeta)$, but also for the second Airy function, $\mathrm{Bi}(\zeta)$. The analysis, absolutely similar to that carried out above (though naturally a bit more bulky), ${ }^{31}$ gives a remarkably simple result:
\[

$$
\begin{equation*}
T_{\mathrm{WKB}} \equiv\left|\frac{f}{a}\right|^{2}=\exp \left\{-2 \int_{x_{c}}^{x_{c}^{\prime}} \kappa(x) d x\right\}=\exp \left\{-\frac{2}{\hbar} \int_{x_{c}}^{x_{c}^{\prime}}(2 m[U(x)-E])^{1 / 2} d x\right\}, \tag{2.117}
\end{equation*}
$$

\]

with no pre-exponential factor. This formula is broadly used in applied quantum mechanics, despite the approximate character of its pre-exponential coefficient for insufficiently soft barriers that do not satisfy Eq. (107). For example, Eq. (80) shows that for a thick rectangular barrier with $k=\kappa$, i.e. $U_{0}=2 E$, the WKB approximation (117) underestimates $T$ by a factor of 4 . However, on the logarithmic scale of Fig. 8 b , such factor, about half an order of magnitude, still looks as a small correction.

Notice that when $E$ approaches the barrier top $U_{\max }$ (Fig. 11), points $x_{c}$ and $x_{c}{ }^{\prime}$ merge, so that, according to Eq. (117), $T_{\mathrm{WKB}} \rightarrow$ 1, i.e. the particle reflection vanishes at $E=U_{\max }$. However, this conclusion is incorrect even for smooth barriers where one could naively expect the WKB approximation to work perfectly. Indeed, near point $x=x_{m}$ where the potential reaches maximum (i.e. $U\left(x_{m}\right)=U_{\max }$, we may always approximate a smooth function $U(x)$ by an inverted parabola,

$$
\begin{equation*}
U(x) \approx U_{\max }-\frac{m \omega_{0}^{2}\left(x-x_{m}\right)^{2}}{2} \tag{2.118}
\end{equation*}
$$

Calculating the derivatives $d U / d x$ and $d^{2} U / d x^{2}$ of this function and plugging them into condition (107), we see that the WKB approximation is only valid if $\left|U_{\max }-E\right| \gg \hbar \omega_{0}$. An exact analysis ${ }^{32}$ of tunneling through barrier (118) gives the following Kemble formula:

$$
\begin{equation*}
T=\frac{1}{1+\exp \left\{-2 \pi\left(E-U_{\max }\right) / \hbar \omega_{0}\right\}}, \tag{2.119}
\end{equation*}
$$

valid for any sign of difference $\left(E-U_{\max }\right)$. This formula describes a gradual approach of $T$ to 1 , i.e. a gradual reduction of reflection at particle energy's increase, with $T=1 / 2$ (rather than 1 ) at $E=U_{\text {max }}$.

Now the last remark of this section: our discussions of the propagator and the WKB approximation open a straight way toward an alternative formulation of quantum mechanics, based on the Feynman path integral, but I will postpone its discussion until a more compact ("bra-ket") notation has been introduced in Chapter 4.

### 2.5. Transfer matrix, resonant tunneling, and metastable states

Let us now explore motion in more complex potential profiles. The piecewise-constant and smooth-potential models of $U(x)$ are not too convenient here, because they both require "stitching" local

[^496]solutions in each classical turning point, which may lead to very cumbersome calculations. However, we may get a very good insight of the physics phenomena in such profiles, using their approximation by a set of Dirac's delta-functions. For that, let us have a look at what our old result (79) gives in the limit of a very thin and high rectangular barrier, $d \ll \delta, E \ll U_{0}$ (giving $k \ll \kappa \ll 1 / d$ ):
\[

$$
\begin{equation*}
T \equiv\left|\frac{F}{A}\right|^{2} \rightarrow \frac{1}{|1+i \alpha|^{2}}=\frac{1}{1+\alpha^{2}}, \tag{2.120}
\end{equation*}
$$

\]

where parameter $\alpha$ is defined as

$$
\begin{equation*}
\alpha \equiv \frac{1}{2}\left(\frac{\kappa^{2}-k^{2}}{\kappa k}\right) \kappa d \approx \frac{1}{2} \frac{\kappa^{2} d}{k} \approx \frac{m}{\hbar^{2} k} U_{0} d . \tag{2.121}
\end{equation*}
$$

The last product, $U_{0} d$, is just the "area"

$$
\begin{equation*}
w \equiv \int_{U(x)>E} U(x) d x \tag{2.122}
\end{equation*}
$$

of the barrier. This fact implies that the very simple result (120) for the transparency may be correct for a barrier of any shape, provided that it is sufficiently thin and high.

Indeed, let us consider the tunneling problem for a very thin barrier with $\kappa d, k d \ll 1$ (Fig. 12), approximating it by Dirac's $\delta$-function:

$$
\begin{equation*}
U(x)=w \delta(x) . \tag{2.123}
\end{equation*}
$$

Fig. 2.12. Delta-functional tunnel barrier.

We already know the solutions in all points but $x=0-$ see Eqs. (63) and (77) - so we only need to analyze boundary conditions in that point to find coefficients $A, B$, and $F$ - or rather the ratios $B / A$ and $F / A$. However, due to the special character of the $\delta$-function, we should be careful here. Indeed, instead of Eq. (68) we now get

$$
\begin{equation*}
\frac{d \psi_{+}}{d x}(0)-\frac{d \psi_{-}}{d x}(0)=\lim _{\varepsilon \rightarrow 0} \int_{-\varepsilon}^{+\varepsilon} \frac{d^{2} \psi}{d x^{2}} d x=\lim _{\varepsilon \rightarrow 0} \frac{2 m}{\hbar^{2}} \int_{-\varepsilon}^{+\varepsilon}[U(x)-E] \psi d x=\frac{2 m}{\hbar^{2}} w_{\psi}(0) . \tag{2.124}
\end{equation*}
$$

On the other hand, the wavefunction itself is still continuous:

$$
\begin{equation*}
\psi_{+}(0)-\psi_{-}(0)=\lim _{\varepsilon \rightarrow 0} \int_{-\varepsilon}^{+\varepsilon} \frac{d \psi}{d x} d x=0 \tag{2.125}
\end{equation*}
$$

Using these boundary conditions, we readily get the following system of two linear equations,

$$
\begin{equation*}
A+B=F, \quad i k F-(i k A-i k B)=\frac{2 m w}{\hbar^{2}} F, \tag{2.126}
\end{equation*}
$$

whose solution yields

$$
\begin{equation*}
\frac{B}{A}=\frac{-i \alpha}{1+i \alpha}, \quad \frac{F}{A}=\frac{1}{1+i \alpha}, \quad \text { where } \alpha \equiv \frac{m w}{\hbar^{2} k} . \tag{2.127}
\end{equation*}
$$

For the barrier transparency $T \equiv|F / A|^{2}$, this result again gives Eq. (120). That formula may be recast to give a simple expression (valid only for $E \ll U_{\max }$ ) for the transmission coefficient,

$$
\begin{equation*}
T=\frac{1}{1+\alpha^{2}}=\frac{E}{E+E_{0}}, \quad \text { where } E_{0} \equiv \frac{m w^{2}}{2 \hbar^{2}} \tag{2.128}
\end{equation*}
$$

that shows that as energy becomes larger than parameter $E_{0}$, the barrier's transparency approaches unity.
However, the most important application of Eqs. (126) is for deriving transparency of more complex potential profiles. For that, let us first introduce very general notions of the scattering and transfer matrices, currently for the 1D case. Consider an arbitrary but finite-length potential "bump" (more formally called a scatterer), localized somewhere between points $x_{1}$ and $x_{2}$, on the flat potential background, say $U=0$ (Fig. 13). We know the general solution, with a certain energy $E$, outside the interval are a set of two sinusoidal waves. Let us present them in the form

$$
\begin{equation*}
\psi_{j}=A_{j} e^{i k\left(x-x_{j}\right)}+B_{j} e^{-i k\left(x-x_{j}\right)}, \tag{2.129}
\end{equation*}
$$

where (for now) $j=1$ or 2 , and $(\hbar k)^{2} / 2 m=E$. Note that each of the wave pairs (129) has, in this notation, its own reference point $x_{j}$, because this is very convenient for the calculations which follow.

Fig. 2.13. A single 1D scatterer.

As we have already discussed, if the wave/particle is incident from the left, the linear Schrödinger equation within the scatterer range ( $x_{1}<x<x_{2}$ ), can provide only linear expressions of the transmitted $\left(A_{2}\right)$ and reflected $\left(B_{1}\right)$ wave amplitudes via the incident wave amplitude $A_{1}$ :

$$
\begin{equation*}
A_{2}=S_{21} A_{1}, \quad B_{1}=S_{11} A_{1} \tag{2.130}
\end{equation*}
$$

where $S_{11}$ and $S_{21}$ are certain (generally, complex) coefficients. In this case, $B_{2}=0$. Alternatively, if a wave, with amplitude $B_{2}$, is incident from the right, it also may induce a transmitted wave $\left(B_{1}\right)$ and reflected wave $\left(A_{2}\right)$ with amplitudes

$$
\begin{equation*}
B_{1}=S_{12} B_{2}, \quad A_{2}=S_{22} B_{2}, \tag{2.131}
\end{equation*}
$$

where coefficients $S_{22}$ and $S_{12}$ are generally different from $S_{11}$ and $S_{21}$. Now we can use the linear superposition principle to argue that if waves $A_{1}$ and $B_{2}$ are simultaneously incident on the scatterer (say,
because wave $B_{2}$ has been partly reflected back by some other scatterer located at $x>x_{2}$ ), the resulting scattered wave amplitudes $A_{2}$ and $B_{1}$ are just the sums of their values for separate incident waves:

$$
\begin{align*}
& B_{1}=S_{11} A_{1}+S_{12} B_{2}  \tag{2.132}\\
& A_{2}=S_{21} A_{1}+S_{22} B_{2}
\end{align*}
$$

These linear relations may be conveniently presented by the so-called scattering matrix (frequently called just "S-matrix"):

Scattering
matrix: definition

$$
\binom{B_{1}}{A_{2}}=\mathrm{S}\binom{A_{1}}{B_{2}}, \quad \mathrm{~S} \equiv\left(\begin{array}{ll}
S_{11} & S_{12}  \tag{2.133}\\
S_{21} & S_{22}
\end{array}\right) .
$$

Scattering matrices, duly generalized, are an important tool for the analysis of wave scattering in more than one dimensions; for 1D problems, however, another matrix is more convenient to present the same linear relations (132). Indeed, let us solve this system for $A_{2}$ and $B_{2}$. The result is

Transfer
matrix: definition

$$
\left.\begin{array}{l}
A_{2}=T_{11} A_{1}+T_{12} B_{1}, \quad \text { i.e. } \quad\binom{A_{2}}{B_{2}}=T_{21} A_{1}+T_{22} B_{1}, \tag{2.134}
\end{array}\right)=\mathrm{T}\binom{A_{1}}{B_{1}}
$$

where T is the transfer matrix with elements

$$
\begin{equation*}
T_{11}=S_{21}-\frac{S_{11} S_{22}}{S_{12}}, \quad T_{12}=\frac{S_{22}}{S_{12}}, \quad T_{21}=-\frac{S_{11}}{S_{21}}, \quad T_{22}=\frac{1}{S_{12}} . \tag{2.135}
\end{equation*}
$$

One can wonder whether matrices $S$ and $T$ obey any universal properties that would be valid for an arbitrary (but time-independent) scatterer. Such universal equations may be readily found from the probability current conservation and the time-reversal symmetry of the Schrödinger equation. Let me leave finding these relations for reader's exercise. The results show, in particular, that the scattering matrix may be rewritten in the following form:

$$
\mathrm{S}=e^{i \theta}\left(\begin{array}{cc}
r e^{i \varphi} & t  \tag{2.136a}\\
t & -r e^{-i \varphi}
\end{array}\right)
$$

where 4 real parameters $r, t, \theta$, and $\varphi$ satisfy just one universal relation:

$$
\begin{equation*}
r^{2}+t^{2}=1 \tag{2.136b}
\end{equation*}
$$

(so that only 3 of the parameters are independent). As a result of this symmetry, $T_{11}$ may be also presented in a simpler form, similar to $T_{22}: T_{11}=\exp \{i \theta\} / t=1 / S_{12}{ }^{*}=1 / S_{21}{ }^{*}$. The last form allows a ready expression of scatterer's transparency via just one coefficient of the transfer matrix:

$$
\begin{equation*}
T \equiv\left|\frac{A_{2}}{A_{1}}\right|_{B_{2}=0}^{2}=\left|S_{21}\right|^{2}=\left|T_{11}\right|^{-2} \tag{2.137}
\end{equation*}
$$

In our current context, the most important property of 1D transfer matrices is that in order to find the total transfer matrix T of a system consisting of several (say, $N$ ) sequential arbitrary scatterers (Fig. 14), it is sufficient to multiply their matrices. Indeed, extending the definition (134) to other points $x_{j}(j$ $=1,2, \ldots, N+1$ ), we can write

$$
\begin{equation*}
\binom{A_{2}}{B_{2}}=\mathrm{T}_{1}\binom{A_{1}}{B_{1}}, \quad\binom{A_{3}}{B_{3}}=\mathrm{T}_{2}\binom{A_{2}}{B_{2}}=\mathrm{T}_{2} \mathrm{~T}_{1}\binom{A_{1}}{B_{1}}, \tag{2.138}
\end{equation*}
$$

etc. (where the matrix indices indicate the scatterers' order on axis $x$ ), so that

$$
\begin{equation*}
\binom{A_{N+1}}{B_{N+1}}=\mathrm{T}_{N} \mathrm{~T}_{N-1} \ldots \mathrm{~T}_{1}\binom{A_{1}}{B_{1}} . \tag{2.139}
\end{equation*}
$$

Fig. 2.14. A sequence of several 1D scatterers.

But we can also define the total transfer matrix similarly to Eq. (134), i.e. as

$$
\begin{equation*}
\binom{A_{N+1}}{B_{N+1}} \equiv \mathrm{~T}\binom{A_{1}}{B_{1}}, \tag{2.140}
\end{equation*}
$$

so that finally

$$
\begin{equation*}
\mathrm{T}=\mathrm{T}_{N} \mathrm{~T}_{N-1} \ldots \mathrm{~T}_{1} \tag{2.141}
\end{equation*}
$$

This formula is valid even if the flat-potential gaps between component scatterers vanish, so that it may be applied to a scatterer with an arbitrary profile $U(x)$, by fragmenting its length into small segments $\Delta x=x_{j+1}-x_{j}$, and treating each fragment as a rectangular barrier of height $\left(U_{j}\right)_{\text {ef }}=\left[U\left(x_{j+1}\right)-\right.$ $\left.U\left(x_{j}\right)\right] / 2$ - see Fig. 15. Since very efficient numerical algorithms are readily available for fast multiplication of matrices (especially as small as $2 \times 2$ ), this approach is broadly used in practice for the computation of transparency of tunnel barriers with complicated profiles $U(x)$. (This is much more efficient then the direct numerical solution of the Schrödinger equation.)

Fig. 2.15. The transfer matrix approach to a long tunnel barrier of an arbitrary

In order to use this approach for several conceptually important systems, let us calculate the transfer matrices for a few elementary scatterers, starting from the delta-functional barrier located at $x=$ 0 . Taking $x_{1}=x_{2}=0$, we can merely change the notation of wave amplitudes in Eq. (127) to get

Transfer matrix of a composite scatterer
profile.

$$
\begin{equation*}
S_{11}=\frac{-i \alpha}{1+i \alpha}, \quad S_{21}=\frac{1}{1+i \alpha} . \tag{2.142a}
\end{equation*}
$$

An absolutely similar analysis of the wave incidence from the left yields

$$
\begin{equation*}
S_{22}=\frac{-i \alpha}{1+i \alpha}, \quad S_{12}=\frac{1}{1+i \alpha}, \tag{2.142b}
\end{equation*}
$$

and using Eqs. (135), we get

Identity matrix

$$
\mathrm{T}_{\alpha}=\left(\begin{array}{cc}
1-i \alpha & -i \alpha  \tag{2.143}\\
i \alpha & 1+i \alpha
\end{array}\right)
$$

The next example may seem strange at the first glance: what if there is no scatterer at all between points $x_{1}$ and $x_{2}$ ? If points $x_{1}$ and $x_{2}$ coincide, the answer is indeed trivial and can be obtained, e.g., from Eq. (143) by taking $W=0$, i.e. $\alpha=0$ :

$$
\mathrm{T}_{0}=\left(\begin{array}{ll}
1 & 0  \tag{2.144}\\
0 & 1
\end{array}\right) \equiv \mathrm{I}
$$

- the so-called identity matrix. However, we are free to choose the reference points $x_{1,2}$ participating in Eq. (129) as we wish. For example, what if $x_{2}-x_{1}=a$ ? Let us first take the forward-propagating wave alone: $B_{2}=0$ (and hence $B_{1}=0$ ); then

$$
\begin{equation*}
\psi_{2}=\psi_{1}=A_{1} e^{i k\left(x-x_{1}\right)}=A_{1} e^{i k\left(x_{2}-x_{1}\right)} e^{i k\left(x-x_{2}\right)} . \tag{2.145}
\end{equation*}
$$

Comparison of this expression with the definition (129) for $j=2$ shows that $A_{2}=A_{1} \exp \left\{i k\left(x_{2}-x_{1}\right)\right\}=A_{1}$ $\exp \{i k a\}$, i.e. $T_{11}=\exp \{i k a\}$. Repeating the calculation for the back-propagating wave, we see that $T_{22}=$ $\exp \{-i k a\}$, and since this "no-potential" (space interval) provides no particle reflection, we finally get

$$
\mathrm{T}_{a}=\left(\begin{array}{cc}
e^{i k a} & 0  \tag{2.146}\\
0 & e^{-i k a}
\end{array}\right)
$$

independently of the mutual position of points $x_{1}$ and $x_{2}$. At $a=0$, we naturally recover the special case (143).

Now let us use these results to analyze the double-barrier system shown in Fig. 16. We could of course calculate its properties as before, writing down explicit expressions for all 5 traveling waves shown by arrows in Fig. 16, and then using boundary conditions (124) and (125) at each of points $x_{1,2}$ to get a system of 4 linear equations, and then solving it for 4 amplitude ratios.

Fig. 2.16. Double-barrier system. Dashed lines show (schematically) the position of metastable energy levels.

However, the transfer matrix approach simplifies the calculations, because we may immediately use Eqs. (141), (143), and (146) to write

$$
\mathrm{T}=\mathrm{T}_{\alpha} \mathrm{T}_{a} \mathrm{~T}_{\alpha}=\left(\begin{array}{cc}
1-i \alpha & -i \alpha  \tag{2.147}\\
i \alpha & 1+i \alpha
\end{array}\right)\left(\begin{array}{cc}
e^{i k a} & 0 \\
0 & e^{-i k a}
\end{array}\right)\left(\begin{array}{cc}
1-i \alpha & -i \alpha \\
i \alpha & 1+i \alpha
\end{array}\right) .
$$

Let me hope that the reader remembers the "row by column" rule of the multiplication of square matrices; ${ }^{33}$ using it for two last matrices, we reduce Eq. (147) to

$$
\mathrm{T}=\left(\begin{array}{cc}
1-i \alpha & -i \alpha  \tag{2.148}\\
i \alpha & 1+i \alpha
\end{array}\right)\left(\begin{array}{cc}
(1-i \alpha) e^{i k a} & -i \alpha e^{i k a} \\
i \alpha e^{-i k a} & (1+i \alpha) e^{-i k a}
\end{array}\right)
$$

Now there is no need to calculate all elements of the full product T, because, according to Eq. (137), for the calculation of barrier transparency $T$ we need only one its element, $T_{11}$ :

$$
\begin{equation*}
T=\frac{1}{\left|T_{11}\right|^{2}}=\frac{1}{\left|\alpha^{2} e^{-i k a}+(1-i \alpha)^{2} e^{i k a}\right|^{2}} . \tag{2.149}
\end{equation*}
$$

This result is similar to that following from Eq. (79) for $E>U_{0}$ : the transparency is a $\pi$-periodic function of the product $k a$, reaching the maximum $(T=1)$ at some point of each period - see Fig. 17a.

(a)

(b)

Fig. 2.17. Resonant tunneling through a quantum well with delta-functional walls :
(a) transparency a function of $k a$, and (b) calculating resonance's FWHM at $\alpha \gg 1$.

However, the new result is different in that for $\alpha \gg 1$, the resonance peaks of transparency are very narrow, reaching their maxima at $k a \approx k_{n} a \equiv n \pi$, with $n=1,2, \ldots$ Physics of this effect is immediately clear from the comparison of this result with our analysis of the simplest quantum well see Fig. 1.7 and its discussion. At $k \approx k_{n}$, the incident wave, which undertakes multiple sequential reflections from the semi-transparent walls of the well, forms a nearly standing wave, which at $\alpha \gg 1$ virtually coincides with one of eigenfunctions of the well with infinite walls, with the standing wave amplitude much larger that that of the incident wave. As a result, the transmitted wave amplitude is
${ }^{33}$ In the analytical form: $(\mathrm{AB})_{i j^{\prime}}=\sum_{j^{\prime \prime}=1}^{N} A_{i j^{\prime \prime}} B_{j^{\prime \prime j^{\prime}}}$, where $N$ is the matrix rank (in our current case, $N=2$ ).
proportionately increased. This is the famous effect of resonant tunneling, ${ }^{34}$ in mathematical description identical to the resonant transmission of light through an optical Fabry-Perot resonator formed by two parallel semi-transparent mirrors. ${ }^{35}$

Probably, the most surprising feature of this system is the fact that its maximum transparency is perfect $\left(T_{\max }=1\right)$ even at $\alpha \rightarrow \infty$, i.e. in the case of a very low transparency of each of two component barriers. ${ }^{36}$ Indeed, the denominator in Eq. (149) may be interpreted as the squared length of the difference between two vectors, one of length $\alpha^{2}$, and another of length $\left|(1-i \alpha)^{2}\right|=1+\alpha^{2}$, with angle $\theta=2 k a+$ const between them. At the resonance, the vectors are aligned, and the difference is smallest (equal to 1 ) - see Fig. 17b, so that $T_{\max }=1$.

We can use the same vector diagram to calculate the so-called FWHM, the common acronym for the Full Width [of the resonance curve at] Half-Maximum, i.e. the difference $\Delta k=k_{+}-k$. between such two points on the opposite slopes of the same resonance, at which $T=T_{\max } / 2-$ see arrows in Fig. 17a. Let the vectors in Fig. 17b be slightly misaligned, by an angle $\theta \sim 1 / \alpha^{2} \ll 1$, so that the length of the difference vector ( of the order of $\alpha^{2} \theta \sim 1$ ) is still much smaller than the length of each vector. In order to double its length squared, and hence reduce $T$ by a factor of 2 in comparison with its maximum value 1 , the arc, $\alpha^{2} \theta$, between the vectors should also become equal $\pm 1$, i.e. $\alpha^{2}\left(2 k_{ \pm} a+\right.$ const $)= \pm 1$. Subtracting these two equations from each other, we finally get

$$
\begin{equation*}
\Delta k \equiv\left(k_{+}-k_{-}\right)=\frac{1}{a \alpha^{2}} \ll k_{ \pm} . \tag{2.150}
\end{equation*}
$$

Now let us use the simple potential shown in Fig. 16 to discuss an issue of large conceptual importance. For that, consider what would happen if at some initial moment (say, $t=0$ ) we have placed a 1D quantum particle inside the double-barrier well with $\alpha \gg 1$, and left it there alone, without any incident wave. To simplify the analysis, let us prepare the initial state so that it coincides with the ground state of the infinite-wall well - see Eq. (1.76):

$$
\begin{equation*}
\Psi(x, 0)=\psi_{1}(x)=\left(\frac{2}{a}\right)^{1 / 2} \sin \left[k_{1}\left(x-x_{1}\right)\right], \quad \text { where } k_{1}=\frac{\pi}{a} \tag{2.151}
\end{equation*}
$$

At $\alpha \rightarrow \infty$, this is an eigenstate of the system, and from our analysis in Sec. 1.5 we know its time evolution:

$$
\begin{equation*}
\Psi(x, t)=\psi_{1}(x) e^{-i \omega_{1} t}, \quad \text { with } \omega_{1}=\frac{E_{1}}{\hbar}=\frac{\hbar k_{1}^{2}}{2 m}=\frac{\hbar \pi^{2}}{2 m a^{2}}, \tag{2.152}
\end{equation*}
$$

telling us that the particle remains in the well at all times with constant probability $W(t)=W(0)=1.37$
However, if parameter $\alpha$ is large but finite, the de Broglie wave should slowly "leak out" from the well, so that $W(t)$ would slowly decrease. Let us consider this effect approximately, assuming that

[^497]the slow leakage, with a characteristic time $\tau \gg 1 / \omega_{1}$, does not affect the instant wave distribution inside the well, besides the reduction of $W .{ }^{38}$ Then we can generalize Eqs. (151), (152) as follows:
\[

$$
\begin{equation*}
\left.\Psi(x, t)=\left(\frac{2 W}{a}\right)^{1 / 2} \sin \left[k_{1}\left(x-x_{1}\right)\right]\right] e^{-i \omega_{1} t} \tag{2.153}
\end{equation*}
$$

\]

making the probability of finding the particle in the well equal to $W$. This solution may be presented as a sum of two traveling waves:

$$
\begin{equation*}
\Psi(x, t)=A e^{i\left(k_{1} x-\omega_{1} t\right)}+B e^{-i\left(k_{1} x+\omega_{1} t\right)} \tag{2.154}
\end{equation*}
$$

with equal magnitudes of their amplitudes and probability currents

$$
\begin{equation*}
|A|=|B|=\left(\frac{W}{2 a}\right)^{1 / 2}, \quad I_{A}=\frac{\hbar}{m}|A|^{2} k_{1}=\frac{\hbar}{m} \frac{W}{2 a} \frac{\pi}{a}, \quad I_{B}=-I_{A} . \tag{2.155}
\end{equation*}
$$

But we already know from Eq. (128) that at $\alpha \gg 1$ the delta-functional wall transparency $T$ approximately equals $1 / \alpha^{2}$, so that the wave carrying current $I_{A}$, incident on the right wall from inside, induces an outcoming waves outside of the well (Fig. 18) with the following probability current:

$$
\begin{equation*}
I_{R}=\frac{1}{\alpha^{2}} I_{A}=\frac{1}{\alpha^{2}} \frac{\pi \hbar W}{2 m a^{2}} . \tag{2.156a}
\end{equation*}
$$

Absolutely similarly,

$$
\begin{equation*}
I_{L}=\frac{1}{\alpha^{2}} I_{B}=-I_{R} \tag{2.156b}
\end{equation*}
$$

Fig. 2.18. Metastable state's decay in the simple model of a 1D potential well with low-transparent walls - schematically.

Now we may combine the 1D version (6) of the probability conservation law for well's interior,

$$
\begin{equation*}
\frac{d W}{d t}+I_{R}-I_{L}=0 \tag{2.157}
\end{equation*}
$$

with Eqs. (156) to write

$$
\begin{equation*}
\frac{d W}{d t}=-\frac{1}{\alpha^{2}} \frac{\pi \hbar}{m a^{2}} W \tag{2.158}
\end{equation*}
$$

[^498]This is just the standard differential equation,

state's decay law

$$
\begin{equation*}
\frac{d W}{d t}=-\frac{1}{\tau} W \tag{2.159}
\end{equation*}
$$

of the exponential decay, with solution $W(t)=W(0) \exp \{-t / \tau\}$, where constant $\tau$, in our case equal to

$$
\begin{equation*}
\tau=\frac{m a^{2}}{\pi \hbar} \alpha^{2} \tag{2.160}
\end{equation*}
$$

is called the metastable state's lifetime. Using expression (2.34) for the de Broglie waves' group velocity, in our particular wave vector giving $v_{\mathrm{gr}}=\hbar k_{1} / m=\pi \hbar / m a$, Eq. (159) may be rewritten as

Metastable state's lifetime

$$
\begin{equation*}
\tau=\frac{t_{A}}{T} \tag{2.161}
\end{equation*}
$$

where in our case the attempt time $t_{A}$ is equal to $a / v_{\mathrm{gr}}$, and $T=1 / \alpha^{2}$. Relation (161), that is valid for a large class of metastable systems, ${ }^{39}$ may be interpreted in the following semi-classical way. The confined particle travels back and forth between the confining walls, with time intervals $t_{A}$ between the moments of incidence, each time making an attempt to leak through the wall, with a success probability of $T$, so the reduction of $W$ per each incidence is $\Delta W=-W T$, immediately leading to Eq. (161).

Another important look at Eq. (160) may be taken by returning to the resonant tunneling problem and expressing the resonance width (150) in terms of incident particle's energy:

$$
\begin{equation*}
\Delta E=\Delta\left(\frac{\hbar^{2} k^{2}}{2 m}\right) \approx \frac{\hbar^{2} k_{1}}{m} \Delta k=\frac{\hbar^{2} k_{1}}{m} \frac{1}{a \alpha^{2}}=\frac{\pi \hbar^{2}}{m a^{2} \alpha^{2}} . \tag{2.162}
\end{equation*}
$$

Comparing Eqs. (160) and (162), we get a remarkably simple formula

Energy-time uncertainty relation

$$
\begin{equation*}
\Delta E \cdot \tau=\hbar \tag{2.163}
\end{equation*}
$$

This so-called energy-time uncertainty relation is certainly more general than our simple model; for example, it is valid for the lifetime and resonance tunneling width of any metastable state. This seems very natural, since because of the energy identification with frequency, $E=\hbar \omega$, typical for quantum mechanics, Eq. (163) may be rewritten as $\Delta \omega \cdot \tau=1$ and seems to follow directly from the Fourier transform in time, just as the Heisenberg's uncertainty relation (1.35) follows from the Fourier transform in space. In some cases, these two relations are indeed interchangeable; for example, Eq. (24) for the Gaussian wave packet width may be rewritten as $\delta E \cdot \Delta t=\hbar$, where $\delta E=\hbar(d \omega / d k) \delta k=\hbar v_{\mathrm{gr}} \delta k$ is the r.m.s. spread of energies of monochromatic components of the packet, while $\Delta t \equiv \delta x / v_{\mathrm{gr}}$ is the time scale of the packet passage through a fixed observation point $x$.

However, Eq. (163) it is much less general than Heisenberg's uncertainty relation (1.35). Indeed, in non-relativistic quantum mechanics, Cartesian coordinates (say, $x$ ) of a particle, components of its momentum (say, $p_{x}$ ), and energy $E$ are regular observables, presented by operators. In contract, time is treated as a $c$-number argument, and is not presented by an operator, so that Eq. (163) cannot be derived

[^499]in such general assumptions as Eq. (1.35). Thus the time-energy uncertainty relation should be applied with great caution. Unfortunately, not everybody is so careful. One can find, for example, wrong claims that due to this relation, the energy dissipated by any system performing an elementary (single-bit) calculation during time interval $\Delta t$ has to be larger than $\hbar / \Delta t$. ${ }^{40}$ Another incorrect statement is that the energy of a system cannot be measured, during time $\Delta t$, with an accuracy better than $\hbar / \Delta t .^{41}$

Now let us use our simple model of metastable state's decay for a preliminary discussion of one aspect of quantum measurements. Figure 18 shows (schematically) the traveling wave packets emitted by the quantum well after its initial state (152) had been prepared at $t=0$. At $t \gg \tau$, the well becomes essentially empty ( $W \ll 1$ ), and the whole probability distribution is localized in two clearly separated wave packets of equal amplitudes, moving from away with speed $v_{\mathrm{gr}}$, each "carrying the particle away" with a probability of $50 \%$. Now assume an experiment has detected the particle on the left side of the well. Though the formalisms suitable for a quantitative analysis of the detection process will not be discussed until Sec. 7.7, due to the wide separation of the packets, we may safely assume that the detection may be done without any actual physical effect on the counterpart wave packet. ${ }^{42}$ But if we know that the particle has been found on the left, there is no chance to find it on the right.

If we attributed the wavefunction to all stages of this particular experiment, this situation might be rather confusing. Indeed, this would mean that the wavefunction within the right packet should instantly turn into zero - the so-called wave packet reduction - a process that could not be described by either Schrödinger equation or any other law of physics. However, if (as was already discussed in Sec. 1.3) we attribute the wavefunction to a statistical ensemble of similar experiments, there is no paradox here at all. While the two-packet picture we have calculated (Fig. 18) describes the full initial ensemble (regardless of the particle detection results), the "reduced packet" picture (with no wave packet on the right of the well) describes only a sub-ensemble of experiments with the particle detected on the left side. As was discussed on completely classical examples in Sec. 1.3, for such sub-ensemble the probability distribution, and hence the wavefunction, may be dramatically different.

### 2.6. Coupled quantum wells

Let us now move on to tunneling through a more complex potential profile shown in Fig. 19: a sequence of $(N-1)$ similar quantum wells separated by $N$ similar delta-functional tunnel barriers. According to Eq. (141), its transfer matrix is the following product

$$
\begin{equation*}
\mathrm{T}=\underbrace{\mathrm{T}_{\alpha} \mathrm{T}_{a} \mathrm{~T}_{\alpha} \ldots \mathrm{T}_{a} \mathrm{~T}_{\alpha}}_{(N-1)+N \text { terms }}, \tag{2.164}
\end{equation*}
$$

with the component matrices given by Eqs. (143) and (146), and the barrier height parameter $\alpha$ defined by the last of Eqs. (127).

[^500]Remarkably, this multiplication may be carried out analytically, ${ }^{43}$ giving

Fig. 2.19. Resonant tunneling through a system of $N$ similar, equidistant barriers, i.e. $(N-1)$ similar quantum wells.

Transparency of $N$
equidistant tunnel barriers

$$
\begin{equation*}
T \equiv\left|T_{11}\right|^{-2}=\left[(\cos N q a)^{2}+\left(\frac{\sin k a-\alpha \cos k a}{\sin q a} \sin N q a\right)^{2}\right]^{-1} \tag{2.165}
\end{equation*}
$$

where $q$ is a new parameter, with the wave number dimensionality, defined by the following relation:

$$
\begin{equation*}
\cos q a \equiv \cos k a+\alpha \sin k a . \tag{2.166}
\end{equation*}
$$

For $N=1$, Eqs. (165) and (166) immediately yield our old result (128), while for $N=2$ they may be reduced to Eq. (149) - see Fig. 17a. Figure 20 shows its predictions for two larger numbers $N$, and several values of parameter $\alpha$.

Fig. 2.20. Transparency of the system shown in Fig. 19 as a function of product $k a$. Since the function $T(\mathrm{ka}$ ) is $\pi$-periodic (just like for $N=2$, see Fig. 17a), only one period is shown.

Let us start discussion of the plots from case $N=3$, i.e. two coupled quantum wells. The comparison of Fig. 20a and Fig. 17a shows that the transmission patterns, and their dependence on parameter $\alpha$, are very similar, besides that in the coupled wells each resonant tunneling peak splits into two, with the $k a$-difference between them scaling as $1 / \alpha$. In order to comprehend the physics of this important result, let us analyze an auxiliary system shown in Fig. 21: two similar quantum wells

[^501]confined by infinitely high potential walls at $x= \pm a$, and coupled via a transparent, short tunnel barrier at $x=0$.

Fig. 2.21. Two lowest eigenfunctions and eigenenergies of a system of two coupled quantum wells - schematically.

The barrier may be again, for calculation simplicity, approximated by a delta-function:

$$
U(x)= \begin{cases}+\infty, & \text { for }|x|>a  \tag{2.167}\\ w \delta(x), & \text { for }|x|<a .\end{cases}
$$

We already know that the standing-wave eigenfunctions $\psi_{n}$ of the Schrödinger equation in regions with $U(x)=0$, in our current case, segments $-a<x<0$ and $0<x<+a$, may be always presented as linear superpositions of $\sin k x$ and $\cos k x$. In order to immediately satisfy the boundary conditions $\psi=0$ at $x=$ $\pm a$, we can take these solutions in the form

$$
\psi_{n}(x)= \begin{cases}C_{-} \sin k(x+a), & \text { for }-a<x<0  \tag{2.168}\\ C_{+} \sin k(x-a), & \text { for } 0<x<+a\end{cases}
$$

What remains is to satisfy the boundary conditions at $x=0$. Plugging Eq. (167) into Eqs. (124) and (125), we get the following system of two linear equations:

$$
\begin{align*}
k\left(C_{+}-C_{-}\right) \cos k a & =\frac{2 m w}{\hbar^{2}} C_{-} \sin k a  \tag{2.169}\\
C_{-} \sin k a & =-C_{+} \sin k a \tag{2.170}
\end{align*}
$$

The system has two types of solutions, with the two lowest-energy eigenfunctions sketched in Fig. 21:
(i) Antisymmetric solutions (which will be marked with index $A$ ),

$$
\begin{equation*}
\left(C_{+}\right)_{A}=\left(C_{-}\right)_{A} \text {, i.e. } \psi_{A}=C_{A} \sin k_{A} x \text {, } \tag{2.171}
\end{equation*}
$$

with eigenvalues independent of $W$,

$$
\begin{equation*}
\sin k_{A} a=0, \quad \text { i.e. } k_{A} a=k n a \equiv \pi n, \quad n=1,2, \ldots \tag{2.172}
\end{equation*}
$$

Notice that these values of $k$, and hence eigenenergies of these antisymmetric states,

$$
\begin{equation*}
E_{A}=\frac{\hbar^{2} k_{A}^{2}}{2 m}=\frac{\pi^{2} n^{2}}{2 m a^{2}}, \tag{2.173}
\end{equation*}
$$

coincide with those of the simple quantum well of width $a$ - see Fig. 1.7 and its discussion.
(ii) Symmetric solutions (index S):

$$
\begin{equation*}
\left(C_{+}\right)_{S}=-\left(C_{-}\right)_{S} \text {, i.e. } \psi_{S}=C_{S}\left|\sin k_{S}(x-a)\right|, \tag{2.174}
\end{equation*}
$$

with Eq. (169) giving the following characteristic equation for constant $k_{S}$ :

Characteristic equation for two coupled quantum wells

$$
\begin{equation*}
\tan k_{S} a=-\frac{1}{\alpha} \tag{2.175}
\end{equation*}
$$

Figure 22 shows the graphic solution of this equation for three values of parameter $\alpha$, i.e. for various quantum well coupling strength. For each solution, $k_{S} a$ is confined within interval

$$
\begin{equation*}
\pi n<k_{S} a<\pi n-\frac{\pi}{2} \tag{2.176}
\end{equation*}
$$

so that the antisymmetric and symmetric states alternate on the scale of $k$ (and hence of the energy), with the difference $k_{A}-k_{S}$, for each pair of adjacent states, smaller then $\pi / 2 a$ for any value of $\alpha$. The physics of the splitting between eigenenergies corresponding to the symmetric and antisymmetric states is very simple: it is the change of kinetic energy of the particle due to different confinement types - see Fig. 21. In each antisymmetric mode, $\psi_{n}(0)=\psi_{n}( \pm a)=0$, i.e. the wavefunction is essentially confined within a segment of length $a$; as a result, its energy (173) does not depend on the barrier height. On the contrary, in the symmetric mode, that does engage the potential barrier, the wavefunction effectively spreads into the counterpart well. As a result, it changes slower, and hence its kinetic energy is also lower that that of the adjacent antisymmetric mode.

Fig. 2.22. Graphical solution of the characteristic equation (175) for the eigenvalue of $k a$ in the symmetric mode, for 3 values of parameter $\alpha$, considering it independent of $k a$. The dashed line shows approximation (178).

By the way, this problem may serve as a toy model of the strongest (and most important) type of atom cohesion - the covalent (or "chemical") bonding in molecules, liquids, and solids. The classical example of such bonding is that of hydrogen atoms in a $\mathrm{H}_{2}$ molecule. ${ }^{44}$ Each of two electrons of this system ${ }^{45}$ reduces its kinetic energy very substantially by spreading its wavefunction around both nuclei

[^502]protons, rather that being confined near one of them - as it had to be in a single atom. As a result, the bonding is very strong: in chemical units, $429 \mathrm{~kJ} / \mathrm{mol}$, i.e. 18.6 eV per molecule. ${ }^{46}$ Somewhat counterintuitive, this energy is substantially larger than the strongest classical (ionic) bonding due to electron transfer between atoms, leading to the Coulomb attraction of the resulting ions. (For example, the atomic cohesion in the NaCl molecule is just 3.28 eV .)

In the limit $\alpha \rightarrow 0$ (no partition between the wells), $k_{s} a \rightarrow \pi(n-1 / 2)$, i.e. the eigenstates approach the shape and energy of symmetric states of a quantum well of width $2 a$. In the opposite limit $\alpha \gg 1, k_{S} a \rightarrow \pi n$, and in the vicinity of each such point we may approximate $\tan k_{S} a$ with $\left(k_{S} a-\pi n\right)-$ see the dashed line in Fig. 22. As a result, the characteristic equation (175) is reduced to

$$
\begin{equation*}
k_{S} a \approx \pi n-\frac{1}{\alpha} \tag{2.177}
\end{equation*}
$$

so that the splitting between the wave numbers and eigenenergies of the adjacent symmetric and antisymmetric states is small:

$$
\begin{equation*}
k_{A}-k_{S} \approx \frac{1}{\alpha a} \ll k_{n}, \quad 2 \delta_{n} \equiv E_{A}-E_{S} \approx \frac{d E}{d k}\left(k_{A}-k_{S}\right)=\frac{\pi n \hbar^{2}}{m a} \frac{1}{\alpha a}=\frac{2 E_{A}}{\pi n \alpha} . \tag{2.178}
\end{equation*}
$$

(By construction, this result is valid only if $\alpha \gg 1$, i.e. $\delta_{n} \ll E_{A} \approx E_{S}$.)
Let us analyze properties of the system in this limit in much more detail - first, because the results will help us to develop the important tight binding approximation in the band theory, and second, because the weakly coupled quantum wells will be our first example of very important two-level (or "spin- $1 / 2$-like") systems. Let us focus on one couple of symmetric and antisymmetric states, corresponding to virtually the same $E_{n}$. According to Eqs. (171) and (174), in the limit $\alpha \rightarrow \infty$, system's eigenfunctions may be approximately represented as follows:

$$
\begin{equation*}
\psi_{S}(x) \approx \frac{1}{\sqrt{2}}\left[\psi_{R}(x)+\psi_{L}(x)\right], \quad \psi_{A}(x)=\frac{1}{\sqrt{2}}\left[\psi_{R}(x)-\psi_{L}(x)\right], \tag{2.179}
\end{equation*}
$$

where $\psi_{R, L}$ are the normalized ground states of the completely insulated wells:

$$
\psi_{R}(x)=\left\{\begin{array}{ll}
0, & \text { for }-a<x<0,  \tag{2.180}\\
(2 / a)^{1 / 2} \sin k_{n} x, & \text { for } 0<x<+a,
\end{array} \quad \psi_{L}(x)= \begin{cases}-(2 / a)^{1 / 2} \sin k_{n} x, & \text { for }-a<x<0 \\
0, & \text { for } 0<x<+a\end{cases}\right.
$$

Let us perform the following conceptually important thought experiment: place the particle, at $t$ $=0$, into one of the localized states, say $\psi_{R}(x)$, and leave the system alone to evolve. Solving Eqs (180) for $\psi_{R}$, we may present the initial state as a linear superposition of eigenfunctions:

$$
\begin{equation*}
\Psi(x, 0)=\psi_{R}(x) \approx \frac{1}{\sqrt{2}}\left[\psi_{S}(x)+\psi_{A}(x)\right] . \tag{2.181}
\end{equation*}
$$

Now, according to the general solution (1.67) of the time-independent Schrödinger equation, time dynamics may be obtained by just multiplying each eigenfunction by the corresponding factor (1.61):

[^503]\[

$$
\begin{equation*}
\Psi(x, t)=\frac{1}{\sqrt{2}}\left[\psi_{S}(x) \exp \left\{-i \frac{E_{S}}{\hbar} t\right\}+\psi_{A}(x) \exp \left\{-i \frac{E_{A}}{\hbar} t\right\}\right] . \tag{2.182}
\end{equation*}
$$

\]

Now, introducing the following natural notation,

$$
\begin{equation*}
E_{n} \equiv \frac{E_{A}+E_{S}}{2}, \quad \delta_{n} \equiv \frac{E_{A}-E_{S}}{2} . \tag{2.183}
\end{equation*}
$$

And using Eqs. (179), this expression may be rewritten as

$$
\begin{align*}
\Psi(x, t) & =\frac{1}{\sqrt{2}}\left[\psi_{S}(x) \exp \left\{i \frac{\delta_{n}}{\hbar} t\right\}+\psi_{A}(x) \exp \left\{-i \frac{\delta_{n}}{\hbar} t\right\}\right] \exp \left\{-i \frac{E_{n}}{\hbar} t\right\}  \tag{2.184}\\
& =\left[\psi_{R}(x) \cos \frac{\delta_{n}}{\hbar} t+i \psi_{L}(x) \sin \frac{\delta_{n}}{\hbar} t\right] \exp \left\{-i \frac{E_{n}}{\hbar} t\right\} .
\end{align*}
$$

This result implies, in particular, that the probabilities $W_{R}$ and $W_{L}$ to find the particle, correspondingly, in the right and left wells change with time as

$$
\begin{equation*}
W_{R}=\cos ^{2} \frac{\delta_{n}}{\hbar} t, \quad W_{L}=\sin ^{2} \frac{\delta_{n}}{\hbar} t \tag{2.185}
\end{equation*}
$$

mercifully leaving the total probability constant $W_{R}+W_{L}=1$. (If our calculation had not passed this sanity check, we would be in a big trouble.)

This is the famous effect of periodic quantum oscillations, with frequency $\omega_{n}=2 \delta_{n} / \hbar=\left(E_{A}-\right.$ $\left.E_{S}\right) / \hbar$, of the particle between two similar quantum wells, due to their coupling through via tunneling through the tunnel barrier. The physics of this effect is straightforward: just as in the single well problem discussed in Sec. 5, the particle initially placed into a certain quantum well tries to escape from it via tunneling through the semi-transparent wall. However, in our current situation (Fig. 21) the particle can only escape into the adjacent well. After the tunneling into that second well, the tries to escape from it, and hence comes back, etc. - just as a classical 1D oscillator, initially deflected from its equilibrium position.

Maybe the most surprising feature of this effect is its relatively high frequency: according to Eq. (178), the time period of the quantum oscillations,

$$
\begin{equation*}
\Delta t_{n} \equiv \frac{2 \pi}{\omega_{n}}=\frac{2 \pi \hbar}{\left(E_{A}-E_{S}\right)} \approx \frac{2 \pi}{n} \frac{m a^{2}}{\pi \hbar} \alpha, \quad \text { for } \alpha \gg 1, \tag{2.186}
\end{equation*}
$$

is a factor of $\alpha / 2 \pi \gg 1$ shorter than the lifetime $\tau(160)$ of the metastable state of the particle in a similar but single quantum well limited by delta-functional walls with similar parameter $\alpha$. This is a very counterintuitive result indeed: the speed of particle tunneling into a similar adjacent well is much higher than that, through a similar barrier, to the free space!

To see whether this result is an artifact of the delta-functional model of the tunnel barrier, let us calculate splitting $2 \delta_{n}$ for system of two similar, symmetric, soft quantum wells formed by a smooth potential profile $U(x)=U(-x)-$ see Fig. 23.

Fig. 2.23. Weak coupling between two similar, soft quantum wells.

If the barrier transparency is low, the quasi-localized wavefunctions $\psi_{R}(x)$ and $\psi_{L}(x)=\psi_{R}(-x)$ and their eigenenergies may be found approximately by solving the Schrödinger equations in one of the wells, neglecting tunneling through the barrier, but finding $\delta_{n}$ requires a little bit more care. Let us write the stationary Schrödinger equations for the symmetric and antisymmetric solutions in the form

$$
\begin{equation*}
\left[E_{A}-U(x)\right] \psi_{A}=-\frac{\hbar^{2}}{2 m} \frac{d^{2} \psi_{A}}{d x^{2}}, \quad\left[E_{S}-U(x)\right] \psi_{S}=-\frac{\hbar^{2}}{2 m} \frac{d^{2} \psi_{S}}{d x^{2}} \tag{2.187}
\end{equation*}
$$

then multiply the former equation by $\psi_{S}$, the latter one by $\psi_{A}$, subtract them from each other, and integrate the result from 0 to $\infty$ :

$$
\begin{equation*}
\left(E_{A}-E_{S}\right) \int_{0}^{\infty} \psi_{S} \psi_{A} d x=\frac{\hbar^{2}}{2 m} \int_{0}^{\infty}\left[\frac{d^{2} \psi_{S}}{d x^{2}} \psi_{A}-\frac{d^{2} \psi_{A}}{d x^{2}} \psi_{S}\right] d x \tag{2.188}
\end{equation*}
$$

If $U(x)$, and hence $d^{2} \psi_{A, S} / d x^{2}$, are finite for all $x,{ }^{47}$ we may integrate the right-hand side by parts to get

$$
\begin{equation*}
\left(E_{A}-E_{S}\right) \int_{0}^{\infty} \psi_{S} \psi_{A} d x=\frac{\hbar^{2}}{2 m}\left[\frac{d \psi_{S}}{d x} \psi_{A}-\frac{d \psi_{A}}{d x} \psi_{S}\right]_{0}^{\infty} \tag{2.189}
\end{equation*}
$$

So far, this is an exact equation. For weakly coupled wells, we can do more. In this case, the left hand side may be approximated as $\left(E_{A}-E_{S}\right) / 2 \equiv \delta_{n}$, because the integral is dominated by the vicinity of point $a$, where the second terms in each of Eqs. (179) are negligible, and the integral is equal to $1 / 2$, due to the proper normalization of function $\psi_{R}(x)$. In the right-hand side, the substitution at $x=\infty$ vanishes (due to the wavefunction decay in the classically forbidden region), and so does the first term at $x=0$, because for the antisymmetric solution $\psi_{A}(0)=0$. As a result, we get

$$
\begin{equation*}
\delta_{n}=\frac{\hbar^{2}}{2 m} \psi_{S}(0) \frac{d \psi_{A}}{d x}(0)=\frac{\hbar^{2}}{m} \psi_{R}(0) \frac{d \psi_{R}}{d x}(0)=\frac{\hbar^{2}}{m} \psi_{L}(0) \frac{d \psi_{R}}{d x}(0)=-\frac{\hbar^{2}}{m} \psi_{L}(0) \frac{d \psi_{L}}{d x}(0) . \tag{2.190}
\end{equation*}
$$

It is straightforward to show that within the limits of the WKB approximation validity, Eq. (190) may be reduced to

$$
\begin{equation*}
\delta_{n}=\frac{\hbar}{t_{A}} \exp \left\{-\int_{x_{c}}^{x_{c}^{\prime}} \kappa\left(x^{\prime}\right) d x^{\prime}\right\} \tag{2.191}
\end{equation*}
$$

[^504][^505]where $t_{A}$ is the time period of classical motion of the particle inside one of the wells, function $\kappa(x)$ is defined by Eq. (97), and $x_{c}$ and $x_{c}{ }^{\prime}$ are the classical turning points limiting the potential barrier at the level $E_{n}$ of particle's energy - see Fig. 23. Comparing this result with Eq. (117), we can notice that again, just as in the case of the delta-functional barriers, the transmission coefficient $T$ of a tunnel barrier (and hence the reciprocal lifetime of a metastable state in a potential well separated by such a barrier from a continuum) scales as the square of the WKB exponent participating in Eq. (191), so that the period of quantum oscillations between the well is much smaller than the lifetime. We will return to the discussion of this result, in a more general form, in Chapter 5.

Returning for a second to Fig. 20a, we may now readily interpret the results for tunneling through the double quantum well: each pair of resonance peaks of transparency corresponds to the alignment of incident particle's energy with the pair of energy levels $E_{A}, E_{S}$ of the symmetric and antisymmetric states of the system.

### 2.7. 1 D band theory

Let us now return to Eqs. (165) and (166) describing the resonant tunneling, and discuss their predictions for larger $N$ - see, for example, Fig. 20b. We see that the increase of $N$ results in the increase of the number of resonant peaks per period to $(N-1)$, and at $N \rightarrow \infty$ the peaks merge into the so-called allowed energy bands (frequently called just the "energy bands") of relatively high transparency, separated from similar bands in the adjacent periods of function $T(k a)$ by energy gaps ${ }^{48}$ where $T \rightarrow 0$. Notice the following important features of the pattern:
(i) at $N \rightarrow \infty$, the band/gap edges become sharp for any $\alpha$, and tend to fixed positions (determined by $\alpha$ but independent of $N$ );
(ii) the larger interwell coupling $(\alpha \rightarrow 0)$, the broader the allowed energy bands and narrower the gaps between them.

Our discussion of resonant tunneling in the previous section gives us an evident clue for a semiquantitative interpretation of this pattern: if $(N-1)$ quantum wells are weakly coupled by tunneling through the tunnel barriers separating them, system's energy spectrum consists of groups ( $N-1$ ) energy levels. Each level corresponds to an eigenfunction that is the set of similar local functions in each well, but with certain phase shifts $\Delta \varphi$ between them. It is natural to expect that, just as for 2 coupled wells ( $N$ $-1=2$ ), that at the upper level, $\Delta \varphi=\pi$ (thus providing the highest confinement), with $k a \rightarrow \pi n$ at $\alpha \rightarrow$ $\infty$, while at the lowest level all $\Delta \varphi=0$, providing the most loose confinement. ${ }^{49}$ However, what about $\Delta \varphi$ for other levels?

Answers to all these questions are easy to get in the most important limit $N \rightarrow \infty$, i.e. for periodic structures - which are, in particular, good 1D approximations for solid state crystals, whose samples may feature more than $10^{10}$ similar atoms or molecules in each direction of the crystal lattice. It is almost self-evident that at $N \rightarrow \infty$, due to the translational invariance of $U(x)$,

$$
\begin{equation*}
U(x+a)=U(x) \tag{2.192}
\end{equation*}
$$

[^506]the phase shift $\Delta \varphi$ between local wavefunctions in all adjacent quantum wells should be the same for each period of the system, i.e.
\[

$$
\begin{equation*}
\psi(x+a)=\psi(x) e^{i \Delta \varphi} \tag{2.193a}
\end{equation*}
$$

\]

for all $x$. (A reasonably fair classical image of $\Delta \varphi$ is the geometric angle between similar objects - e.g., similar paper clips - attached at equal distances to a long, uniform rubber band. If the band's ends are twisted, the twist is equally distributed between the structure's periods, representing the constancy of $\Delta \varphi{ }^{50}$ )

Equation (193a) is the (1D version of the) much-celebrated Bloch theorem. ${ }^{51}$ Mathematical rigor aside, ${ }^{52}$ it is a virtually evident fact, because the particle's density $w(x)=\psi^{*}(x) \psi(x)$, that has to be periodic in this $a$-periodic system, may be so only $\Delta \varphi$ is constant. For what follows, it is more convenient to present the real number $\Delta \varphi$ in the form $q a$ (there is no loss of generality here, because parameter $q$ may depend on $a$ as well as other parameters of the system), so that the Bloch theorem takes the form

$$
\begin{equation*}
\psi(x+a)=\psi(x) e^{i q a} \tag{2.193b}
\end{equation*}
$$

1D Bloch theorem

The physical sense of parameter $q$ will be discussed in detail below; for now just note that according to Eq. (193b), an addition of ( $2 \pi / a$ ) to it yields the same wavefunction; hence all observables have to be ( $2 \pi / a$ )-periodic functions of $q .{ }^{53}$

Now let us use the Bloch theorem to find eigenfunctions and eigenenergies for a particular, and probably the simplest periodic function $U(x)$ : an infinite set of similar quantum wells separated by deltafunctional tunnel barriers (Fig. 24).

Fig. 2.24. The simplest periodic potential: an infinite set of similar, equidistant, delta-functional tunnel barriers.

[^507]To start, consider two points separated by distance $a$ : one of them, $x_{j}$, just left of position of one of the barriers, and another one, $x_{j+1}$, just left of the following barrier. Eigenfunctions in each of the points may be presented as linear superpositions of two simple waves $\exp \{ \pm i k x\}$, and amplitudes of their components should be related by a $2 \times 2$ transfer matrix T of the potential fragment separating them. According to Eq. (141), this matrix may be found as the product of the matrix (146) of one interval $a$ and the matrix (143) of one barrier:

$$
\binom{A_{j+1}}{B_{j+1}}=\mathrm{T}_{\mathbf{a}} \mathrm{T}_{\alpha}\binom{A_{j}}{B_{j}}=\left(\begin{array}{cc}
e^{i k a} & 0  \tag{2.194}\\
0 & e^{-i k a}
\end{array}\right)\left(\begin{array}{cc}
1-i \alpha & -i \alpha \\
i \alpha & 1+i \alpha
\end{array}\right)\binom{A_{j}}{B_{j}} .
$$

However, according to the Bloch theorem (193b), the component amplitudes should be also related as

$$
\binom{A_{j+1}}{B_{j+1}}=e^{i q a}\binom{A_{j}}{B_{j}}=\left(\begin{array}{cc}
e^{i q a} & 0  \tag{2.195}\\
0 & e^{i q a}
\end{array}\right)\binom{A_{j}}{B_{j}} .
$$

The condition of self-consistency of these two equations leads to the following characteristic equation:

$$
\left(\begin{array}{cc}
e^{i k a} & 0  \tag{2.196}\\
0 & e^{-i k a}
\end{array}\right)\left(\begin{array}{cc}
1-i \alpha & -i \alpha \\
i \alpha & 1+i \alpha
\end{array}\right)-\left(\begin{array}{cc}
e^{i q a} & 0 \\
0 & e^{i q a}
\end{array}\right)=0
$$

In Sec. 5, we have already calculated the matrix product participating in this equation - see Eq. (148). Using it, we see that Eq. (196) is reduced to the same simple Eq. (166) that has already jumped at us from the solution of the different (resonant tunneling) problem. Let us explore that simple result in detail. First of all, the right hand part of Eq. (166) is a sinusoidal function of $k a$, with amplitude $(1+$ $\left.\alpha^{2}\right)^{1 / 2}$ - see Fig. 25, while its left hand part is a sinusoidal function of $q a$ with amplitude 1.

Fig. 2.25. Graphical solution of the characteristic equation (166) for a fixed value of parameter $\alpha$. The ranges of $k a$ that yield with $|\cos q a|<1$, correspond to the allowed energy bands, while those with $|\cos q a|>1$, to gaps between them.

As a result, within each period $\Delta(k a)=2 \pi$, the characteristic equation does not have a real solution for $q$ inside two intervals of $k a$ - and hence inside two intervals of energy $E=\hbar^{2} k^{2} / 2 m$. (These intervals are exactly the energy gaps mentioned above, while the complementary intervals of $k a$ and $E$, where a real $q$ exists, are the allowed energy bands.) In contrast, parameter $q$ can take any real values, so it is more convenient to plot the eigenenergy $E=\hbar^{2} k^{2} / 2 m$ as the function of $q$ (or, even more
conveniently, $q a$ ) rather than $k a .{ }^{54}$ While doing that, we need to recall that parameter $\alpha$, defined by the last of Eqs. (127), depends on wave vector $k$ as well, so that if we vary $q$ (and hence $k$ ), it is better to characterize the structure by a different, $k$-independent dimensionless parameter, for example

$$
\begin{equation*}
\beta \equiv(k a) \alpha=\frac{m a w}{\hbar^{2}}, \tag{2.197}
\end{equation*}
$$

so that Eq. (166) becomes

$$
\begin{equation*}
\cos q a \equiv \cos k a+\beta \frac{\sin k a}{k a} \tag{2.198}
\end{equation*}
$$

Characteristic equation for system in Fig. 24

Figure 26 shows the plots of $E$ and $k$, following from Eq. (198), for a particular, moderate value of parameter $\beta$. The band structure of the energy spectrum is apparent. Another evident feature is the $2 \pi$-periodicity of the pattern, that we have already predicted from the general Bloch theorem arguments. (Due to this periodicity, the complete band/gap pattern may be studied on just one interval $-\pi \leq q a \leq+$ $\pi$, called the $I^{\text {st }}$ Brillouin zone - the so-called reduced zone picture. For some applications, however, it is more convenient to use the extended zone picture with $-\infty \leq q a \leq+\infty-$ see, e.g., the next section.)

Fig. 2.26. (a) "Real" momentum $k$ of a particle in the periodic delta-functional potential profile shown in Fig. 24, and (b) its energy $E=\hbar^{2} k^{2} / 2 m$ (in units of $E_{0} \equiv \hbar^{2} / 2 m a^{2}$ ), as functions of the quasi-momentum $q$, for a particular value $(\beta=3)$ of the dimensionless potential parameter $\beta \equiv(k a) \alpha=m W a / \hbar^{2}$. Arrows in the lower right corner of panel (b) illustrate the definition of the energy band $\left(\Delta E_{n}\right)$ and energy gap $\left(\Delta_{n}\right)$ widths.

[^508]However, maybe the most surprising fact, clearly visible in Fig. 26, is that there is a infinite number of energy bands, with different energies $E_{n}(q)$ for the same value of $q$. Mathematically, it is evident from Eq. (198) - see also Fig. 25. Indeed, for each value of $q a$ there are two solutions $k a$ to this equation on each period $\Delta(k a)=2 \pi$ - see also panel (a) in Fig. 26. Each of such solutions gives a different value of particle energy $E=\hbar^{2} k^{2} / 2 m$. A continuous set of similar solutions for various $q a$ forms a particular energy band.

Since the band theory is one of the most vital results of quantum mechanics, it is important to understand the physics of these different solutions - and hence of the whole band picture. For that, let us explore analytically two different potential strength limits. An important advantage of this approach is that both analyses may be carried out for an arbitrary periodic potential $U(x)$, rather than for the simplest model shown in Fig. 24.
(i) Tight-binding approximation. This approximation is sound when eigenenergy $E_{n}$ is much lower than the height of the potential barriers separating the potential minima (serving as quantum wells) - see Fig. 27. As should be clear from our discussion in Sec. 6, the wavefunction is mostly localized in the classically allowed regions at points $x_{j}$ of the potential energy minima - see the dashed lines in Fig. 27. Essentially the only role of coupling between these quantum well states (via tunneling through the separating barriers) is to establish certain phase shifts $\Delta \varphi=q a$ between the pairs of adjacent quasi-localized wavefunction "lumps" $u\left(x-x_{j}\right)$ and $u\left(x-x_{j+1}\right)$.

Fig. 2. 27. Tight binding approximation (schematically).

To describe this effect quantitatively, let us first return to the problem of two coupled wells considered in Sec. 6, and recast result (184) as

$$
\begin{equation*}
\Psi_{n}(x, t)=\left[a_{R}(t) \psi_{R}(x)+a_{L}(t) \psi_{L}(x)\right] \exp \left\{-i \frac{E_{n}}{\hbar} t\right\}, \tag{2.199}
\end{equation*}
$$

where functions $a_{R}$ and $a_{L}$ oscillate sinusoidally in time:

$$
\begin{equation*}
a_{R}(t)=\cos \frac{\delta_{n}}{\hbar} t, \quad a_{L}(t)=i \sin \frac{\delta_{n}}{\hbar} t . \tag{2.200}
\end{equation*}
$$

This evolution satisfies the following system of two equations whose structure reminds Eq. (1.59):

$$
\begin{equation*}
i \hbar \dot{a}_{R}=-\delta_{n} a_{L}, \quad i \hbar \dot{a}_{L}=-\delta_{n} a_{R} . \tag{2.201}
\end{equation*}
$$

Later in the course (in Chapter 6) we will prove that such equations are indeed valid, in the tightbinding approximation, for any system of two coupled quantum wells. These equations may be readily generalized to the case of many similar coupled wells. Here, in this case, instead of Eq. (199), we evidently should write

$$
\begin{equation*}
\Psi_{n}(x, t)=\exp \left\{-i \frac{E_{n}}{\hbar} t\right\} \sum_{j} a_{j}(t) u_{n}\left(x-x_{j}\right), \tag{2.202}
\end{equation*}
$$

where $E_{n}$ are the eigenenergies, and $u_{n}$ the eigenfunctions of each isolated well. In the tight binding limit, only the adjacent wells are coupled, so that instead of Eq. (201) we should write an infinite system of similar equations

$$
\begin{equation*}
i \hbar \dot{a}_{j}=-\delta_{n} a_{j-1}-\delta_{n} a_{j+1} \tag{2.203}
\end{equation*}
$$

for each well number $j$, where parameters $\delta_{n}$ describe the coupling between two adjacent quantum wells. Repeating the calculation outlined in the end of Sec. 6 for our new situation, we get the result essentially similar to the last form of Eq. (190):

$$
\begin{equation*}
\delta_{n}=\frac{\hbar^{2}}{m} u_{n}\left(x_{0}\right) \frac{d u_{n}}{d x}\left(a-x_{0}\right), \tag{2.204}
\end{equation*}
$$

Tight binding limit: coupling energy
where $x_{0}$ is the distance between the well bottom and the middle of the tunnel barrier on the right of it see Fig. 27. The only substantial new feature of this expression in comparison with Eq. (190) is that the sign of $\delta_{n}$ alternates with the level number $n: \delta_{1}>0, \delta_{2}<0, \delta_{3}>0$, etc. Indeed, the number of "wiggles" (formally, zeros) of eigenfunctions $u_{n}(x)$ of any potential well increases as $n-$ see, e.g., Fig. $1.7,{ }^{55}$ so that the difference of the exponential tails of the functions, sneaking under the left and right barriers limiting the well also alternates with $n$.

The infinite system of ordinary differential equations (203) allows one to explore a large range of important problems (such as the spread of the wavefunction that was initially localized in one well, etc.), but our main task now is to find its stationary states, i.e. the solutions proportional to $\exp \{-$ $\left.i\left(\varepsilon_{n} / \hbar\right) t\right\}$, where $\varepsilon_{n}$ is a still unknown, $q$-dependent addition to the background energy $E_{n}$ of $n$-th level. In order to satisfy the Bloch theorem (193) as well, such solution should have the form

$$
\begin{equation*}
a_{j}(t)=a \exp \left\{i q x_{j}-i \frac{\varepsilon_{n}}{\hbar} t+\text { const }\right\}, \tag{2.205}
\end{equation*}
$$

where $a$ is a constant. Plugging this solution into Eq. (203) and canceling the common exponent, we get

$$
\begin{equation*}
E=E_{n}+\varepsilon_{n}=E_{n}-\delta_{n}\left(e^{-i q a}+e^{i q a}\right)=E_{n}-2 \delta_{n} \cos q a \tag{2.206}
\end{equation*}
$$

so that in this approximation, the energy band width $\Delta E_{n}$ (see Fig. 26b) equals $4\left|\delta_{n}\right|$.
Relation (206), whose validity is restricted to $\left|\delta_{n}\right| \ll E_{n}$, describes the particular lowest energy bands plotted in Fig. 26b reasonably well. (For larger $\beta$, the agreement would be even better.) So, this calculation explains what the energy bands really are - in the tight binding limit they are best interpreted as isolated well's energy levels $E_{n}$, broadened into bands by the interwell interaction. Also, this result gives a clear proof that the energy band extremes correspond to $q a=2 \pi l$ and $q a=2 \pi(l+1 / 2)$, with integer $l$. Finally, the sign alteration of the coupling coefficient $\delta_{n}(204)$ with number $n$ explains why the energy maxima of one band are aligned, on the $q a$ axis, with energy minima of the adjacent bands.

[^509]Tight binding
limit: energy bands
(ii) Weak-potential limit. Surprisingly, the energy band structure is also compatible with a completely different physical picture that can be developed in the opposite limit. Let energy $E$ be so high that the periodic potential $U(x)$ may be treated as a small perturbation. Naively, we would have the parabolic dispersion relation between particle's energy and momentum. However, if we are plotting energy as a function of $q$ rather than $k$, we need to add $2 \pi l / a$, with arbitrary integer $l$, to the argument. Let us show this by expanding all variables into the spatial Fourier series. For a periodic potential energy $U(x)$ such an expansion is straightforward: ${ }^{56}$

$$
\begin{equation*}
U(x)=\sum_{l^{\prime \prime}} U_{l^{\prime \prime}} \exp \left\{-i \frac{2 \pi x}{a} l^{\prime \prime}\right\}, \tag{2.207}
\end{equation*}
$$

where the summation is over all integers $l$ ", from $-\infty$ to $+\infty$. However, for the wavefunction we should show due respect to the Bloch theorem (193). To understand how to proceed, let us define another function

$$
\begin{equation*}
u(x) \equiv \psi(x) e^{-i q x} \tag{2.208}
\end{equation*}
$$

and study its periodicity:

$$
\begin{equation*}
u(x+a)=\psi(x+a) e^{-i q(x+a)}=\psi(x) e^{-i q x}=u(x) \tag{2.209}
\end{equation*}
$$

We see that the new function is $a$-periodic, and hence we can use Eqs. (208)-(209) to rewrite the Bloch theorem as

$$
\begin{equation*}
\psi(x)=u(x) e^{i q x}, \quad \text { with } u(x+a)=u(x) \tag{2.210}
\end{equation*}
$$

Now it is safe to expand the periodic function $u(x)$ exactly as $U(x)$ :

$$
\begin{equation*}
u(x)=\sum_{l^{\prime}} u_{l^{\prime}} \exp \left\{-i \frac{2 \pi x}{a} l^{\prime}\right\}, \tag{2.211}
\end{equation*}
$$

so that, according to the Bloch theorem,

$$
\begin{equation*}
\psi(x)=e^{i q x} \sum_{l^{\prime}} u_{l^{\prime}} \exp \left\{-i \frac{2 \pi x}{a} l^{\prime}\right\}=\sum_{l^{\prime}} u_{l^{\prime}} \exp \left\{i\left(q-\frac{2 \pi}{a} l^{\prime}\right) x\right\} . \tag{2.212}
\end{equation*}
$$

The only nontrivial part of plugging this expression into the stationary Schrödinger equation (61) is the calculation of the product term, using expansions (207) and (211):

$$
\begin{equation*}
U(x) \psi=\sum_{l, l^{\prime \prime}} U_{l^{\prime \prime}} u_{l^{\prime}} \exp \left\{i\left(q-\frac{2 \pi x}{a}\left(l^{\prime}+l^{\prime \prime}\right)\right)\right\} . \tag{2.213}
\end{equation*}
$$

At fixed $l^{\prime}$, we may change summation over $l^{\prime \prime}$ to that over $l \equiv l^{\prime}+l^{\prime \prime}$ (so that $l^{\prime \prime}=l-l$ '), and write:

$$
\begin{equation*}
U(x) \psi=\sum_{l} \exp \left\{i\left(q-\frac{2 \pi x}{a} l\right)\right\} \sum_{l^{\prime}} u_{l} U_{l-l^{\prime}} \tag{2.214}
\end{equation*}
$$

[^510]Now plugging Eqs. (212) (with index $l$ ' now replaced by $l$ ) and (214) into the stationary Schrödinger equation (61), and requiring the coefficients of each spatial exponent to match, we get an infinite system of linear equations for $u_{l}:{ }^{57}$

$$
\begin{equation*}
\sum_{l^{\prime}} U_{l-l^{\prime}} u_{l^{\prime}}=\left[E-\frac{\hbar^{2}}{2 m}\left(q-\frac{2 \pi}{a} l\right)^{2}\right] u_{l} . \tag{2.215}
\end{equation*}
$$

So far, this system is an equivalent alternative to the initial Schrödinger equation - and, by the way, is very efficient for fast numerical calculations, for virtually any potential strength, though in systems with tight binding it may require taking into account a large number of harmonics $u_{l}$. In the weak potential limit, i.e. if all the Fourier coefficients $U_{n}$ are small,58 we can complete all the calculation analytically. ${ }^{59}$ Indeed, in the so-called $0^{\text {th }}$ approximation we can ignore all $U_{n}$, so that in order to have at least one $u_{l}$ different from 0, Eq. (215) requires that

$$
\begin{equation*}
E \rightarrow E_{l} \equiv \frac{\hbar^{2}}{2 m}\left(q-\frac{2 \pi l}{a}\right)^{2} \tag{2.216}
\end{equation*}
$$

( $u_{l}$ itself should be obtained from the normalization condition). This result means that the dispersion relation $E(q)$ has an infinite number of similar quadratic branches numbered by integer $l-$ see Fig. 28.

Fig. 2.28. 1D band picture in the weak potential case $\left(\Delta_{n} \ll E^{(n)}\right)$. Shading shows the $1^{\text {st }}$ Brillouin zone.

On any branch, the eigenfunction has just one Fourier coefficient, i.e. presents a monochromatic traveling wave

$$
\begin{equation*}
\psi_{l} \rightarrow u_{l} e^{i k x}=u_{l} \exp \left\{i\left(q-\frac{2 \pi l}{a}\right) x\right\} . \tag{2.217}
\end{equation*}
$$

[^511]This fact allows us to rewrite Eq. (215) in a more transparent form

$$
\begin{equation*}
\sum_{l \neq l} U_{l^{\prime}-l} u_{l^{\prime}}=\left(E-E_{l}\right) u_{l}, \tag{2.218}
\end{equation*}
$$

that may be formally solved for $u_{i}$ :

$$
\begin{equation*}
u_{l}=\frac{1}{E-E_{l}} \sum_{l \neq l} U_{l^{\prime}-l} u_{l^{\prime}} . \tag{2.219}
\end{equation*}
$$

If the Fourier coefficients $U_{n}$ are nonvanishing but small, this formula shows that wavefunctions do acquire other Fourier components (besides the main one, with the index corresponding to the branch number), but these additions are all small, besides narrow regions near the points $E_{l}=E_{l}$, where two branches (216) of the dispersion relation $E(q)$, with some specific numbers $l$ and $l^{\prime}$, cross. This happens when

$$
\begin{equation*}
\left(q-\frac{2 \pi}{a} l\right) \approx-\left(q-\frac{2 \pi}{a} l^{\prime}\right), \tag{2.220}
\end{equation*}
$$

i.e. at $q \approx q_{m} \equiv \pi m / a$ (with integer $\left.m \equiv l+l^{\prime}\right)^{60}$ corresponding to
 energy gap positions

$$
\begin{equation*}
\frac{E_{l}-E_{l^{\prime}}}{2} \approx \gamma \widetilde{q}, \quad \text { with }\left.\gamma \equiv \frac{d E_{l}}{d q}\right|_{q=q_{m}}=\frac{\pi \hbar^{2} n}{m a}=\frac{2 a E^{(n)}}{\pi n}, \quad \text { and } \widetilde{q} \equiv q-q_{m} \tag{2.225}
\end{equation*}
$$

while parameters $E_{\text {ave }} \equiv\left(E_{l}+E_{l}\right) / 2=E^{(n)}$ and $U_{n} U_{n}^{*}=\left|U_{n}\right|^{2}$ do not depend on $\widetilde{q}$, i.e. the distance from the central point $q_{m}$. This is why Eq. (224) may be plotted as the famous level anticrossing (also called "avoided crossing", or intended crossing", or "non-crossing") diagram (Fig. 29), with the energy gap width $\Delta_{n}$ equal to $2\left|U_{n}\right|$, i.e. just double the magnitude of the $n$-th Fourier harmonic of the periodic potential $U(x)$. Such anticrossings are also clearly visible in Fig. 28 that shows the results of the exact solution of Eq. (198) for $\beta=0.5 .{ }^{62}$

We will run into the anticrossing diagram again and again in the course, notably at the discussion of spin. Such diagram characterizes any quantum systems with two weakly-interacting eigenstates with close energies. It is also repeatedly met in classical mechanics, for example at the calculation of eigenfrequencies of coupled oscillators. ${ }^{63,64}$ In our current case of the weak potential limit, the diagram describes the weak interaction of two sinusoidal de Broglie waves (216), with oppositely directed wave vectors, $l$ and $-l^{\prime}$, via the $\left(l-l^{\prime}\right)^{\text {th }}$ (i.e. $\left.n^{\text {th }}\right)$ Fourier harmonic of the potential profile $U(x)$. This effect exists also for the classical wave theory, and is known as the Bragg reflection, describing, for example, the 1D case of the wave reflection by a crystal lattice (Fig. 1.5) in the limit of weak interaction between the incident particles and the lattice.

Returning for the last time to our initial result - the band structure for the delta-functional $U(x)$ (Fig. 24), shown in Fig. 26, we may wonder how general it is, taking into account the peculiar properties of the delta-function approximation. A partial answer may be obtained from the band structure for two more realistic and relatively simple periodic functions $U(x)$ : the sinusoidal potential (Fig. 30a) and the rectangular Kronig-Penney potential shown in Fig. 30b.

For the sinusoidal potential (Fig. 30a), with $U(x)=U_{1} \cos (2 \pi x / a)$, the stationary Schrödinger equation (61) takes the form

[^512]\[

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m} \frac{d^{2} \psi}{d x^{2}}+U_{1} \cos \frac{2 \pi x}{a} \psi=E \psi \tag{2.226}
\end{equation*}
$$

\]

By the introduction of dimensionless variables

$$
\begin{equation*}
\xi \equiv \frac{\pi x}{a}, \quad \alpha \equiv \frac{E}{E^{(1)}}, \quad 2 \beta \equiv \frac{U_{1}}{E^{(1)}}, \tag{2.227}
\end{equation*}
$$

where $E^{(1)}$ is defined by Eq. (221), Eq. (226) may be reduced to the canonical form of the well-known Mathieu equation ${ }^{65}$

$$
\begin{equation*}
\frac{d^{2} \psi}{d \xi^{2}}+(\alpha-2 \beta \cos 2 \xi) \psi=0 \tag{2.228}
\end{equation*}
$$

(b)

Figure 31 shows the so-called characteristic curves of the Mathieu equation, i.e. the relations between parameters $\alpha$ and $\beta$, corresponding to the energy band edges separating them from the adjacent bands. (Such curves may be readily calculated numerically, for example, using Eqs. (215) with the bandedge values $q a=0$ and $q a=\pi$ ). In such "phase plane" plots, the detailed information about the energy dependence on the quasi-momentum is lost, but we already know from Fig. 26 that the dependence is not too eventful. The most remarkable feature of these plots is the fast (exponential) disappearance of the allowed energy bands at $2 \beta>\alpha$ (in Fig. 31, above the red dashed line), i.e. at $E<U_{1}$. This may be readily explained by our tight-binding approximation result (206): as soon as the eigenenergy drops significantly below the potential maximum $U_{\max }=U_{1}$ (see Fig. 30a), quantum states in the adjacent potential wells are only connected by tunneling through the separating potential barriers, with exponentially small amplitudes $\delta_{n}$ - see Eq. (204).

On the other hand, the characteristic curves below the dashed line, i.e. at $2 \beta<\alpha$, correspond to virtually free motion of the particle with energy $E$ above $U_{\max }=U_{1}$. Naturally, in this region the energy bands rapidly expand while gaps virtually disappear. This could be expected from the weak potential limit analysis (see Fig. 28 and its discussion); however, based on that analysis one could expect that the

[^513]energy gaps $\Delta_{n} \approx 2\left|U_{n}\right|$ would disappear more gradually. The fast decline of the gaps at $U_{1} \rightarrow 0$ (i.e. $\beta$ $\rightarrow 0$ ) in the Mathieu equation is an artifact of the sinusoidal potential $U(x)$, with no Fourier harmonics $U_{n}$ above the first one. (In order to calculate the correct asymptotic behavior $\Delta_{n} \propto \beta^{n}$ at $\beta \rightarrow 0$, one needs to go beyond the first approximation we have used in the weak potential limit analysis.)

Fig. 2.31. Characteristic curves of the Mathieu equation. In application to the band theory, dotted regions correspond to the energy gaps, while regions between them, to energy bands. The red dashed line corresponds to condition $\alpha=2 \beta$, i.e. $E=U_{1}$ $\equiv U_{\max }$, separating the regions of tunneling and over-barrier motion. Figure adapted from http://www.enm.bris.ac.uk/teaching/.

If one wants to study the details of transition between the two limits in the 1 D band theory without the artifacts of the delta-functional model shown in Fig. 24 (with infinite number of harmonics $U_{n}$ independent of $n$ ) and of the Mathieu equation (with all $U_{n}=0$ for $n \neq \pm 1$ ), the standard way is to examine the Kronig-Penney potential shown in Fig. 30b. For this potential, the characteristic equation may be readily derived using our rectangular barrier analysis in Sec. 3. For the case $E<U_{0}$, the result is the following natural generalization of Eq. (166):

$$
\begin{equation*}
\cos q a=\cosh \kappa d \cos k(a-d)+\frac{1}{2}\left(\frac{\kappa}{k}-\frac{k}{\kappa}\right) \sinh \kappa d \sin k(a-d) \tag{2.229}
\end{equation*}
$$

where parameters $k$ and $\kappa$ are defined, as functions of $E$ and $U_{0}$, by Eqs. (62) and (65). In the opposite case $E>U_{0}$, one can use the same formula with the replacement (73). Plots $E(q)$, described by these formulas, ${ }^{66}$ are very similar to those shown in Figs. $26 b$ and 28 above. In order to see some difference, one needs to plot the characteristic curves $U_{0}(E)$. This may be done by taking $q a=0$ and $q a=\pi$ (i.e. $\cos q a= \pm 1$ ) in Eq. (229), and solving the resulting transcendental equation for $U_{0}$ numerically. The curves are generally similar to those shown in Fig. 31, but, in accordance with Eq. (224), exhibit a more gradual decrease of energy gaps:

$$
\begin{equation*}
\Delta_{n} \rightarrow 2\left|U_{n}\right| \propto \frac{U_{0}}{n}, \quad \text { at } E \sim E^{(n)} \gg U_{0} . \tag{2.230}
\end{equation*}
$$

To conclude this section, let me address the effect of periodic potential on the number of eigenstates in 1D systems of large but finite length $l \gg a, k^{-1}$. Surprisingly, the Bloch theorem makes the analysis of this problem elementary, for arbitrary $U(x)$. Indeed, let us assume that $l$ is comprised of

[^514]an integer number of periods $a$, and its ends are described by the similar boundary conditions - both assumptions evidently inconsequential for $l \gg a$ (such as a $1-\mathrm{cm}$-scale crystal with $\sim 10^{8}$ atoms along each direction). Then, according to Eq. (210), the boundary conditions impose, on the quasi-momentum $q$, exactly the same quantization condition as we had for $k$ for a free 1D motion. Hence, instead of Eq. (1.94) we can write

1D density of states summation
rule

$$
\begin{equation*}
d N=\frac{l}{2 \pi} d q \tag{2.231}
\end{equation*}
$$

with the corresponding change of the summation rule:

$$
\begin{equation*}
\sum_{q} f(q) \rightarrow \frac{l}{2 \pi} \int f(q) d k \tag{2.232}
\end{equation*}
$$

Hence, the density of states in 1D $q$-space, $d N / d q=l / 2 \pi$, does not depend on the potential profile at all! Note, however, that the profile does affect the density of states on the energy axis, $d N / d E$. As an extreme example, on the bottom and at the top of each energy band we have $d E / d q \rightarrow 0$, and hence

$$
\begin{equation*}
\frac{d N}{d E}=\frac{d N}{d q} / \frac{d E}{d q}=\frac{l}{2 \pi} / \frac{d E}{d q} \rightarrow \infty \tag{2.233}
\end{equation*}
$$

This divergence (which survives in higher spatial dimensionalities as well) of the state density has important implications for the operation of several electron and optical devices, in particular semiconductor lasers.

### 2.8. Effective mass and the Bloch oscillations

The band structure of the energy spectrum has profound implications not only on the density of states, but also on the dynamics of particles in periodic potentials. In order to see that, let us consider the simplest case: motion of a wave packet consisting of Bloch functions (210), all in the same (say, $n^{\text {th }}$ ) energy band. Similarly to Eq. (27) for the a free particle, we can describe such a packet as

$$
\begin{equation*}
\Psi(x, t)=\int a_{q} u_{q}(x) e^{i[q x-\omega(q) t]} d q \tag{2.234}
\end{equation*}
$$

where the $a$-periodic functions $u(x)$, defined by Eq. (208), are now indexed to emphasize their dependence on the quasi-momentum, and $\omega(q) \equiv E_{n}(q) / \hbar$ is the function of $q$ describing the shape of the corresponding energy band - see, e.g., Fig. 26b or Fig. 28. If the packet is narrow, i.e. the width $\delta q$ of the distribution $a_{q}$ is much smaller than all the characteristic scales of the dispersion relation $\omega(q)$, in particular $\pi / a$, we may simplify Eq. (234) exactly as we have done in Sec. 2 for a free particle, despite the presence of factors $u_{q}(x)$ under the integral. In the linear approximation of the Taylor expansion, we again get Eq. (32), but now with ${ }^{67}$

$$
\begin{equation*}
v_{\mathrm{gr}}=\left.\frac{d \omega}{d q}\right|_{q=q_{0}}, \quad \text { and } v_{\mathrm{ph}}=\left.\frac{\omega}{q}\right|_{q=q_{0}} \tag{2.235}
\end{equation*}
$$

[^515]where $q_{0}$ is the central point of the quasi-momentum distribution. Despite the formal similarity with Eq. (33) for the free particle, this result is much more eventful; for example, as evident from the dispersion relation's topology (see Figs. 26b, 28), the group velocity vanishes not only at $q=0$, but at all values of $q$ that are multiples of $(\pi / a)$, at the bottom and on the top of each energy band. At these points, packet's envelope does not move in either direction - though may keep spreading. ${ }^{68}$

Even more fascinating phenomena take place if a particle in the periodic potential is the subject of an additional external force $F(t)$. (For electrons in a crystal lattice, this may be, for example, the Lorentz force of the applied electric and/or magnetic field.) Let the force be relatively weak, so that product $F a$ (i.e. the scale of energy increment from the additional force per one lattice period) is much smaller than the relevant energy scales the dispersion relation $E(q)$ - see Fig. 26b:

$$
\begin{equation*}
F a \ll \Delta E_{n}, \Delta_{n} . \tag{2.236}
\end{equation*}
$$

This relation allows one to neglect the force-induced interband transitions, so that the wave packet (234) includes the Bloch eigenfunctions belonging to only one (initial) energy band at all times. For the time evolution of its center $q_{0}$, theory yields ${ }^{69}$ an extremely simple equation of motion

$$
\begin{equation*}
\dot{q}_{0}=\frac{1}{\hbar} F(t) . \tag{2.237}
\end{equation*}
$$

Time evolution of quasimomentum

This equation is physically very transparent: it is essentially the $2^{\text {nd }}$ Newton law for the time evolution of the quasi-momentum $\hbar q$ under the effect of the additional force $F(t)$ only, excluding the periodic force $-\partial U(x) / \partial x$ of the background potential $U(x)$. This is very natural, because $\hbar q$ is essentially the particle's momentum averaged over potential's period, and the periodic force effect drops out at such an averaging.

Despite the simplicity of Eq. (237), the results of its solution may be highly nontrivial. First, let us use Eqs. (235) and (237) find the instant group acceleration of the particle (i.e. the acceleration of its wave packet's envelope):

$$
\begin{equation*}
a_{\mathrm{gr}} \equiv \frac{d v_{\mathrm{gr}}}{d t}=\frac{d}{d t} \frac{d \omega\left(q_{0}\right)}{d q_{0}}=\frac{d}{d q_{0}} \frac{d \omega\left(q_{0}\right)}{d q_{0}} \frac{d q_{0}}{d t}=\frac{d^{2} \omega\left(q_{0}\right)}{d q_{0}^{2}} \frac{d q_{0}}{d t}=\left.\frac{1}{\hbar} \frac{d^{2} \omega}{d q^{2}}\right|_{q=q_{0}} F(t) . \tag{2.238}
\end{equation*}
$$

This means that the second derivative of the dispersion relation plays the role of the effective reciprocal mass of the particle:

$$
\begin{equation*}
m_{\mathrm{ef}}=\frac{\hbar}{d^{2} \omega / d q^{2}}=\frac{\hbar^{2}}{d^{2} E / d q^{2}} \tag{2.239}
\end{equation*}
$$

For the particular case of a free particle, described by Eq. (216), this expression is reduced to the original (and constant) mass $m$, but generally the effective mass depends on the wave packet's momentum. According to Eq. (239), at the bottom of any energy band, $m_{\text {ef }}$ is always positive, but depends on the strength of particle's interaction with the periodic potential. In particular, according to Eq. (206), in the tight binding limit, the effective mass is very large:

[^516]\[

$$
\begin{equation*}
\left|m_{\mathrm{ef}}\right|_{q=(\pi / a) n}=\frac{\hbar^{2}}{2 \delta_{n} a^{2}}=m \frac{E^{(1)}}{\pi^{2} \delta_{n}} \gg m . \tag{2.240}
\end{equation*}
$$

\]

On the contrary, in the weak potential limit, the effective mass is close to $m$ at most points of each energy band, but at the edges of the (narrow) bandgaps it is much smaller. Indeed, expanding Eq. (224) in the Taylor series near point $q=q_{m}$, we get

$$
\begin{equation*}
\left.E_{ \pm}\right|_{E \approx E^{(n)}} \approx \pm\left|U_{n}\right| \pm \frac{1}{2\left|U_{n}\right|}\left(\frac{d E_{l}}{d q}\right)_{q=q_{m}}^{2} \quad \widetilde{q}^{2}= \pm\left|U_{n}\right| \pm \frac{\gamma^{2}}{2\left|U_{n}\right|} \widetilde{q}^{2} \tag{2.241}
\end{equation*}
$$

where $\gamma$ and $\widetilde{q}$ are defined by Eq. (225), so that

$$
\begin{equation*}
\left|m_{\mathrm{ef}}\right|_{q=q_{m}}=\left|U_{n}\right| \frac{\hbar^{2}}{\gamma^{2}}=m \frac{\left|U_{n}\right|}{2 E^{(n)}} \ll m . \tag{2.242}
\end{equation*}
$$

The effective mass effects in real solids may be very significant. For example, the charge carriers in the ubiquitous field-effect transistors of silicon integrated circuits have $m_{\mathrm{ef}} \approx 0.19 m_{e}$ in the lowest normally-empty energy band (traditionally called the conduction band), and $m_{\mathrm{ef}} \approx 0.98 m_{e}$ in the lower, normally-filled valence band. In some semiconducting compounds the conduction-band electron mass may be even smaller - down to $0.0145 m_{\mathrm{e}}$ in InSb!

However, the absolute value of the effective mass in not the most surprising effect. The more shocking corollary of Eq. (239) is that on the top of each energy band the effective mass is negative please revisit Figs. 26, 28, and 29 again. This means that the particle (or more strictly its wave packet's envelope) is accelerated in the direction opposite to the force. This is exactly what electronic engineers, working with electrons in semiconductors, call holes, characterizing them by positive mass and positive charge. If the particle does not leave a close vicinity of the energy band's top (say, due to scattering effects), such flip of signs does not lead to an error, because the Lorentz force is proportional to electron's charge $(q=-e)$, so that particle's acceleration $a_{\mathrm{gr}}$ is proportional to ratio ( $q / m_{\mathrm{ef}}$ ). ${ }^{70}$

However, at some phenomena the usual image of a hole as a particle with $q>0$ and $m_{\text {ef }}>0$ is unacceptable. For example, let us form a narrow wave packet at the bottom of the lowest energy band, ${ }^{71}$ and then exert on it a constant force $F>0$ - say, due to a constant external electric field directed along axis $x$. According to Eq. (237), this would lead to a linear growth of $q_{0}$ in time, so that in the quasimomentum space, the packet's center would slide, with constant speed, along the $q$ axis - see Fig. 32a. Close to the energy band bottom, this motion would correspond to a positive effective mass (possibly, somewhat larger than the genuine particle's mass $m$ ), and hence be close to free particle's acceleration. However, as soon as $q_{0}$ has reached the inflection point, where $d^{2} E_{1} / d q^{2}=0$, the effective mass, and hence acceleration (238) change signs to negative, i.e. the packet starts to slow down (in the direct space

[^517]$x$ ) while still moving ahead in the quasi-momentum space. Finally, at the energy band's top the particle stops at certain $x_{\text {max }}$, while continuing to move in the $q$-space.

Fig. 2.32. The Bloch oscillations (red lines) and the Landau-Zener tunneling (blue arrows) within: (a) the time-domain picture, and (b) the energy-domain picture. On panel (b), the tilted gray strips show the allowed energy bands, and the bold red lines, the Wannier-Stark ladder.

Now we have two alternative ways to look at the further time evolution of the wave packet. From the extended zone picture (which is the simplest for this analysis, see Fig. 32a), ${ }^{72}$ we may say that the particle crosses the $1^{\text {st }}$ Brillouin zone boundary and starts going forward in $q$, i.e. down the lowest energy band. According to Eq. (235), this region (up to the next inflection point) corresponds to a negative group velocity. After $q_{0}$ has reached the next minimum of the energy band at $q a=2 \pi$, the whole process repeats again (and again, and again).

These are the famous Bloch oscillations - the effect that was predicted (by the same F. Bloch) as early as in 1929, but evaded experimental observation until the 1980s - see below. Their time period may be readily found from Eq. (237):

$$
\begin{equation*}
\Delta t_{\mathrm{B}}=\frac{\Delta q}{d q / d t}=\frac{2 \pi / a}{F / \hbar}=\frac{2 \pi \hbar}{F a}, \tag{2.243}
\end{equation*}
$$

so that the Bloch oscillation frequency

$$
\begin{equation*}
\omega_{\mathrm{B}} \equiv \frac{2 \pi}{\Delta t_{\mathrm{B}}}=\frac{F a}{\hbar} . \tag{2.244}
\end{equation*}
$$

Bloch oscillations: frequency

The direct-space motion of the wave packet's center $x_{0}(t)$ during the Bloch oscillation process may be analyzed by integrating Eq. (235) over some time interval $\Delta t$ :

[^518]\[

$$
\begin{equation*}
\Delta x_{0}(t)=\int_{0}^{\Delta t} v_{\mathrm{gr}} d t=\int_{0}^{\Delta t} \frac{d \omega\left(q_{0}\right)}{d q_{0}} d t=\int_{0}^{\Delta t} \frac{d \omega\left(q_{0}\right)}{d q_{0} / d t}=\frac{\hbar}{F} \int_{t=0}^{t=\Delta t} d \omega=\frac{\hbar}{F} \Delta \omega\left(q_{0}\right) . \tag{2.245}
\end{equation*}
$$

\]

If interval $\Delta t$ is equal to the Bloch oscillation period $\Delta t_{\mathrm{B}}$ (234), the initial and final moments of $E\left(q_{0}\right)=$ $\hbar \omega\left(q_{0}\right)$ are equal, giving $\Delta x_{0}=0$ : in the end of the period, the wave packet returns to its initial position. However, if we carry this integration only from the smallest to the largest values of $\omega\left(q_{0}\right)$, i.e. the points where the group velocity vanishes, we get the oscillation swing
 spatial swing

$$
\begin{equation*}
\Delta x_{\max }=\frac{\hbar}{F}\left(\omega_{\max }-\omega_{\min }\right)=\frac{\Delta E_{1}}{F} \tag{2.246}
\end{equation*}
$$

This simple result may interpreted using an alternative energy diagram (Fig. 32b) that results from the following arguments. The additional force $F$ may be described not only via the $2^{\text {nd }}$ Newton law version (237), but, alternatively, by its contribution $U_{F}=-F x$ to the total ("Gibbs" ${ }^{73}$ ) potential energy

$$
\begin{equation*}
U_{\Sigma}(x)=U(x)-F x \tag{2.247}
\end{equation*}
$$

of the system. The direct solution of the Schrödinger equation (61) with such potential may be hard to find, but if the force is weak in the sense of Eq. (236), as we are assuming now, one can argue that our quantum-mechanical treatment including the periodic potential $U(x)$ should be still correct, if the second term in Eq. (247) is considered as a constant at the wave packet width scale $\delta x$, but dependent on position $x_{0}$ of the packet's center. In this approximation, the total energy of the wave packet may be found as

$$
\begin{equation*}
E_{\Sigma}=E\left(q_{0}\right)-F x_{0} . \tag{2.248}
\end{equation*}
$$

In a plot of such energy as a function of $x_{0}$ (Fig. 32b), the information on energy dependence on $q_{0}$ is lost, but we already know it is rather uneventful, and well characterized by the position of band-gap edges on the energy axis. ${ }^{74}$ In this representation, the Bloch oscillations of a relatively wide $(\delta x \gg a)$ wave packet should keep the full energy $E_{\Sigma}$ constant, i.e. follow a horizontal line in Fig. 32b, limited by the classical turning points corresponding to the bottom and the top of the allowed energy band. The distance $\Delta x_{\text {max }}$ between these point is evidently given by Eq. (246).

Besides this second look at the oscillation swing result, the total energy diagram shown in Fig. 32b enables one more remarkable result. Let a wave packet be so narrow in the momentum space ( $\delta q \rightarrow$ 0 ) that $1 / q \gg \Delta x_{\max }$; then the horizontal line segment in Fig. 32b presents the spatial extension of the eigenfunction of the Schrödinger equation with potential (247). But this equation is evidently invariant with respect to the following simultaneous translation in coordinate and energy:

$$
\begin{equation*}
x \rightarrow x+a, \quad E \rightarrow E-F a \tag{2.249}
\end{equation*}
$$

WannierStark ladder

This means that it is satisfied with an infinite set of similar solutions, each corresponding to one of the horizontal red lines shown in Fig. 32b. This is the famous Wannier-Stark ladder, with the step height

$$
\begin{equation*}
\Delta E_{S}=F a \tag{2.250}
\end{equation*}
$$

[^519]The importance of this alternative representation of the Bloch oscillations is due to the following fact. In most experimental realizations, the power of radiation at frequency (244), that may be extracted from the oscillations by their electromagnetic coupling to an external detector, is very low, so that their direct detection presents a hard problem. ${ }^{75}$ However, let us apply to a Bloch oscillator an additional rf field at frequency $\omega \sim \omega_{\mathrm{B}}$. As these frequencies are brought close together, the external signal should synchronize ("phase lock") Bloch oscillations, ${ }^{76}$ resulting in certain observable changes - for example, a resonant absorption of the external radiation. Now let us notice that Eqs. (244) and (250) yield the following remarkable relation:

$$
\begin{equation*}
\Delta E_{S}=\hbar \omega_{\mathrm{B}} . \tag{2.251}
\end{equation*}
$$

This means that the resonant phenomena at $\omega \approx \omega_{\mathrm{B}}$ allow for an alternative (but equivalent) interpretation - as the result of rf-induced transitions ${ }^{77}$ between the steps of the Wannier-Stark ladder! (Such occasions when two very different languages may be used for the interpretation of the same phenomenon is one of the most beautiful features of physics.)

This effect has been used for the first experimental confirmation of the Bloch oscillation theory. For this purpose, the natural periodic structures, solid state crystals, are inconvenient due to their very small period $a \sim 10^{-10} \mathrm{~m}$. Indeed, according to Eq. (244), such structures require very high forces $F$ (and hence high electric fields $\varepsilon=F / e$ ) to bring $\omega_{\mathrm{B}}$ to an experimentally convenient range. This problem has been overcome by fabricating artificial periodic structures (superlattices) of certain semiconductor compounds, such as $\mathrm{Ga}_{1-x} \mathrm{Al}_{x} \mathrm{As}$ with various degrees $x$ of gallium to aluminum atom replacement, whose layers may be grown over each other epitaxially, i.e., without very few crystal structure violations. These superlattices, with periods $a \sim 10 \mathrm{~nm}$, has allowed a clear observation of resonant effects at $\omega \approx \omega_{\mathrm{B}}$, and hence the measurement of the Bloch oscillation frequency, in particular its proportionality to the applied dc electric field, predicted by Eq. (244). ${ }^{78}$

Very soon after this observation, the Bloch oscillations have been observed in small Josephson junctions. ${ }^{79}$ Since this experiment involved two important conceptual issues, let me discuss it in a little bit more detail. As was discussed in Sec. 2.3, the Josephson junction dynamics may be reasonably well described by two simple equations (54) and (55). They may be combined to calculate the work of an external voltage source at Josephson phase change between arbitrary initial ( $\varphi_{\text {ini }}$ ) and final ( $\varphi_{\text {fin }}$ ) values, as the integral of its power $I V$ over the time interval $\Delta t$ of the change:

$$
\begin{equation*}
\text { work }=\int_{\Delta t} I V d t=\int_{\Delta t}\left(I_{c} \sin \varphi\right)\left(\frac{\hbar}{2 e} \frac{d \varphi}{d t}\right) d t=\frac{\hbar I_{c}}{2 e} \int_{\varphi_{\mathrm{ini}}}^{\varphi_{\mathrm{fin}}} \sin \varphi d \varphi=-\frac{\hbar I_{c}}{2 e}\left(\cos \varphi_{\mathrm{fin}}-\cos \varphi_{\mathrm{ini}}\right) . \tag{2.252}
\end{equation*}
$$

We see that the work depends only on the initial and final values of $\varphi$ (but not on the law phase evolution in time $)$, i.e. may be presented as the difference $U\left(\varphi_{\text {fin }}\right)-U\left(\varphi_{\text {ini }}\right)$, where function

[^520]Josephson
coupling energy

$$
\begin{equation*}
U(\varphi)=-E_{\mathrm{J}} \cos \varphi+\mathrm{const}, \quad \text { with } E_{\mathrm{J}} \equiv \frac{\hbar I_{C}}{2 e} \tag{2.250}
\end{equation*}
$$

may be interpreted as the potential energy of the junction (if we consider the Josephson phase as a generalized coordinate). This energy apart, the Josephson junction, as a system of two close, nearly isolated (super)conductors, has a certain capacitance $C$ and the associated electrostatic energy $E_{C}=$ $C V^{2} / 2$. Using Eq. (54) again, we may present it as

$$
\begin{equation*}
E_{C}=\frac{C}{2} V^{2}=C\left(\frac{\hbar}{2 e}\right)^{2}\left(\frac{d \varphi}{d t}\right)^{2} . \tag{2.251}
\end{equation*}
$$

This means that from the point of view at phase $\varphi$ as a generalized coordinate, $E_{C}$ should be considered the kinetic energy of the system, whose dependence on the generalized velocity $d \varphi / d t$ is similar to that of a 1D mechanical particle, with an effective mass ${ }^{81}$

$$
\begin{equation*}
m_{\mathrm{J}}=C\left(\frac{\hbar}{2 e}\right)^{2} \tag{2.252}
\end{equation*}
$$

Hence the total energy of the junction, $E_{C}+U(\varphi)$, is formally similar to that of a 1 D non-relativistic particle in the sinusoidal potential with the $\varphi$-axis period $a_{\mathrm{J}}=2 \pi$.

However, before using the results of the 1D band theory to this system, we have to resolve one paradox (that was the subject of a lively discussion just about 30 years ago). When we develop the band theory, we imply that its translation by period $a$ is (in principle) measurable, i.e. particle positions $x$ and $(x+a)$ are distinguishable - otherwise Eq. (193) with $q \neq 0$ would not have much sense. For a mechanical particle this assumption is very plausible, but less so for a Josephson junction. Indeed, for example, if we change $\varphi$ by $a_{\mathrm{J}}=2 \pi$ via changing the phase of one of superconductors, say $\varphi_{1}$ (Fig. 3) by $2 \pi$, then its wavefunction becomes $|\psi| \exp \left\{i\left(\varphi_{1}+2 \pi\right)\right\}=|\psi| \exp \left\{i \varphi_{1}\right\}$, and it is not immediately clear whether these two states may be distinguished. In order to resolve this contradiction, it is sufficient to have a look at Eq. (54). It shows that if $\varphi$ changes in time by $2 \pi$ (say, by a fast ramp-up), voltage $V$ across the junction exhibits a pulse with "area"

$$
\begin{equation*}
\int V(t) d t=\frac{\hbar}{2 e} \int \frac{d \varphi}{d t} d t=\frac{\hbar}{2 e} \int d \varphi=\frac{\hbar}{2 e} 2 \pi=\frac{h}{2 e} \approx 2 \times 10^{-15} \mathrm{~V} \cdot \mathrm{~s} . \tag{2.253}
\end{equation*}
$$

Such single-flux-quantum (SFQ) pulses ${ }^{82}$ not only may be measured experimentally, but even have been used for signaling and ultrafast (sub-THz) computation, to the best of my knowledge still keeping the absolute records for the highest speed and smallest energy consumption at computation. ${ }^{83}$

Hence, the $2 \pi$-shifts of phase $\varphi$ are measurable, and in the absence of dissipation the Josephson junction dynamics is indeed similar to that of a 1D particle in a periodic (sinusoidal) potential, and its energy spectrum forms energy bands and gaps described by the Mathieu equation - see Fig. 31. Experimentally, the easiest way to verify this picture is to measure the corresponding Bloch oscillations

[^521]induced by an external current $I_{\mathrm{ex}}(t)$. In order to find the frequency of these oscillations, it is sufficient to replace Eq. (237), which expresses the $2^{\text {nd }}$ Newton law averaged over period a of potential $U(x)$, with the charge balance equation
\[

$$
\begin{equation*}
\frac{d Q}{d t}=I_{\mathrm{ex}}(t) \tag{2.254}
\end{equation*}
$$

\]

where $Q$ is the "quasi-charge" ${ }^{84}$, i.e. the electric charge of the capacitor averaged over the period $2 \pi$ of the periodic potential $U(\varphi)$. (Notice that at such averaging, current (55) is averaged out from the equation, so that is affects the phenomena "only" via its contribution to the energy band structure.)

Since the Josephson-junction analog of the genuine wave number $k=m(d x / d t) / \hbar$ of a particle is

$$
\begin{equation*}
k_{\mathrm{J}}=\frac{m_{\mathrm{J}}}{\hbar} \frac{d \varphi}{d t}=\frac{m_{\mathrm{J}}}{\hbar} \frac{2 e}{\hbar} V=\frac{C V}{2 e}, \tag{2.255}
\end{equation*}
$$

and $C V$ is the genuine charge on the capacitor, the analog of $q$ (the quasi-momentum divided by $\hbar$ ) may be obtained just by the replacement of that product with quasi-charge $Q$ :

$$
\begin{equation*}
q_{\mathrm{J}}=\frac{Q}{2 e} . \tag{2.256}
\end{equation*}
$$

Comparing this expression with Eq. (254), we see that $q_{\mathrm{J}}$ obeys the following equation of motion:

$$
\begin{equation*}
\frac{d q_{\mathrm{J}}}{d t}=\frac{I_{\mathrm{ex}}(t)}{2 e} \tag{2.257}
\end{equation*}
$$

so that the role of force $F$ is now played by $F_{\mathrm{J}}=\hbar I / 2 e$. Hence if $I_{\mathrm{ex}}(t)=$ const $=\bar{I}$, we can use Eq. (244) with that replacement, and also $a \rightarrow a_{\mathrm{J}}=2 \pi$, to get

$$
\begin{equation*}
f_{\mathrm{B}} \equiv \frac{\omega_{\mathrm{B}}}{2 \pi}=\frac{1}{2 \pi} \frac{F_{\mathrm{J}} a_{\mathrm{J}}}{\hbar}=\frac{\bar{I}}{2 e} . \tag{2.258}
\end{equation*}
$$

This very simple result has the following physical sense. ${ }^{85}$ In the quantum operation mode, the junction is recharged by the external current, following Eq. (256), until its electric charge reaches $e$ (i.e. $q_{\mathrm{J}} a_{\mathrm{J}}=(Q / 2 e) 2 \pi$ reaches $\pi$-see Fig. 32a); then one Cooper pair passes through the junction changing its charge to $e-(2 e)=-e$, with the same charging energy (251) - the process analogous to crossing the border of the $1^{\text {st }}$ Brillouin zone; then the process repeats again and again. It is remarkable that Eq. (258), describing the frequency of such a quantum property of the Josephson phase $\varphi$ as its Bloch oscillations, does not include the Planck constant, while Eq. (56), describing the classical motion of $\varphi$, does. ${ }^{86}$

[^522]In this context, one may wonder which of these two types of oscillations would a dc-biased Josephson junction generate. For the dissipation-free junction, the answer is: the Bloch oscillations (258) with frequency proportional to dc current. However, any practical junction has some energy losses that may be (approximately) described by a certain Ohmic conductance $G$ connected in parallel to the junction. Very luckily for Dr. Josephson and his Nobel Prize, it is much easier to fabricate and test junctions with $G \gg 1 / R_{Q}$, where $R_{Q}$ is the so-called quantum unit of resistance

$$
\begin{equation*}
R_{Q} \equiv \frac{\pi \hbar}{2 e^{2}} \approx 6.45 \mathrm{k} \Omega \tag{2.259}
\end{equation*}
$$

the fundamental constant that jumps out at analysis of several other effects as well - see, e.g., Sec. 3.2. As will be discussed in Chapter 7, such high energy losses provide what is called dephasing - the suppression of the quantum coherence between different quantum states of the system - in our current case, between the wavefunctions $u(\varphi-2 \pi j)$ localized at different minima of the periodic potential $U(\varphi)$, and thus make the dynamics of the Josephson phase $\varphi$ virtually classical, obeying equations (54) and (55). As we have seen in Sec. 2, dc biasing of such a junction leads to Josephson oscillations with frequency (56) proportional to the applied dc voltage.

### 2.9. Landau-Zener tunneling

All the Bloch oscillation discussion in the last section was based on the premise that the particle stays within one (say, the lowest) energy band. However, just a single look at Fig. 32 shows that this assumption becomes unrealistic if the energy gap separating this band from the next one becomes very small, $\Delta_{1} \rightarrow 0$. Indeed, in the weak potential approximation, that is adequate in this limit, at $\left|U_{1}\right| \rightarrow 0$, the two dispersion curve branches (216) cross without any interaction, so that if our particle (the wave packet) is driven to approach that point, it should continue to move up in energy - see the dashed blue arrow in Fig. 32a. Similarly, in the "energy-domain" presentation shown in Fig. 32b, it is intuitively clear that at $\Delta_{1} \rightarrow 0$, the particle residing at one of the steps of the Wannier-Stark ladder should able to somehow overcome the vanishing spatial gap $\Delta x_{0}=\Delta_{1} / F$ and to leak into the next band - see the horizontal dashed blue arrow on that panel.

This process, called the Landau-Zener (or "interband", or "band-to-band") tunneling ${ }^{87}$ is indeed possible. In order to analyze it, let us first take $F=0$, and consider what happens if a quantum particle described by an $x$-long (i.e. $E$-narrow) wave packet is incident from the free space upon a periodic structure of a large but finite length $l \gg a$. If packet's energy $E$ is within one of the energy bands, it may evidently propagate through the structure (though may be partly reflected from its front end). The corresponding quasi-momentum may be found by solving the dispersion relation for $q$; for example, in the weak-potential limit, Eq. (224), which is valid near the gap, yields

$$
\begin{equation*}
q=q_{m}+\widetilde{q}, \quad \widetilde{q}= \pm \frac{1}{\gamma}\left[\widetilde{E}^{2}-\left|U_{n}\right|^{2}\right]^{1 / 2}, \quad \text { where } \widetilde{E} \equiv E_{ \pm}-E^{(n)} \tag{2.260}
\end{equation*}
$$

and $\gamma$ is given by the second of Eqs. (225).

[^523]Now, if energy $E$ corresponds to one of the energy gaps $\Delta_{n}$, the propagation is impossible, so that the packet is completely reflected back. However, our analysis of the potential step problem in Sec. 3 implies that the wavefunction would still have an exponential tail protruding into the periodic structure and decaying on some length $\delta$ - see Eq. (67). Indeed, a review of the calculation leading to Eq. (260) shows that they remain valid within the gap as well, if the quasi-momentum is understood as a purely imaginary number:

$$
\begin{equation*}
\widetilde{q} \rightarrow \pm i \kappa, \quad \text { where } \kappa \equiv \frac{1}{\gamma}\left[\left.U_{n}\right|^{2}-\widetilde{E}^{2}\right]^{1 / 2}, \quad \text { for } \widetilde{E}^{2} \leq\left|U_{n}\right|^{2} . \tag{2.261}
\end{equation*}
$$

With such contribution, the Bloch solution (193b) indeed describes an exponential decay of the wavefunction at length $\delta=1 / \kappa$.

Now returning to the effects of weak force $F$ in the energy-domain approach, presented by Eq. (248) and illustrated in Fig. 32b, we may recast Eq. (261) as

$$
\begin{equation*}
\kappa \rightarrow \kappa(x)=\frac{1}{\gamma}\left[\left.U_{n}\right|^{2}-(F \tilde{x})^{2}\right]^{1 / 2}, \tag{2.262}
\end{equation*}
$$

where $\tilde{x}$ is particle's (i.e. wave packet center's) deviation from the mid-gap point. Thus the gap has created a potential barrier of a finite width $\Delta x_{0}=2\left|U_{n}\right| / F$, through which the wave packet may tunnel with a finite probability. As we already know, in the WKB approximation (in our case requiring $\kappa \Delta x_{0}$ $\gg 1$ ) this probability is just the tunnel barrier's transparency $T$, which may be calculated from Eq. (117):

$$
\begin{equation*}
-\ln T=2 \int_{\kappa(x)^{2}>0} \kappa(x) d x=\frac{2}{\gamma} \int_{-x_{c}}^{x_{c}}\left[\left|U_{n}\right|^{2}-(F \widetilde{x})^{2}\right]^{1 / 2} d \widetilde{x}=\frac{2\left|U_{n}\right|}{\gamma} 2 x_{c} \int_{0}^{1}\left(1-\xi^{2}\right)^{1 / 2} d \xi \tag{2.263}
\end{equation*}
$$

where $\pm x_{c} \equiv \pm \Delta x_{0} / 2= \pm\left|U_{n}\right| / F$ are the classical turning points. Working out this simple integral (which may be viewed upon as the quarter of the unit circle's area, and hence equal to $\pi / 4$ ), we get

$$
\begin{equation*}
T=\exp \left\{-\frac{\pi\left|U_{n}\right|^{2}}{\gamma F}\right\} . \tag{2.264}
\end{equation*}
$$

This famous result was obtained by Landau and Zener in a more complex way, whose advantage is a constructive proof that Eq. (264) is valid for arbitrary relation between $\gamma F$ and $\left|U_{n}\right|^{2}$, i.e. arbitrary $T$, while our simple derivation was limited to the WKB approximation, i.e. to $T \ll 1.88$

Returning to Eq. (225) and (237), we can rewrite the product $\gamma F$ participating in Eq. (264) as

$$
\begin{equation*}
\gamma F=\frac{1}{2}\left|\frac{d\left(E_{l}-E_{l^{\prime}}\right)}{d q_{0}}\right|_{E_{l}=E_{l}=E_{n}} \hbar \frac{d q_{0}}{d t}=\frac{\hbar}{2}\left|\frac{d\left(E_{l}-E_{l^{\prime}}\right)}{d t}\right|_{E_{l}=E_{l}=E_{n}}=\frac{\hbar u}{2}, \tag{2.265}
\end{equation*}
$$

where $u$ has the meaning of the "speed" of the energy level crossing in the absence of the gap. Hence, Eq. (264) may be presented in a form

[^524]\[

$$
\begin{equation*}
T=\exp \left\{-\frac{2 \pi\left|U_{n}\right|^{2}}{\hbar u}\right\} \tag{2.266}
\end{equation*}
$$

\]

that is more physically transparent. ${ }^{89}$ Indeed, the fraction $2\left|U_{n}\right| / u=\Delta_{n} u$ gives the time scale $\Delta t$ of energy's crossing the gap region, and according to the Fourier transform, its reciprocal, $\omega_{\max } \sim 1 / \Delta t$ gives the upper cutoff of frequencies involved in the Bloch oscillation process. Hence Eq. (266) means that

$$
\begin{equation*}
-\ln T \approx \frac{\Delta_{n}}{\hbar \omega_{\max }} \tag{2.267}
\end{equation*}
$$

This formula allows us to interpret the Landau-Zener tunneling as for system's excitation across the energy gap $\Delta_{\mathrm{n}}$, by the maximum energy quantum $\hbar \omega_{\max }$ available from the Bloch oscillation process.

The interband tunneling is an important ingredient of several physical phenomena and even some practical devices, for example the tunneling (or "Esaki") diodes. This simple device is just a junction of two semiconductor electrodes, one of them is so strongly $n$-doped by electron donors that the additional electrons form a degenerate Fermi gas at the bottom of the conduction band. Similarly, the opposite electrode is $p$-doped so strongly that the Fermi level of electrons in the valence band is lowered below the band edge (Fig. 33).

Eig. 2.33. Tunneling diode: (a) the band edge diagram of the device at zero bias; (b) the same diagram at modest positive bias $\mathrm{eV} \sim \Delta / 2$, and (c) the $I-V$ curve (schematically). Dashed lines show the Fermi level positions.

At thermal equilibrium, and in the absence of external voltage bias, the Fermi levels self-align, ${ }^{90}$ leading to the build-up of the contact potential difference $\phi / e$, with $\phi$ somewhat larger than the energy bandgap $\Delta$ - see Fig. 33a. This potential difference creates an internal electric field that tilts the energy bands (just as the external field did in Fig. 32b), and leads to the formation of the so-called deletion layer in which the Fermi level located is within the energy gap and hence there are no charge carriers ready to move. In usual $p-n$ junctions, this layer is broad and prevents any current at applied voltages $V$ lower than $\sim \Delta / e$. In contrast, in a tunneling diode the depletion layer is so thin (below $\sim 10 \mathrm{~nm}$ ) that the

[^525]interband tunneling is possible and provides a substantial Ohmic current at small applied voltages - see Fig. 33c.

However, at substantial positive bias, $e V \sim \Delta / 2$, the conduction band become aligned with the middle of the gap in the $p$-doped electrode, and electrons cannot tunnel there. Similarly, these are no electrons in the $n$-doped semiconductor to tunnel into the available states just above the Fermi level in the $p$-doped electrode - see Fig. 33b. As a result, current drops significantly, to grow again only when $e V$ exceeds $\sim \Delta$ and allows the electron motion through the within each energy band. Thus the tunnel junction's $I-V$ curve has a part with negative differential resistance $(d V / d I<0)$. This effect may be used for the amplification of analog signals, including self-excitation of electrical oscillators (i.e. rf signal generation), ${ }^{91}$ and signal swing restoration in digital electronics.

### 2.10. Harmonic oscillator: A brute force approach

To complete our review of 1D systems, we have to consider the famous harmonic oscillator, i.e. a 1 D particle moving in the quadratic-parabolic potential (111). This is just a smooth quantum well providing "soft" confinement, whose discrete spectrum we have already found in the WKB approximation - see Eq. (114). Let us try to solve the same problem exactly - not because there is anything conceptually interesting in it (there is not :-), but because of its enormous importance for applications. For that, let us write the stationary Schrödinger equation for potential (111):

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m} \frac{d^{2} \psi}{d x^{2}}+\frac{m \omega_{0}^{2}}{2} x^{2} \psi=E \psi \tag{2.268}
\end{equation*}
$$

From the solution of Exercise Problem 1.5, the reader already knows ${ }^{92}$ one of the eigenfunctions of this equation,

$$
\begin{equation*}
\psi_{0}=C_{0} \exp \left\{-\frac{m \omega_{0} x^{2}}{2 \hbar}\right\} \tag{2.269}
\end{equation*}
$$

and the corresponding eigenenergy

$$
\begin{equation*}
E_{0}=\frac{\hbar \omega_{0}}{2} \tag{2.270}
\end{equation*}
$$

Expression (269) shows that the characteristic scale of wavefunction's spatial spread ${ }^{93}$ is equal to

$$
\begin{equation*}
x_{0} \equiv\left(\frac{\hbar}{m \omega_{0}}\right)^{1 / 2} \tag{2.271}
\end{equation*}
$$

Due to the importance of this scale, let us give its crude estimates for several typical systems:

[^526](i) Electrons in solids and fluids: $m \approx 10^{-30} \mathrm{~kg}, \omega_{0} \sim 10^{15} \mathrm{~s}^{-1}$, giving $x_{0} \sim 0.3 \mathrm{~nm}$, comparable with inter-atomic distances $a$. As a result, classical mechanics is not valid at all for the analysis of their motion.
(ii) Atoms in solids: $m \approx 10^{-24}-10^{-26} \mathrm{~kg}, \omega_{0} \sim 10^{13} \mathrm{~s}^{-1}$, giving $x_{0} \sim 0.01-0.1 \mathrm{~nm}$, i.e. from $\sim$ a few percent to a few tens percent of $a$. Because of that, methods based classical mechanics (e.g., molecular dynamics) are approximately valid for the analysis of atomic motion, though may miss some fine effects of motion of lighter atoms - e.g., quantum tunneling of hydrogen atoms through energy barriers of the potential profile created by its neighbors.
(iii) Probe masses in modern gravity-wave detectors (Advanced LIGO, VIRGO, KAGRA, etc.): ${ }^{94} m \sim 10^{2} \mathrm{~kg}, \omega_{0} \sim 10^{2} \mathrm{~s}^{-1}$, giving $x_{0} \sim 10^{-19} \mathrm{~m}$. After several decades of development, the sensitivity of these instruments is still limited by various noise sources at the level of the order of $10^{-18} \mathrm{~m} .{ }^{95}$ Thus the prospects of observing quantum-mechanical effects in such installations do not look very realistic.

Returning to the Schrödinger equation (268), let us recast it into a dimensionless form by introducing dimensionless variable $\xi \equiv x / x_{0}$. This gives

$$
\begin{equation*}
-\frac{d^{2} \psi}{d \xi^{2}}+\xi^{2} \psi=\varepsilon \psi \tag{2.272}
\end{equation*}
$$

where $\varepsilon \equiv 2 E / \hbar \omega_{0}=E / E_{0}$. In this notation, the ground state wavefunction is proportional to $\exp \left\{-\xi^{2} / 2\right\}$, so that let us look for the solutions to Eq. (272) in the form

$$
\begin{equation*}
\psi=C \exp \left\{-\frac{\xi^{2}}{2}\right\} H(\xi) \tag{2.273}
\end{equation*}
$$

where $H(\xi)$ is a new function. With this substitution, Eq. (272) yields

$$
\begin{equation*}
\frac{d^{2} H}{d \xi^{2}}-2 \xi \frac{d H}{d \xi}+(\varepsilon-1) H=0 \tag{2.274}
\end{equation*}
$$

It is evident that $H=$ const and $\varepsilon=1$ is one of its solutions, describing the eigenstate (269) with energy (270), but what are the other eigenstates and eigenvalues? This equation has been studied in detail in the mid-1800s by C. Hermite who has shown that all eigenvalues are given by equation

$$
\begin{equation*}
\varepsilon_{n}-1=2 n, \quad \text { with } \quad n=0,1,2, \ldots, \tag{2.275}
\end{equation*}
$$

so that our WKB result (114) is indeed exact for any $n$, and Eqs. (269) and (270) describe the groundstate of the oscillator. The eigenfunction corresponding to eigenvalue $\varepsilon_{n}$ is a polynomial (now called the Hermite polynomial) of degree $n$, that may be most conveniently calculated using the following explicit formula:

Hermite polynomials

$$
\begin{equation*}
H_{n}=(-1)^{n} \exp \left\{\xi^{2}\right\} \frac{d^{n}}{d \xi^{n}} \exp \left\{-\xi^{2}\right\} . \tag{2.276}
\end{equation*}
$$

[^527]It is easy to use this formula to calculate several lowest-degree polynomials - see Fig. 34a:

$$
\begin{equation*}
H_{0}=1, \quad H_{1}=2 \xi, \quad H_{2}=4 \xi^{2}-2, \quad H_{3}=8 \xi^{3}-12 \xi, \quad H_{4}=16 \xi^{4}-48 \xi^{2}+12, \ldots \tag{2.277}
\end{equation*}
$$

(a)

Fig. 2.34. (a) A few lowest Hermite polynomials and (b) the corresponding eigenenergies (dashed lines) and eigenfunctions (solid lines) of the harmonic oscillator. The black dashed line shows the potential profile $U(x)$, drawn on the same scale as energies $E_{n}$, so that the line crossings with the energy levels correspond to the classical turning points.

The most important properties of the polynomials are as follows:
(i) their "parity" (symmetry-antisymmetry) alternates with number $n$,
(ii) $H_{n}(\xi)$ crosses the $\xi$-axis exactly $n$ times (has $n$ zeros), and
(iii) the polynomials are mutually orthonormal in the following sense:

$$
\begin{equation*}
\int_{-\infty}^{+\infty} H_{n}(\xi) H_{n^{\prime}}(\xi) \exp \left\{-\xi^{2}\right\} d \xi=\pi^{1 / 2} 2^{n} n!\delta_{n, n^{\prime}} \tag{2.278}
\end{equation*}
$$

Using Eq. (273) to translate this result to functions $\psi_{n}(x)$, we get the following orthonormal eigenfunctions of the harmonic oscillator (Fig.34b): ${ }^{96}$

$$
\begin{equation*}
\psi_{n}(x)=\frac{1}{\left(2^{n} n!\right)^{1 / 2} \pi^{1 / 4} x_{0}^{1 / 2}} \exp \left\{-\frac{x^{2}}{2 x_{0}^{2}}\right\} H_{n}\left(\frac{x}{x_{0}}\right) \tag{2.279}
\end{equation*}
$$

Besides its own importance, this is a typical example of eigenstates of particle confined in a softwall quantum well. It is very instructive to compare them with eigenstates of a the rectangular quantum well, with its ultimately-hard walls - see Eq. (1.76) and Fig. 1.7. Let us list their similar features:
(i) Wavefunctions oscillate in the classically-allowed regions with $E_{n}>U(x)$, while dropping exponentially beyond the boundaries of that region.
(ii) Each step up the energy level ladder increases the number of the oscillation halfwaves (and hence the number of its zeros), by one. ${ }^{97}$

Here are the major features specific for the soft confinement:
(i) The spatial spread of the wavefunction grows with $n$, following the gradual increase of the classically allowed region.
(ii) Correspondingly, $E_{n}$ exhibits a slower growth than the $E_{n} \propto n^{2}$ law given by Eq. (1.77), because of the gradual reduction of confinement, which moderates the growth of kinetic energy.

Unfortunately, the brute-force approach to the harmonic oscillator problem, discussed above, is not too appealing intellectually. First, the proof of Eq. (276) is rather longish. More importantly, it is hard to use Eq. (279) for calculation of the so-called matrix elements of the system - as we will see in Chapter 4, virtually the only numbers important for applications. Finally, it is also almost evident that there should be some straightforward math leading to any formula as simple as Eq. (114) for $E_{n}$. Indeed, there is a much more efficient, operator-based approach to this problem; it will be described in Sec. 5.4.

### 2.11. Exercise problems

2.1. The initial wave packet of a free 1D particle is described by Eq. (2.20) of the lecture notes:

$$
\Psi(x, 0)=\int a_{k} e^{i k x} d k
$$

(i) Obtain a compact expression for the expectation value $\langle p\rangle$ of particle's momentum. Does $\langle p\rangle$ depend on time?
(ii) Calculate $\langle p\rangle$ for the case when function $\left|a_{k}\right|^{2}$ is symmetric with respect to some value $k_{0}$.
2.2. Calculate the function $a_{k}$, defined by Eq. (2.20), for the wave packet with a rectangular envelope:

[^528]\[

\Psi(x, 0)=\left\{$$
\begin{array}{cc}
C \exp \left\{i k_{0} x\right\}, & \text { for }-a / 2 \leq x \leq+a / 2 \\
0, & \text { otherwise }
\end{array}
$$\right.
\]

Analyze the result in the limit $k_{0} a \rightarrow \infty$.
2.3. Prove Eq. (49) for the 1D propagator of a free quantum particle, starting from Eq. (48).
2.4. Express the 1D propagator, defined by Eq. (44), via eigenfunctions and eigenenergies of a particle moving in an arbitrary stationary potential $U(x)$. (For the notation simplicity, assume that the energy spectrum of the system is discrete.)
2.5. Calculate the change of the wavefunction of a 1 D particle, resulting from a short pulse of an external force, which may be approximated by the delta-function: ${ }^{98}$

$$
F(t)=P \delta(t)
$$

2.6. Analyze the effect of phase locking of Josephson oscillations on the dc current flowing through the junction, assuming that external microwave source applies a fixed sinusoidal ac voltage,

$$
V(t)-\bar{V}=A \cos \omega t
$$

to a junction with sinusoidal current-phase relation (55), using Eq. (54) for time evolution of phase $\varphi$.
2.7. Calculate the transmission coefficient $T$ as a function of particle's energy $E$ for the rectangular potential barrier,

$$
U(x)=\left\{\begin{array}{cc}
0, & \text { for } x<-d / 2 \\
U_{0}, & \text { for }-d / 2<x<+d / 2 \\
0, & \text { for } d / 2<x
\end{array}\right.
$$

for the case $E>U_{0}$. Analyze and interpret the result, taking into account that $U_{0}$ may be either positive or negative. (In the last case, we are speaking about particle's passage over a rectangular potential well of finite depth.)
2.8. Looking at the lower (red) line in Fig. 1.7, it seems plausible that the 1 D ground-state function $X(x) \propto \sin (\pi x / a)$ of the simple quantum well (1.69) may be well approximated by an inverted parabola:

$$
X_{\text {trial }}(x)=C x(a-x),
$$

where $C$ is the normalization constant, and $a \equiv a_{x}$ for brevity. Explore how good this approximation is. ${ }^{99}$
2.9. Spell out the stationary wavefunctions of a harmonic oscillator in the WKB approximation, and use them to calculate the expectation values $\left\langle x^{2}\right\rangle$ and $\left\langle x^{4}\right\rangle$ for arbitrary state number $n$.

[^529]2.10. ${ }^{*}$ A 1D particle of mass $m$ is placed into the following triangular quantum well: ${ }^{100}$
\[

U(x)=\left\{$$
\begin{array}{ll}
+\infty, & \text { for } x<0, \\
F x, & \text { for } x>0,
\end{array}
$$ with F>0 .\right.
\]

(i) Calculate its energy spectrum using the WKB approximation.
(ii) Estimate the ground state energy using the variational method.
(iii) Calculate the three lowest energy levels, and also for the $10^{\text {th }}$ level, with at least $0.1 \%$ accuracy, from the exact solution of the problem.
(iv) Compare and discuss the results.

## Hints:

- In Task (ii), try to incorporate a certain parameter $\lambda$ into your trial wavefunction, and then use its adjustment to minimize the expectation value of system's Hamiltonian (mentioned in Chapter 1):

$$
\langle H\rangle_{\text {trial }} \equiv \int_{-\infty}^{+\infty} \psi_{\text {trial }}^{*} \hat{H} \psi_{\text {trial }} d x,
$$

where the trial function is assumed to be properly normalized. The variational method is based on the easily provable ${ }^{101}$ fact that this expectation value cannot be less than the genuine $E_{g}$, coinciding with it only if the trial function exactly coincides with the genuine wavefunction $\psi_{g}$ of the ground state. Hence, the lower $\langle H\rangle_{\text {trial }}$ you reach, the better is your result.

- The values of the first zeros of the Airy function, necessary for Task (iii), may be found in many math handbooks, for example, in Table 10.13 of the collection edited by Abramowitz and Stegun - see MA Sec. 16(i).
2.11. For a 1D particle of mass $m$ placed into a potential well with the following profile,

$$
U(x)=a x^{2 s}, \quad \text { with } a>0 \text { and } s>0,
$$

(i) calculate its energy spectrum using the WKB approximation, and
(ii) estimate the ground state energy using the variational method.

Compare the ground state energy results for parameter $s$ equal to $1,2,3$, and 100 .
2.12. Prove Eq. (117) for the case $T_{\mathrm{WKB}} \ll 1$, using the connection formulas (104).
2.13. Use the WKB approximation to express the expectation value of the kinetic energy of a 1 D particle, confined in a soft potential well, in its $n^{\text {th }}$ stationary state, via the derivative $d E_{n} / d n$, for $n \gg 1$.
2.14.* Use the WKB approximation to calculate the transparency $T$ as a function of particle energy $E$, for the following triangular potential barrier:

$$
U(x)=\left\{\begin{array}{cc}
0, & \text { for } x<0 \\
U_{0}-F x, & \text { for } x>0,
\end{array}\right.
$$

[^530]with $F, U_{0}>0$.
Hint: Be careful treating the sharp potential step at $x=0$.
2.15.* Prove that the symmetry of the scattering matrix elements describing an arbitrary timeindependent scatterer allows its representation in the form (136a), with the additional restriction (136b).
2.16. Prove the universal relations between elements of the transfer matrix T of a stationary (but otherwise arbitrary) 1D scatterer, which were mentioned in Sec. 5.
2.17. For a deep and narrow 1 D quantum well, modeled by a delta-function,
\[

$$
\begin{equation*}
U(x)=-w \delta(x), \quad \text { with } w>0, \tag{*}
\end{equation*}
$$

\]

find the localized eigenfunction(s) $\psi_{n}$ (with $\left|\psi_{n}(x)\right| \rightarrow 0$ at $|x| \rightarrow \infty$ ), and the corresponding value(s) $E_{n}$.
2.18. A 1D particle was localized in the delta-functional well, with $U(x)=-w \delta(x)$, such as the one analyzed in the previous problem. Then (say, at $t=0$ ) the well's bottom is suddenly lifted, so that the particle becomes free to move. Calculate the probability density, $w(k)$ to find the particle in a state with wave number $k$ at $t>0$, and the final total energy of the system.
2.19. Calculate the lifetime of the metastable localized state of a 1D particle in the potential

$$
U(x)=-w \delta(x)-F x, \quad \text { with } w>0
$$

using the WKB approximation. Formulate the condition of validity of the result.
2.20. Analyze the localized eigenfunction(s) and the characteristic equation(s) for eigenenergies of a 1D particle in the following two-well potential

$$
U(x)=-w\left[\delta\left(x-\frac{a}{2}\right)+\delta\left(x+\frac{a}{2}\right)\right], \quad \text { with } w>0
$$

Explore asymptotic behaviors of the eigenenergies in the limits of very strong and very weak potential, and find the number of localized states as a function of distance $a$.
2.21. ${ }^{*}$ Consider a symmetric system of two quantum wells of the type shown in Fig. 23, but with $U(0)=U( \pm \infty)=0-$ see Fig. on the right. What is the sign of well interaction force due to a quantum particle of mass $m$, shared by them, for the cases when the particle is in:
(i) a symmetric eigenstate, with $\psi_{s}(-x)=\psi_{s}(x)$ ?
(ii) an asymmetric eigenstate, with $\psi_{a}(-x)=-\psi_{a}(x)$ ?

Use a different approach to confirm your result for the particular case of delta-functional wells, considered in the previous problem.

2.22. Derive and analyze the characteristic equation for eigenvalues for a particle in a rectangular well of a finite depth:

$$
U(x)=\left\{\begin{array}{cl}
-U_{0}, & \text { for }|x| \leq a / 2 \\
0, & \text { otherwise }
\end{array}\right.
$$

In particular, calculate the number of localized states as a function of well's width $a$, and explore the limit $U_{0} \ll \hbar^{2} / 2 m a^{2}$.
2.23. Calculate energy $E$ of the localized state in a quantum well of an arbitrary shape $U(x)$, provided that its width $a$ is finite, and the average depth is very small:

$$
|\bar{U}| \ll \frac{\hbar^{2}}{2 m a^{2}}, \quad \text { where } \bar{U} \equiv \frac{1}{a} \int_{\text {well }} U(x) d x
$$

2.24.* A particle of mass $m$ is moving in a field with the following potential:

$$
U(x)=U_{0}(x)+w \delta(x)
$$

where $U_{0}(x)$ describes a smooth, symmetric function with $U_{0}(0)=0$, growing monotonically at $x \rightarrow \pm \infty$.
(i) Use the WKB approximation to derive the characteristic equation for the energy spectrum;
(ii) semi-quantitatively describe the spectrum structure evolution at the increase of $|\boldsymbol{w}|$, for both signs of this parameter, and make the results more specific for the quadratic potential

$$
U_{0}(x)=\frac{m}{2} \omega_{0}^{2} x^{2}
$$

2.25. Prove Eq. (191), starting from Eq. (190).
2.26. For the problem explored in the beginning of Sec. 7, i.e. 1D particle's motion in a deltafunctional periodic potential shown in Fig. 24,

$$
U(x)=w \sum_{j=-\infty}^{+\infty} \delta(x-j a), \quad \text { with } w>0
$$

(where $j$ are integers), write explicit expressions for its eigenfunctions:
(i) at the bottom, and
(ii) at the top
of the lowest energy band. Sketch both eigenfunctions.
2.27.* A 1D particle of mass $m$ moves in an infinite periodic system of very narrow and deep quantum wells that may be described by delta-functions:

$$
U(x)=w \sum_{j=-\infty}^{+\infty} \delta(x-j a), \quad \text { with } w<0
$$

(i) Sketch the energy band structure of the system for relatively small and relatively large values of the quantum well's "area" $|\mathcal{W}|$, and
(ii) calculate explicitly the ground state energy of the system in the limits of very small and very large $|\boldsymbol{\psi}|$.
2.28.* For the system discussed in the previous problem, write explicit expressions for the eigenfunctions of the system, corresponding to:
(i) the bottom points of the lowest energy band, and
(ii) the top points of that band, and
(iii) the lowest points of each higher energy band, and sketch the functions.
2.29.* The 1D "crystal", analyzed in the last two problems, now extends along only to $x>0$, while bordering a flat potential step at $x=0:{ }^{102}$

$$
U(x)= \begin{cases}w \sum_{j=1}^{+\infty} \delta(x-j a), & \text { with } w<0, \\ U_{0}>0, & \text { for } x>0 \\ x<0\end{cases}
$$

Prove that the system can have a set of so-called Tamm states, localized near the "surface" $x=0$, and calculate their energies in the limit when $U_{0}$ is very large but finite. (Quantify this condition.)
2.30. Calculate the whole transfer matrix of the rectangular tunnel barrier, specified by Eq. (76), for particle energies both below and above $U_{0}$.
2.31. Use results of the previous problem to calculate the transfer matrix of one period of the periodic Kronig-Penney potential shown in Fig. 30b (reproduced in Fig. on the right).

2.32. Using results of the previous problem, derive the characteristic equations for particle's motion in the periodic Kronig-Penney potential, for both $E<U_{0}$ and $E>U_{0}$. Try to bring the equations to a form similar to that obtained in Sec. 5 for the delta-functional barriers - see Eq. (166). Use the equations to formulate the conditions of applicability of the tight-binding and weak-potential approximations, in terms of parameters $U_{0}, d$, and $a$ of the potential profile, and particle's mass $m$ and energy $E$.
2.33.* For the Kronig-Penney potential, use the tight binding approximation to calculate the widths of the allowed energy bands. Compare the results with those of the previous problem (in the corresponding limit).

[^531]2.34.* For the same Kronig-Penney potential, use the weak potential limit formulas to calculate the energy gap widths. Again, compare the results with those of Problem 30, in the corresponding limit.
2.35. 1D periodic chains of atoms may exhibit what is called the so-called Peierls instability, leading to the Peierls transition to phase in which atoms are slightly displaced by $\Delta x_{j}=(-1)^{j} \Delta x$, with $\Delta x$ $\ll a$. These displacements lead to the alternation of coupling amplitudes $\delta_{n}$ (see Eq. (204)) between some values $\delta_{n}^{+}$and $\delta_{n}^{-}$. Use the tight-binding approximation to calculate the resulting change of the $n^{\text {th }}$ energy band, and discuss the result.
2.36. Assuming the quantum effects to be small, calculate the lower part of the energy spectrum of the following system: a small bead of mass $m$, free to move without friction along a ring of radius $R$ that is rotated about its vertical diameter with a constant angular velocity $\omega$ - see Fig. on the right. ${ }^{103}$ Formulate a quantitative condition of validity of your results.

2.37. A 1D harmonic oscillator (with mass $m$ and frequency $\omega_{0}$ ) had been in its ground state; then an additional force $F$ was suddenly applied (and retained constant in time). Find the probability of the oscillator staying in its ground state.
2.38. A 1D particle of mass $m$ has been placed into a quadratic potential well (111),
$$
U(x)=\frac{m \omega_{0}^{2}}{2} x^{2}
$$
and allowed to relax into the ground state. harmonic oscillator had been in its ground state. At $t=0$, the well starts to be moved with velocity $v$, without changing its profile, so that at $t \geq 0$ the above formula for $U$ is valid with the replacement $x \rightarrow x$ ' $\equiv x-v t$. Calculate the probability for the system to still be in the ground state at $t>0$.
2.39. A 1 D particle is placed into the following potential well:
\[

U(x)= $$
\begin{cases}+\infty, & \text { for } x<0 \\ m \omega_{0}^{2} x^{2} / 2, & \text { for } x \geq 0\end{cases}
$$
\]

(i) Find its eigenstates and eigenenergies.
(ii) This system had been let to relax into its ground state, and then the potential wall at $x<0$ was rapidly removed, so that the system was instantly turned into the usual harmonic oscillator (with the same $m$ and $\omega_{0}$ ). Find the probability for the oscillator to be in its ground state.
2.40. Prove the following formula for the propagator of the 1 D harmonic oscillator:

[^532]$$
G\left(x, t ; x_{0}, t_{0}\right)=\left(\frac{m \omega_{0}}{2 \pi i \hbar \sin \left[\omega_{0}\left(t-t_{0}\right)\right]}\right)^{1 / 2} \exp \left\{\frac{i m \omega_{0}}{2 \hbar \sin \left[\omega_{0}\left(t-t_{0}\right)\right]}\left[\left(x^{2}+x_{0}^{2}\right) \cos \left[\omega_{0}\left(t-t_{0}\right)\right]-2 x x_{0}\right]\right\} .
$$

Discuss the relation between this formula and the propagator of a free 1D particle.
2.41. Use the variational method to estimate the ground state energy $E_{g}$ of the following confined 1D systems:
(i) a harmonic oscillator, with $U(x)=m \omega_{0}^{2} x^{2} / 2$, and
(ii) a particle in the following potential well: $U(x)=-U_{0} \exp \left\{-\alpha^{2} x^{2}\right\}$, and $U_{0}>0$.

In the latter case, get explicit results in the limits of small and large $U_{0}$, and give their interpretation.
2.42.* Use the WKB approximation to calculate the lifetime of the metastable ground state of a 1D particle of mass $m$ in the "pocket" of the potential profile

$$
U(x)=\frac{m \omega_{0}^{2}}{2} x^{2}-\alpha x^{3}
$$

Contemplate the significance of this problem.
2.43. In the context of the Sturm oscillation theorem mentioned in Sec. 10, prove that the number of zeros of stationary wavefunctions of a particle, confined in an arbitrary potential well, always increases with energy.

Hint: You may like to use the suitably modified Eq. (189).

## Chapter 3. Higher Dimensionality Effects

The coverage of multi-dimensional problems of wave mechanics in this course is minimal: it is limited to a few phenomena (such as the AB effect and Landau levels) that cannot take place in one dimension due to topological reasons, and a few key 3D problems (such as the Born approximation in scattering theory and the Bohr atom) whose solutions are necessary for numerous applications.

### 3.1. Quantum interference and the AB effect

In the past two chapters, we have already discussed some effects of the de Broglie wave interference. For example, standing waves inside a quantum well, or even on the top of a tunnel barrier, may be considered as a result of the incident and reflected waves. However, there are some remarkable new effects made possible by the spatial separation of such traveling waves, and such separation requires a higher (either 2D or 3D) dimensionality. A good example of such separation is provided by the Young-type experiment (Fig. 1) in which particles are passed through two narrow holes (or slits) is an otherwise opaque partition.

If the particles emitted by the source do not interact (which is always true if the emission rate is sufficiently low), the average rate of particle counting by the detector is proportional to the probability density $w(\mathbf{r}, t)=\Psi(\mathbf{r}, t) \Psi^{*}(\mathbf{r}, t)$ to find a single particle at the detector's location $\mathbf{r}$, where $\Psi(\mathbf{r}, t)$ is the solution of the single-particle Schrödinger equation (1.25). Let us describe this experiment for the case when the particles may be represented by monochromatic waves of energy $E$ (e.g., very $\mathbf{r}$-long wave packets), so that the wavefunction may be taken in the form given by Eqs. (1.56) and (1.61): $\Psi(\mathbf{r}, t)=$ $\psi(\mathbf{r}) \exp \{-i E t / \hbar\}$. In this case, in the free-space parts of the system, $\psi(\mathbf{r})$ satisfies the stationary Schrödinger equation (1.60) with Hamiltonian (1.27a):

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m} \nabla^{2} \psi=E \psi . \tag{3.1a}
\end{equation*}
$$

With the standard definition $k \equiv(2 m E)^{1 / 2} / \hbar$, it may be rewritten as the 3D Helmholtz equation

$$
\begin{equation*}
\nabla^{2} \psi+k^{2} \psi=0 \tag{3.1b}
\end{equation*}
$$

- an evident 3D generalization of Eqs. (1.75) or (2.81).

The opaque parts of the partition may be well described as classically forbidden regions, so if their size scale $a$ is much larger than the wavefunction penetration depth $\delta(2.67)$, we can use on their surface $S$ the same boundary conditions as for the quantum barrier of infinite height:

$$
\begin{equation*}
\left.\psi\right|_{S}=0 \tag{3.2}
\end{equation*}
$$

Equations (1) and (2) formulate the standard boundary problem of the theory of propagation of scalar waves of any nature. For an arbitrary geometry, such problem does not have a simple analytical solution. However, for a conceptual discussion of interference we use certain natural assumptions that will allow us to find its particular, approximate solution.

First, let us discuss wave emission, into free space, by a small-size source located at the origin. Naturally, the emitted wave should be spherically-symmetric: $\psi(\mathbf{r})=\psi(r)$. Using the well-known expression for the Laplace operator in spherical coordinates, ${ }^{1}$ we then reduce Eq. (1) to an ordinary differential equation

$$
\begin{equation*}
\frac{1}{r^{2}} \frac{d}{d r}\left(r^{2} \frac{d \psi}{d r}\right)+k^{2} \psi=0 \tag{3.3}
\end{equation*}
$$

Let us introduce a new function, $f(r)=r \psi(r)$. Plugging the reciprocal relation $\psi=f / r$ into Eq. (3), we see that it is reduced to the 1 D wave equation,

$$
\begin{equation*}
\frac{d^{2} f}{d r^{2}}+k^{2} f=0 \tag{3.4}
\end{equation*}
$$

whose solutions were discussed in detail in Sec. 2.2. For a fixed $k$, the general solution of Eq. (4) is

$$
\begin{equation*}
f=f_{+} e^{i k r}+f_{-} e^{-i k r} \tag{3.5}
\end{equation*}
$$

so that the full wavefunction

$$
\begin{equation*}
\psi(\mathbf{r})=\frac{f_{+}}{r} e^{i k r}+\frac{f_{-}}{r} e^{-i k r} \text {, i.e. } \Psi(\mathbf{r}, t)=\frac{f_{+}}{r} e^{i(k r-\omega t)}+\frac{f_{-}}{r} e^{-i(k r+\omega t)}, \quad \text { with } \omega \equiv \frac{E}{\hbar}=\frac{\hbar k^{2}}{2 m} . \tag{3.6}
\end{equation*}
$$

If the source is located at point $\mathbf{r}^{\prime} \neq 0$, the obvious generalization of Eq. (6)

$$
\begin{equation*}
\Psi(\mathbf{r}, t)=\frac{f_{+}}{R} e^{i(k R-\omega t)}+\frac{f_{-}}{R} e^{-i(k R+\omega t)}, \quad \text { with } R \equiv|\mathbf{R}|, \quad \mathbf{R} \equiv \mathbf{r}-\mathbf{r}^{\prime} \tag{3.7}
\end{equation*}
$$

The first term of this solution describes a spherically-symmetric wave propagating from the source outward, while the second one, a wave converging onto the source point $\mathbf{r}$ ' from large distances. Though the latter solution is possible at some very special circumstances (say, when the outgoing wave is reflected back from a spherical shell), for our problem, only the outgoing waves are relevant, so that we may keep only the first term (proportional to $f_{+}$) in Eq. (7). Note that factor $R$ is the denominator (that was absent in 1D geometry) has a simple physical sense: it provides the independence of the full probability current $I=4 \pi R^{2} j(R)$, with $j(R) \propto k \Psi \Psi^{*} \propto 1 / R^{2}$, of the distance $R$ between the observation point and the source.

[^533]Now let us assume that the partition's geometry is not too complicated - for example, it is planar as shown in Fig. 1, and consider the region of the particle detector location far behind the partition (at $z$ $\gg 1 / k$ ), and at a relatively small angle to it: $|x| \ll z$. Then it should be physically clear that the spherical waves (7) emitted by each point inside the slit cannot be perturbed too much by the opaque parts of the partition, and their only role is the restriction of the set of such emitting points by the area of the slits. Hence, an approximate solution of the boundary problem is given by the following Huygens principle: the wave behind the partition looks as if it was the sum of contributions (7) of point sources located in the slits, with each source's strength $f_{+}$proportional to the amplitude of the wave arriving at this pseudo-source from the real source - see Fig. 1. This principle finds its confirmation in strict wave theory, which shows ${ }^{2}$ that with our assumptions, the solution of the boundary problem (1)-(2) may be presented as the following Kirchhoff integral:

Kirchhoff integral

$$
\begin{equation*}
\psi(\mathbf{r})=c \int_{\text {slits }} \frac{\psi\left(\mathbf{r}^{\prime}\right)}{R} e^{i k R} d^{2} r^{\prime}, \quad \text { with } c=\frac{k}{2 \pi i} . \tag{3.8}
\end{equation*}
$$

If the source is also far from the partition, its wave front is almost parallel to the slit plane, and the slits are not too broad, we can take $\psi\left(\mathbf{r}^{\prime}\right)$ constant $\left(\psi_{1,2}\right)$ at each slit, so that Eq. (8) is reduced to

$$
\begin{equation*}
\psi(\mathbf{r})=a_{1}^{\prime \prime} \exp \left\{i k l_{1}\right\}+a_{2}^{\prime \prime} \exp \left\{i k l_{2}^{\prime \prime}\right\}, \quad \text { with } a_{1,2}^{\prime \prime}=\frac{c A_{1,2}}{l_{1,2}^{\prime \prime}} \psi_{1,2}, \tag{3.9}
\end{equation*}
$$

where $A_{1,2}$ are the slit areas. The wavefunctions on the slits be calculated approximately ${ }^{3}$ by applying the same Eq. (7) to the space before the slits: $\psi_{1,2} \approx\left(f_{+} / l^{\prime}{ }_{1,2}\right) \exp \left\{i k l_{1,2}\right\}$. As a result, Eq. (9) may be rewritten as

Wave-
function superposition

Quantum interference: the pattern and phase shift

$$
\begin{equation*}
\psi(\mathbf{r})=a_{1} \exp \left\{i k l_{1}\right\}+a_{2} \exp \left\{i k l_{2}\right\}, \quad \text { with } l_{1,2} \equiv l_{1,2}^{\prime}+l_{1,2}^{\prime \prime}, \quad a_{1,2} \equiv \frac{c f_{+} A_{1,2}}{l_{1,2}^{\prime} l_{1,2}^{\prime \prime}} \tag{3.10}
\end{equation*}
$$

(As Fig. 1 shows, each of $l_{1,2}$ is the length of the full classical path of the particle from the source, through the corresponding slit, and further to the observation point $\mathbf{r}-$ see Fig. 1).

According to Eq. (10), the resulting rate of particle counting is proportional to

$$
\begin{equation*}
w(\mathbf{r})=\psi(\mathbf{r}) \psi^{*}(\mathbf{r})=\left|a_{1}\right|^{2}+\left|a_{2}\right|^{2}+2\left|a_{1} a_{2}\right| \cos \varphi_{12} \tag{3.11}
\end{equation*}
$$

where

$$
\begin{equation*}
\varphi_{12} \equiv k\left(l_{2}-l_{1}\right) \tag{3.12}
\end{equation*}
$$
