is the difference of the total wave phase accumulations along each of two alternative trajectories. The last expression may be evidently generalized as

[^534]\[

$$
\begin{equation*}
\varphi_{12}=\oint_{C} \mathbf{k} \cdot d \mathbf{r} \tag{3.13}
\end{equation*}
$$

\]

with integration along the virtually closed contour $C$ (see the dashed line in Fig. 1), i.e. from point 1, in the positive (i.e. counterclockwise) direction to point 2. (From our experience with the 1D WKB approximation we may expect such generalization to be valid even if $k$ changes, sufficiently slowly, along the paths.)

Our result (11) shows that the counting rate oscillates as a function of the difference ( $l_{2}-l_{1}$ ) that in turn changes with detector's position, giving the famous interference pattern, with the amplitude proportional to the product $\left|a_{1} a_{2}\right|$, and hence vanishing if any of the slits is closed. For a wave theory, this is a well-known result, ${ }^{4}$ but for particle physics, is was (and still is :-) rather shocking. Indeed, our analysis pertains to a very low particle emission/detection rate, so that there is no other way to interpret it rather than resulting from particle's interference with itself, or rather the interference of its wavefunction parts passing through each of two slits.

Let us now discuss a very interesting effect of magnetic field on the quantum interference. In order to make the discussion simpler, let us consider an alternative version of the two-slit experiment, in which each of alternative path is fixed to a narrow channel using a partial confinement - see Fig. 2. (In this arrangement, moving the particle detector without changing channels' geometry, and hence local values of $k$ may be more problematic in experimental practice, so let us think about its position $\mathbf{r}$ fixed.)

In this case, because of the effect of the walls providing the path confinement, we cannot use expressions (10) for amplitudes $a_{1,2}$. However, from the discussions in Sec. 1.6 and Sec. 2.2, it should be clear that the first of expressions (10) remains valid, though may be with a value of $k$ specific for each channel.

The benefit of this geometry is that we can now apply magnetic field $\mathcal{B}$, perpendicular to the plane of particle motion, that would pierce contour $C$, but would not touch the particle propagation channels. In classical physics, magnetic field's effect on a particle with electric charge $q$ is described by the Lorentz force ${ }^{5}$

$$
\begin{equation*}
\mathbf{F}_{\mathbb{B}}=q \mathbf{v} \times \mathbf{B}, \tag{3.14}
\end{equation*}
$$

[^535]where $B$ is the field value at the point of its particle's location, so that for the experiment shown in Fig. $2, \mathbf{F}_{\mathcal{B}}=0$, and the field would not affect the particle motion at all. In quantum mechanics, this is not so, and the field does affect the probability density $w$, even if $B=0$ in all points where the wavefunction $\psi(\mathbf{r})$ is not equal to zero.

In order to describe this surprising effect, let us first develop a general framework for account of effects of electromagnetic fields on a quantum particle, which will also give us some important byproduct results. In order to do that, we need to calculate the Hamiltonian operator of a charged particle in the field. For an electrostatic field, this hardly present any problem. Indeed, from classical electrodynamics we know that such field may be presented as a gradient of its electrostatic potential $\phi$,

$$
\begin{equation*}
\varepsilon=-\nabla \phi(\mathbf{r}) \tag{3.15}
\end{equation*}
$$

so that the force exerted by the field on a particle with electric charge $q$,

$$
\begin{equation*}
\mathbf{F}_{\mathcal{E}}=q \mathcal{E}, \tag{3.16}
\end{equation*}
$$

may be described by adding the potential energy of the field,

$$
\begin{equation*}
U(\mathbf{r})=q \phi(\mathbf{r}) \tag{3.17}
\end{equation*}
$$

to other (possible) components of the full potential energy of the particle. As we have already discussed, such a function of coordinates may be included to the Hamiltonian operator just by adding it to the kinetic energy operator (1.27).

However, magnetic field's effect is peculiar: since its Lorentz force (14) cannot do any work on the particle:

$$
\begin{equation*}
d W_{\mathcal{B}} \equiv \mathbf{F}_{\mathcal{B}} \cdot d r=\mathbf{F}_{\mathcal{B}} \cdot \mathbf{v} d t=q(\mathbf{v} \times \mathcal{B}) \cdot \mathbf{v} d t=0 \tag{3.18}
\end{equation*}
$$

the field cannot be presented by any potential energy, so it may not be immediately clear how to account for it in the Hamiltonian. Help comes from the analytical-mechanics approach to classical electrodynamics: ${ }^{6}$ in the non-relativistic limit, the Hamiltonian function of a particle in electromagnetic field looks superficially like that in electrostatic field only:

$$
\begin{equation*}
H=\frac{m v^{2}}{2}+U=\frac{p^{2}}{2 m}+q \phi \tag{3.19}
\end{equation*}
$$

however, the momentum $\mathbf{p} \equiv m \mathbf{v}$ that participates in this expression is now the difference

$$
\begin{equation*}
\mathbf{p}=\mathbf{P}-q \mathbf{A} . \tag{3.20}
\end{equation*}
$$

Here $\mathbf{A}$ is the vector-potential, defined by the well-known relations for the electric and magnetic field: ${ }^{7}$

$$
\begin{equation*}
\varepsilon=-\nabla \phi-\frac{\partial \mathbf{A}}{\partial t}, \quad B=\nabla \times \mathbf{A} \tag{3.21}
\end{equation*}
$$

while $\mathbf{P}$ is the canonical momentum whose Cartesian components may be calculated (in classics) from the Lagrangian function, ${ }^{8}$ using the standard formula of analytical mechanics,

[^536]\[

$$
\begin{equation*}
P_{j} \equiv \frac{\partial L}{\partial v_{j}} . \tag{3.22}
\end{equation*}
$$

\]

To emphasize the difference between the two momenta, $\mathbf{p}=m \mathbf{v}$ is frequently called the kinematic momentum (or " $m \mathbf{v}$-momentum"). The distinction between $\mathbf{p}$ and $\mathbf{P}=\mathbf{p}+q \mathbf{A}$ becomes even more clear if we notice that vector-potential is not gauge-invariant: according to the second of Eqs. (21), at the so-called gauge transformation

$$
\begin{equation*}
\mathbf{A} \rightarrow \mathbf{A}+\nabla \chi \tag{3.23}
\end{equation*}
$$

with an arbitrary single-valued scalar gauge function $\chi=\chi(\mathbf{r}, t)$, the magnetic field does not change. Moreover, according to the first of Eqs. (21), if we make the simultaneous replacement

$$
\begin{equation*}
\phi \rightarrow \phi-\frac{\partial \chi}{\partial t} \tag{3.24}
\end{equation*}
$$

the gauge transformation does not affect the electric field either. With that, the gauge function does not change the classical particle's equation of motion, and hence the velocity $\mathbf{v}$ and momentum $\mathbf{p}$. Hence, the kinematic momentum is gauge-invariant, while $\mathbf{P}$ is not, because it changes by $q \nabla \chi$.

Now the standard way of transfer to quantum mechanics is to treat the canonical rather than kinematic momentum according to correspondence postulate discussed in Sec. 1.2. This means that in the coordinate representation, the operator of this variable is given by Eq. (1.26): ${ }^{9}$

$$
\begin{equation*}
\hat{\mathbf{P}}=-i \hbar \nabla \tag{3.25}
\end{equation*}
$$

Hence the Hamiltonian operator corresponding to the classical function (19) is

$$
\begin{equation*}
\hat{H}=\frac{1}{2 m}(-i \hbar \nabla-q \mathbf{A})^{2}+q \phi=-\frac{\hbar^{2}}{2 m}\left(\nabla-\frac{i q}{\hbar} \mathbf{A}\right)^{2}+q \phi \tag{3.26}
\end{equation*}
$$

so that the Schrödinger equation of a particle moving in electromagnetic field (but otherwise free) is

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m}\left(\nabla-\frac{i q}{\hbar} \mathbf{A}\right)^{2} \psi+q \phi \psi=E \psi \tag{3.27}
\end{equation*}
$$

We may now repeat all the calculations of Sec. 1.4 for the case $\mathbf{A} \neq 0$, and readily get the following generalized expression for the probability current density:

$$
\begin{equation*}
\mathbf{j}=\frac{\hbar}{2 i m}\left[\psi^{*}\left(\nabla-\frac{i q}{\hbar} \mathbf{A}\right) \psi-\text { c.c }\right]=\frac{1}{2 m}\left[\psi^{*} \hat{\mathbf{p}} \psi-\text { c.c }\right]=\frac{\hbar}{m}|\psi|^{2}\left(\nabla \varphi-\frac{q}{\hbar} \mathbf{A}\right) . \tag{3.28}
\end{equation*}
$$

$$
L=\frac{m v^{2}}{2}+q \mathbf{v} \cdot \mathbf{A}-q \phi
$$

- see EM Sec. 9.7. Note that this function includes $\mathbf{A}$ within a term that cannot be interpreted as either the purely kinetic energy (as the first term) or the purely potential energy (as the last term with the minus sign).
${ }^{9}$ The validity of this choice is clear from the fact that if the kinetic momentum was described by this differential operator, the Hamiltonian operator corresponding to the classical Hamiltonian function (19) would not include the magnetic field at all, and hence solutions of the corresponding Schrödinger equation could not satisfy the correspondence principle.

We see that the current density is gauge-invariant (as required for any observable) only if the wavefunction's phase $\varphi$ changes as

$$
\begin{equation*}
\varphi \rightarrow \varphi+\frac{q}{\hbar} \chi . \tag{3.29}
\end{equation*}
$$

This may be a point of concern: since the quantum interference is described by the spatial dependence of phase $\varphi$, can the observed interference pattern depend on the gauge function choice (which would not make sense)? Fortunately, this is not true, because the spatial phase difference between two interfering paths, participating in Eq. (11), is gauge-transformed as

$$
\begin{equation*}
\varphi_{12} \rightarrow \varphi_{12}+\frac{q}{\hbar}\left(\chi_{2}-\chi_{1}\right) . \tag{3.30}
\end{equation*}
$$

But $\chi$ has to be a single-valued function of coordinates, hence in the limit when points 1 and 2 coincide, $\chi_{1}=\chi_{2}$, so that $\Delta \varphi$ (and hence the interference pattern) is gauge-invariant.

However, the difference $\varphi$ may be affected by the magnetic field, even if it is localized outside the channels in which the particle propagates. Indeed, in this case the field cannot not affect particle's velocity and current density $\mathbf{j}$ :

$$
\begin{equation*}
\left.\mathbf{j}(\mathbf{r})\right|_{\mathfrak{B} \neq 0}=\left.\mathbf{j}(\mathbf{r})\right|_{\mathfrak{B}=0}, \tag{3.31}
\end{equation*}
$$

so that the last form of Eq. (28) yields

$$
\begin{equation*}
\left.\nabla \varphi(\mathbf{r})\right|_{\mathcal{B} \neq 0}=\left.\nabla \varphi(\mathbf{r})\right|_{\mathcal{B}=0}+\frac{q}{\hbar} \mathbf{A} . \tag{3.32}
\end{equation*}
$$

Integrating this equation along contour $C$ (Fig. 2), for the phase difference between points 1 and 2 we get

$$
\begin{equation*}
\left.\varphi_{12}\right|_{\mathcal{B} \neq 0}=\left.\varphi_{12}\right|_{\mathcal{B}=0}+\frac{q}{\hbar} \oint_{C} \mathbf{A} \cdot d \mathbf{r}, \tag{3.33}
\end{equation*}
$$

where the integral should be taken along the same virtually closed contour $C$ as before (in Fig. 2, from point 1 , counterclockwise along the dashed line to point 2 ). But from the classical electrodynamics we know $^{10}$ that as points 1 and 2 are overlapped, i.e. contour $C$ becomes closed, the last integral is just the magnetic flux $\Phi \equiv \int \mathcal{B}_{n} d^{2} r$ through any smooth surface limited by contour $C$, so that Eq. (33) may be presented as

$$
\begin{equation*}
\left.\varphi_{12}\right|_{\mathcal{B} \neq 0}=\left.\varphi_{12}\right|_{\mathcal{B}=0}+\frac{q}{\hbar} \Phi \tag{3.34a}
\end{equation*}
$$

In terms of the interference pattern, this means a shift of interference fringes, proportional to the magnetic flux (Fig. 3). This phenomenon is usually called the "Aharonov-Bohm" (or just the $A B$ ) effect. ${ }^{11}$ For particles with a single elementary charge, $q= \pm e$, this result is frequently presented as

[^537]\[

$$
\begin{equation*}
\left.\varphi_{12}\right|_{\mathcal{B} \neq 0}=\left.\varphi_{12}\right|_{\mathcal{B}=0} \pm 2 \pi \frac{\Phi}{\Phi_{0}{ }^{\prime}}, \tag{3.34b}
\end{equation*}
$$

\]

where the fundamental constant $\Phi_{0}{ }^{\prime} \equiv 2 \pi \hbar / e=h / e \approx 4.14 \times 10^{-15} \mathrm{~Wb}$ has the meaning of flux necessary to change $\varphi_{12}$ by $2 \pi$, i.e. shift the interference pattern (11) by one period, and is called the normal magnetic flux quantum, because of the reasons we will soon discuss.

(b)

Fig. 3.3. Typical results of a two-paths interference experiment by A. Tonomura et al., Phys. Rev. Lett. 56, 792 (1986), showing the AB effect for electrons well shielded from the applied magnetic field. In this particular experimental geometry, the AB effect produces a relative shift of the interference patterns inside and outside the dark ring. (a) $\Phi=\Phi_{0}{ }^{\prime} / 2$, (b) $\Phi=\Phi_{0}{ }^{\prime}$. © 1986 APS.

The AB effect may be "almost explained" classically, in terms of Faraday's electromagnetic induction. Indeed, a change $\Delta \Phi$ of magnetic flux in time causes a vortex-like electric field $\Delta \mathcal{\varepsilon}$ around it. That field is not restricted to the magnetic field's location, i.e. may reach particle's trajectories. The field's magnitude ( or rather of its integral along contour $C$ ) may be readily calculated by integration of the first of Eqs. (21):

$$
\begin{equation*}
\Delta V \equiv \oint_{C} \Delta \boldsymbol{\varepsilon} \cdot d \mathbf{r}=-\frac{d \Phi}{d t}, \tag{3.35}
\end{equation*}
$$

I hope that in this expression the reader readily recognizes the integral ("undergraduate") form of Faraday's induction law. Now let us assume that the variable separation described in Sec. 1.5 may be applied to the end points 1 and 2 of particle's alternative trajectories as two independent systems, ${ }^{12}$ and that the magnetic flux' change by certain amount $\Delta \Phi$ does not change the spatial parts $\psi_{j}$ of wavefunctions of these systems. Then change (35) leads to the change of potential energy difference $\Delta U$ $=q \Delta V$ between the two points, and repeating the arguments that were used in Sec. 2.3 at the discussion of the Josephson effect, we may rewrite Eq. (2.53) as

$$
\begin{equation*}
\frac{d \varphi_{12}}{d t}=-\frac{\Delta U}{\hbar}=-\frac{q}{\hbar} \Delta V=\frac{q}{\hbar} \frac{d \Phi}{d t} . \tag{3.36}
\end{equation*}
$$

Integrating this relation over the time of magnetic field's change, we get
experimental observation by R. Chambers in 1960 and several other groups soon after that. Later, the experiments were improved, using ferromagnetic cores and/or superconducting shielding to provide better separation between the electron trajectories and the applied magnetic field,- see in the work whose results are shown in Fig. 3.
${ }^{12}$ This assumption may seem a bit of a stretch, but the resulting relation (37) may be indeed proven for a rather realistic model, though that would take more time and space that I can afford.

$$
\begin{equation*}
\Delta \varphi_{12}=\frac{q}{\hbar} \Delta \Phi \tag{3.37}
\end{equation*}
$$

- superficially, the same result as given by Eq. (34).

However, this interpretation of the AB effect is limited. Indeed, it requires the particle to be in the system (on the way from the source to the detector) during the flux change, i.e. when the induced electric field $\varepsilon$ may affect its dynamics. On the contrary, Eq. (34) predicts that the interference pattern would shift even if the field change has been made when the there is no particle in the system, and hence field $\varepsilon$ could not be felt by it. Experiment confirms the latter conclusion. Hence, there is something in the space where a particle propagates (i.e., outside of the magnetic field region), which transfers information about even the static magnetic field to the particle. The standard interpretation of this surprising fact is as follows: the vector-potential $\mathbf{A}$ is not just a convenient mathematical tool, but a physical reality (just as its electric counterpart $\phi$ ), despite the large freedom of choice we have in prescribing specific spatial and temporal dependences of these potentials without affecting any observable - see Eqs. (23)-(24).

Let me briefly discuss the very interesting form the AB effect takes in superconductivity. In this case, our results require two changes. The first one is simple: since superconductivity may be interpreted as the Bose-Einstein condensate of Cooper pairs with electric charge $q=2 e, \Phi_{0}$ ' has to be replaced by the so-called superconducting flux quantum ${ }^{13}$

$$
\begin{equation*}
\Phi_{0} \equiv \frac{\pi \hbar}{e} \approx 2.07 \times 10^{-15} \mathrm{~Wb}=2.07 \times 10^{-7} \mathrm{Gs} \cdot \mathrm{~cm}^{2} \tag{3.38}
\end{equation*}
$$

Second, since the pairs are Bose particles and are all condensed in the same quantum state, described by the same wavefunction, the total electric current density, proportional to the probability current density $j$, may be extremely large - in real superconducting materials, up to $\sim 10^{12} \mathrm{~A} / \mathrm{m}^{2}$. In these conditions, one cannot neglect the contribution of that current into the magnetic field and hence its flux $\Phi$, which (according to the Lenz rule of the Faraday induction law) tries to compensate changes in external flux. In order to see possible results of this contribution, let us consider a closed superconducting loop (Fig. 4).

Fig. 3.4. Flux quantization in a superconducting loop.

Due to the Meissner effect (which is just another version of the flux self-compensation), current and magnetic field penetrate inside the superconductor by only a small distance (called the London

[^538]penetration depth) $\delta_{\mathrm{L}} \sim 10^{-7} \mathrm{~m} .{ }^{14}$ If the loop is made of a superconducting wire that is considerably thicker than $\delta_{\mathrm{L}}$, we can draw a contour deep inside the wire, at that the current density is negligible. According to Eq. (28), everywhere at the contour,
\[

$$
\begin{equation*}
\nabla \varphi-\frac{q}{\hbar} \mathbf{A}=0 . \tag{3.39}
\end{equation*}
$$

\]

Integrating this equation along the contour as before (from point 1 to the virtually coinciding point 2 ), we need to have the phase difference $\varphi_{12}=2 \pi n$, because the wavefunction $\psi \propto \exp \{i \varphi\}$ in the initial and final points 1 and 2 should be "essentially" the same, i.e. produce the same observables. As a result, we get

$$
\begin{equation*}
\Phi=\oint_{C} \mathbf{A} \cdot d \mathbf{r}=\frac{2 \pi \hbar}{q} n=\frac{\pi \hbar}{e} n=n \Phi_{0} . \tag{3.40}
\end{equation*}
$$

This is the famous flux quantization effect, ${ }^{15}$ which justifies the term "magnetic flux quantum" for the constant $\Phi_{0}$ given by Eq. (38).

Here I have to mention in passing very interesting effects of "partial flux quantization", that arise when a superconductor loop is closed by a Josephson junction, forming the so-called Superconductor QUantum Interference Device - "SQUID". Such devices are used, in particular, for supersensitive magnetometry and ultrafast, low-power computing. ${ }^{16}$

### 3.2. Landau levels and quantum Hall effect

In the last section, we have used the Schrödinger equation (27) for analysis of static magnetic field effects in "almost-1D", circular geometries shown in Figs. 1, 2, and 4. However, this equation describes very interesting effects in higher dimensions as well, especially in the 2D case. Let us consider a uniform 2D quantum well (say, parallel to the $[x, y]$ plane), with strong confinement in the perpendicular direction $z$. According to the discussion in Sec. 1.6, energy-relaxed particles will always reside in the lowest energy subband, with constant quantization energy $\left(E_{z}\right)_{1}$. Adding this shift to well's flat floor $U(x, y)=$ const, and taking the resulting constant energy as the reference, for the 2D motion of the particle in the well, we reduce Eq. (27) to the similar equation, but with the Laplace operator acting only in directions $x$ and $y$ :

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m}\left(\mathbf{n}_{x} \frac{\partial}{\partial x}+\mathbf{n}_{y} \frac{\partial}{\partial y}-i \frac{q}{\hbar} \mathbf{A}\right)^{2} \psi=E \psi \tag{3.41}
\end{equation*}
$$

Let us find its solutions for the simplest case when the applied static magnetic field is uniform and perpendicular to the plane:

$$
\begin{equation*}
B=B \mathbf{n}_{z} . \tag{3.42}
\end{equation*}
$$

[^539]According to the second of Eqs. (21), this imposes the following restriction on the choice of vectorpotential:

$$
\begin{equation*}
\mathcal{B}=\frac{\partial A_{y}}{\partial x}-\frac{\partial A_{x}}{\partial y}, \tag{3.43}
\end{equation*}
$$

but the gauge transformations still give us a lot of freedom in its choice. The "natural" axiallysymmetric form, $\mathbf{A}=\mathbf{n}_{\varphi} \rho B / 2$, where $\rho=\left(x^{2}+y^{2}\right)^{1 / 2}$ is the distance from some $z$-axis, leads to a cumbersome math. In 1930, L. Landau realized that the energy spectrum of Eq. (41) may be obtained by making a very simple choice

$$
\begin{equation*}
A_{x}=0, \quad A_{y}=\mathcal{B}\left(x-x_{0}\right), \tag{3.44}
\end{equation*}
$$

(with arbitrary $x_{0}$ ), which evidently satisfies Eq. (43), though it ignores the physical equivalence of the $x$ and $y$ directions. Now, expanding the eigenfunction into the Fourier integral in direction $y$ :

$$
\begin{equation*}
\psi(x, y)=\int X_{k}(x) e^{i k\left(y-y_{0}\right)} d k \tag{3.45}
\end{equation*}
$$

we see that for each component of this integral, Eq. (41) yields a specific equation

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m}\left[\mathbf{n}_{x} \frac{d}{d x}+i \mathbf{n}_{y}\left(k-\frac{q}{\hbar} \mathcal{B}\left(x-x_{0}\right)\right)\right]^{2} X_{k}=E X_{k} . \tag{3.46}
\end{equation*}
$$

Since the vectors inside the square brackets are mutually perpendicular, its square has no crossterms, so that Eq. (46) may be rewritten as

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m} \frac{d^{2}}{d x^{2}} X_{k}+\frac{\hbar^{2}}{2 m}\left[\frac{q}{\hbar} B\left(x-x_{0}{ }^{\prime}\right)\right]^{2} X_{k}=E X_{k}, \quad \text { where } x_{0}{ }^{\prime} \equiv x_{0}+\frac{\hbar k}{q B} . \tag{3.47}
\end{equation*}
$$

But this 1D Schrödinger equation is identical to Eq. (2.268) for the 1D harmonic oscillator, but with the center at point $x_{0}$ ', and frequency $\omega_{0}$ equal to

$$
\begin{equation*}
\omega_{c}=\frac{|q| \mathcal{B}}{m} . \tag{3.48}
\end{equation*}
$$

In this expression, it is easy to recognize the classical cyclotron frequency of particle's motion in the magnetic field. (It may be readily obtained using the $2^{\text {nd }}$ Newton law for a circular orbit of radius $r$,

$$
\begin{equation*}
m \frac{v^{2}}{r}=F_{\mathcal{B}}=q v \mathcal{B}, \tag{3.49}
\end{equation*}
$$

and noting that the resulting ratio $v / r=q B / m$ is just the radius-independent angular velocity $\omega_{c}$ of particle's rotation.) Hence, the energy spectrum for each Fourier component of integral (45) is the same:

$$
\begin{equation*}
E_{n}=\hbar \omega_{c}\left(n+\frac{1}{2}\right) \tag{3.50}
\end{equation*}
$$

and does not depend on either $x_{0}$, or $y_{0}$, or $k$.
This is an example of a highly degenerate system: for each eigenvalue $E_{n}$, there are many different eigenfunctions that differ by the positions $\left\{x_{0}, y_{0}\right\}$ of their center on axis $x$, and the rate $k$ of
their phase change along axis $y$. They may be used to assemble a large variety of linear combinations, including 2D wave packets whose centers move along classical circular orbits with some radius $r$ determined by initial conditions. Note, however, that such radius cannot be smaller than the so-called Landau radius,

$$
\begin{equation*}
r_{\mathrm{L}} \equiv\left(\frac{\hbar}{q B}\right)^{1 / 2} \tag{3.51}
\end{equation*}
$$

which characterizes the minimum radius of the wave packet itself, and results from Eq. (2.271) after replacement (48). This radius is remarkably independent on particle's mass, and may be interpreted in the following way: the scale $B A_{\text {min }}$ of the applied magnetic field's flux through the effective area $A_{\text {min }}=$ $2 \pi r_{\mathrm{L}}{ }^{2}$ of the smallest wave packet is just one normal flux quantum $\Phi_{0}{ }^{\prime}=2 \pi \hbar / q$.

A detailed analysis of such wave packets (for which we would not have time in this course) shows that magnetic field does not change the average density $d N_{2} / d E$ of different 2 D states on the energy scale, but just "assembles" them on the Landau levels (see Fig. 5a), so that the number of states on each Landau area (per unit area) is

$$
\begin{equation*}
n_{L} \equiv \frac{N_{2}}{A}=\left.\frac{1}{A} \frac{d N_{2}}{d E}\right|_{\mathcal{B} \neq 0} \Delta E=\left.\frac{1}{A} \frac{d N_{2}}{d E}\right|_{\mathcal{B}=0} \Delta E=\frac{m}{2 \pi \hbar^{2}} \hbar \omega_{c}=\frac{q \mathcal{B}}{2 \pi \hbar}=\frac{q \mathcal{B}}{h} . \tag{3.52}
\end{equation*}
$$

This expression may again be interpreted in terms of magnetic flux quanta: $n_{\mathrm{L}} \Phi_{0}{ }^{\prime}=\mathcal{B}$, i.e. there is one particular state on each Landau level per each flux quantum.

Fig. 3.5. (a) "Condensation" of 2D states on Landau levels, and (b) filling the levels by external electrons at the quantum Hall effect.

The most famous application of the Landau levels concept is the explanation of the quantum Hall effect ${ }^{17}$. Generally, the Hall effect ${ }^{18}$ is observed in the geometry sketched in Fig. 6, where electric current $I$ is passed through a thin rectangular conducting sample (frequently called the Hall bar) placed into a magnetic field $\mathcal{B}$ perpendicular to the sample plane. The classical analysis of the effect is based on the notion of the Lorentz force (14). This force the deviates charge carriers (say, electrons) from their straight motion from one external electrode to another, bending them to the isolated edges of the bar (in Fig. 6, parallel to axis $x$ ). Here the carriers accumulate, generating a gradually increasing electric field $\varepsilon$, until its force (16) exactly balances the Lorentz force (14):

[^540]\[

$$
\begin{equation*}
q \varepsilon_{y}=q v_{x} \mathcal{B}, \tag{3.53}
\end{equation*}
$$

\]

where $v_{x}$ is the drift velocity of the electrons along the bar (Fig. 6), providing the sustained balance condition $\varepsilon_{y} / v_{x}=\mathcal{B}_{z}$ at each point of the 2 D sample.

Fig. 3.6. Hall bar geometry. Darker rectangles show external (3D) electrodes.

With $n_{2}$ carriers per unit area, in a sample of width $W$, this condition yields the following classical expression for the so-called Hall resistance $R_{H}$ :

Classical Hall
effect

$$
\begin{equation*}
R_{H} \equiv \frac{V_{y}}{I_{x}}=\frac{\varepsilon_{y} W}{q n_{2} v_{x} W}=\frac{B}{q n_{2}} . \tag{3.54}
\end{equation*}
$$

This formula is broadly used in practice for the measurement of the carrier density $n_{2}$, and (in semiconductors) the carrier type - negative electrons or positive holes.

However, in experiments with high-quality (low-defect) 2D quantum wells at very low, subkelvin temperatures ${ }^{19}$ and high magnetic fields, the linear growth of $R_{H}$ with $\mathcal{B}$, described by Eq. (54), is interrupted by virtually horizontal plateaus (Fig. 7) with constant values

$$
\begin{equation*}
R_{H}=\frac{1}{i} R_{K}, \tag{3.55}
\end{equation*}
$$

where $i$ (only in this context, following tradition!) is an integer, and value

$$
\begin{equation*}
R_{K} \approx 25.812807557 \mathrm{k} \Omega \tag{3.56}
\end{equation*}
$$

is reproduced with extremely high accuracy $\left(\sim 10^{-9}\right)$ from experiment to experiment and from sample to sample. Such stability is a very rare exception in solid state physics were most results are noticeably dependent on the particular material and particular sample under study.

Let us apply the Landau level picture. The 2D sample is typically in a weak contact with 3D electrodes whose conductivity electrons form a Fermi sea with certain Fermi energy $E_{F}$, so that at low temperatures all states with $E<E_{F}$ are filled with electrons - see Fig. 5b. As $\mathcal{B}$ is increased, spacing $\hbar \omega_{c}$ between the Landau levels increases, so that fewer and fewer of these levels are below $E_{F}$ and are filled, and within broad ranges of field variation, the number $i$ of filled levels is constant. (In Fig. 5b, $i=$ 2.) So, plugging $n_{2}=i n_{L}$ and $q= \pm e$ into Eq. (54), we get

$$
\begin{equation*}
R_{H}=\frac{1}{i} \frac{B}{q n_{L}}=\frac{1}{i} \frac{2 \pi \hbar}{e^{2}}=\frac{1}{i} \frac{h}{e^{2}}, \tag{3.57}
\end{equation*}
$$

[^541]i.e. exactly the experimental result (55), with
\[

$$
\begin{equation*}
R_{K}=\frac{h}{e^{2}} \equiv 4 \frac{\pi \hbar}{2 e^{2}} . \tag{3.58}
\end{equation*}
$$

\]

This constant, exactly 4 times the quantum unit of resistance $R_{Q}$ given by Eq. (2.259), is in an excellent agreement with experimental value (56), and is sometimes called the Klitzing constant.

Fig. 3.7. Typical record of the quantum Hall effect. The lower trace (with sharp peaks) shows the longitudinal component, $V_{x} / I_{x}$, of the resistance tensor. (Adapted from www.prequark.org/Prequark.htm.)

However, this oversimplified explanation of the quantum Hall effect does not take into account several important factors, including:
(i) the role of nonuniformity of the quantum well bottom potential $U(x, y)$, and of the localized states this nonuniformity produces, and the surprisingly small effect of these factors on the extraordinary accuracy of Eq. (55); ${ }^{20}$ and
(ii) the mutual Coulomb interaction of the electrons, in high-quality samples leading to the formation of $R_{H}$ plateaus with not only integer, but also fractional values of $i\left(1 / 3,2 / 5,3 / 7\right.$, etc.). ${ }^{21}$

Unfortunately, a thorough discussion of these interesting features is well beyond the framework of this course. ${ }^{22}$

### 3.3. Scattering and diffraction

The second class of quantum effects that become more rich in multi-dimensional space is typically referred to as either diffraction or scattering - depending on the context. (Diffraction is essentially the interference, but of waves emitted by several many coherent sources.) Just as in the two -

[^542]slits in the Young-type experiment (Fig. 1), these sources are most frequently the elementary re-emitters of some initial wave from a single source. More generally, such re-emitting is called scattering; this term is also applied to particles - even if their quantum properties may be ignored. ${ }^{23}$

Figure 8 shows the general scattering situation. Most commonly, the detector of scattered particles (in the quantum case, read de Broglie waves) is located at a large distance $r \gg a$ from the scatterer. ${ }^{24}$ In this case, the main observable independent of $r$ is the flux (number of particles per unit time) of particles scattered in a certain direction, i.e. their flux per unit solid angle. Since such flux is proportional to the incident flux of particles per unit area, the ability of the scatterer to re-emit in a particular direction may be characterized by the ratio of these two fluxes. This ratio has the dimensionality of area per unit angle, and is called the differential cross-section of the scatterer:

Full
cross-
section

$$
\begin{equation*}
\frac{d \sigma}{d \Omega} \equiv \frac{\text { flux of scatterd particles per unit solid angle }}{\text { flux of incident particles per unit area }} . \tag{3.58}
\end{equation*}
$$

Such name and notation stem from the fact that the integral of $d \sigma / d \Omega$ over all scattering angles,

$$
\begin{equation*}
\sigma \equiv \oint \frac{d \sigma}{d \Omega} d \Omega=\frac{\text { total flux of scattered particles }}{\text { incident flux per per unit area }} \tag{3.59}
\end{equation*}
$$

(also with the dimensionality of area), has a simple interpretation as the full cross-section of scattering. For the simplest case when a macroscopic solid object scatters all classical particles hitting its surface, but does not affect the particles flying by it, $\sigma$ is just the geometrical cross-section of the object, as visible from the direction of incoming particles.

In classical mechanics, ${ }^{25}$ we first calculate the particle scattering angle as a function of the impact parameter $b$, and then average the result over all values of $b$, considered random. In this sense the calculations in wave mechanics are simpler, because a parallel beam of incident particles of fixed energy $E$ may be fairly presented by a plane de Broglie wave

$$
\begin{equation*}
\psi_{0}=a_{0} e^{i \mathbf{k}_{0} \cdot \mathbf{r}}, \tag{3.60}
\end{equation*}
$$

[^543]with the free-space wave number $k_{0}=(2 m E)^{1 / 2} / \hbar$ and constant probability current density (1.49):
\[

$$
\begin{equation*}
\mathbf{j}_{0}=\left|a_{0}\right|^{2} \frac{\hbar}{m} \mathbf{k}_{0} . \tag{3.61}
\end{equation*}
$$

\]

This current density is exactly the flux of incident particles per unit area that is used in the denominator of definition (58), so the "only" remaining thing to do is to calculate the numerator of that fraction.

To do this, let us write the Schrödinger equation for the scattering problem (now in the whole space including the scatterer) in the form

$$
\begin{equation*}
\left(E-\hat{H}_{0}\right) \psi=U(\mathbf{r}) \psi \tag{3.62}
\end{equation*}
$$

where

$$
\begin{equation*}
\hat{H}_{0} \equiv-\frac{\hbar^{2}}{2 m} \nabla^{2}, \quad \text { and } \quad E=\frac{\hbar^{2} k_{0}^{2}}{2 m}=\frac{\hbar^{2} k^{2}}{2 m} . \tag{3.63}
\end{equation*}
$$

the potential energy $U(\mathbf{r})$ describes the effect of scatterer. Looking for the solution of Eq. (62) in the natural form

$$
\begin{equation*}
\psi=\psi_{0}+\psi_{s}, \tag{3.64}
\end{equation*}
$$

where $\psi_{0}$ is the incident wave (60), and $\psi_{\mathrm{s}}$ has the sense of the scattered wave, and taking into account that former wave satisfies the free-space equation

$$
\begin{equation*}
\hat{H}_{0} \psi_{0}=E \psi_{0} \tag{3.65}
\end{equation*}
$$

we may reduce Eq. (62) to

$$
\begin{equation*}
\left(E-\hat{H}_{0}\right) \psi_{s}=U(\mathbf{r})\left(\psi_{0}+\psi_{s}\right) \tag{3.66}
\end{equation*}
$$

The most straightforward (and common) simplification of this problem is possible if the scattering potential $U(\mathbf{r})$ is in some sense weak. (We will derive the exact condition of this smallness below.) Then since at $U(\mathbf{r})=0$ the scattering wave $\psi_{s}$ disappears, we may expect that at small but nonvanishing $U(\mathbf{r})$, the main part of $\psi_{s}$ is proportional to its scale $U_{0}$. Then all terms in Eq. (66) are proportional to $U_{0}$, besides the product $U \psi_{s}$, which is proportional to $U_{0}{ }^{2}$. Hence, in the first approximation in $U_{0}$, that term may be ignored, and Eq. (66) reduces to the famous equation of the Born approximation: ${ }^{26}$

$$
\begin{equation*}
\left(E-\hat{H}_{0}\right) \psi_{s}=U(\mathbf{r}) \psi_{0} \tag{3.67a}
\end{equation*}
$$

[^544]This simplification changes the situation drastically, because the linear superposition principle allows finding an explicit solution of this equation (in the form of an integral) for an arbitrary function $U(\mathbf{r})$. Indeed, after rewriting Eq. (67a) as

[^545]\[

$$
\begin{equation*}
\left(\nabla^{2}+k^{2}\right) \psi_{s}=\frac{2 m}{\hbar^{2}} U(\mathbf{r}) \psi_{0}(\mathbf{r}) \tag{3.67b}
\end{equation*}
$$

\]

we may notice that $\psi_{s}$ is just a response of a linear system to a certain "excitation" (represented by the right-hand part) that is fixed, i.e. does not depend on the solution. Hence we can present $\psi_{s}$ as a sum of responses to elementary excitations from elementary volumes $d^{3} r^{\prime}$ :

$$
\begin{equation*}
\psi_{s}(\mathbf{r})=\frac{2 m}{\hbar^{2}} \int U\left(\mathbf{r}^{\prime}\right) \psi_{0}\left(\mathbf{r}^{\prime}\right) G\left(\mathbf{r}, \mathbf{r}^{\prime}\right) d^{3} r^{\prime} \tag{3.68}
\end{equation*}
$$

Spatial Green's function

Here $G(\mathbf{r}, \mathbf{r}$ ') is the spatial Green's function, defined as such an elementary response of the free-space Schrödinger equation to a point excitation, i.e. the solution of the following equation ${ }^{27}$

$$
\begin{equation*}
\left(\nabla^{2}+k^{2}\right) G=\delta\left(\mathbf{r}-\mathbf{r}^{\prime}\right) \tag{3.69}
\end{equation*}
$$

But we already know the physically-relevant spherically-symmetric solution of this equation - see Eq. (7) and its discussion:

$$
\begin{equation*}
G\left(\mathbf{r}, \mathbf{r}^{\prime}\right)=\frac{f_{+}}{R} e^{i k R} \tag{3.70}
\end{equation*}
$$

so that we need just to calculate the coefficient $f_{+}$for Eq. (67). This can be done in several ways, for example by noticing that at $r \ll k^{-1}$, the second term in Eq. (70) is negligible, and it is reduced to the well-known Poisson equation with delta-functional right-hand part, which describes, for example, the electrostatic potential generated by a point electric charge. Either recalling the Coulomb law, or applying the Gauss theorem, ${ }^{28}$ we readily get the asymptote

$$
\begin{equation*}
G \rightarrow-\frac{1}{4 \pi R}, \quad \text { at } k r \ll 1, \tag{3.71}
\end{equation*}
$$

which is compatible with Eq. (70) only if $f_{+}=-1 / 4 \pi$, i.e. if

Green's function for free space

$$
\begin{equation*}
G\left(\mathbf{r}, \mathbf{r}^{\prime}\right)=-\frac{1}{4 \pi R} e^{i k R} \tag{3.72}
\end{equation*}
$$

Plugging this result into Eq. (68), we get the final solution of Eq. (67):

$$
\begin{equation*}
\psi_{s}(\mathbf{r})=-\frac{m}{2 \pi \hbar^{2}} \int U\left(\mathbf{r}^{\prime}\right) \frac{\psi_{0}\left(\mathbf{r}^{\prime}\right)}{R} e^{i k R} d^{3} r^{\prime} \tag{3.73}
\end{equation*}
$$

Note that if function $U(\mathbf{r})$ is smooth, the singularity in the denominator is integrable (i.e. not dangerous); indeed, the contribution of a sphere of radius $R \rightarrow 0$, with the center in point $\mathbf{r}^{\prime}=0$, scales as

$$
\begin{equation*}
\int_{R<R} \frac{d^{3} R}{R}=4 \pi \int_{0}^{R} \frac{R^{2} d R}{R}=4 \pi \int_{0}^{R} R d R=2 \pi R^{2} \rightarrow 0 \tag{3.74}
\end{equation*}
$$

[^546]Actually, Eq. (73) gives us more than we wanted: it evaluates the scattered wave at any point, including those within of the scattering object, while our goal was to find the wave far from the scatterer - please revisit Fig. 8 if you need. However, before going to that limit, we can use the general formula to find the quantitative criterion of the Born approximation's validity. Indeed, let us estimate the magnitude of the right hand part of this equation, for a scatterer of linear size $\sim a$, and the potential magnitude scale $U_{0}$, in two limits:
(i) If $k a \ll 1$, then inside the scatterer (i.e., at distances $r^{\prime} \sim a$ ), both $\psi_{0} \sim \exp \{i k r\}$ and the second exponent under the integral change slowly, so that a crude estimate of the solution is

$$
\begin{equation*}
\left|\psi_{s}\right| \sim \frac{m}{2 \pi \hbar^{2}} U_{0}\left|\psi_{0}\right| a^{2} . \tag{3.75}
\end{equation*}
$$

(ii) In the opposite limit $k a \gg 1$, the integration along one of the dimensions (that of the wave propagation) is cut out on distances of the order of the de Broglie wavelength $k^{-1}$, so that the integral is correspondingly smaller:

$$
\begin{equation*}
\left|\psi_{\mathrm{s}}\right| \sim \frac{m}{2 \pi \hbar^{2}} U_{0}\left|\psi_{0}\right| \frac{a^{2}}{k a} \tag{3.76}
\end{equation*}
$$

Since the reduction of Eq. (66) to Eq. (67) requires $\left|\psi_{s}\right| \ll\left|\psi_{0}\right|$ everywhere within the scatterer, we may now formulate the conditions of this requirement as

$$
\begin{equation*}
U_{0} \ll \frac{\hbar^{2}}{m a^{2}} \max [k a, 1] . \tag{3.77}
\end{equation*}
$$

In the first factor of the right-hand part, we may readily recognize the scale of the kinetic (quantumconfinement) energy $E_{a}$ of the particle inside a quantum well of size $\sim a$, so that the Born approximation is valid essentially if the potential energy of particle's interaction with the scatterer is smaller than $E_{a}$. Note, however, that estimates (75) and (76) are not valid in special situations when the effects of scattering accumulate in some direction. This is frequently the case for small scattering angles in extended objects (when $k a \gg 1$ but $k a \theta<1$ ), and especially in 1D (or quasi-1D) scatterers oriented along the incident particle beam.

Now let us proceed to large distances $r \gg r^{\prime} \sim a$, and simplify Eq. (73) using an approximation similar to the dipole expansion in electrodynamics. ${ }^{29}$ In denominator's $R$, we can merely ignore $r$ ' in comparison with $r$, but the exponent requires more care, because even if $r^{\prime} \sim a \ll r$, the product $k r^{\prime} \sim k a$ may still be larger than 1. In the first approximation in $r^{\prime}$, we can take (Fig. 9a):

Fig. 3.9. (a) Dipole expansion in the Born approximation and (b) definitions of vector $\mathbf{q}$ and angles $\chi$ and $\theta$.

[^547]\[

$$
\begin{equation*}
R \equiv\left|\mathbf{r}-\mathbf{r}^{\prime}\right| \approx r-\mathbf{n}_{r} \cdot \mathbf{r}^{\prime}, \tag{3.78}
\end{equation*}
$$

\]

and since the directions of vectors $\mathbf{k}$ and $\mathbf{r}$ coincide, i.e. $\mathbf{k}=k \mathbf{n}_{r}$,

$$
\begin{equation*}
k R \approx k r-\mathbf{k} \cdot \mathbf{r}^{\prime}, \quad \text { and } e^{i k R} \approx e^{i k r} e^{-i \mathbf{k} \cdot \mathbf{r}^{\prime}} \tag{3.79}
\end{equation*}
$$

With this replacement, and the incident wave in form (60), the Born approximation yields

$$
\begin{equation*}
\psi_{s}(\mathbf{r})=-\frac{m}{2 \pi \hbar^{2}} \frac{a_{0}}{r} e^{i k r} \int U\left(\mathbf{r}^{\prime}\right) e^{-i\left(\mathbf{k}-\mathbf{k}_{0}\right) \cdot \mathbf{r}^{\prime}} d^{3} r^{\prime} \tag{3.80}
\end{equation*}
$$

This relation may be presented in a general form ${ }^{30}$

Scattering function

$$
\begin{equation*}
\psi_{s}=a_{0} \frac{f\left(\mathbf{k}, \mathbf{k}_{0}\right)}{r} e^{i k r} \tag{3.81}
\end{equation*}
$$

where $f\left(\mathbf{k}, \mathbf{k}_{0}\right)$ is called the scattering function. ${ }^{31}$ Its physical sense becomes clear from the calculation of the corresponding probability current density $\mathbf{j}_{s}$. For that, generally we need to use Eq. (1.47) with the gradient operator having all spherical-coordinate components. ${ }^{32}$ However, at $k r \gg 1$ the main contribution to $\nabla \psi_{s}$, proportional to $k \gg 1 / r$, is provided by the term $\exp \{i k r\}$ which changes fast in the common direction of vectors $\mathbf{r}$ and $\mathbf{k}$, so that

$$
\begin{equation*}
\nabla \psi_{s} \approx \mathbf{n}_{r} \frac{\partial}{\partial r} \psi_{s} \approx \mathbf{k} \psi_{s}, \quad \text { at } k r \gg 1 \tag{3.82}
\end{equation*}
$$

so that Eq. (1.47) yields

$$
\begin{equation*}
\mathbf{j}_{s}(\theta) \approx \frac{\hbar}{m}\left|a_{0}\right|^{2} \frac{\left|f\left(\mathbf{k}, \mathbf{k}_{0}\right)\right|^{2}}{r^{2}} \mathbf{k} \tag{3.83}
\end{equation*}
$$

Since this vector is parallel to $\mathbf{k}$ and hence to $\mathbf{r}$, the flux in the numerator of Eq. (58), i.e. the probability current per unit solid angle, is just $r^{2} j_{s}$. Hence, the differential cross-section is simply

$$
\begin{equation*}
\frac{d \sigma}{d \Omega}=\frac{j_{s} r^{2}}{j_{0}}=\left|f\left(\mathbf{k}, \mathbf{k}_{0}\right)\right|^{2}, \tag{3.84}
\end{equation*}
$$

and the total cross-section is

$$
\begin{equation*}
\sigma=\oint\left|f\left(\mathbf{k}, \mathbf{k}_{0}\right)\right|^{2} d \Omega \tag{3.85}
\end{equation*}
$$

so that the scattering function $f\left(\mathbf{k}, \mathbf{k}_{0}\right)$ gives us everything we need (and in fact more, because the function also contains information about the phase of the scattered wave).

[^548]According to Eq. (80), in the Born approximation the scattering function may be presented as the Born integral

$$
\begin{equation*}
f\left(\mathbf{k}, \mathbf{k}_{0}\right)=-\frac{m}{2 \pi \hbar^{2}} \int U(\mathbf{r}) e^{-i \mathbf{q} \cdot \mathbf{r}^{3}} d^{3} r \tag{3.86}
\end{equation*}
$$

where for the notation simplicity I have replaced $\mathbf{r}$ ' with $\mathbf{r}$, and also introduced the scattering vector

$$
\begin{equation*}
\mathbf{q} \equiv \mathbf{k}-\mathbf{k}_{0} \tag{3.87}
\end{equation*}
$$

with length $q=2 k \sin (\theta / 2)$, where $\theta$ is the scattering angle between vectors $\mathbf{k}$ and $\mathbf{k}_{0}-$ see Fig. 9 b . For the differential cross-section, Eq. (86) yields

$$
\begin{equation*}
\frac{d \sigma}{d \Omega}=\left(\frac{m}{2 \pi \hbar^{2}}\right)^{2}\left|\int U(\mathbf{r}) e^{-i \mathbf{q} \cdot \mathbf{r}} d^{3} r\right|^{2} \tag{3.88}
\end{equation*}
$$

and the total cross-section may be now readily calculated from the first of Eqs. (59). ${ }^{33}$
This is the main result of this section; it may be further simplified for spherically-symmetric scatterers, with

$$
\begin{equation*}
U(\mathbf{r})=U(r) \tag{3.89}
\end{equation*}
$$

Here, it is convenient to present the exponent in the Born integral as $\exp \{-i q r \cos \chi\}$, where $\chi$ is the angle between vectors $\mathbf{k}$ (i.e. the direction $\mathbf{n}_{r}$ toward the detector) and $\mathbf{q}$ (rather than the incident wave vector $\mathbf{k}_{0}!$ ) - see Fig. 9b. Now, for fixed $\mathbf{q}$, we can take this vector's direction as the polar axis of a spherical coordinate system, and reduce Eq. (86) to a 1D integral:

$$
\begin{align*}
f\left(\mathbf{k}, \mathbf{k}_{0}\right) & =-\frac{m}{2 \pi \hbar^{2}} \int r^{2} d r U(r) \int_{0}^{2 \pi} d \varphi \int_{0}^{\pi} \sin \chi d \chi \exp \{-i q r \cos \chi\}  \tag{3.90}\\
& =-\frac{m}{2 \pi \hbar^{2}} \int r^{2} d r U(r) 2 \pi \frac{2 \sin q r}{q r}=-\frac{2 m}{\hbar^{2} q} \int U(r) \sin (q r) r d r .
\end{align*}
$$

As a simple example, let us use the Born approximation to analyze scattering on the following spherically-symmetric potential:

$$
\begin{equation*}
U(\mathbf{r})=U_{0} \exp \left\{-\frac{r^{2}}{2 a^{2}}\right\} \tag{3.91}
\end{equation*}
$$

In this particular case, it is better to avoid the temptation to exploit the spherical symmetry by using Eq. (90), and instead use the generic Eq. (88), because it falls apart into a product of three similar Cartesian factors:

$$
\begin{equation*}
f\left(\mathbf{k}, \mathbf{k}_{0}\right)=-\frac{m U_{0}}{2 \pi \hbar^{2}} I_{x} I_{y} I_{z} \tag{3.92}
\end{equation*}
$$

with

[^549]\[

$$
\begin{equation*}
I_{x}=\int_{-\infty}^{+\infty} \exp \left\{-\left(\frac{x^{2}}{2 a^{2}}+i q_{x} x\right)\right\} d x \tag{3.93}
\end{equation*}
$$

\]

and similar integrals for $I_{y}$ and $I_{z}$. From Chapter 2, we already know that Gaussian integrals like $I_{x}$ may be readily worked out by complementing the exponent to the full square, in our current case giving

$$
\begin{equation*}
I_{x}=(2 \pi)^{1 / 2} a \exp \left\{-\frac{q_{x}^{2} a^{2}}{2}\right\}, \quad \text { etc. } \tag{3.94}
\end{equation*}
$$

so that, finally,

$$
\begin{equation*}
\frac{d \sigma}{d \Omega}=\left|f\left(\mathbf{k}, \mathbf{k}_{0}\right)\right|^{2}=\left(\frac{m U_{0}}{2 \pi \hbar^{2}} I_{x} I_{y} I_{z}\right)^{2}=2 \pi a^{2}\left(\frac{m U_{0} a^{2}}{\hbar^{2}}\right)^{2} e^{-q^{2} a^{2}} . \tag{3.95}
\end{equation*}
$$

Now, the total cross-section $\sigma$ is an integral of $d \sigma / d \Omega$ over all directions of vector $\mathbf{k}$. Since in our case the scattering intensity does not depend on the azimuthal angle $\varphi$, the integration is reduced to that over the scattering angle $\theta$ (Fig. 9b):

$$
\begin{align*}
& \sigma \equiv \oint \frac{d \sigma}{d \Omega} d \Omega=2 \pi \int_{0}^{\pi} \frac{d \sigma}{d \Omega} \sin \theta d \theta=4 \pi^{2} a^{2}\left(\frac{m U_{0} a^{2}}{\hbar^{2}}\right)^{2} \int_{0}^{\pi} \sin \theta d \theta \exp \left\{-\left(2 k \sin \frac{\theta}{2}\right)^{2} a^{2}\right\}  \tag{3.96}\\
& =4 \pi^{2} a^{2}\left(\frac{m U_{0} a^{2}}{\hbar^{2}}\right)^{2} \int_{\theta=0}^{\theta=\pi} \exp \left\{-2 k^{2} a^{2}(1-\cos \theta)\right\} d(1-\cos \theta)=\frac{2 \pi^{2}}{k^{2}}\left(\frac{m U_{0} a^{2}}{\hbar^{2}}\right)^{2}\left[1-e^{-4 k^{2} a^{2}}\right]
\end{align*}
$$

Let us analyze these formulas. In the low-energy limit, $k a \ll 1$ (and hence $q a \ll 1$ for any scattering angle), the scattered wave is virtually isotropic: $d \sigma / d \Omega \approx$ const - a very typical feature of scattering by small objects, in any approximation. Notice that in this limit, the Born expression for $\sigma$,

$$
\begin{equation*}
\sigma \approx 8 \pi^{2} a^{2}\left(\frac{m U_{0} a^{2}}{\hbar^{2}}\right)^{2} \tag{3.97}
\end{equation*}
$$

is only valid if $\sigma$ is much smaller than the scale $a^{2}$ of the physical cross-section of the scatterer.
In the opposite, high-energy limit $k a \gg 1$, the scattering is dominated by small angles $\theta \approx q / k \sim$ $1 / k a \sim \lambda / a$ :

$$
\begin{equation*}
\frac{d \sigma}{d \Omega} \approx 2 \pi a^{2}\left(\frac{m U_{0} a^{2}}{\hbar^{2}}\right)^{2} \exp \left\{-(k a \theta)^{2}\right\} \tag{3.98}
\end{equation*}
$$

This is, again, very typical for diffraction. Notice, however, that due to the smooth character of the Gaussian potential (91), the diffraction pattern exhibits no oscillations; such oscillations of $d \sigma / d \Omega$ as function of angle naturally appear for potentials with sharp borders - see, e.g., Problems 2 and 3.

The Born approximation, while being very simple and used more often than any other scattering theory, is not without substantial shortcomings, as is clear from the following example. It is not too difficult to prove the following general optical theorem, valid for an arbitrary scatterer:

$$
\begin{equation*}
\operatorname{Im} f\left(\mathbf{k}_{0}, \mathbf{k}_{0}\right)=\frac{k}{4 \pi} \sigma \tag{3.99}
\end{equation*}
$$

However, Eq. (86) shows that in the Born approximation, function $f$ is purely real at $q=0$ (i.e. $\mathbf{k}=\mathbf{k}_{0}$ ), and hence cannot satisfy the optical theorem. Even more evidently, it cannot describe such a simple effect as a dark shadow $(\psi \approx 0)$ cast by an opaque object (say, with $U_{0} \gg E$ ).

There are several ways to improve the Born approximation, while still holding the general idea of approximate treatment of $U$.
(i) Instead of the main assumption $\psi_{s} \propto U_{0}$, we can use a complete perturbation series:

$$
\begin{equation*}
\psi_{s}=\psi_{1}+\psi_{2}+\ldots \tag{3.100}
\end{equation*}
$$

with $\psi_{n} \propto U_{0}{ }^{n}$, and find successive approximations $\psi_{n}$ one by one. In the $1^{\text {st }}$ approximation we of course return to the Born formula, but already the $2^{\text {nd }}$ approximation yields

$$
\begin{equation*}
\operatorname{Im} f_{2}\left(\mathbf{k}_{0}, \mathbf{k}_{0}\right)=\frac{k}{4 \pi} \sigma_{1}, \tag{3.101}
\end{equation*}
$$

where $\sigma_{1}$ is the full cross-section calculated in the 1st approximation, so that the optical theorem (99) is "almost" satisfied. ${ }^{34}$
(ii) As was mentioned above, the Born approximation does not work very well for small-angle scattering by extended objects. This deficiency may be corrected by the so-called eikonal approximation (from Greek word $\varepsilon 1 \kappa 0 v$, meaning "icon") that replaces the plane wave exponent $\exp \left\{i k_{0} x\right\}$ representation of the incident wave by a WKB-like exponent, though still in the first nonvanishing approximation in $U \rightarrow 0$ :

$$
\begin{equation*}
\exp \left\{i k_{0} x\right\} \rightarrow \exp \left\{i \int_{0}^{x} k\left(x^{\prime}\right) d x^{\prime}\right\}=\exp \left\{i \int_{0}^{x} \frac{\left\{2 m\left[E-U\left(x^{\prime}\right)\right]\right\}^{1 / 2}}{\hbar} d x^{\prime}\right\} \approx \exp \left\{i\left[k_{0} x-\frac{m}{\hbar^{2} k_{0}} \int_{0}^{x} U\left(x^{\prime}\right) d x^{\prime}\right]\right\} . \tag{3.102}
\end{equation*}
$$

This approximation's results satisfy the optical theorem (99) already in the $1^{\text {st }}$ approximation in $U$.

### 3.4. Energy bands in higher dimensions

In Sec. 2.5, we have discussed the 1 D band theory for potential profiles $U(x)$ that obey the periodicity condition (2.192). For what follows, let us notice that that condition may be rewritten as

$$
\begin{equation*}
U(x+X)=U(x), \tag{3.103}
\end{equation*}
$$

[^550]where $X=\tau a$, with $\tau$ being an arbitrary integer. One can say that the set of points $X$ forms a periodic $l D$ lattice in the direct ( $x$-) space. We have also seen that each Bloch state (i.e., each eigenstate of the Schrödinger equation for such periodic potential) is characterized by the quasi-momentum $\hbar q$ and its energy does not change if $q$ is changed by a multiple of $2 \pi / a$. Hence if we form, in the reciprocal ( $k$-) space, a 1D lattice of points $Q=l b$, with $b=2 \pi / a$ and integer $l$, any pair of points from these two mutually reciprocal lattices satisfies the following rule:
\[

$$
\begin{equation*}
\exp \{i Q X\}=\exp \left\{i l \frac{2 \pi}{a} \tau a\right\}=e^{2 \pi i \tau l}=1 \tag{3.104}
\end{equation*}
$$

\]

In this form, the results of Sec. 2.5 may be readily extended to $d$-dimensional periodic potentials whose translational symmetry obeys the following generalization of Eq. (103):

$$
\begin{equation*}
U(\mathbf{r}+\mathbf{R})=U(\mathbf{r}) \tag{3.105}
\end{equation*}
$$

where points $\mathbf{R}$, which may be numbered by $d$ integers $\tau_{j}$, form the so-called Bravais lattice ${ }^{35}$ of points

$$
\begin{equation*}
\mathbf{R}=\sum_{j=1}^{d} \tau_{j} \mathbf{a}_{j} \tag{3.106}
\end{equation*}
$$

with $d$ primitive vectors $\mathbf{a}_{j}$. The simplest example of a 3D Bravais lattice are given by the simple cubic lattice (Fig. 10a), which may be described by the system of mutually perpendicular primitive vectors $\mathbf{a}_{j}$ of equal length. However, not in any lattice these vectors are perpendicular; for example Figs. 10b and 10c show possible sets of the primitive vectors describing the face-centered cubic lattice (fcc) and bodycentered cubic lattice (bcc). In 3D, the science of crystallography, based on the group theory, distinguishes, by their symmetry properties, 14 Bravais lattices grouped into 7 different lattice systems. ${ }^{36}$
(a)

(b)

Fig. 3.10. The simplest (and most common) 3D Bravais lattices: (a) simple cubic, (b) face-centered cubic (fcc), and (c) body-centered cubic (bcc), and possible choices of their primitive vector sets (blue arrows).

Note, however, not all highly symmetric sets of points form Bravais lattices. As probably the most striking example, nodes of the very simple 2D honeycomb lattice (Fig. 11a) cannot be described by

[^551]a Bravais lattice - while the 2D hexagonal lattice, shown in Fig. 11b, can. The most prominent 3D case of such a lattice is the diamond structure (Fig. 11c), which describes, in particular, atoms of world's most important crystal - silicon. ${ }^{37}$ In cases like these, the band theory is much facilitated by the fact that the Bravais lattices using some point assemblies (called primitive unit cells) may describe these point systems. For example, Fig. 11a shows the possible choice of primitive vectors for the honeycomb structure, ${ }^{38}$ with the primitive unit cell formed by any two adjacent points of the original lattice (say, within the dashed ellipses in Fig. 11a). Similarly, the diamond lattice may be described as the fcc Bravais lattice with two-point primitive unit cell. ${ }^{39}$

Now we are ready for the following generalization of the 1D Bloch theorem, given by Eqs. (2.193) and (2.210), to higher dimensions. Any eigenfunction of the Schrödinger equation describing particle's motion in the periodic potential (105) may be presented either as
or as

$$
\begin{equation*}
\psi(\mathbf{r}+\mathbf{R})=\psi(\mathbf{r}) e^{i \mathbf{q} \cdot \mathbf{R}} \tag{3.107}
\end{equation*}
$$

$$
\begin{equation*}
\psi(\mathbf{r})=u(\mathbf{r}) e^{i \mathbf{q} \cdot \mathbf{r}}, \quad \text { with } u(\mathbf{r}+\mathbf{R})=u(\mathbf{r}) \tag{3.108}
\end{equation*}
$$

where the quasi-momentum $\hbar \mathbf{q}$ is again a constant of motion, but now is a vector.

(c)

Two forms of the 3D Bloch theorem

Fig. 3.11. Some important periodic structures that require two-point primitive cells for their Bravais lattice presentation: (a) 2D honeycomb lattice and their primitive vectors and (c) 3D diamond lattice. For a contrast, panel (b) shows the 2D hexagonal structure which forms a Bravais lattice with a single-point primitive cell.

The key notion of the band theory is the reciprocal lattice in the wavevector space, formed as

$$
\begin{equation*}
\mathbf{Q}=\sum_{j=1}^{d} l_{j} \mathbf{b}_{j} \tag{3.109}
\end{equation*}
$$

Reciprocal lattice in q-space

[^552]with integer $l_{j}$, and vectors $\mathbf{b}_{j}$ selected in such way that the following generalization of Eq. (104) is valid for any pair of points of the direct and reciprocal lattices:
\[

$$
\begin{equation*}
e^{i \mathbf{Q} \cdot \mathbf{R}}=1 \tag{3.110}
\end{equation*}
$$

\]

The importance of lattice $\mathbf{Q}$ is immediately clear from the first formulation of the Bloch theorem, given by Eq. (107): if we add to $\mathbf{q}$ any vector $\mathbf{Q}$ of the reciprocal lattice, the wavefunction does not change. This means that all information about the system is contained in just one elementary cell of the reciprocal space $\mathbf{q}$. Its most frequent choice, called the $l^{s t}$ Brillouin zone, is the set of all points $\mathbf{q}$ that are closer to the origin than to any other point of lattice $\mathbf{Q}$.

It is easy to see that primitive vectors $\mathbf{b}_{\mathbf{j}}$ of the reciprocal 3D lattice ${ }^{40}$ may be constructed from those of the initial, direct lattice as

Primitive vectors of the reciprocal lattice

$$
\begin{equation*}
\mathbf{b}_{1}=2 \pi \frac{\mathbf{a}_{2} \times \mathbf{a}_{3}}{\mathbf{a}_{1} \cdot\left(\mathbf{a}_{2} \times \mathbf{a}_{3}\right)}, \quad \mathbf{b}_{2}=2 \pi \frac{\mathbf{a}_{3} \times \mathbf{a}_{1}}{\mathbf{a}_{1} \cdot\left(\mathbf{a}_{2} \times \mathbf{a}_{3}\right)}, \quad \mathbf{b}_{3}=2 \pi \frac{\mathbf{a}_{1} \times \mathbf{a}_{2}}{\mathbf{a}_{1} \cdot\left(\mathbf{a}_{2} \times \mathbf{a}_{3}\right)} . \tag{3.111}
\end{equation*}
$$

Indeed, from the "operand rotation rule" of the vector algebra ${ }^{41}$ it is evident that $\mathbf{a}_{j} \cdot \mathbf{b}_{j}$ ' $=2 \pi \delta_{j j}$. Hence, the exponent in the left-hand part of Eq. (110) is reduced to

$$
\begin{equation*}
e^{i \mathbf{Q} \cdot \mathbf{R}}=\exp \left\{2 \pi i\left(l_{1} \tau_{1}+l_{2} \tau_{2}+l_{3} \tau_{3}\right)\right\} \tag{3.112}
\end{equation*}
$$

Since all $l_{j}$ and $\tau_{j}$ are integers, the expression in the parentheses is also an integer, so the exponent indeed equals 1 , thus satisfying the definition of the reciprocal lattice given by Eq. (110).

As the simplest example, let us return to the simple cubic lattice of period $a$ (Fig. 10a), oriented in space so that

$$
\begin{equation*}
\mathbf{a}_{1}=a \mathbf{n}_{x}, \quad \mathbf{a}_{2}=a \mathbf{n}_{y}, \quad \mathbf{a}_{3}=a \mathbf{n}_{z} \tag{3.113}
\end{equation*}
$$

According to Eq. (111), its reciprocal lattice is (of course) also cubic:

$$
\begin{equation*}
\mathbf{Q}=\frac{2 \pi}{a}\left(l_{x} \mathbf{n}_{x}+l_{y} \mathbf{n}_{y}+l_{z} \mathbf{n}_{z}\right), \tag{3.114}
\end{equation*}
$$

so that the $1^{\text {st }}$ Brillouin zone is a cube with side $b=2 \pi / a$. Almost similarly simple calculations show that the reciprocal lattice of fcc is bcc, and vice versa. Figure 12 shows the resulting $1^{\text {st }}$ Brillouin zone of the fcc lattice.

The notion of the reciprocal lattice ${ }^{42}$ makes the multi-dimensional band theory not much more complex than that in 1 D , especially for numerical calculations, at least for the single-point Bravais lattices. Indeed, repeating all the steps that have led to Eq. (2.218), but now with a $d$-dimensional Fourier expansion of functions $U(\mathbf{r})$ and $u_{l}(\mathbf{r})$, we readily get its generalization:

$$
\begin{equation*}
\sum_{\mathbf{I}^{\prime} \neq 1} U_{\mathbf{1}^{\prime}-1} u_{\mathbf{I}^{\prime}}=\left(E-E_{\mathbf{1}}\right) u_{\mathbf{1}} \tag{3.115}
\end{equation*}
$$

[^553]where $\mathbf{l}$ is now a $d$-dimensional vector of integer indices $l_{j}$. The summation in Eq. (115) should be carried over all (essential) components of this vector (i.e. over all relevant nodes of the reciprocal lattice), so writing a corresponding computer code requires a bit more care than in 1 D ; however, this is just a homogeneous system of linear equations, and numerous routines of finding its eigenvalues $E$ are readily available from both public sources and commercial software packages. ${ }^{43}$

Fig. 3.12. $1^{\text {st }}$ Brillouin zone of the fcc lattice, and the traditional notation of its main directions. Adapted from http://en.wikipedia.org/wiki/Band structure.

What is indeed more complex than in 1D is the presentation (and hence the comprehension :-), of the calculation results and experimental data. Typically, the presentation is limited to plotting the Bloch state eigenenergy as a function of components of vector $q$ along certain special directions the reciprocal space of quasi-momentum (see, e.g., the lines shown in Fig. 12), typically plotted on single panel. Figure 12 shows perhaps the most famous (and certainly the most practically important) of such plots, the band structure of silicon. The dashed horizontal lines mark the "indirect" gap of width 1.12 eV between the "valence" and "conduction" energy bands, which is the playground of virtually all siliconbased electronics.

Fig. 3.13. Band structure of silicon, along the special directions shown in Fig. 12. (Adapted from http://www.tf.uni-kiel.de/matwis/amat/semi en/.)

[^554]In order to understand the reason of this band structure presentation complexity, let us see how we would start to develop the weak-potential approximation for the simplest case of a 2 D square lattice (which is a subset of the cubic lattice, with $\tau_{3}=0$ ). Its $1^{\text {st }}$ Brillouin zone is of course also a square, of area $(2 \pi / a)^{2}$. Let us draw the lines of constant energy of a free particle $(U=0)$ in this zone. Repeating the arguments of Sec. 2.7 (see especially Fig. 2.28 and its discussion), we should conclude that Eq. (2.216) should now be generalized as follows,

$$
\begin{equation*}
E=E_{\mathbf{1}}=\frac{\hbar^{2} k^{2}}{2 m}=\frac{\hbar^{2}}{2 m}\left[\left(q_{x}-\frac{2 \pi l_{x}}{a}\right)^{2}+\left(q_{y}-\frac{2 \pi l_{y}}{a}\right)^{2}\right] \tag{3.116}
\end{equation*}
$$

with all possible integers $l_{x}$ and $l_{y}$. Considering the result only within the $1^{\text {st }}$ Brillouin zone, we see that as energy $E$ grows, the lines of equal energy evolve as shown in Fig. 14. Just like in 1D, the weakpotential effects are only important at the Brillouin zone boundaries, and may be crudely considered as the appearance of narrow energy gaps, but one can see that the band structure in $\mathbf{q}$-space is complex enough even without these effects.

(c)

Fig. 3.14. Lines of constant energy $E$ of a free particle, within the $1^{\text {st }}$ Brillouin zone of a square Bravais lattice, for: (a) $E / E_{1} \approx 0.95$, (b) $E / E_{1}$ $\approx 1.05$; and (c) $E / E_{1} \approx 2.05$, where $E_{1} \equiv \pi^{2} \hbar^{2} / 2 m a^{2}$.

The tight-binding approximation is usually easier to follow. For example, for the same square 2D lattice, we may repeat the arguments that have led us to Eq. (2.203), to write ${ }^{44}$

$$
\begin{equation*}
i \hbar \frac{d a_{0,0}}{d t}=-\delta_{n}\left(a_{-1,0}+a_{+1,0}+a_{0,+1}+a_{0,-1}\right) \tag{3.117}
\end{equation*}
$$

where indices correspond to the deviations of integers $\tau_{x}$ and $\tau_{y}$ from an arbitrarily selected minimum of the potential energy - and hence wavefunction's "hump" quasi-localized at this minimum. Now, looking for the stationary solution of these equations, that corresponds to the Bloch theorem (107), instead of Eq. (2.206) we get

$$
\begin{equation*}
E=E_{n}+\varepsilon_{n}=E_{n}-\delta_{n}\left(e^{i q_{x} a}+e^{-i q_{x} a}+e^{i q_{y} a}+e^{-i q_{y} a}\right)=E_{n}-2 \delta_{n}\left(\cos q_{x} a+\cos q_{y} a\right) . \tag{3.118}
\end{equation*}
$$

Figure 15 shows this result, within the $1^{\text {st }}$ Brillouin zone, in two forms: as the color-coded lines of equal energy and as a 3D plot (also enhanced by color).

[^555]

Fig. 3.15. Allowed band energy $\varepsilon_{n}=E-E_{n}$ for a square 2D lattice, in the tight-binding approximation.

It is evident that the plots of this function along different lines on the $\mathbf{q}$-plane, for example along one of axes (say, $q_{x}$ ) and along a diagonal of the $1^{\text {st }}$ Brillouin zone (say, $q_{x}=q_{y}$ ) give different curves, qualitatively similar to those of silicon (Fig. 13). The latter structure is complicated by the fact that the primitive cell of their Bravais lattices contains more than 2 atoms - see Fig. 11c and its discussion. In this case, even the tight-binding picture becomes more complex. Indeed, even if the atoms in the different positions of the primitive unit cell are similar (as they are, for example, in both graphene and silicon), and hence the potential well shape near those points and the corresponding local wavefunctions $u(\mathbf{r})$ are similar as well, the Bloch theorem (which only pertains to Bravais lattices!) does not forbid them to have different complex amplitudes $a(t)$ whose time evolution should be described by a specific differential equation.

For example, in order to describe the honeycomb lattice shown in Fig. 11a, we have to prescribe different amplitudes to the "top" and "bottom" points of its primitive cell - say, $\alpha$ and $\beta$, correspondingly. Since each of these points is surrounded (and hence weakly interacts) with 3 neighbors of the opposite type, instead of Eq. (117) we have to write two equations

$$
\begin{equation*}
i \hbar \frac{d \alpha}{d t}=-\delta_{n} \sum_{j=1}^{3} \beta_{j}, \quad i \hbar \frac{d \beta}{d t}=-\delta_{n} \sum_{j^{\prime}=1}^{3} \alpha_{j^{\prime}} \tag{3.119}
\end{equation*}
$$

where each summation is over 3 next-neighbor points. (I am using different summation indices just to emphasize that these directions are different for the "top" and "bottom" points of the primitive cell - see Fig. 11a.) Now using the Bloch theorem (107) in the form similar to Eq. (2.205), we get two coupled systems of linear algebraic equations:

$$
\begin{equation*}
\left(E-E_{n}\right) \alpha=-\delta_{n} \beta \sum_{j=1}^{3} e^{i \mathbf{q} \cdot \mathbf{r}_{j}}, \quad\left(E-E_{n}\right) \beta=-\delta_{n} \alpha \sum_{j^{\prime}=1}^{3} e^{i \mathbf{q} \cdot \mathbf{r}_{j^{\prime}}^{\prime}}, \tag{3.120}
\end{equation*}
$$

where $\mathbf{r}_{j}$ and $\mathbf{r}^{\prime}{ }_{j}$, are the next-neighbor positions, as seen from the top and bottom points, respectively. Writing the condition of consistency of this system, we get two equal and opposite values for energy correction for each value of $\mathbf{q}$ :

$$
\begin{equation*}
E_{ \pm}=E_{n} \pm \delta_{n} \Sigma^{1 / 2}, \quad \text { where } \Sigma \equiv \sum_{j, j^{\prime}=1}^{3} e^{i \mathbf{q} \cdot\left(\mathbf{r}_{j}+\mathbf{r}_{j^{\prime}}^{\prime}\right)} \tag{3.121}
\end{equation*}
$$

According to Eq. (120), these two energy bands correspond to the phase shifts (on the top of the regular Bloch shift $\mathbf{q} \cdot \Delta \mathbf{r}$ ) of either 0 or $\pi$ between the adjacent quasi-localized wavefunctions $u(\mathbf{r})$.

The most interesting corollary of such energy symmetry, augmented by the honeycomb lattice symmetry, is that for certain values $\mathbf{q}_{\mathrm{D}}$ of vector $\mathbf{q}$ (that turn out to be in each of 6 corners of the honeycomb-shaped $1^{\text {st }}$ Brillouin zone), the double sum $\Sigma$ vanishes, i.e. the two band surfaces $E_{ \pm}(\mathbf{q})$ touch each other. As a result, in vicinities of these Dirac points ${ }^{45}$ the dispersion relation is linear:

$$
\begin{equation*}
\left.E_{ \pm}\right|_{\mathbf{q} \approx \mathbf{q}_{\mathrm{D}}} \approx E_{n} \pm \hbar v_{n}|\widetilde{\mathbf{q}}|, \quad \text { where } \widetilde{\mathbf{q}} \equiv \mathbf{q}-\mathbf{q}_{\mathrm{D}} \tag{3.122}
\end{equation*}
$$

with $v_{n} \propto \delta_{n}$ being a constant with the dimension of velocity (for graphene, close to $10^{6} \mathrm{~m} / \mathrm{s}$ ). Such a linear dispersion relation ensures several interesting transport properties of graphene. For their discussion, I have to refer the reader to special literature. ${ }^{46}$

### 3.5. Axially-symmetric systems

I cannot conclude this chapter (and hence our review of wave mechanics) without addressing the issue of eigenstates and eigenvalues at full confinement in multi-dimensional potentials $U(\mathbf{r})$. For an arbitrary potential, the stationary Schrödinger equation does not have an analytical solution, but a substantial symmetry of function $U(\mathbf{r})$ may make such solution possible. This pertains, in particular, to the axial symmetry in 2D problems and the spherical symmetry in 3D problems, which are typical for several important situations (or their reasonable models), especially in atomic and nuclear physics.

In rare cases such symmetry may be exploited by the separation of variables in Cartesian coordinates. The most famous example is the $d$-dimensional harmonic oscillator, i.e. a particle moving inside the potential

$$
\begin{equation*}
U=\frac{m \omega_{0}^{2}}{2} \sum_{j=1}^{d} r_{j}^{2} . \tag{3.123}
\end{equation*}
$$

Separating the variables exactly as we did for the rectangular quantum well (see Sec. 1.5), for each degree of freedom we get the Schrödinger equation (2.268) of a 1D oscillator, whose eigenfunctions are given by Eq. (2.278), and the energy spectrum is described by Eq. (2.114). As a result, the total energy spectrum may be indexed by a vector $\mathbf{n}=\left\{n_{1}, n_{2}, \ldots, n_{d}\right\}$ of $d$ independent integers (quantum numbers):

$$
\begin{equation*}
E_{\mathbf{n}}=\hbar \omega_{0}\left(\sum_{j=1}^{d} n_{j}+\frac{d}{2}\right), \tag{3.124}
\end{equation*}
$$

[^556]all of them ranging from 0 to $\infty$. Note that every energy level of this system, with the only exception of the ground state,
\[

$$
\begin{equation*}
\psi_{g}=\prod_{j=1}^{d} \psi_{0}\left(r_{j}\right)=\frac{1}{\pi^{d / 4} x_{0}^{d / 2}} \exp \left\{-\frac{1}{2 x_{0}^{2}} \sum_{j=1}^{d} r_{j}^{2}\right\}, \tag{3.125}
\end{equation*}
$$

\]

is degenerate: several different wavefunctions, each with its own different set of quantum numbers $n_{j}$, but the same value of their sum, have the same energy.

However, the harmonic oscillator problem is an exception: for other central- and sphericallysymmetric problems the solution is made easier by using more appropriate coordinates. Let us start with the simplest axially-symmetric problem: the so-called planar rigid rotator (or "rotor"), i.e. a particle constrained (confined) to move along a plane, round circle of radius $R$ (Fig. 15). ${ }^{47}$

Fig. 3.16. Planar rigid rotator.

The planar rotator has just one degree of freedom, say the displacement arc $l=R \varphi$. So, its classical energy (and Hamiltonian function) is $H=p_{l}^{2} / 2 m, p_{l} \equiv m v=m(d l / d t)$. This function is similar to that of a free 1D particle (with the replacement $x \rightarrow l$ ), and hence rotator's quantum properties may be described by a similar Hamiltonian operator:

$$
\begin{equation*}
\hat{H}=\frac{\hat{p}^{2}}{2 m}, \quad \text { with } \quad \hat{p}=-i \hbar \frac{\partial}{\partial l} \tag{3.126}
\end{equation*}
$$

and its eigenfunctions have a similar structure:

$$
\begin{equation*}
\psi=C e^{i k l} \tag{3.127}
\end{equation*}
$$

The "only" new feature is that in the rotator, all observables should be $2 \pi R$-periodic functions of $l$, and hence, as we have already discussed in the context of the magnetic flux quantization (see Fig. 4 and its discussion), as the particle makes one turn about the center, its wavefunction's phase $k l$ may only change by $2 \pi n$, with an arbitrary integer $n$ (from $-\infty$ to $+\infty$ ),:

$$
\begin{equation*}
\psi_{n}(l+2 \pi R)=\psi_{n}(l) e^{2 \pi i n} . \tag{3.128}
\end{equation*}
$$

With eigenfunctions (127), this immediately gives condition gives $k 2 \pi R=2 \pi n$. Thus, wavenumber $k$ can take only quantized values $k_{n}=n / R$, so that the eigenfunctions should be indexed by $n$ :

$$
\begin{equation*}
\psi_{n}=C_{n} \exp \left\{i n \frac{l}{R}\right\} \tag{3.129}
\end{equation*}
$$

[^557]and the energy spectrum is discrete:
\[

$$
\begin{equation*}
E_{n}=\frac{p_{n}^{2}}{2 m}=\frac{\hbar^{2} k_{n}^{2}}{2 m}=\frac{\hbar^{2} n^{2}}{2 m R^{2}} . \tag{3.130}
\end{equation*}
$$

\]

So, while the free translation motion of a quantum particle is continuous, in the sense that its momentum has a continuous spectrum, its rotation is quantized - the most important fact, which has so many implications (including the existence of atoms, molecules, and hence us humans, and hence science including this course :-).

This simple model allows an exact analysis of external magnetic field effects on a quantumconfined motion of an electrically charged particle. Indeed, if this field is uniform and directed perpendicular to rotator's plane, it does not violate the axial symmetry of the system. According to Eq. (26), in this case we have to generalize Eq. (126) as

$$
\hat{H}=\frac{1}{2 m}\left(-i \hbar \mathbf{n}_{\varphi} \frac{\partial}{\partial l}-q \mathbf{A}\right)^{2} .
$$

Here, in contrast to the gauge choice (44), which was so instrumental in the Landau level problem, it is now clearly beneficial to take the vector-potential in a manifestly axially-symmetric form $\mathbf{A}=A(\rho) \mathbf{n}_{\varphi}$, where $\rho \equiv\{x, y\}$ is the 2D radius-vector. Using the well-known expression for curl in cylindrical coordinates, ${ }^{48}$ we can readily check that the requirement $\nabla \times \mathbf{A}=\mathcal{B}_{z}$, with $\mathcal{B}=$ const, is satisfied by the following function:

$$
\begin{equation*}
\mathbf{A}=\mathbf{n}_{\varphi} \frac{B \rho}{2} . \tag{3.132}
\end{equation*}
$$

For the planar rotator, $\rho=R=$ const, so that the stationary Schrödinger equation becomes

$$
\begin{equation*}
\frac{1}{2 m}\left(-i \hbar \frac{\partial}{\partial l}-q \frac{B R}{2}\right)^{2} \psi_{n}=E_{n} \psi_{n} . \tag{3.133}
\end{equation*}
$$

A little bit surprisingly, this equation is still satisfied with the sine-wave eigenfunctions (127). Moreover, since the periodicity condition (128) is also unaffected by the applied magnetic field, we return to field-independent eigenfunctions (129). However, the field does affect the system's energy:

$$
\begin{equation*}
E_{n}=\frac{1}{2 m}\left(\frac{\hbar n}{R}-q \frac{B R}{2}\right)^{2}=\frac{\hbar^{2}}{2 m R^{2}}\left(n-\frac{\Phi}{\Phi_{0}^{\prime}}\right)^{2} \tag{3.134}
\end{equation*}
$$

where $\Phi \equiv \pi R^{2} \mathcal{B}$ is the magnetic flux through the area limited by the particle's trajectory, and $\Phi_{0}{ }^{\prime} \equiv$ $2 \pi \hbar / q$ is the "normal" magnetic flux quantum we have already met in the AB effect context - see Eq. (34) and its discussion. The field also changes the electric current of the particle in $n$-th state:

$$
\begin{equation*}
I_{n}=q \frac{\hbar}{2 i m}\left[\psi_{n}^{*}\left(\frac{\partial}{\partial l}-\frac{i q R \mathcal{B}}{2 \hbar}\right) \psi_{n}-\text { c.c. }\right]=q \frac{\hbar}{m R}\left|C_{n}\right|^{2}\left(n-\frac{\Phi}{\Phi_{0}{ }^{\prime}}\right) . \tag{3.135}
\end{equation*}
$$

Normalizing wavefunction (129) to have $W_{n}=1$, we get $\left|C_{n}\right|^{2}=1 / 2 \pi R$, so that Eq. (135) becomes

[^558]\[

$$
\begin{equation*}
I_{n}=I_{0}\left(n-\frac{\Phi}{\Phi_{0}^{\prime}}\right), \quad \text { with } I_{0} \equiv \frac{\hbar q}{2 \pi m R^{2}} \tag{3.136}
\end{equation*}
$$

\]

Functions $E_{n}(\Phi)$ and $I_{n}(\Phi)$ are shown in Fig. 17. Note that since $\Phi_{0}{ }^{\prime} \propto 1 / q$, for any sign of the particle's charge, $d I_{n} / d \Phi<0$. It is easy to check that this means that the current is diamagnetic, ${ }^{49}$ i.e. corresponds to the Lenz rule of the Faraday's electromagnetic induction: the field-induced current flows in such direction that its own magnetic field tries to compensate the external magnetic flux applied to the loop.

Fig. 3.17. Effect of magnetic field on a charged planar rotator. Dashed lines show possible inelastic transitions between metastable and ground states, due to weak interaction with environment, as the magnetic field is being increased.

This result may be interpreted as a different implementation of the AB effect. ${ }^{50}$ In contrast to the two-slit interference experiment that was discussed in Sec. 1, in the situation shown in Fig. 17 the particle is not absorbed by the detector, but travels around the ring continuously. As a result, its wavefunction is rigid: due to the boundary condition (128), the topological quantum number $n$ is discrete, and magnetic field cannot change the wavefunction gradually. In this sense, the system is similar to a superconducting loop - see Fig. 4 and its discussion. The difference between these systems is two-fold:
(i) For a single charged particle, in a macroscopic systems with practicable values of $q, R$, and $m$, the current scale $I_{0}$ is very small. For example, for $m=m_{e}, q=-e$, and $R=1 \mu \mathrm{~m}$, Eq. (136) yields $I_{0} \approx 3$ pA. ${ }^{51}$ The contribution $L I \sim \mu_{0} R I_{0} \sim 10^{-24} \mathrm{~Wb}$ of the current so small into the net magnetic flux is

[^559]negligible in comparison with $\Phi_{0}{ }^{\prime} \sim 10^{-15} \mathrm{~Wb}$, so that the quantization of $n$ does not lead to the magnetic flux quantization.
(ii) As soon as the magnetic field raises the eigenstate energy $E_{n}$ above that of another eigenstate $E_{n}$, the former state becomes metastable, and weak interactions of the system with its environment (which are neglected in our simple model) may induce a quantum transition of the system to the lowerenergy state, thus reducing the diamagnetic current's magnitude - see the dashed lines in Fig. 17. The flux quantization in superconductors is much more robust to such perturbations. ${ }^{52}$

Now let us return, for one more time, to Eq. (129), and see what do they give for one more observable, particle's angular momentum

$$
\begin{equation*}
\mathbf{L} \equiv \mathbf{r} \times \mathbf{p} \tag{3.137}
\end{equation*}
$$

In our current problem, vector $\mathbf{L}$ has just one component perpendicular to the rotator plane,

$$
\begin{equation*}
L_{z}=R p . \tag{3.138}
\end{equation*}
$$

In classical mechanics, $L_{z}$ of the rotator should be conserved (due to the absence of external torque), but can take arbitrary values. In quantum mechanics the situation changes: with $p=\hbar k$, our result $k_{n}=n / R$ may be rewritten as

$$
\begin{equation*}
L_{z}=\left(L_{z}\right)_{n}=R \hbar k_{n}=\hbar n \tag{3.139}
\end{equation*}
$$

Thus, the angular momentum is quantized: it may be only a multiple of the Planck constant $\hbar-$ confirming Bohr's guess - see Eq. (1.10). As we will see in Chapter 5, this result is very general (though may be modified by spin effects) and that wavefunctions (129) may be interpreted as eigenfunctions of the angular momentum operator.

In order to implement the planar rotator in our 3D world, we needed to provide rigid confinement of the particle both in the motion plane, and along radius $\rho$. Let us proceed to the more general problem when only the former confinement is strict, i.e. to a 2 D particle moving in an arbitrary centrally-symmetric potential

$$
\begin{equation*}
U(\boldsymbol{p})=U(\rho) \tag{3.140}
\end{equation*}
$$

Using the well-known expression for the 2D Laplace operator in polar coordinates, ${ }^{53}$ we may present the 2D stationary Schrödinger equation in the form

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m}\left[\frac{1}{\rho} \frac{\partial}{\partial \rho}\left(\rho \frac{\partial}{\partial \rho}\right)+\frac{1}{\rho^{2}} \frac{\partial^{2}}{\partial \varphi^{2}}\right] \psi+U(\rho) \psi=E \psi . \tag{3.141}
\end{equation*}
$$

Separating the radial and angular variables as ${ }^{54}$
dephasing effects of electron scattering by phonons and other electrons, the effect's observation requires submicron samples and millikelvin temperatures.
${ }^{52}$ Interrupting a superconducting ring with a weak link (Josephson junction), i.e. forming a SQUID, we may get the switching behavior similar to that shown with dashed arrows in Fig. 17 - see, e.g., EM Sec. 6.3.
${ }^{53}$ See, e.g., MA Eq. (10.3) with $\partial / \partial z=0$.
${ }^{54}$ At this stage, I do not want to mark the particular solution (eigenfunction) $\psi$ and corresponding eigenenergy $E$ by any index, because we already may suspect that in a 2 D problem the role of this index will be played by two integers - two quantum numbers.

$$
\begin{equation*}
\psi=R(\rho) F(\varphi), \tag{3.142}
\end{equation*}
$$

we get，after the division by $\psi$ and multiplication by $\rho^{2}$ ，the following equation：

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m}\left[\frac{\rho}{R} \frac{d}{d \rho}\left(\rho \frac{d R}{d \rho}\right)+\frac{1}{F} \frac{d^{2} F}{d \varphi^{2}}\right]+\rho^{2} U(\rho)=\rho^{2} E . \tag{3.143}
\end{equation*}
$$

It is clear that the fraction $\left(d^{2} F / d \varphi^{2}\right) / F$ should be a constant（because all other terms of the equation may be only functions of $\rho$ alone），so that we get for function $F(\varphi)$ an ordinary differential equation，

$$
\begin{equation*}
\frac{d^{2} F}{d \varphi^{2}}+v^{2} F=0, \tag{3.144}
\end{equation*}
$$

where $v^{2}$ is the variable separation constant．The fundamental solution of Eq．（144）is evidently $F \propto$ $\exp \{ \pm i v \varphi\}$ ．Now requiring，as we did for the planar rotator，the $2 \pi$ periodicity of any observable，i．e．

$$
\begin{equation*}
F(\varphi+2 \pi)=F(\varphi) e^{2 \pi i n} \tag{3.145}
\end{equation*}
$$

so that constant $v$ has to be integer（say，$n$ ），and we can write：${ }^{55}$

$$
\begin{equation*}
F_{n}=C_{n} e^{i n \varphi}, \tag{3.146}
\end{equation*}
$$

Plugging the resulting relation $\left(d^{2} F / d \varphi^{2}\right) / F=-n^{2}$ into Eq．（143），we may rewrite is as

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m}\left[\frac{1}{\rho 尺} \frac{d}{d \rho}\left(\rho \frac{d 尺}{d \rho}\right)-\frac{n^{2}}{\rho^{2}}\right]+U(\rho)=E . \tag{3.147}
\end{equation*}
$$

The physical interpretation of this equation is that the full energy is a sum，

$$
\begin{equation*}
E=E_{\rho}+E_{\varphi}, \tag{3.148}
\end{equation*}
$$

of the radial－motion part

$$
\begin{equation*}
E_{\rho}=-\frac{\hbar^{2}}{2 m} \frac{1}{\rho} \frac{d}{d \rho}\left(\rho \frac{d 尺}{d \rho}\right)+U(\rho) \tag{3.149}
\end{equation*}
$$

and the angular－motion part

$$
\begin{equation*}
E_{\varphi}=\frac{\hbar^{2} n^{2}}{2 m \rho^{2}} . \tag{3.150}
\end{equation*}
$$

Now let us notice that a similar separation exists in classical mechanics，${ }^{56}$ because the total energy of a particle moving in a central field may be presented，within the plane of motion，as

$$
\begin{equation*}
E=\frac{m}{2} v^{2}+U(\rho)=\frac{m}{2}\left(\dot{\rho}^{2}+\rho^{2} \dot{\varphi}^{2}\right)+U(\rho)=E_{\rho}+E_{\varphi} \tag{3.151}
\end{equation*}
$$

where

[^560]\[

$$
\begin{equation*}
E_{\rho} \equiv \frac{p_{\rho}^{2}}{2 m}+U(\rho), \quad E_{\varphi} \equiv \frac{L_{z}^{2}}{2 m \rho^{2}} . \tag{3.152}
\end{equation*}
$$

\]

The comparison of the latter relation with Eqs. (139) and (150) gives us grounds to suspect that the quantization rule $L_{z}=n \hbar$ may be valid for this problem as well, and may be in other cases as well. In Sec. 5.6 , we will see that this is indeed the case.

Returning to Eq. (147), on the basis of our experience with 1D wave mechanics we may expect that this ordinary, linear, second-order differential equation should have (for a motion confined to a certain final region of its argument $\rho$ ), for any fixed $n$, a discrete energy spectrum described by some other integer quantum number (say, $l$ ). This means that eigenfunctions (142), and corresponding eigenenergies (148) should be indexed by two quantum numbers. Note, however, that since the radial function obeys equation (147), which already depends on $n$, function X $\rho$ ) should carry both indices, so the variable separation is not so "clean" as it was for the rectangular quantum well. Normalizing the angular function to the full circle, $\Delta \varphi=2 \pi$, we may rewrite Eq. (142) as

$$
\begin{equation*}
\psi_{n, l}=R_{n, l}(\rho) F_{n}(\varphi)=\frac{1}{(2 \pi) 1 / 2} R_{n, l}(\rho) e^{i n \varphi} . \tag{3.153}
\end{equation*}
$$

A good (and important) example of a solvable problem of this type is a free 2D particle whose motion is rigidly confined to a disk of radius $R$ :

$$
U(\rho)=\left\{\begin{array}{l}
0, \quad \text { for } 0 \leq \rho<R  \tag{3.154}\\
+\infty, \quad \text { for } R<\rho
\end{array}\right.
$$

In this case, the solutions $\mathbb{R}_{n, l}(\rho)$ of Eq. (147) are proportional to the first-order Bessel functions $J_{n}\left(k_{l} \rho\right),{ }^{57}$ and the spectrum of possible values of parameter $k_{l}$ should found the boundary condition $R_{n, l}(R)=0$. Let me leave the detailed solution and analysis of this problem for reader's exercise.

### 3.6. Spherically-symmetric systems: Brute force approach

Now let us address the (mathematically more involved) case of 3D motion, with sphericallysymmetric potential

$$
\begin{equation*}
U(\mathbf{r})=U(r) . \tag{3.155}
\end{equation*}
$$

Let me start, again, with a rigid rotator - now a spherical rotator, i.e. a particle confined to move on the surface of a sphere of radius $R$. It has 2 degrees of freedom, because any position on the spherical surface is completely described by two coordinates - say, the polar angle $\theta$ and the azimuthal angle $\varphi$. In this case, the kinetic energy we need to consider is limited to its angular part, so that in the Laplace operator in spherical coordinates ${ }^{58}$ we may keep only those parts, with fixed $r=R$. Then the stationary Schrödinger equation becomes

[^561]\[

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m R^{2}}\left[\frac{1}{\sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial}{\partial \theta}\right)+\frac{1}{\sin ^{2} \theta} \frac{\partial^{2}}{\partial \varphi^{2}}\right] \psi=E \psi \tag{3.156}
\end{equation*}
$$

\]

(Again, I abstain from attaching any indices to $\psi$ and $E$ for the time being.) With the usual variable separation assumption,

$$
\begin{equation*}
\psi=\Theta(\theta) F(\varphi) \tag{3.157}
\end{equation*}
$$

Eq. (156), with all terms multiplied by $\sin ^{2} \theta / \Theta F$, yields

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m R^{2}}\left[\frac{\sin \theta}{\Theta} \frac{d}{d \theta}\left(\sin \theta \frac{d \Theta}{d \theta}\right)+\frac{1}{F} \frac{d^{2} F}{d^{2} \varphi}\right]=E \sin ^{2} \theta \tag{3.158}
\end{equation*}
$$

Just as in Eq. (143), fraction $\left(d^{2} F / d x^{2}\right) / F$ may be a function of $\varphi$ only, and hence has to be constant, giving for it an equation similar to Eq. (144). So, the azimuthal functions are just the sine waves (146) again, and we can use the same periodicity condition (145) to write them in the normalized form ${ }^{59}$

$$
\begin{equation*}
F_{m}(\varphi)=\frac{1}{(2 \pi)^{1 / 2}} e^{i m \varphi} \tag{3.159}
\end{equation*}
$$

With that, fraction $\left(d^{2} F / d \varphi^{2}\right) / F$ equals $\left(-m^{2}\right)$, and Eq. (158), after multiplication by $\Theta / \sin ^{2} \theta$, is reduced to the following ordinary, linear differential equation for function $\Theta(\theta)$ :

$$
\begin{equation*}
-\frac{1}{\sin \theta} \frac{d}{d \theta}\left(\sin \theta \frac{d \Theta}{d \theta}\right)+\frac{m^{2}}{\sin ^{2} \theta} \Theta=\varepsilon \Theta, \quad \text { with } \quad \varepsilon \equiv E /\left(\frac{\hbar^{2}}{2 m R^{2}}\right), \tag{3.160}
\end{equation*}
$$

It is convenient to recast it into an equation for a new variable $P(\xi) \equiv \Theta(\theta)$, with $\xi \equiv \cos \theta$ :

$$
\begin{equation*}
\frac{d}{d \xi}\left[\left(1-\xi^{2}\right) \frac{d P}{d \xi}\right]+\left[l(l+1)-\frac{m^{2}}{1-\xi^{2}}\right] P=0 \tag{3.161}
\end{equation*}
$$

where a new notation for the normalized energy is introduced: $l(l+1) \equiv \varepsilon$. The motivation for such notation is that, according to a mathematical analysis, ${ }^{60}$ Eq. (161) with integer $m$, has solutions only if parameter $l$ is integer: $l=0,1,2, \ldots$, and only if that integer is not smaller than $|m|$, i.e. if

$$
\begin{equation*}
-l \leq m \leq+l . \tag{3.162}
\end{equation*}
$$

This immediately gives the following energy spectrum of the spherical rotator:

$$
\begin{equation*}
E_{l}=\frac{\hbar^{2} l(l+1)}{2 m R^{2}} \tag{3.163}
\end{equation*}
$$

[^562]so that the only effect of the magnetic quantum number $m$ here is imposing the restriction (162) on the orbital quantum number $l$. This means, in particular, that each of energy level (163) corresponds to ( $2 l+$ 1) different values of $m$, i.e. is $(2 l+1)$-degenerate.

To understand the physics of this degeneracy, we need to explore the corresponding eigenfunctions of Eq. (161). They are naturally numbered by two integers, $m$ and $l$, and are called the associated Legendre functions $P_{l}^{m}$. For the particular, simplest case $m=0$, these functions are just (Legendre) polynomials $P_{l}(\xi) \equiv P_{1}^{0}(\xi)$, which may be either defined as the solutions of the Legendre equation following from Eq. (161) at $m=0$ :

Legendre equation

$$
\begin{equation*}
\frac{d}{d \xi}\left[\left(1-\xi^{2}\right) \frac{d}{d \xi} P\right]+l(l+1) P=0 \tag{3.164}
\end{equation*}
$$

or calculated explicitly from the following Rodrigues formula: ${ }^{61}$

Rodrigues formula for Legendre polynomials

$$
\begin{equation*}
P_{l}(\xi)=\frac{1}{2^{l} l!} \frac{d^{l}}{d \xi^{l}}\left(\xi^{2}-1\right)^{l}, \quad l=0,1,2, \ldots \tag{3.165}
\end{equation*}
$$

Using this formula, it easy to spell out a few lowest Legendre polynomials:

$$
\begin{equation*}
P_{0}(\xi)=1, \quad P_{1}(\xi)=\xi, \quad P_{2}(\xi)=\frac{1}{2}\left(3 \xi^{2}-1\right), \quad P_{3}(\xi)=\frac{1}{2}\left(5 \xi^{3}-3 \xi\right), \ldots \tag{3.166}
\end{equation*}
$$

though such expressions become more and more bulky as $l$ is increased. As Fig. 18 shows, as argument $\xi$ is decreased, all these functions start in one point, $P_{l}(+1)=+1$, and end up either in the same point or in the opposite point: $P_{l}(-1)=(-1)^{l}$. On the way between these two end points, the $l^{\text {th }}$ polynomial crosses the horizontal axis exactly $l$ times, i.e. has $l$ roots. ${ }^{62}$ It may be shown that on the segment $[-1,+1]$, the Lagrange polynomials form a full orthogonal set of functions, with the following normalization rule:

$$
\begin{equation*}
\int_{-1}^{+1} P_{l}(\xi) P_{l^{\prime}}(\xi) d \xi=\frac{2}{2 l+1} \delta_{l l^{\prime}} . \tag{3.167}
\end{equation*}
$$

Fig. 3.18. A few lowest Legendre polynomials.

[^563]For $m>0$, the associated Legendre functions may be expressed via the Legendre polynomials (165) using the following formula, which reminds Eq. (165):

$$
\begin{equation*}
P_{l}^{m}(\xi)=(-1)^{m}\left(1-\xi^{2}\right)^{m / 2} \frac{d^{m}}{d \xi^{m}} P_{l}(\xi), \tag{3.168}
\end{equation*}
$$

while if the index $m$ is negative, the following simple relation may be used:

$$
\begin{equation*}
P_{l}^{-m}(\xi)=(-1)^{m} \frac{(l-m)!}{(l+m)!} P_{l}^{m}(\xi) \tag{3.169}
\end{equation*}
$$

On the segment $\xi=[-1,+1]$, each set of the associated Legendre functions with fixed index $m$ forms a full orthogonal set, with the normalization relation,

$$
\begin{equation*}
\int_{-1}^{+1} P_{l}^{m}(\xi) P_{l^{\prime}}^{m}(\xi) d \xi=\frac{2}{2 l+1} \frac{(l+m)!}{(l-m)!} \delta_{l l^{\prime}} \tag{3.170}
\end{equation*}
$$

which is evidently a generalization of Eq. (167) for arbitrary $m$.
Since the difference between angles $\theta$ and $\varphi$ is to some extent artificial (caused by the arbitrary direction of the polar axis), physicists prefer to use not the functions $\Theta(\theta) \propto P_{l}^{m}(\cos \theta)$ and $F_{m}(\varphi) \propto$ $\exp \{i m \varphi\}$ separately, but their products (157), which are called spherical harmonics:

$$
\begin{equation*}
Y_{l}^{m}(\theta, \varphi) \equiv\left[\frac{(2 l+1)}{4 \pi} \frac{(l-m)!}{(l+m)!}\right]^{1 / 2} P_{l}^{m}(\cos \theta) e^{i m \varphi} \tag{3.171}
\end{equation*}
$$

The specific coefficient in Eq. (171) is chosen in a way to simplify the following two relations: the equation for negative $m$,

$$
\begin{equation*}
Y_{l}^{-m}(\theta, \varphi)=(-1)^{m}\left[Y_{l}^{m}(\theta, \varphi)\right]^{*}, \tag{3.172}
\end{equation*}
$$

and the normalization relation

$$
\begin{equation*}
\oint Y_{l}^{m}(\theta, \varphi)\left[Y_{l^{\prime}}^{m^{\prime}}(\theta, \varphi)\right]^{*} d \Omega=\delta_{l l} \delta_{m m^{\prime}}, \tag{3.173}
\end{equation*}
$$

with integration over the whole solid angle $4 \pi$. The last relation shows that the spherical harmonics form an orthonormal set of functions. This set is also full, so that any function defined on a sphere may be uniquely presented as a linear combination of $Y_{l}^{m}$.

Despite a somewhat intimidating formulas given above, they yield rather simple expressions for the lowest spherical harmonics:

$$
\begin{align*}
& l=0: \quad Y_{0}^{0}=(1 / 4 \pi)^{1 / 2}  \tag{3.174}\\
& l=1: \quad\left\{\begin{array}{l}
Y_{1}^{1}=-(3 / 8 \pi)^{1 / 2} \sin \theta e^{i \varphi} \\
Y_{1}^{0}=(3 / 4 \pi)^{1 / 2} \cos \theta \\
Y_{1}^{-1}=+(3 / 8 \pi)^{1 / 2} \sin \theta e^{-i \varphi}
\end{array}\right. \tag{3.175}
\end{align*}
$$

$$
l=2:\left\{\begin{array}{l}
Y_{2}^{2}=+(15 / 32 \pi)^{1 / 2} \sin ^{2} \theta e^{2 i \varphi}  \tag{3.176}\\
Y_{2}^{1}=-(15 / 8 \pi)^{1 / 2} \sin \theta \cos \theta e^{i \varphi}, \\
Y_{2}^{0}=(3 / 16 \pi)^{1 / 2}\left(3 \cos ^{2} \theta-1\right) \\
Y_{2}^{-1}=+(15 / 8 \pi)^{1 / 2} \sin \theta \cos \theta e^{-i \varphi} \\
Y_{2}^{-2}=-(15 / 32 \pi)^{1 / 2} \sin ^{2} \theta e^{-2 i \varphi}
\end{array}\right.
$$

It is important to understand the symmetry of these functions. Since spherical functions with $m \neq$ 0 are complex, the most popular way of their graphical representation is first to form their real combinations corresponding to two opposite values of $m,{ }^{63}$

$$
Y_{l m} \equiv \frac{1}{\sqrt{2}}\left[Y_{l}^{|m|}+\operatorname{sgn}(m)(-1)^{m} Y_{l}^{-|m|}\right] \propto \begin{cases}\cos m \varphi, & \text { for } m>0,  \tag{3.177}\\ \sin m \varphi, & \text { for } m<0,\end{cases}
$$

(for $m=0, Y_{l 0} \equiv Y_{l}^{0}$ ), and then plot the magnitude of these combinations in spherical coordinates as the distance from the origin, while using two colors to show their sign - see Fig. 19.

[^564]Let us starting from the simplest case $l=0$. According to Eq. (162), there could be only one such $s$ state, ${ }^{64}$ with $m=0$. The spherical harmonic corresponding to that state is just a constant, so that the wavefunction is uniformly distributed over the sphere. Since the functions does not have gradient in any direction, the kinetic energy (163) of the particle equals is zero.

For $l=1$, there could be 3 different $p$ states, with $m=-1,0$, and +1 . As the second row in Fig. 19 shows, these states are essentially identical in structure, and are just differently oriented in space, thus explaining the 3 -fold degeneracy of the kinetic energy - see Eq. (163). This is not quite true for 5 different $d$ states $(l=2)$, shown in the bottom row of Fig. 19, as well as states with higher $l$ : despite their equal energies, they differ not only by their special orientation. The states with $m=0$ have gradient only in the $\theta$ direction, while the states with the ultimate values of $m(m= \pm l)$ change only gradually (as $\left.\sin ^{l} \theta\right)$ in the polar direction, while oscillating in the azimuthal direction. The states with intermediate values of $m$ provide a crossover between these two extremes, oscillating in both directions, stronger and stronger in the direction of $\varphi$ as $|m|$ is increased. Still, the magnetic quantum number, surprisingly, does not affect the energy for any $l$. Another surprising feature of the spherical harmonics follows from the comparison of Eq. (163) with the second of classical relations (152). These expressions coincide if we interpret constant

$$
\begin{equation*}
L^{2} \equiv \hbar^{2} l(l+1), \tag{3.178}
\end{equation*}
$$

as the value of the full angular momentum squared $L^{2}=|\mathbf{L}|^{2}$ (including its both $\theta$ and $\varphi$ components) in the eigenstate with eigenfunction $Y_{l}^{m}$. On the other hand, the structure of the azimuthal component $F(\varphi)$ of the wavefunction is exactly the same as in 2D axially-symmetric problems, suggesting that Eq. (139) still gives correct values (in our new notation, $L_{z}=m \hbar$ ) for the $z$-component of the angular momentum. If this is so, why for any state with $l>0,\left(L_{z}\right)^{2}=m^{2} \hbar^{2} \leq l^{2} \hbar^{2}$ is less than $L^{2}=l(l+1) \hbar^{2}$ ? In other words, what prevents the angular momentum vector to be fully aligned with axis $z$ ?

Besides that issue, though the above analysis of the spherical rotator is formally (mathematically) complete, it is as unsatisfactory on the physics level as the harmonic oscillator analysis in Sec. 2.6. In particular, it does not explain the meaning of the extremely simple relations for eigenvalues of energy and angular momentum on the backdrop of rather complicated wavefunctions.

We will obtain natural answers to all these questions and concerns in Sec. 5.6, but now let us complete our survey of wave mechanics by extending it to 3D motion in an arbitrary sphericallysymmetric potential (155). In this case we have to use the full form of the Laplace operator in spherical coordinates. The variable separation procedure is an evident generalization of what we have done before, with the particular solution

$$
\begin{equation*}
\psi=R(\rho) \Theta(\theta) F(\varphi), \tag{3.179}
\end{equation*}
$$

whose substitution into the stationary Schrödinger equation yields

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m r^{2}}\left[\frac{1}{尺} \frac{d}{d r}\left(r^{2} \frac{d 尺}{d r}\right)+\frac{1}{\Theta} \frac{1}{\sin \theta} \frac{d}{d \theta}\left(\sin \theta \frac{d \Theta}{d \theta}\right)+\frac{1}{\sin ^{2} \theta} \frac{1}{F} \frac{d^{2} F}{d \varphi^{2}}\right]+U(r)=E . \tag{3.180}
\end{equation*}
$$

[^565]It is evident that the angular part（the two last terms in square brackets）separates from the radial part，and for the former part we get Eq．（156）again，with the only change，$R \rightarrow r$ ．This change does not affect the fact that the eigenfunctions of that equation are the spherical harmonics（171），and the angular eigenenergy is given by Eq．（163），again with the replacement $R \rightarrow r$ ．This means that for the radial function，Eq．（180）gives the following equation，

$$
\begin{equation*}
-\frac{\hbar^{2}}{2 m r^{2}}\left[\frac{1}{尺} \frac{d}{d r}\left(r^{2} \frac{d 尺}{d r}\right)-l(l+1)\right]+U(r)=E . \tag{3.181}
\end{equation*}
$$

Note that no information about the magnetic quantum number $m$ has not crept into the radial equation （besides establishing the limitation（162）for possible values of $l$ ），so that this equation depends only on the latter quantum number．

The radial equation becomes rather simple for $U(r)=0$ ，and may be used，for example，to solve the eigenproblem for the free 3D motion of a particle inside the sphere of radius $R$ ．Leaving that problem for the reader＇s exercise，I will proceed to the most important Bohr atom problem，i．e．of motion in the so－called attractive Coulomb potential ${ }^{65}$

Attractive Coulomb potential

$$
\begin{equation*}
U(r)=-\frac{C}{r}, \quad \text { with } C>0 \tag{3.182}
\end{equation*}
$$

The natural scales of $r$ and $E$ are，respectively，${ }^{66}$

$$
\begin{equation*}
r_{0} \equiv \frac{\hbar^{2}}{m C} \quad \text { and } E_{0} \equiv \frac{\hbar^{2}}{m r_{0}^{2}} \equiv m\left(\frac{C}{\hbar}\right)^{2} \tag{3.183}
\end{equation*}
$$

In the normalized units $\varepsilon \equiv E / E_{0}$ and $\xi \equiv r / r_{0}$ ，Eq．（181）looks simpler，

$$
\begin{equation*}
\frac{d^{2} 尺}{d \xi^{2}}+\frac{2}{\xi} \frac{d 尺}{d \xi}-l(l+1) R+2\left(\varepsilon+\frac{1}{\xi}\right) 尺=0 \tag{3.184}
\end{equation*}
$$

but unfortunately its eigenfunctions may be called elementary only in the most generous meaning of the word．With the adequate normalization，

$$
\begin{equation*}
\int_{0}^{\infty} \mathbb{R}_{n, l} \mathbb{R}_{n^{\prime}, l} r^{2} d r=\delta_{n n^{\prime}}, \tag{3.185}
\end{equation*}
$$

these（mutually orthogonal）functions may be presented as

[^566]\[

$$
\begin{equation*}
\mathrm{R}_{n, l}(r)=-\left\{\left(\frac{2}{n r_{0}}\right)^{3} \frac{(n-l-1)!}{2 n[(n+l)!]^{3}}\right\}^{1 / 2} \exp \left\{-\frac{r}{n r_{0}}\right\}\left(\frac{2 r}{n r_{0}}\right)^{l} L_{n-l-1}^{2 l+1}\left(\frac{2 r}{n r_{0}}\right) \tag{3.186}
\end{equation*}
$$

\]

Bohr

Here $L_{p}^{q}(\xi)$ are the so-called associated Laguerre polynomials, which may be calculated as

$$
\begin{equation*}
L_{p}^{q}(\xi)=(-1)^{q} \frac{d^{q}}{d \xi^{q}} L_{p+q}(\xi) \tag{3.187}
\end{equation*}
$$

Associated Laguerre polynomials
from simple Laguerre polynomials $L_{p}(\xi) \equiv L_{p}{ }^{0}(\xi) .{ }^{67}$ In turn, the easiest way to obtain $L_{p}(\xi)$ is to use the following Rodrigues formula: 68

$$
\begin{equation*}
L_{p}(\xi)=e^{\xi} \frac{d^{p}}{d \xi^{p}}\left(\xi^{p} e^{-\xi}\right) \tag{3.188}
\end{equation*}
$$

Notice that in contrast with the associated Legendre functions $P_{l}^{m}$ participating in spherical harmonics, $L_{p}{ }^{q}$ are just polynomials, and those with small indices $p$ and $q$ are indeed simple.

Returning to Eq. (186), we see that the natural quantization of the radial equation (184) has brought us a new quantum number (integer) $n$. In order to understand its range, we should notice that according to Eq. (188), the highest power of terms in polynomial $L_{p+q}$ is $(p+q)$, and hence, according to Eq. (187), that of $L_{p}{ }^{q}$ is $p$, so that of the highest power in the polynomial participating in Eq. (186) is ( $n$ $-l-1$ ). Since the power cannot be negative (to avoid the unphysical divergence of wavefunctions at $r$ $\rightarrow 0$ ), the radial quantum number $n$ has to obey the restriction $n \geq l+1$. Since $l$, as we already know, may take values $l=0,1,2, \ldots$, we may conclude that $n$ may only take values

$$
\begin{equation*}
n=1,2, \ldots \tag{3.189}
\end{equation*}
$$

What makes this relation important is the following, most surprising result of the theory: the eigenenergies corresponding to wavefunctions (179), which are indexed with 3 quantum numbers:

$$
\begin{equation*}
\psi_{n, l . m}=R_{n, l}(r) Y_{l}^{m}(\theta, \varphi), \tag{3.190}
\end{equation*}
$$

depend only on $n$ and agree with Bohr's formula (1.8):

$$
\begin{equation*}
E_{n}=-\frac{E_{0}}{2 n^{2}}=-\frac{1}{2 n^{2}} m\left(\frac{C}{\hbar}\right)^{2} \tag{3.191}
\end{equation*}
$$

Because of this reason, $n$ is usually called the principal quantum number, and the above relation between it and "more subordinate" $l$ is rewritten as

$$
\begin{equation*}
l \leq n-1 . \tag{3.192}
\end{equation*}
$$

Together with inequality (162), this gives us the most important hierarchy of the 3 quantum numbers involved in the problem:

$$
\begin{equation*}
1 \leq n \leq \infty \quad \Rightarrow \quad 0 \leq l \leq n-1 \quad \Rightarrow \quad-l \leq m \leq+l \tag{3.193}
\end{equation*}
$$

Bohr atom's quantum numbers

[^567]Taking into account the $(2 l+1)$-degeneracy related to the magnetic number $m$, and using the well-known formula for the arithmetic progression, ${ }^{69}$ we see that each energy level (191) has the following orbital degeneracy:

$$
\begin{equation*}
g=\sum_{l=0}^{n-1}(2 l+1)=2 \sum_{l=0}^{n-1} l+\sum_{l=0}^{n-1} 1=2 \frac{n(n-1)}{2}+n=n^{2} . \tag{3.194}
\end{equation*}
$$

Due to its importance for applications, let us spell out the quantum number hierarchy of a few lowestenergy states, using the traditional notation in which the value of $n$ is followed by the letter that denotes the value of $l$ :

$$
\begin{array}{cccc}
n=1: & l=0 & \text { (one } 1 s \text { state) } & m=0 . \\
n=2: & l=0 & \text { (one } 2 s \text { state) } & m=0, \\
& l=1 & \text { (three } 2 p \text { states) } & m=0, \pm 1 . \\
n=3: & l=0 & \text { (one } 3 s \text { state) } & m=0 \\
& l=1 & \text { (three } 3 p \text { states) } & m=0, \pm 1  \tag{3.197}\\
& l=2 & \text { (five } 3 d \text { states) } & m=0, \pm 1, \pm 2 .
\end{array}
$$

Figure 20 shows plots of the radial functions (186) of the listed states. The most important of them is of course the ground (1s) state with $n=1$ and hence $E=-E_{0} / 2$, whose radial function (186) is just

$$
\begin{equation*}
\mathrm{R}_{1,0}(r)=\frac{2}{r_{0}^{3 / 2}} e^{-r / r_{0}} \tag{3.198}
\end{equation*}
$$

and the angular distribution is uniform - see Eq. (174). The gap between the ground energy and the energy $E=-E_{0} / 8$ of the lowest excited states (with $n=2$ ) in a hydrogen atom (in which $E_{0}=E_{\mathrm{H}} \approx 27.2$ eV ) is as large as $\sim 10 \mathrm{eV}$, so that their thermal excitation requires temperatures as high as $\sim 10^{5} \mathrm{~K}$, and the overwhelming part of all hydrogen atoms in the visible Universe are in their ground state. Since atomic hydrogen makes up about $75 \%$ of the "normal" matter, we are very fortunate that such simple formulas as Eqs. (174) and (198) describe the atomic states most frequently met in Mother Nature! ${ }^{70}$

The radial functions of the next states, $2 s$ and $2 p$, are also not too complex:

$$
\begin{equation*}
R_{2,0}(r)=\frac{1}{\left(2 r_{0}\right)^{3 / 2}}\left(2-\frac{r}{r_{0}}\right) e^{-r / 2 r_{0}}, \quad R_{2,1}(r)=\frac{1}{\left(2 r_{0}\right)^{3 / 2}} \frac{r}{3^{1 / 2} r_{0}} e^{-r / 2 r_{0}} \tag{3.199}
\end{equation*}
$$

(Note again that the former of these states $(2 s)$ can only have a uniform angular distribution, while three $2 p$ states have different values of $m=0, \pm 1$, and hence have different angular distributions - see Eq. (175) and the second row of Fig. 19.) The most important trend here is a larger radius of decay of the exponent ( $2 r_{0}$ for $n=2$ instead of $r_{0}$ for $n=1$ ), and hence the radial extension of the states. This trend is confirmed by the following general formula: ${ }^{71}$

[^568]\[

$$
\begin{equation*}
\langle r\rangle_{n, l}=\frac{r_{0}}{2}\left[3 n^{2}-l(l+1)\right] . \tag{3.200}
\end{equation*}
$$

\]

The second important trend is that at fixed $n$, the orbital quantum number $l$ determines how fast does the wavefunction change with $r$ near the origin, and how much it oscillates in the radial direction at larger $r$. For example, the $2 s$ eigenfunction $\mathbb{R}_{2,0}(r)$ is nonvanishing at $r=0$, and makes one "wiggle" (has one root) in the radial direction, while eigenfunctions $2 p$ equal zero at $r=0$, and do not oscillate at all in the radial direction. Instead, those wavefunctions always oscillate as functions of some angle - see the second row of Fig. 19. The same trend in clearly visible for $n=3$ (see Fig. 20), and continues for the higher values of $n$.

Fig. 3.20. The lowest radial functions of the Bohr atom problem.

The interpretation of these results is that the states with $l=l_{\text {max }}=n-1$ may be viewed as analogs of the circular motion of a particle in a plane whose orientation defines the quantum number $m$, with an almost fixed radius $r \approx r_{0}\left(n^{2} \pm n\right)$. On the other hand, the best classical image of an $s$-state $(l=0)$ is the purely radial motion of the particle to and from the attracting center. (The latter image is especially imperfect, because the motion would need to happen simultaneously in all radial directions.) The classical language becomes reasonable only for the so-called Rydberg states, with $n \gg 1$, whose linear superpositions may be used to compose wave packets closely following the classical, circular or elliptic trajectories of the particle - just as was discussed in Sec. 2.2 for the free 1D motion.

Besides Eq. (200), mathematics gives us several other simple relations for the radial functions $R_{n, l}$ (and, since the spherical harmonics are normalized to 1 , for the eigenfunctions as the whole), including those that we will use later in the course: ${ }^{72}$

$$
\begin{equation*}
\left\langle\frac{1}{r}\right\rangle_{n, l}=\frac{1}{n^{2} r_{0}}, \quad\left\langle\frac{1}{r^{2}}\right\rangle_{n, l}=\frac{1}{n^{3}(l+1 / 2) r_{0}^{2}}, \quad\left\langle\frac{1}{r^{3}}\right\rangle_{n, l}=\frac{1}{n^{3} l(l+1 / 2)(l+1) r_{0}^{3}} . \tag{3.201}
\end{equation*}
$$

In particular, the first of them means that for any eigenfunction $\psi_{n, l, m}$, with all its complicated radial and angular dependencies, there is a simple relation between the potential and full energies:

$$
\begin{equation*}
\langle U\rangle_{n, l}=-C\left\langle\frac{1}{r}\right\rangle_{n, l}=-\frac{C}{n^{2} r_{0}}=-\frac{E_{0}}{n^{2}}=2 E_{n}, \tag{3.202}
\end{equation*}
$$

so that the average kinetic energy of the particle, $\langle T\rangle_{n, l}=E_{n}-\langle U\rangle_{n, l}$, is equal to $\left|E_{n}\right|>0$.
These simple results are in a sharp contrast with the rather complicated expressions for the eigenfunctions, and motivate a search for more general methods of quantum mechanics, which would replace or at least complement our brute-force (wave-mechanics) approach, to reveal their real nature. Such an approach will be the main topic of the next chapter.

### 3.7. Atoms

Before proceeding to that chapter, let me show that, rather strikingly, the classification of quantum numbers in the simple potential well (182), carried out in the last section, together with very modest borrowings from the further theory, allows an semi-quantitative explanation of the whole system of chemical elements. The "only" two additions we need are the following facts:
(i) due to interaction with relatively low-temperature environments, atoms tend to relax into their lowest-energy state, and
(ii) due to the Pauli principle (valid for electrons as Fermi particles), each orbital eigenstate discussed above can be occupied with 2 electrons with opposite spins.

Of course, atomic electrons do interact, so that their quantitative description requires quantum mechanics of multiparticle systems, which is rather complex. (Its main concepts will be discussed in Chapter 8.) However, the lion's share of this interaction reduces to simple electrostatic screening, i.e. the partial compensation of the electric charge of the atomic nucleus, as felt by a particular electron, by other electrons of the atom. This screening changes the qualitative results (such as the energy scale) dramatically; however, the quantum number hierarchy, and hence their classification, is not affected.

The system of atoms is most often presented as the famous periodic table of chemical elements, ${ }^{73}$ whose simple version is shown in Fig. 21, while Fig. 22 presents a sequential list of the elements with their electron configurations. The numbers in table's cells (and the first column in the list) are the

[^569]atomic numbers $Z$, which physically are the numbers of protons in the atomic nucleus, and hence the numbers of electrons in the electrically neutral atom. The electron configuration in Fig. 22 follows the convention already used in Eqs. (195)-(197), with the additional upper index showing the number of electrons with the indicated values of quantum numbers $n$ and $l$.

The lightest atom, with $Z=1$, is hydrogen (chemical symbol H ) - the only atom for each the theory discussed in Sec. 6 is quantitatively correct. ${ }^{74}$ According to Eq. (191), the $1 s$ ground state of its only electron corresponds to quantum numbers $n=1, l=0$, and $m=0$ - see Eq. (196). In most versions of the periodic table, the cell of H is placed in the top left corner. In the next atom, helium ( $\mathrm{He}, Z=2$ ), the same orbital quantum state $(1 s)$ is filled with two electrons with different spins. ${ }^{75}$ Note that due to the twice higher electric charge of the nucleus, i.e. the twice higher value of constant $C$ in Eq. (182), resulting in a 4 -fold increase of constant $E_{0}$ (183), the binding energy of each electron is crudely 4 times higher than that of the hydrogen atom - though the electron interaction decreases it by about $25 \%$ - see Sec. 7.2. This is why taking one electron away (i.e. positive ionization) of the helium atom requires a very high energy, 23.4 eV , which is not available in usual chemical reactions. On the other hand, a neural helium atom cannot bind one more electron (i.e. form a negative ion) either. As a result, helium, and all other elements with fully completed electron shells (sets of states with eigenenergies well separated from higher energy levels) is a chemically inert noble gas, thus starting the whole right-most column of the periodic table, committed to such elements.

Fig. 3.22. Atomic electron configurations. The upper index shows the number of electrons in states with the indicated quantum numbers $n$ (the first digit) and $l$ (letter-coded as listed above).

The situation changes dramatically as we move to the next element, lithium (Li), with $Z=3$ electrons. Two of them are still accommodated by the inner shell $n=1$ (listed in Fig. 22 as the helium shell $[\mathrm{He}])$, but the third one has to reside in the next shell with $n=2$ and $l=0$, i.e. in the $2 s$ state. According to Eq. (191), the binding energy of this electron is much lower, especially if we take into account that according to Eq. (200), the $1 s$ electrons of the [He] shell are much closer to the nucleus and almost completely compensate two thirds of its electric charge $+3 e$. As a result, the $2 s$ electron is reasonably well described by Eq. (199), with binding energy of just 5.39 eV , so that a lithium atom can give out that electron rather easily - to either atoms of other elements to form chemical compounds, or into the common conduction band of solid state lithium - and as a result it is a typical alkali metal. The similarity of chemical properties of lithium and hydrogen, with the chemical valence of one, ${ }^{76}$ places Li as the starting element of the second period (row), with the first period limited to only H and He .

In the next element, beryllium $(Z=4)$, the $2 s$ state $(n=2, l=0)$ picks up one more electron, with the opposite spin. Due to the higher electric charge of the nucleus, $Q=4 e$, with only half of it compensated by $1 s$ electrons of the [He] shell, the binding energy of the $2 s$ electrons is higher than in lithium, so that the ionization energy increases to 9.32 eV . As a result, beryllium is also chemically active but not as active as lithium, with the valence of two, and is also is metallic in its solid state phase, but does not conduct electric current as well as lithium.

Moving in this way along the second row of the periodic table (from $Z=3$ to $Z=10$ ), we see the gradual filling of all 4 different orbital states of the $n=2$ shell, by 2 electrons each, with gradually growing ionization potential (up to 21.6 eV in Ne with $Z=10$ ), i.e. the growing reluctance to have metallic conductance or form positive ions. However, the final elements of the row, such as oxygen (O, with $Z=8$ ) and especially fluorine ( F , with $Z=9$ ) can readily pick up extra electrons to fill their $2 p$ states, i.e. form negative ions. As a result, these elements are chemically active, with the double valence for oxygen and single valence for fluorine. However, the final element of this row, neon, has its $n=2$ shell full, and cannot form a stable negative ion. This is why it is a noble gas, like helium. Traditionally, in the periodic table it is placed right under helium (Fig. 21), to emphasize the similarity of their chemical and physical properties. But this necessitates making an at least 6 -cell gap in the $1^{\text {st }}$ row. (Actually, the gap is often made larger, to accommodate next rows - keep reading.)

Period 3, i.e. the $3^{\text {rd }}$ row of the table starts exactly like period 2 , with sodium ( Na , with $\mathrm{Z}=11$ ), also a chemically active alkali metal whose atom features 10 electrons filling shells with $n=1$ and $n=2$ (in Fig. 22 collectively called the neon shell, [Ne]), plus one electron in a $3 s$ state ( $n=3, l=0, m=0$ ), which may be reasonably well described by the hydrogen atom theory - see, e.g., the red trace on the last panel of Fig. 20. Naively we could expect that, according to Eq. (194), and with the account of double spin degeneracy, this period of the table should have $2 n^{2}=2 \times 3^{2}=18$ elements, with gradual filling of two $3 s$ states, six $3 p$ states, and ten $3 d$ states. However, here we run into a big surprise: after argon (Ar, with $Z=18$ ), a relatively inert element with ionization energy of 15.7 eV due to the fully filled $3 s$ and $3 p$ shells, the next element, potassium ( K , with $Z=19$ ) is an alkali metal again!

The reason for that is the difference of the actual electron energies from those of the hydrogen atom, which is due mostly to inter-electron interactions and gradually accumulates with the growth of $Z$. It may be semi-quantitatively understood from the results of Sec. 6. In hydrogen-like atoms, electron state energies do not depend on the quantum number $l$ (as well as $m$ ) - see Eq. (191). However, the

[^571]orbital quantum number does affect the wavefunction of an electron. As Fig. 20 shows, the larger $l$ the less the probability for an electron to be close to the nucleus, where its positive charge is less compensated by other electrons. As a result of this effect (and also the relativistic corrections to be discussed in Sec. 6.3), electron's energy grows with $l$. Actually, this effect was visible even in period 2: it manifests itself in the filling order ( $p$ states after $s$ states). However, for potassium ( K , with $\mathrm{Z}=19$ ) and calcium ( Ca , with $Z=20$ ), energies of $3 d$ states become so high that energies of two $4 s$ states (with opposite spins) are lower, and they are filled first. As described by factor 3 in the square brackets of Eq. (200), and also by Eq. (201), the effect of the principal number $n$ on the distance from the nucleus is stronger than that of $l<n$, so that $4 s$ wavefunctions of K and Ca are relatively far from the nucleus, and determine the chemical valence (equal to 1 and 2, correspondingly) of these elements. The next atoms, from $\mathrm{Sc}(Z=21)$ to $\mathrm{Zn}(Z=30)$, with the gradually filled "internal" $3 d$ states, are the so-called transition metals whose (comparable) ionization energies and chemical properties are determined by $4 s$ electrons.

This fact is the origin of the difference between various forms of the "periodic" table. In its most popular option, shown in Fig. 21, K is used to start the next, period 4, and then a new period is started each time and only when the first electron with the next principal quantum number ( $n$ ) appears. ${ }^{77}$ This topology provides a very clear mapping on the chemical properties of the first element of each period (an alkali metal), as well as its last element (a noble gas). This also automatically means making gaps in all previous rows. Usually, this gap is made between the atoms with completely filled $s$ states and with the first electron in a $p$ state, because here the properties of the elements make a somewhat larger step. (For example, the step from Be to B makes the material an insulator, but it is not large enough to make a similar difference between Mg to Al .) As a result, elements of the same column have approximately similar chemical valence and physical properties.

However, to accommodate longer lowest rows, such presentation is inconvenient, because the whole table would be too broad. This is why the so-called rare earths, including lanthanides (with $Z$ from 57 to 70 , of the $6^{\text {th }}$ row, with gradual filling of $4 f$ and $5 d$ states) and actinides ( Z from 89 to 103 , of the $7^{\text {th }}$ row, with gradual filling of $5 f$ and $6 d$ states), are presented as outlet lines (Fig. 21). This is quite acceptable for the purposes of standard chemistry, because chemical properties of elements within each group are rather close.

To summarize, the "periodic table of elements" is not periodic in the strict sense of the word. Nevertheless, it has had an enormous historic significance for chemistry, as well as atomic and solid state physics, and is still very convenient for many purposes. For our course, the most important aspect of its discussion is the surprising possibility to describe, at least for classification purposes, such a complex multi-electron system as an atom as a set of quasi-independent electrons in certain quantum states indexed with the same quantum numbers $n, l$, and $m$ as those of the hydrogen atom. This fact enables the use of various perturbation theories, which give more quantitative description of atomic properties. Some of these techniques will be reviewed in Chapters 6 and 8 of this course. ${ }^{78}$

[^572]
### 3.8. Exercise problems

3.1. A particle of energy $E$ is incident (in Fig. on the right, within the plane of drawing) on a sharp potential step:

$$
U(\mathbf{r})=\left\{\begin{array}{cc}
0, & \text { for } x<0 \\
U_{0}, & \text { for } 0<x .
\end{array}\right.
$$

Find the particle reflection probability $R$ as a function of the incidence angle $\theta$;
 sketch and discuss the function, for different magnitudes and signs of $U_{0}$.
3.2. Use the finite difference method with step $h=a / 2$ to calculate as many eigenenergies as possible, for a free particle confined to the interior of:
(i) a square with side $a$;
(ii) a cube with side $a$.

For the square, repeat the calculations, using a finer step: $h=a / 3$. Compare the results for different $h$, with the exact formula.

Hint: It is advisable to first solve (or review the solution of :-) the similar 1D problem in Chapter 1 , or start from reading about the finite difference method. ${ }^{79}$ Also, try to exploit problem's symmetry.
3.3. Use the variational method to estimate the ground state energy of a particle of mass $m$, moving in a spherically-symmetric potential

$$
U(\mathbf{r})=a r^{4} .
$$

3.4. In the classical version of the Landau level problem discussed in Sec. 2, the center of particle's orbit is an integral of motion, determined by initial conditions. Calculate the commutation relations between the quantum-mechanical operators corresponding to the Cartesian coordinates of the center, and to the sum of their squares.
3.5.* Analyze how are the Landau levels (3.50) modified by an additional constant electric field $\mathbf{E}$, directed along the particle plane. Contemplate the physical meaning of your result, and its implications for the quantum Hall effect in a gate-defined Hall bar. (The area $L \times W$ area of such a bar [see Fig. 3.6 of the lecture notes] is defined by metallic gate electrodes parallel to
 the 2D electron gas plane - see Fig. on the right. The negative voltage $V_{g}$, applied to the gates, chases the electrons gas out of the confinement plane at the remaining sample area.)
3.6. Analyze how are the Landau levels (50) modified if a 2D particle is confined in an additional 1D potential well $U(x)=m \omega_{0}{ }^{2} x^{2} / 2$

[^573]3.7. Find the eigenfunctions of a spinless, charged 3D particle moving in "crossed" (perpendicular), uniform electric and magnetic fields. For each eigenfunction, calculate the expectation value of particle's velocity in the direction perpendicular to both fields, and compare the result with the solution of the corresponding classical problem.

Hint: Generalize Landau's solution for 2D particles, discussed in Sec. 2.
3.8. Use the Born approximation to calculate the angular dependence and the full cross-section of scattering of an incident plane wave, propagating along axis $x$, by the following pair of point inhomogeneities:

$$
U(\mathbf{r})=W\left[\delta\left(\mathbf{r}-\mathbf{n}_{z} \frac{a}{2}\right)+\delta\left(\mathbf{r}+\mathbf{n}_{z} \frac{a}{2}\right)\right] .
$$

Analyze the results in detail. Derive the condition of the Born approximation's validity for such deltafunctional scatterers.
3.9. Use the Born approximation to calculate the differential and full cross-sections of a spherical scatterer:

$$
U(\mathbf{r})=\left\{\begin{array}{cc}
U_{0}, & \text { for } r<R \\
0, & \text { otherwise }
\end{array}\right.
$$

Analyze both results, especially the angular dependence of $d \sigma / d \Omega$, in detail, for $k R \ll 1$ and $k R \gg 1$.
3.10. Use the Born approximation to calculate differential and full cross-sections of electron scattering by a screened Coulomb field of a point charge $Z e$, with electrostatic potential

$$
\phi(\mathbf{r})=\frac{Z e}{4 \pi \varepsilon_{0} r} e^{-\lambda r}
$$

neglecting the spin interaction effects, and analyzed their dependence on the screening parameter $\lambda$. Compare the results with those given by the classical ("Rutherford") formula ${ }^{80}$ for the unscreened Coulomb potential ( $\lambda \rightarrow 0$ ), and formulate the condition of Born approximation's validity in this limit.
3.11. A quantum particle of mass $m$ with electric charge $Q$ is scattered by a localized distributed charge with a spherically-symmetric density $\rho(r)$ and zero total charge. Use the Born approximation to calculate the differential cross-section of forward scattering (with scattering angle $\theta=0$ ), and evaluate it for scattering of electrons by a hydrogen atom in its ground state.
3.12. Reformulate the Born approximation for the 1D case. Use the result to find the scattering and transfer matrices of a "rectangular" scatterer

$$
U(x)=\left\{\begin{aligned}
U_{0}, & \text { for }|x|<d / 2 \\
0, & \text { otherwise }
\end{aligned}\right.
$$

[^574]Compare the results with the those of the exact calculations carried out earlier in the course.
3.13. Use Eq. (88) to show that the Bragg rule for the diffraction wave maxima, $\mathbf{k}=\mathbf{k}_{0}+\mathbf{Q}$, where $\mathbf{Q}$ is any vector of the reciprocal lattice defined by Eq. (110), is valid not only for electromagnetic waves, but also for non-relativistic quantum particle scattering by a periodic (Bravais) lattice.
3.14. In the tight-binding approximation, calculate the eigenstates and eigenenergies of three similar, weakly coupled quantum wells located in the vertices of an equilateral triangle.
3.15. Figure on the right shows a fragment of a periodic 2D lattice, with open and solid points showing the location of different local potentials - say, different atoms.
(i) Find the reciprocal lattice and the $1^{\text {st }}$ Brillouin zone;
(ii) Find wave number $k$ of the monochromatic radiation incident along axis $x$, at which the lattice creates the first-order diffraction peak within the $[x, y]$ plane, and the direction towards this peak.

(iii) Semi-qualitatively, describe the evolution of the intensity of the peak if the local potentials represented by the open and solid points tend to each other.
3.16. For the 2D hexagonal lattice (Fig. 11b):
(i) find the reciprocal lattice $\mathbf{Q}$ and the $1^{\text {st }}$ Brillouin zone;
(ii) use the tight-binding approximation to calculate the dispersion relation $E(\mathbf{q})$ for a 2D particle moving in a potential with such periodicity, close to the eigenenergy of an axially-symmetric state quasi-localized at the potential minima;
(iii) analyze and sketch (or plot) the resulting dispersion relation $E(\mathbf{q})$ inside the $1^{\text {st }}$ Brillouin zone.
3.17. ${ }^{*}$ Complete the tight-binding approximation calculation of band structure of the honeycomb lattice, started in the end of Sec. 4. Analyze the results. Prove that the Dirac points $\mathbf{q}_{\mathrm{D}}$ are located in the corners of the $1^{\text {st }}$ Brillouin zone, and express the velocity $v_{n}$, participating in Eq. (122), in terms of the coupling energy $\delta_{n}$. Show that the final results do not change if the quasi-localized wavefunctions are not axially-symmetric, but are proportional to $\exp \{\operatorname{in} \varphi\}$ - as they are, with $n=1$, for the $2 p_{z}$ electrons of carbon atoms in graphene, which are responsible for its transport properties.
3.18. Examine basic properties of the so-called Wannier functions defined as

$$
\phi_{\mathbf{R}}(\mathbf{r})=\operatorname{const} \times \int_{B Z} \psi_{\mathbf{q}}(\mathbf{r}) e^{-i \mathbf{q} \cdot \mathbf{R}} d^{3} q
$$

where $\psi_{\mathbf{q}}(\mathbf{r})$ is the Bloch wavefunction (3.108), $\mathbf{R}$ is any vector of the Bravais lattice, and the integration over quasi-momentum $\mathbf{q}$ is extended over any (e.g., the first) Brillouin zone.
3.19. Evaluate the long-range electrostatic interaction (the so-called London dispersion force) between two similar, electrically-neutral but polarizable molecules, modeling them as isotropic 3D harmonic oscillators.

Hint: Using the classical expression for the interaction between two electric dipoles, ${ }^{81}$ try to present the total Hamiltonian of the system as a sum of Hamiltonians of several independent harmonic oscillators, and calculate their ground-state energy as a function of distance between the molecules.
3.20. Use the variable separation method to find expressions for the eigenfunctions and the corresponding eigenenergies of a free 2 D particle confined inside a thin round disk of radius $R$ :

$$
U=\left\{\begin{array}{l}
0, \quad \text { for } 0 \leq \rho<R, \\
+\infty, \quad \text { for } R<\rho,
\end{array}\right.
$$

where $\rho \equiv\{x, y, 0\}$. What is the level degeneracy? Calculate 5 lowest energy levels with accuracy better than $1 \%$.
3.21. Calculate the ground-state energy of a 2 D particle localized in a shallow flat-bottom potential well

$$
U(\rho)=\left\{\begin{array}{ll}
-U_{0}, & \text { for } \rho<R \\
0, & \text { for } \rho>R
\end{array}\right\}, \quad \text { with } 0<U_{0} \ll \frac{\hbar^{2}}{m R^{2}} .
$$

3.22. Spell out the explicit form of spherical harmonics $Y_{4}^{0}(\theta, \varphi)$ and $Y_{4}^{4}(\theta, \varphi)$.
3.23. Calculate $\langle x\rangle$ and $\left\langle x^{2}\right\rangle$ in the ground state of the planar and spherical rotators of radius $R$. What can you say about averages $\left\langle p_{x}\right\rangle$ and $\left\langle p_{x}{ }^{2}\right\rangle$ ?
3.24. According to the discussion in the beginning of Sec. 5, eigenfunctions of a 3D harmonic oscillator may be calculated as products of three 1D "Cartesian oscillators" - see, in particular Eq. (124), with $d=3$. However, according to the discussion in Sec. 3.6, wavefunctions of the type (190), proportional to spherical harmonics $Y_{l}^{m}$, are also eigenstates of this spherically-symmetric system. Represent:
(i) the ground state of the oscillator, and
(ii) each of its lowest excited states,
taken in the form (190), as linear combinations of products of 1D oscillator wavefunctions. Also, calculate the degeneracy of $n^{\text {th }}$ energy level of the oscillator.
3.25. A spherical rotator (with $r \equiv\left(x^{2}+y^{2}+z^{2}\right)^{1 / 2}=R=$ const) of mass $m$ is in the state with wavefunction

$$
\psi=\operatorname{const} \times\left(\frac{1}{3}+\sin ^{2} \theta\right)
$$

Calculate the system's energy.
3.26. ${ }^{*}$ Calculate the eigenfunctions and the energy spectrum of a 3 D particle free to move inside a sphere of radius $R$ :

[^575]\[

U=\left\{$$
\begin{array}{c}
0, \quad \text { for } 0 \leq r<R, \\
+\infty, \quad \text { for } R<r .
\end{array}
$$\right.
\]

Calculate 5 lowest energy levels with a $1 \%$ accuracy, and indicate the degeneracy of each level.
Hint: The solution of this problem requires the so-called spherical Bessel functions $j_{l}(\xi)$, whose description is available in most math handbooks. ${ }^{82}$
3.27. Find the smallest value of depth $U_{0}$ for that the spherical quantum well

$$
U=\left\{\begin{array}{c}
-U_{0}, \quad \text { for } r<R, \\
0, \quad \text { for } R<r,
\end{array}\right.
$$

has a bound (localized) eigenstate. Does such a state exist for a very narrow and deep well $U=-w \delta(\mathbf{r})$, with a positive and finite 20 .
3.28. Calculate the smallest value of depth $U_{0}$ for that the following spherically-symmetric quantum well,

$$
U(r)=-U_{0} e^{-r / R}, \quad \text { with } U_{0}, R>0
$$

has a bound (localized) eigenstate.
Hint: Try to introduce the following new variables: $f \equiv r \mathrm{R}$ and $\xi \equiv C e^{-r / 2 R}$, with an appropriate choice of constant $C$.
3.29. Calculate the lifetime of the lowest metastable state in the spherical-shell potential

$$
U(r)=w \delta(r-R), \quad \text { with } \quad w>0,
$$

in the limit of large $w$. Specify the limit of validity of your result.
3.30. Calculate the condition at which a particle of mass $m$, moving in the field of a very thin spherically-symmetric shell, with

$$
U(\mathbf{r})=-w \delta(r-R), \quad \text { with } w>0
$$

has at least one localized ("bound") stationary state. Compare the result with that for potential

$$
U_{0}(\mathbf{r})=-w_{0} \delta(\mathbf{r}), \quad \text { with } w_{0}>0
$$

Hint: Note that the first delta-function is one-dimensional, while the second one is threedimensional, so that parameters $w$ and $w_{0}$ have different dimensionalities.
3.31. A particle, moving in a central potential $U(r)$, with $U(r) \rightarrow 0$ at $r \rightarrow \infty$, has a stationary state with the following wavefunction:

$$
\psi=C r^{\alpha} e^{-\beta r} \cos \theta
$$

where $C, \alpha$, and $\beta$ are constants. Calculate:

[^576](i) probabilities of all possible values of quantum numbers $m$ and $l$,
(ii) the confining potential, and
(iii) state's energy.
3.32. Calculate the energy spectrum of a particle moving in a monotonic, but otherwise arbitrary attractive central potential $U(r)$, in the approximation of large orbital quantum numbers $l$. Formulate the quantitative condition(s) of validity of your theory. Check that for the Coulomb potential $U(r)=-C / r$, your result agrees with Eq. (191).
3.33. An electron had been in the ground state of a hydrogen-like atom/ion with nuclear charge $Z e$, when the charge suddenly changed to $(Z+1) e .{ }^{83}$ Calculate the probabilities for the electron of the changed system to be:
(i) in the ground state, and
(ii) in the lowest excited state.

Evaluate these probabilities for the particular case of the beta decay of tritium, with the formation of a single-positive ion of ${ }^{3} \mathrm{He}$.
3.34. Calculate $\left\langle x^{2}\right\rangle$ and $\left\langle p_{x}{ }^{2}\right\rangle$ in the ground state of a hydrogen-like atom. Compare the results with Heisenberg's uncertainty relation. What do these results tell about electron's velocity in the atom?
3.35. Apply to Eq. (181) the Hellmann-Feynman theorem (see Problem 1.4) to prove:
(i) the first of Eqs. (3.201), and
(ii) the fact that for a spinless particle in an arbitrary spherically-symmetric attractive potential $U(r)$, the ground state is always an $s$-state (with the orbital quantum number $l=0$ ).
3.36. For the ground state of a hydrogen atom, calculate the expectation values of $\varepsilon$ and $\varepsilon^{2}$, where $\varepsilon$ is the electric field created by the atom at distance $r \gg r_{0}$ from its nucleus. Interpret the resulting relation between $\langle\varepsilon\rangle^{2}$ and $\left\langle\varepsilon^{2}\right\rangle$ (at the same observation point).

[^577]

## Chapter 4. Bra-ket Formalism

The objective of this chapter is a discussion of Dirac's bra-ket formalism of quantum mechanics, which not only overcomes some inconveniences of wave mechanics, but also allows a natural description of such "internal" properties of particles as their spin. In the course of discussion of the formalism I will give several simple examples of its use, leaving more involved applications for the following chapters.

### 4.1. Motivation

We have seen that wave mechanics gives many results of primary importance. Moreover, it is fully (or mostly) sufficient for many applications, for example, for solid state electronics and device physics. However, in the course of our survey we have filed several grievances about this approach. Let me briefly summarize these complaints:
(i) Wave mechanics is focused on the spatial dependence of wavefunctions. On the other hand, our attempts to analyze the temporal evolution of quantum systems within this approach (beyond the trivial time behavior of the eigenfunctions, described by Eq. (1.61)), run into technical difficulties. For example, we could derive Eq. (2.159) describing time dynamics of the metastable state, or Eq. (2.185) describing quantum oscillations in coupled wells, only for the simplest potential profiles, though it is intuitively clear that these simple results should be common for all problem of this kind. Deriving the equations of such processes for arbitrary potential profiles is possible using perturbation theories (to be reviewed in Chapter 6), but that in the wave mechanics language they would require very bulky formulas.
(ii) The same is true concerning other issues that are conceptually addressable within wave mechanics, e.g., the Feynman path integral approach, description of coupling to environment, etc. Addressing them in wave mechanics would lead to formulas so bulky that I had (wisely :-) postponed them until we have got a more compact formalism on hand.
(iii) In the discussion of several key problems (for example the harmonic oscillator and spherically-symmetric potentials) we have run into rather complicated eigenfunctions coexisting with simple energy spectra - that infer some simple background physics. It is very important to get this physics revealed.
(iv) In the wave mechanics postulates, formulated in Sec. 1.2, quantum mechanical operators of the coordinate and momentum are treated very unequally - see Eqs. (1.26b). However, some key expressions, e.g., for the fundamental eigenfunction of a free-particle,

$$
\begin{equation*}
\exp \left\{i \frac{\mathbf{p} \cdot \mathbf{r}}{\hbar}\right\} \tag{4.1}
\end{equation*}
$$

or the harmonic oscillator's Hamiltonian,

$$
\begin{equation*}
\hat{H}=\frac{1}{2 m} \hat{p}^{2}+\frac{m \omega_{0}^{2}}{2} \hat{r}^{2}, \tag{4.2}
\end{equation*}
$$

invite a similar treatment of momentum and coordinate.

However, the strongest motivation for a more general formalism comes from wave mechanics' conceptual incapability to describe elementary particles' spins and other internal quantum degrees of freedom, such as quark flavors or lepton numbers. In this context, let us review the basic facts on spin (which is a very representative and experimentally the most accessible of all internal quantum numbers), to understand what a more general formalism should explain - as a minimum.

Figure 1 shows the conceptual scheme of the simplest spin-revealing experiment, first carried out by O. Stern and W. Gerlach in 1922. ${ }^{1}$ A collimated beam of electrons is passed through a gap between poles of a strong magnet, where the magnetic field $B$, whose orientation is taken for axis $z$ in Fig. 1, is non-uniform, so that both $\mathcal{B}_{z}$ and $d \mathcal{B}_{z} / d z$ are not equal to zero. As a result, the beam splits into two parts of equal intensity.

Fig. 4.1. The simplest SternGerlach experiment.

This simplest experiment can be semi-quantitatively explained on classical, though somewhat phenomenological grounds by assuming that each electron has an intrinsic, permanent magnetic dipole moment $\mathbf{m}$. Indeed, classical electrodynamics ${ }^{2}$ tells us that the potential energy $U$ of a magnetic dipole in an external magnetic field is equal to $(-\mathbf{m} \cdot \boldsymbol{B})$, so that the force acting on the particle,

$$
\begin{equation*}
\mathbf{F}=-\nabla U=-\nabla(-\mathbf{m} \cdot \boldsymbol{B}), \tag{4.3}
\end{equation*}
$$

has a nonvanishing vertical component

$$
\begin{equation*}
F_{z}=-\frac{\partial}{\partial z}\left(-m_{z} \cdot \mathcal{B}_{z}\right)=m_{z} \frac{\partial \mathcal{B}_{z}}{\partial z} . \tag{4.4}
\end{equation*}
$$

Hence if we further postulate the existence of two possible, discrete values of $m_{\mathrm{z}}= \pm \mu$, this explains the Stern-Gerlach effect qualitatively, as a result of the incident electrons having a random sign, but similar magnitude of $m_{z}$. A quantitative explanation of the beam splitting angle requires the magnitude of $\mu$ to be equal (or close) to the so-called Bohr magneton ${ }^{3}$

$$
\begin{equation*}
\mu_{\mathrm{B}} \equiv \frac{\hbar e}{2 m_{e}} \approx 0.9274 \times 10^{-23} \frac{\mathrm{~J}}{\mathrm{~T}} \tag{4.5}
\end{equation*}
$$

Bohr magneton

As we will see below, this value cannot be explained by any internal motion of the electron, say its rotation about axis $z$.

[^578]Much more importantly, this semi-classical language cannot explain the results of the following set of multi-stage Stern-Gerlach experiments, shown in Fig. 2 - even qualitatively. In the first of the experiments, the electron beam is first passed through a magnetic field oriented (together with its gradient) along axis $z$, just as in Fig. 1. Then one of the two resulting beams is absorbed (or otherwise removed from the setup), while the other one is passed through a similar but $x$-oriented field. The experiment shows that this beam is split again into two components of equal intensity. A classical explanation of this experiment would require a very unnatural suggestion that the initial electrons had random but discrete components of the magnetic moment simultaneously in two directions, $z$ and $x$.

However, even this assumption cannot explain the results of the three-stage Stern-Gerlach experiment shown on the middle panel of Fig. 2. Here, the previous two-state setup is complemented with one more absorber and one more magnet, now with the $z$-orientation again. Completely counterintuitively, it again gives two beams of equal intensity, as if we have not yet filtered out the electrons with $m_{z}$ corresponding to the lower beam, in the first, $z$-stage.

Fig. 4.2. Three multi-stage Stern-Gerlach experiments.
 Boxes SG (...) denote magnets similar to one shown in Fig. 1, with the axis oriented in the indicated direction.

The only way to save the classical explanation here is to say that maybe, electrons somehow interact with the magnetic field, so that the $x$-polarized (non-absorbed) beam becomes spontaneously depolarized again somewhere between magnetic stages. But any hope for such explanation is ruined by the control experiment shown on the bottom panel of Fig. 2, whose results indicate that no such depolarization happens.

We will see below that all these (and many more) results find a natural explanation in the matrix mechanics pioneered by W. Heisenberg, M. Born and P. Jordan in 1925. However, the matrix formalism is inconvenient for the solution of most problems discussed in Chapters 1-3, and for a time it was eclipsed by Schrödinger's wave mechanics, which had been put forward just a few months later. However, very soon P. A. M. Dirac introduced a more general bra-ket formalism, which provides a generalization of both approaches and proves their equivalence. Let me describe it.

### 4.2. States, state vectors, and linear operators

The basic notion of the general formulation of quantum mechanics is the quantum state of a system. ${ }^{4}$ To get some gut feeling of this notion, if a quantum state $\alpha$ of a particle may be adequately described by wave mechanics, this description is given by the corresponding wavefunction $\Psi_{\alpha}(\mathbf{r}, t)$. Note, however, the state as such is not a mathematical object (such as a function), ${ }^{5}$ and can participate in mathematical formulas only as a "pointer" - e.g., the index of function $\Psi_{\alpha \text {. On the other hand, the }}$ wavefunction is not a state, but a mathematical object (a complex function of space and time) giving a quantitative description of the state - just as the radius-vector as a function of time is a mathematical object describing the motion of a classical particle - see Fig. 3. Similarly, in the Dirac formalism a certain quantum state $\alpha$ is described by either of two mathematical objects, called the state vectors: the ket-vector $|\alpha\rangle$ and bra-vector $\langle\alpha| .{ }^{6}$

One should be cautions with the term "vector" here. Usual "geometric" vectors are defined in the usual geometric (say, Euclidean) space. In contrast, bra- and ket-vectors are defined in abstract Hilbert spaces of a given system, ${ }^{7}$ and, despite certain similarities with the geometric vectors, are new mathematical objects, so that we need new rules for handling them. The primary rules are essentially postulates and are justified only the correct description/prediction of all experimental observations their corollaries. While these is a general consensus among physicists what the corollaries are, there are many possible ways to carve from them the basic postulate sets. Just as in Sec. 1.2, I will not try too hard to beat the number of the postulates to the smallest possible minimum, trying instead to keep their physical meaning transparent.

Fig. 4.3. Particle's state and its descriptions.
(i) Ket-vectors. Let us start with ket-vectors - sometimes called just kets for short. Perhaps the most important property of the vectors concerns their linear superposition. Namely, if several ketvectors $\left|\alpha_{j}\right\rangle$ describe possible states of a quantum system, then any linear combination (superposition)

$$
\begin{equation*}
|\alpha\rangle=\sum_{j} c_{j}\left|\alpha_{j}\right\rangle \tag{4.6}
\end{equation*}
$$

[^579]where $c_{j}$ are any (possibly complex) $c$-numbers, also describes a possible state of the same system. (One may say that vector $|\alpha\rangle$ belongs to the same Hilbert space as all $\left|\alpha_{j}\right\rangle$.) Actually, since ket-vectors are new mathematical objects, the exact meaning of the right-hand part of Eq. (6) becomes clear only after we have postulated the following rules of summation of these vectors,
\[

$$
\begin{equation*}
\left|\alpha_{j}\right\rangle+\left|\alpha_{j^{\prime}}\right\rangle=\left|\alpha_{j^{\prime}}\right\rangle+\left|\alpha_{j}\right\rangle, \tag{4.7}
\end{equation*}
$$

\]

and their multiplication by $c$-numbers:

$$
\begin{equation*}
c_{j}\left|\alpha_{j}\right\rangle=\left|\alpha_{j}\right\rangle c_{j} . \tag{4.8}
\end{equation*}
$$

Note that in the set of wave mechanics postulates, statements parallel to (7) and (8) were unnecessary, because wavefunctions are the usual (albeit complex) functions of space and time, and we know from the usual algebra that such relations are valid.

As evident from Eq. (6), the complex coefficient $c_{j}$ may be interpreted as the "weight" of state $\alpha_{j}$ in the linear superposition $\alpha$. One important particular case is $c_{j}=0$, showing that state $\alpha_{j}$ does not participate in the superposition $\alpha$. By the way, the corresponding term of sum (6), i.e. product

Null-state
vector

$$
\begin{equation*}
0\left|\alpha_{j}\right\rangle \tag{4.9}
\end{equation*}
$$

has a special name: the null-state vector. (It is important to avoid confusion between the null-state corresponding to vector (9), and the ground state of the system, which is frequently denoted by ketvector $|0\rangle$. In some sense, the null-state does not exist at all, while the ground state does - and frequently is the most important quantum state of the system.)
(ii) Bra-vectors and inner ("scalar") products. Bra-vectors $\langle\alpha|$, which obey the rules similar to Eqs. (7) and (8), are not new, independent objects: if a ket-vector $|\alpha\rangle$ is known, the corresponding bravector $\langle\alpha|$ describes the same state. In other words, there is a unique dual correspondence between $|\alpha\rangle$ and $\langle\alpha|,{ }^{8}$ very similar (though not identical) to that between a wavefunction $\Psi$ and its complex conjugate $\Psi^{*}$. The correspondence between these vectors is described by the following rule: if a ket-vector of a linear superposition is described by Eq. (6), then the corresponding bra-vector is

Linear
superposition of bra-vectors

$$
\begin{equation*}
\langle\alpha|=\sum_{j} c_{j}^{*}\left\langle\alpha_{j}\right|=\sum_{j}\left\langle\alpha_{j}\right| c_{j}^{*} \tag{4.10}
\end{equation*}
$$

The mathematical convenience of using two types of vectors, rather than just one, becomes clear from the notion of their inner product (also called the short bracket):

Inner bra-ket product

$$
\begin{equation*}
\langle\beta \| \alpha\rangle \equiv\langle\beta \mid \alpha\rangle . \tag{4.11}
\end{equation*}
$$

This is a (generally, complex) ${ }^{9}$ scalar, whose main property is the linearity with respect to any of its component vectors. For example, if a linear superposition $\alpha$ is described by the ket-vector (6), then

[^580]\[

$$
\begin{equation*}
\langle\beta \mid \alpha\rangle=\sum_{j} c_{j}\left\langle\beta \mid \alpha_{j}\right\rangle \tag{4.12}
\end{equation*}
$$

\]

while if Eq. (10) is true, then

$$
\begin{equation*}
\langle\alpha \mid \beta\rangle=\sum_{j} c_{j}^{*}\left\langle\alpha_{j} \mid \beta\right\rangle . \tag{4.13}
\end{equation*}
$$

In plain English, $c$-numbers may be moved either into, or out of the inner products.
The second key property of the inner product is

$$
\begin{equation*}
\langle\alpha \mid \beta\rangle=\langle\beta \mid \alpha\rangle^{*} \tag{4.14}
\end{equation*}
$$

It is compatible with Eq. (10); indeed, the complex conjugation of both parts of Eq. (12) gives:

$$
\begin{equation*}
\langle\beta \mid \alpha\rangle^{*}=\sum_{j} c_{j}^{*}\left\langle\beta \mid \alpha_{j}\right\rangle^{*}=\sum_{j} c_{j}^{*}\left\langle\alpha_{j} \mid \beta\right\rangle=\langle\alpha \mid \beta\rangle . \tag{4.15}
\end{equation*}
$$

Finally, one more rule: the inner product of the bra- and ket-vectors describing the same state (called the norm squared) is real and non-negative,

$$
\begin{equation*}
\|\alpha\|^{2} \equiv\langle\alpha \mid \alpha\rangle \geq 0 \tag{4.16}
\end{equation*}
$$

Inner product's complex conjugate

In order to give the reader some feeling about the meaning of this rule: we will show below that if state $\alpha$ may be described by wavefunction $\Psi_{\alpha}(\mathbf{r}, t)$, then

$$
\begin{equation*}
\langle\alpha \mid \alpha\rangle=\int \Psi_{\alpha}^{*} \Psi_{\alpha} d^{3} r \geq 0 \tag{4.17}
\end{equation*}
$$

Hence the role of the bra-ket is very similar to the complex conjugation of the wavefunction, and Eq. (10) emphasizes this similarity. (Note that, by convention, there is no conjugation sign in the bra-part of the inner product; its role is played by the angular bracket inversion.)
(iii) Operators. One more key notion of the Dirac formalism are quantum-mechanical linear operators. Just as for the operators discussed in wave mechanics, the function of an operator is the "generation" of one state from another: if $|\alpha\rangle$ is a possible ket of the system, and $\hat{A}$ is a legitimate operator, then the following combination,

$$
\begin{equation*}
\hat{A}|\alpha\rangle \tag{4.18}
\end{equation*}
$$

is also a ket-vector describing a possible state of the system, i.e. a ket-vector in the same Hilbert space as the initial vector $|\alpha\rangle$. As follows from the adjective "linear", the main rules governing the operators is their linearity with respect to both any superposition of vectors:

$$
\begin{equation*}
\hat{A}\left(\sum_{j} c_{j}\left|\alpha_{j}\right\rangle\right)=\sum_{j} c_{j} \hat{A}\left|\alpha_{j}\right\rangle \tag{4.19}
\end{equation*}
$$

and any superposition of operators:

$$
\begin{equation*}
\left(\sum_{j} c_{j} \hat{A}_{j}\right)|\alpha\rangle=\sum_{j} c_{j} \hat{A}_{j}|\alpha\rangle \tag{4.20}
\end{equation*}
$$

These rules are evidently similar to Eqs. (1.53)-(1.54) of wave mechanics.
The above rules imply that an operator "acts" on the ket-vector on its right; however, a combination of the type $\langle\alpha| \hat{A}$ is also legitimate and presents a new bra-vector. It is important that, generally, this vector does not represent the same state as ket-vector (18); instead, the bra-vector isomorphic to ket-vector (18) is

Hermitian conjugate operator

Hermitian operator's definition

$$
\begin{equation*}
\langle\alpha| \hat{A}^{\dagger} \tag{4.21}
\end{equation*}
$$

This statement serves as the definition of the Hermitian conjugate (or "Hermitian adjoint") $\hat{A}^{\dagger}$ of the initial operator $\hat{A}$. For an important class of operators, called the Hermitian operators, the conjugation is inconsequential, i.e. for them

$$
\begin{equation*}
\hat{A}^{\dagger}=\hat{A} . \tag{4.22}
\end{equation*}
$$

(This equality, as well as any other operator equation below, means that these operators act similarly on any bra- or ket-vector.) ${ }^{10}$

To proceed further, we need an additional postulate, called the associative axiom of multiplication: into any legitimate bra-ket expression, ${ }^{11}$ not including an explicit summation, we may insert or remove parentheses (just in the ordinary product of scalars), meaning as usual that the operation inside the parentheses is performed first. The first two examples of this postulate are given by Eqs. (19) and (20), but the associative axiom is more general and says, for example:

$$
\begin{equation*}
\langle\beta|(\hat{A}|\alpha\rangle)=(\langle\beta| \hat{A})|\alpha\rangle \equiv\langle\beta| \hat{A}|\alpha\rangle, \tag{4.23}
\end{equation*}
$$

This equality serves as the definition of the last form, called the long bracket (evidently, also a scalar), with an operator sandwiched between a bra-vector and a ket-vector. This definition, when combined with the definition of the Hermitian conjugate and Eq. (14), yields an important corollary:

$$
\begin{equation*}
\langle\beta| \hat{A}|\alpha\rangle=\langle\beta|(\hat{A}|\alpha\rangle)=\left(\left(\langle\alpha| \hat{A}^{\dagger}\right)|\beta\rangle\right)^{*}=\langle\alpha| \hat{A}^{\dagger}|\beta\rangle^{*} \tag{4.24}
\end{equation*}
$$

which is most frequently rewritten as

$$
\begin{equation*}
\langle\alpha| \hat{A}|\beta\rangle^{*}=\langle\beta| \hat{A}^{\dagger}|\alpha\rangle \tag{4.25}
\end{equation*}
$$

The associative axiom also enables to readily explore the following definition of one more, outer product of bra- and ket-vectors:

[^581]\[

$$
\begin{equation*}
|\beta\rangle\langle\alpha| \tag{4.26}
\end{equation*}
$$

\]

In contrast to the inner product (12), which is a scalar, this mathematical construct is an operator. Indeed, the associative axiom allows us to remove parentheses in the following expression:

$$
\begin{equation*}
(|\beta\rangle\langle\alpha|) \gamma\rangle=|\beta\rangle\langle\alpha \mid \gamma\rangle . \tag{4.27}
\end{equation*}
$$

But the last bra-ket is just a scalar; hence the mathematical object (26) acting on a ket-vector (in this case, $|\gamma\rangle$ ) gives a new ket-vector, which is the essence of operator's action. Very similarly,

$$
\begin{equation*}
\langle\delta|(|\beta\rangle\langle\alpha|)=\langle\delta \mid \beta\rangle\langle\alpha| \tag{4.28}
\end{equation*}
$$

- again a typical operator's action on a bra-vector.

Now let us perform the following calculation. We may use the parentheses insertion into the braket equality following from Eq. (14),

$$
\begin{equation*}
\langle\gamma \mid \alpha\rangle\langle\beta \mid \delta\rangle=(\langle\delta \mid \beta\rangle\langle\alpha \mid \gamma\rangle)^{*}, \tag{4.29}
\end{equation*}
$$

to transform it to the following form:

$$
\begin{equation*}
\langle\gamma|(|\alpha\rangle\langle\beta|)|\delta\rangle=(\langle\delta|(|\beta\rangle\langle\alpha|)|\gamma\rangle)^{*} . \tag{4.30}
\end{equation*}
$$

Since this equation should be valid for any vectors $\langle\gamma|$ and $|\beta\rangle$, its comparison with Eq. (25) gives the following operator equality

$$
\begin{equation*}
(|\alpha\rangle\langle\beta|)^{\dagger}=|\beta\rangle\langle\alpha| . \tag{4.31}
\end{equation*}
$$

This is the conjugate rule for outer products; it reminds rule (14) for inner products, but involves the Hermitian (rather than the usual complex) conjugation.

The associative axiom is also valid for the operator "multiplication":

$$
\begin{equation*}
(\hat{A} \hat{B})|\alpha\rangle=\hat{A}(\hat{B}|\alpha\rangle), \quad\langle\beta|(\hat{A} \hat{B})=(\langle\beta| \hat{A}) \hat{B} \tag{4.32}
\end{equation*}
$$

showing that the action of an operator product on a state vector is nothing more than the sequential action of the operands. However, we have to be rather careful with the operator products; generally they do not commute: $\hat{A} \hat{B} \neq \hat{B} \hat{A}$. This is why the commutator, the operator defined as

$$
\begin{equation*}
[\hat{A}, \hat{B}] \equiv \hat{A} \hat{B}-\hat{B} \hat{A} \tag{4.33}
\end{equation*}
$$

is a very useful option. Another similar notion is the anticommutator: ${ }^{12}$

$$
\begin{equation*}
\{\hat{A}, \hat{B}\} \equiv \hat{A} \hat{B}+\hat{B} \hat{A} . \tag{4.34}
\end{equation*}
$$

Finally, the bra-ket formalism broadly uses two special operators: the null operator $\hat{0}$ defined by the following relations:

[^582]Identity
operator

Expansion over
basis vectors

$$
\begin{equation*}
\hat{0}|\alpha\rangle \equiv 0|\alpha\rangle, \quad\langle\alpha| \hat{0} \equiv\langle\alpha| 0, \tag{4.35}
\end{equation*}
$$

for an arbitrary state $\alpha$; we may say that the null operator "kills" any state, turning it into the null-state. Another elementary operator is the identity operator, which is also defined by its action (or rather "inaction" :-) on an arbitrary state vector:

$$
\begin{equation*}
\hat{I}|\alpha\rangle \equiv|\alpha\rangle, \quad\langle\alpha| \hat{I} \equiv\langle\alpha| \tag{4.36}
\end{equation*}
$$

### 4.3. State basis and matrix representation

While some operations in quantum mechanics may be carried out in the general bra-ket formalism outlined above, most calculations are done for specific quantum systems that feature at least one full and orthonormal set $\{u\}$ of states $u_{j}$, frequently called a basis. These terms mean that any state vector of the system may be represented as a unique sum of the type (6) or (10) over its basis vectors:

$$
\begin{equation*}
|\alpha\rangle=\sum_{j} \alpha_{j}\left|u_{j}\right\rangle, \quad\langle\alpha|=\sum_{j} \alpha_{j}^{*}\left\langle u_{j}\right| \tag{4.37}
\end{equation*}
$$

(so that, in particular, if $\alpha$ is one of the basis states, say $u_{j}$, then $\alpha_{j}=\delta_{j j}$,), and that

For the systems that may be described by wave mechanics, examples of the full orthonormal bases are
represented by any orthonormal set of eigenfunctions calculated in the previous 3 chapters - as the
For the systems that may be described by wave mechanics, examples of the full orthonormal bases are
represented by any orthonormal set of eigenfunctions calculated in the previous 3 chapters - as the simplest example, see Eq. (1.76).

Due to the uniqueness of expansion (37), the full set of coefficients $\alpha_{j}$ gives a complete description of state $\alpha$ (in a fixed basis $\{u\}$ ), just as the usual Cartesian components $A_{x}, A_{y}$, and $A_{z}$ give a complete description of a usual geometric 3D vector A (in a fixed reference frame). Still, let me emphasize some differences between the quantum-mechanical bra- and ket-vectors and the usual geometric vectors:
(i) a basis set may have a large or even infinite number of states $u_{j}$, and
(ii) the expansion coefficients $\alpha_{j}$ may be complex.

With these reservations in mind, the analogy with geometric vectors may be pushed even further.
inner-multiply both parts of the first of Eqs. (37) by a bra-vector $\left\langle u_{j^{\prime}}\right\rangle$ and then transform the
With these reservations in mind, the analogy with geometric vectors may be pushed even further.
Let us inner-multiply both parts of the first of Eqs. (37) by a bra-vector $\left\langle u_{j}{ }^{\prime}\right|$ and then transform the relation using the linearity rules discussed in the previous section, and Eq. (38):

$$
\begin{equation*}
\left\langle u_{j^{\prime}} \mid \alpha\right\rangle=\left\langle u_{j^{\prime}}\right| \sum_{j} \alpha_{j}\left|u_{j}\right\rangle=\sum_{j} \alpha_{j}\left\langle u_{j^{\prime}} \mid u_{j}\right\rangle=\alpha_{j^{\prime}}, \tag{4.39}
\end{equation*}
$$

Together with Eq. (14), this means that any of the expansion coefficients in Eq. (37) may be presented as an inner product:

Expansion coefficients as inner products

$$
\begin{equation*}
\left\langle u_{j} \mid u_{j^{\prime}}\right\rangle=\delta_{j j^{\prime}} \tag{4.38}
\end{equation*}
$$

七-
these relations are analogs of equalities $A_{j}=\mathbf{n}_{j} \cdot \mathbf{A}$ of the usual vector algebra. Using these important relations (which we will use on numerous occasions), expansions (37) may be rewritten as

$$
\begin{equation*}
|\alpha\rangle=\sum_{j}\left|u_{j}\right\rangle\left\langle u_{j} \mid \alpha\right\rangle \equiv \sum_{j} \hat{\Lambda}_{j}|\alpha\rangle, \quad\langle\alpha|=\sum_{j}\left\langle\alpha \mid u_{j}\right\rangle\left\langle u_{j}\right| \equiv \sum_{j}\langle\alpha| \hat{\Lambda}_{j}, \tag{4.41}
\end{equation*}
$$

A comparison of these relations with Eq. (26) shows that the outer product defined as

$$
\begin{equation*}
\hat{\Lambda}_{j} \equiv\left|u_{j}\right\rangle\left\langle u_{j}\right|, \tag{4.42}
\end{equation*}
$$

is a legitimate linear operator. Such an operator, acting on any state vector of the type (37), singles out just one of its components, for example,

$$
\begin{equation*}
\hat{\Lambda}_{j}|\alpha\rangle=\left|u_{j}\right\rangle\left\langle u_{j} \mid \alpha\right\rangle=\alpha_{j}\left|u_{j}\right\rangle, \tag{4.43}
\end{equation*}
$$

i.e. kills all components of the linear superposition but one. In the geometric analogy, such operator "projects" the state vector on its ( $j^{\text {th }}$ ) "direction", hence its name - the projection operator. Probably, the most important property of the projection operators, called the closure (or completeness) relation, immediately follows from Eq. (41): their sum over the full basis is equivalent to the identity operator:

$$
\begin{equation*}
\sum_{j}\left|u_{j}\right\rangle\left\langle u_{j}\right|=\hat{I} \tag{4.44}
\end{equation*}
$$

This means in particular that we may insert the left-hand part of Eq. (44) into any bra-ket relation, at any place - the trick that we will use again and again.

Let us see how expansions (37) transform all the notions introduced in the last section, starting from the short bra-ket (11) (the inner product of two state vectors):

$$
\begin{equation*}
\langle\beta \mid \alpha\rangle=\sum_{j, j^{\prime}}\left\langle u_{j}\right| \beta_{j}^{*} \alpha_{j^{\prime}}\left|u_{j^{\prime}}\right\rangle=\sum_{j, j^{\prime}} \beta_{j}^{*} \alpha_{j^{\prime}} \delta_{j j^{\prime}}=\sum_{j} \beta_{j}^{*} \alpha_{j} . \tag{4.45}
\end{equation*}
$$

Besides the complex conjugation, this expression is similar to the scalar product of the usual vectors. Now, let us explore the long bra-ket (23):

$$
\begin{equation*}
\langle\beta| \hat{A}|\alpha\rangle=\sum_{j, j^{\prime}} \beta_{j}^{*}\left\langle u_{j}\right| \hat{A}\left|u_{j^{\prime}}\right\rangle \alpha_{j^{\prime}} \equiv \sum_{j, j^{\prime}} \beta_{j}^{*} A_{j j^{\prime}} \alpha_{j^{\prime}} . \tag{4.46}
\end{equation*}
$$

Here, the last step uses a very important notion of matrix elements of the operator, defined as

$$
\begin{equation*}
A_{j j^{\prime}} \equiv\left\langle u_{j}\right| \hat{A}\left|u_{j^{\prime}}\right\rangle \tag{4.47}
\end{equation*}
$$

while for the identity operator $\hat{I}$, defined by Eqs. (36), we readily get

$$
\begin{equation*}
I_{i j^{\prime}}=\left\langle u_{j}\right| \hat{I}\left|u_{j^{\prime}}\right\rangle=\left\langle u_{j} \mid u_{j^{\prime}}\right\rangle=\delta_{j j^{\prime}}, \tag{4.49}
\end{equation*}
$$

i.e. its matrix (called the identity matrix) is diagonal - also in any basis:

Identity matrix

$$
\mathrm{I} \equiv\left(\begin{array}{ccc}
1 & 0 & \ldots  \tag{4.50}\\
0 & 1 & \ldots \\
\ldots & \ldots & \ldots
\end{array}\right) .
$$

The convenience of the matrix language extends well beyond the presentation of particular operators. For example, let us use definition (47) to calculate matrix elements for a product of two operators:

$$
\begin{equation*}
(A B)_{j j^{\prime \prime}}=\left\langle u_{j}\right| \hat{A} \hat{B}\left|u_{j^{\prime \prime}}\right\rangle . \tag{4.51}
\end{equation*}
$$

Here we can use Eq. (44) for the first (but not the last!) time, inserting the identity operator between the two operators, and then expressing it via a sum of projection operators:

Matrix element of an operator product

$$
\begin{equation*}
(A B)_{j j^{\prime \prime}}=\left\langle u_{j}\right| \hat{A} \hat{B}\left|u_{j^{\prime \prime}}\right\rangle=\left\langle u_{j}\right| \hat{A} \hat{I} \hat{B}\left|u_{j^{\prime \prime}}\right\rangle=\sum_{j^{\prime}}\left\langle u_{j}\right| \hat{A}\left|u_{j^{\prime}}\right\rangle\left\langle u_{j^{\prime}}\right| \hat{B}\left|u_{j^{\prime \prime}}\right\rangle=\sum_{j^{\prime}} A_{j j^{\prime}} B_{j j^{\prime \prime}} \tag{4.52}
\end{equation*}
$$

This result corresponds to the standard "row by column" rule of calculation of an arbitrary element of the matrix product

$$
\mathrm{AB}=\left(\begin{array}{ccc}
A_{11} & A_{12} & \ldots  \tag{4.53}\\
A_{21} & A_{22} & \ldots \\
\ldots & \ldots & \ldots
\end{array}\right)\left(\begin{array}{ccc}
B_{11} & B_{12} & \ldots \\
B_{21} & B_{22} & \ldots \\
\ldots & \ldots & \ldots
\end{array}\right) .
$$

Hence the product of operators may be presented (in a fixed basis!) by that of their matrices (in the same basis). This is so convenient that the same language is often used to present not only the long bracket,

Long
bracket
as a matrix product

Short bracket as a matrix product

$$
\langle\beta| \hat{A}|\alpha\rangle=\sum_{j^{\prime}} \beta_{j}^{*} A_{j j} \alpha_{j^{\prime}}=\left(\beta_{1}^{*}, \beta_{2}^{*}, \ldots\right)\left(\begin{array}{ccc}
A_{11} & A_{12} & \ldots  \tag{4.54}\\
A_{21} & A_{22} & \ldots \\
\ldots & \ldots & \ldots
\end{array}\right)\left(\begin{array}{c}
\alpha_{1} \\
\alpha_{2} \\
\ldots
\end{array}\right)
$$

but even the simpler short bracket:

$$
\langle\beta \mid \alpha\rangle=\sum_{j} \beta_{j}^{*} \alpha_{j}=\left(\beta_{1}^{*}, \beta_{2}^{*}, \ldots\right)\left(\begin{array}{c}
\alpha_{1}  \tag{4.55}\\
\alpha_{2} \\
\ldots
\end{array}\right)
$$

although these equalities require the use of non-square matrices: rows of (complex-conjugate!) expansion coefficients for the presentation of bra-vectors, and columns of these coefficients for the presentation of ket-vectors. With that, the mapping of states and operators on matrices becomes completely general.

Now let us have a look at the outer product operator (26). Its matrix elements are just

$$
\begin{equation*}
(|\alpha\rangle\langle\beta|)_{i j^{\prime}}=\left\langle u_{j} \mid \alpha\right\rangle\left\langle\beta \mid u_{j^{\prime}}\right\rangle=\alpha_{j} \beta_{j^{\prime}}^{*} . \tag{4.56}
\end{equation*}
$$

These are elements of a very special square matrix, whose filling requires the knowledge of just 2 N scalars (where $N$ is the basis set size), rather than $N^{2}$ scalars as for an arbitrary operator. However, a simple generalization of such outer product may present an arbitrary operator. Indeed, let us insert two identity operators (44), with different summation indices, on both sides of any operator:

$$
\begin{equation*}
\hat{A}=\hat{I} \hat{A} \hat{I}=\left(\sum_{j}\left|u_{j}\right\rangle\left\langle u_{j}\right|\right) \hat{A}\left(\sum_{j^{\prime}}\left|u_{j^{\prime}}\right\rangle\left\langle u_{j^{\prime}}\right|\right), \tag{4.57}
\end{equation*}
$$

and use the associative axiom to rewrite this expression as

$$
\begin{equation*}
\hat{A}=\sum_{j, j^{\prime}}\left|u_{j}\right\rangle\left\langle u_{j}\right| \hat{A}\left|u_{j^{\prime}}\right\rangle\left\langle u_{j^{\prime}}\right| . \tag{4.58}
\end{equation*}
$$

But the expression in the middle long bracket is just the matrix element (47), so that we may write

$$
\begin{equation*}
\hat{A}=\sum_{j, j^{\prime}}\left|u_{j}\right\rangle A_{j j^{\prime}}\left\langle u_{j^{\prime}}\right| . \tag{4.59}
\end{equation*}
$$

Operator's expression via its matrix elements
The reader has to agree that this formula, which is a natural generalization of Eq. (44), is extremely elegant. Also note the following parallel: if we consider the matrix element definition (47) as some sort of analog of Eq. (40), then Eq. (59) is a similar analog of the expansion expressed by Eq. (37).

The matrix presentation is so convenient that it makes sense to move it by one level lower - from state vector products to "bare" state vectors resulting from operator's action upon a given state. For example, let us use Eq. (59) to present the ket-vector (18) as

$$
\begin{equation*}
\left.\left|\alpha^{\prime}\right\rangle \equiv \hat{A}|\alpha\rangle=\left(\sum_{j, j^{\prime}}\left|u_{j}\right\rangle A_{i j^{\prime}}\left\langle u_{j^{\prime}}\right|\right) \alpha\right\rangle=\sum_{j, j^{\prime}}\left|u_{j}\right\rangle A_{j j^{\prime}}\left\langle u_{j^{\prime}} \mid \alpha\right\rangle . \tag{4.60}
\end{equation*}
$$

According to Eq. (40), the last short bracket is just $\alpha_{j}$, so that

$$
\begin{equation*}
\left|\alpha^{\prime}\right\rangle=\sum_{j, j^{\prime}}\left|u_{j}\right\rangle A_{i j j^{\prime}} \alpha_{j^{\prime}}=\sum_{j}\left(\sum_{j^{\prime}} A_{i j^{\prime}} \alpha_{j^{\prime}}\right)\left|u_{j}\right\rangle \tag{4.61}
\end{equation*}
$$

But expression in middle parentheses is just the coefficient $\alpha_{j}^{\prime}$ of expansion (37) of the resulting ketvector (60) in the same basis, so that

$$
\begin{equation*}
\alpha_{j}^{\prime}=\sum_{j^{\prime}} A_{j j^{\prime}} \alpha_{j^{\prime}} \tag{4.62}
\end{equation*}
$$

This result corresponds to the usual rule of multiplication of a matrix by a column, so that we may represent any ket-vector by its column matrix, with the operator action looking like

$$
\left(\begin{array}{c}
\alpha_{1}^{\prime}  \tag{4.63}\\
\alpha_{2}^{\prime} \\
\ldots
\end{array}\right)=\left(\begin{array}{ccc}
A_{11} & A_{12} & \ldots \\
A_{21} & A_{22} & \ldots \\
\ldots & \ldots & \ldots
\end{array}\right)\left(\begin{array}{c}
\alpha_{1} \\
\alpha_{2} \\
\ldots
\end{array}\right) .
$$

Absolutely similarly, the operator action on the bra-vector (21), represented by its row-matrix, is

$$
\left({\alpha_{1}^{\prime *}}^{*}, \alpha_{2}^{\prime *}, \ldots\right)=\left(\alpha_{1}^{*}, \alpha_{2}^{*}, \ldots\right)\left(\begin{array}{ccc}
\left(A^{\dagger}\right)_{11} & \left(A^{\dagger}\right)_{12} & \ldots  \tag{4.64}\\
\left(A^{\dagger}\right)_{21} & \left(A^{\dagger}\right)_{22} & \ldots \\
\ldots & \ldots & \ldots
\end{array}\right) .
$$

By the way, Eq. (64) naturally raises the following question: what are the elements of the matrix in its right-hand part, or more exactly, what is the relation between the matrix elements of an operator and its Hermitian conjugate? The simplest way to get an answer is to use Eq. (25) with two arbitrary states (say, $u_{j}$ and $u_{j}$ ) of the same basis in the role of $\alpha$ and $\beta$. Together with the orthonormality relation (38), this immediately gives ${ }^{13}$

Hermitian conjugate's matrix elements

$$
\begin{equation*}
\left(\hat{A}^{\dagger}\right)_{i j j^{\prime}}=\left(A_{j^{\prime} j}\right)^{*} \tag{4.65}
\end{equation*}
$$

Thus, the matrix of the Hermitian conjugate operator is the complex conjugated and transposed matrix of the initial operator. This result exposes very clearly the essence of the Hermitian conjugation. It also shows that for the Hermitian operators, defined by Eq. (22),

$$
\begin{equation*}
A_{j j^{\prime}}=A_{j^{\prime} j}^{*}, \tag{4.66}
\end{equation*}
$$

i.e. any pair of their matrix elements, symmetric about the main diagonal, should be complex conjugate of each other. As a corollary, the main-diagonal elements have to be real:

$$
\begin{equation*}
A_{i j}=A_{i j}^{*} \text {, i.e. } \operatorname{Im} A_{j j}=0 \tag{4.67}
\end{equation*}
$$

(Matrix (50) evidently satisfies Eq. (66), so that the identity operator is Hermitian.)
In order to fully appreciate the special role played by Hermitian operators in the quantum theory, let us introduce the key notions of eigenstates $a_{j}$ (described by their eigenvectors $\left\langle a_{j}\right|$ and $\left|a_{j}\right\rangle$ ) and eigenvalues (c-numbers) $A_{j}$ of an operator $\hat{A}$, defined by the equation they have to satisfy: ${ }^{14}$

Operator's eigenstates eigenvalues

Hermitian operator's eigenvalues

Let us prove that eigenvalues of any Hermitian operator are real, ${ }^{15}$

$$
\begin{equation*}
A_{j}=A_{j}^{*}, \quad \text { for } j=1,2, \ldots, N \tag{4.69}
\end{equation*}
$$

[^583]while the eigenstates corresponding to different eigenvalues are orthogonal:
\[

$$
\begin{equation*}
\left\langle a_{j} \mid a_{j^{\prime}}\right\rangle=0, \quad \text { if } A_{j} \neq A_{j^{\prime}} . \tag{4.70}
\end{equation*}
$$

\]

The proof of both statements is surprisingly simple. Let us inner-multiply both sides of Eq. (68) by bra-vector $\left\langle a_{j}\right\rangle$. In the right-hand part of the result, the eigenvalue $A_{j}$, as a $c$-number, may be taken out of the bra-ket, giving

$$
\begin{equation*}
\left\langle a_{j^{\prime}}\right| \hat{A}\left|a_{j}\right\rangle=A_{j}\left\langle a_{j^{\prime}} \mid a_{j}\right\rangle . \tag{4.71}
\end{equation*}
$$

This equality should hold for any pair of eigenstates, so that we may swap the indices in Eq. (71), and complex-conjugate the result:

$$
\begin{equation*}
\left\langle a_{j}\right| \hat{A}\left|a_{j^{\prime}}\right\rangle^{*}=A_{j^{\prime}}^{*}\left\langle a_{j} \mid a_{j^{\prime}}\right\rangle^{*} . \tag{4.72}
\end{equation*}
$$

Now using Eqs. (14) and (25), together with the Hermitian operator definition (22), we may transform Eq. (72) to the following form:

$$
\begin{equation*}
\left\langle a_{j^{\prime}}\right| \hat{A}\left|a_{j}\right\rangle=A_{j^{\prime}}^{*}\left\langle a_{j^{\prime}} \mid a_{j}\right\rangle . \tag{4.73}
\end{equation*}
$$

Subtracting this equation from Eq. (71), we get

$$
\begin{equation*}
0=\left(A_{j}-A_{j^{\prime}}^{*}\right)\left\langle a_{j^{\prime}} \mid a_{j}\right\rangle . \tag{4.74}
\end{equation*}
$$

There are two possibilities to satisfy this equation. If indices $j$ and $j$ ' are equal (denote the same eigenstate), then the bra-ket is the state's norm squared, and cannot be equal to zero. Then the left parentheses (with $j=j^{\prime}$ ) have to be zero, i.e. Eq. (69) is valid. On the other hand, if $j$ and $j$ ' correspond to different eigenvalues of $\hat{A}$, the parentheses cannot equal zero (we have just proved that all $A_{j}$ are real!), and hence the state vectors indexed by $j$ and $j$ ' should be orthogonal, e.g., Eq. (70) is valid.

As will be discussed below, these properties make Hermitian operators suitable for the description of physical observables.

### 4.4. Change of basis and matrix diagonalization

From the discussion of last section, it may look that the matrix language is fully similar to, and in many instances more convenient than the general bra-ket formalism. In particular, Eqs. (52), (54), (55) show that any part of any bra-ket expression may be directly mapped on the similar matrix expression, with the only slight inconvenience of using not only columns, but also rows (with their elements complex-conjugated), for state vector presentation. In this context, why do we need the bra-ket language at all? The answer is that the elements of the matrices depend on the particular choice of the basis set, very much like the Cartesian components of a usual vector depend on the particular choice of reference frame orientation (Fig. 4), and very frequently it is convenient to use two or more different basis sets for the same system.

With this motivation, let us study what happens if we change from one basis, $\{u\}$, to another one, $\{v\}$ - both full and orthonormal. First of all, let us prove that for each such pair of bases, there exists such an operator $\hat{U}$ that, first,

Basis transform

$$
\begin{equation*}
\left|v_{j}\right\rangle=\hat{U}\left|u_{j}\right\rangle \tag{4.75}
\end{equation*}
$$

and, second,

Unitary operator's definition

Unitary operator of basis transform

$$
\begin{equation*}
\hat{U} \hat{U}^{\dagger}=\hat{U}^{\dagger} \hat{U}=\hat{I} \tag{4.76}
\end{equation*}
$$

(Due to the last property, ${ }^{16} \hat{U}$ is called a unitary operator, and Eq. (75), a unitary transformation.)

Fig. 4.4. Transformation of components of a 2 D vector at a reference frame rotation.

A very simple proof of both statements may be achieved by construction. Indeed, let us take

$$
\begin{equation*}
\hat{U} \equiv \sum_{j^{\prime}}\left|v_{j^{\prime}}\right\rangle\left\langle u_{j^{\prime}}\right| \tag{4.77}
\end{equation*}
$$

- an evident generalization of Eq. (44). Then

$$
\begin{equation*}
\hat{U}\left|u_{j}\right\rangle=\sum_{j^{\prime}}\left|v_{j^{\prime}}\right\rangle\left\langle u_{j^{\prime}} \mid u_{j}\right\rangle=\sum_{j^{\prime}}\left|v_{j^{\prime}}\right\rangle \delta_{j^{\prime} j}=\left|v_{j}\right\rangle, \tag{4.78}
\end{equation*}
$$

so that Eq. (75) has been proved. Now, applying Eq. (31) to each term of sum (77), we get

$$
\begin{equation*}
\hat{U}^{\dagger} \equiv \sum_{j^{\prime}}\left|u_{j^{\prime}}\right\rangle\left\langle v_{j^{\prime}}\right| \tag{4.79}
\end{equation*}
$$

so that

$$
\begin{equation*}
\hat{U} \hat{U}^{\dagger}=\sum_{j, j^{\prime}}\left|v_{j}\right\rangle\left\langle u_{j} \mid u_{j^{\prime}}\right\rangle\left\langle v_{j^{\prime}}\right|=\sum_{j, j^{\prime}}\left|v_{j}\right\rangle \delta_{j j^{\prime}}\left\langle v_{j^{\prime}}\right|=\sum_{j}\left|v_{j}\right\rangle\left\langle v_{j}\right| . \tag{4.80}
\end{equation*}
$$

But according to the closure relation (44), the last expression is just the identity operator, q.e.d. ${ }^{17}$ (The proof of the second equality in Eq. (76) is absolutely similar.)

As a by-product of our proof, we have also got another important expression (79). It implies, in particular, that while, according to Eq. (77), operator $\hat{U}$ performs the transform from the "old" basis $u_{j}$ to the "new" basis $v_{j}$, its Hermitian adjoint $\hat{U}^{\dagger}$ performs the reciprocal unitary transform:

Reciprocal
basis transform

$$
\begin{equation*}
\hat{U}^{\dagger}\left|v_{j}\right\rangle=\sum_{j^{\prime}}\left|u_{j^{\prime}}\right\rangle \delta_{j^{\prime} j}=\left|u_{j}\right\rangle . \tag{4.81}
\end{equation*}
$$

[^584]Now, let us see how do the matrix elements of the unitary transform operators look like. Generally, as was stated above, operator's elements depend on the basis we calculate them in, so we should be careful - initially. For example, let us calculate the elements in basis $\{u\}$ :

$$
\begin{equation*}
U_{i j^{\prime} \mid \text { in } u} \equiv\left\langle u_{j}\right| \hat{U}\left|u_{j^{\prime}}\right\rangle=\left\langle u_{j}\right|\left(\sum_{k}\left|v_{k}\right\rangle\left\langle u_{k}\right|\right)\left|u_{j^{\prime}}\right\rangle=\left\langle u_{j} \mid v_{j^{\prime}}\right\rangle . \tag{4.82}
\end{equation*}
$$

Now performing a similar calculation in basis $\{v\}$, we get

$$
\begin{equation*}
\left.U_{i j^{\prime}}\right|_{\text {in } v} \equiv\left\langle v_{j}\right| \hat{U}\left|v_{j^{\prime}}\right\rangle=\left\langle v_{j}\right|\left(\sum_{k}\left|v_{k}\right\rangle\left\langle u_{k}\right|\right)\left|v_{j^{\prime}}\right\rangle=\left\langle u_{j} \mid v_{j^{\prime}}\right\rangle . \tag{4.83}
\end{equation*}
$$

Surprisingly, the result is the same! This is of course true for the Hermitian conjugate of the unitary transform operator as well:

$$
\begin{equation*}
\left.U_{i j^{\prime}}^{\dagger}\right|_{\text {in } u}=\left.U_{i j^{\prime}}^{\dagger}\right|_{\text {in } v}=\left\langle v_{j} \mid u_{j^{\prime}}\right\rangle . \tag{4.84}
\end{equation*}
$$

These expressions may be used, first of all, to rewrite Eq. (75) in a more direct form. Applying the first of Eqs. (41) to state $v_{j}$ ' of the "new" basis, we get

$$
\begin{equation*}
\left|v_{j^{\prime}}\right\rangle=\sum_{j}\left|u_{j}\right\rangle\left\langle u_{j} \mid v_{j^{\prime}}\right\rangle=\sum_{j} U_{i j^{\prime}}\left|u_{j}\right\rangle \tag{4.85}
\end{equation*}
$$

Similarly, the reciprocal transform is

$$
\begin{equation*}
\left|u_{j^{\prime}}\right\rangle=\sum_{j}\left|v_{j}\right\rangle\left\langle v_{j} \mid u_{j^{\prime}}\right\rangle=\sum_{j} U_{j j^{\prime}}^{\dagger}\left|v_{j}\right\rangle \tag{4.86}
\end{equation*}
$$

These equations are very convenient for applications; we will use them already later in this section.
Next, we may use Eqs. (83), (84) to express the effect of the unitary transform on expansion coefficients (37) of vectors of an arbitrary state $\alpha$. In the "old" basis $\{u\}$, they are given by Eq. (40). Similarly, in the "new" basis $\{v\}$,

$$
\begin{equation*}
\left.\alpha_{j}\right|_{\text {in } v}=\left\langle v_{j} \mid \alpha\right\rangle . \tag{4.87}
\end{equation*}
$$

Again inserting the identity operator in the form of closure (44), with internal index $j^{\prime}$, and then using Eq. (84), we get

$$
\begin{equation*}
\left.\alpha_{j}\right|_{\text {in } v}=\left\langle v_{j}\right|\left(\sum_{j^{\prime}}\left|u_{j^{\prime}}\right\rangle\left\langle u_{j^{\prime}}\right|\right)|\alpha\rangle=\sum_{j^{\prime}}\left\langle v_{j} \mid u_{j^{\prime}}\right\rangle\left\langle u_{j^{\prime}} \mid \alpha\right\rangle=\sum_{j^{\prime}} U_{j j^{\prime}}^{\dagger}\left\langle u_{j^{\prime}} \mid \alpha\right\rangle=\sum_{j^{\prime}} U_{j j^{\prime}}^{\dagger} \alpha_{j^{\prime} \mid \text { in } u} . \tag{4.88}
\end{equation*}
$$

The reciprocal transform is (of course) performed by matrix elements of operator $\hat{U}$ :

$$
\begin{equation*}
\left.\alpha_{j}\right|_{\text {in } u}=\sum_{j^{\prime}} U_{j j^{\prime}},\left.\alpha_{j^{\prime}}\right|_{\text {in } v} \tag{4.89}
\end{equation*}
$$

Both structurally and philosophically, these expressions are similar to the transformation of components of a usual vector at coordinate frame rotation. For example, in two dimensions (Fig. 4):

$$
\binom{\alpha_{x}^{\prime}}{\alpha_{y}^{\prime}}=\left(\begin{array}{cc}
\cos \varphi & \sin \varphi  \tag{4.90}\\
-\sin \varphi & \cos \varphi
\end{array}\right)\binom{\alpha_{x}}{\alpha_{y}}
$$

(In this analogy, the equality to 1 of the determinant of the rotation matrix in Eq. (90) corresponds to the unitary property (76) of the unitary transform operators.) Please pay attention here: while the transform (75) from the "old" basis $\{u\}$ to the "new" basis $\{v\}$ is performed by the unitary operator, the change (88) of a state vectors components at this transformation requires its Hermitian conjugate. Actually, this is also natural from the point of view of the geometric analog of the unitary transform (Fig. 4): if the "new" reference frame $\left\{x, y^{\prime}\right\}$ is obtained by a counterclockwise rotation of the "old" frame $\{x, y\}$ by some angle $\varphi$, for the observer rotating with the frame, vector $\alpha$ (which is itself unchanged) rotates clockwise. Due to the analogy between expressions (88) and (89) on one hand, and our old friend Eq. (62) on the other hand, it is tempting to skip indices in our new results by writing

$$
\begin{equation*}
|\alpha\rangle_{\text {in } v}=\hat{U}^{\dagger}|\alpha\rangle_{\text {in } u}, \quad|\alpha\rangle_{\text {in } u}=\hat{U}|\alpha\rangle_{\text {in } v} . \tag{4.91}
\end{equation*}
$$

Since matrix elements of $\hat{U}$ and $\hat{U}^{\dagger}$ do not depend on basis, such language is not too bad; still, the symbolic Eq. (91) should not be confused with genuine (basis-independent) bra-ket equalities.

Now let us use the same trick of identity operator insertion, repeated twice, to find the transformation rule for matrix elements of an arbitrary operator:

$$
\begin{equation*}
\left.A_{j j^{\prime}}\right|_{\text {in } v} \equiv\left\langle v_{j}\right| \hat{A}\left|v_{j^{\prime}}\right\rangle=\left\langle v_{j}\right|\left(\sum_{k}\left|u_{k}\right\rangle\left\langle u_{k}\right|\right) \hat{A}\left(\sum_{k^{\prime}}\left|u_{k^{\prime}}\right\rangle\left\langle u_{k^{\prime}}\right|\right)\left|v_{j^{\prime}}\right\rangle=\left.\sum_{k, k^{\prime}} U_{j k}^{\dagger} A_{k k^{\prime}}\right|_{\text {in } u} U_{k j^{\prime}} ; \tag{4.92}
\end{equation*}
$$

Matrix elements' transforms
absolutely similarly, we can get

$$
\begin{equation*}
A_{i j^{\prime}} \mid \text { in } u \sum_{k, k^{\prime}} U_{j k} A_{k k^{\prime} \mid \text { in } v} U_{k j^{\prime}}^{\dagger} \tag{4.93}
\end{equation*}
$$

In the spirit of Eq. (91), we may present these results symbolically as well, in a compact bra-ket form:

$$
\begin{equation*}
\left.\hat{A}\right|_{\text {in } v}=\left.\hat{U}^{\dagger} \hat{A}\right|_{\text {in } u} \hat{U},\left.\quad \hat{A}\right|_{\text {in } u}=\left.\hat{U} \hat{A}\right|_{\text {in } v} \hat{U}^{\dagger} . \tag{4.94}
\end{equation*}
$$

As a sanity check, let us apply this result to the identity operator:

$$
\begin{equation*}
\left.\hat{I}\right|_{\text {in } v}=\left(\hat{U}^{\dagger} \hat{I} \hat{U}\right)_{\text {in } u}=\left(\hat{U}^{\dagger} \hat{U}\right)_{\text {in } u}=\left.\hat{I}\right|_{\text {in } u} \tag{4.95}
\end{equation*}
$$

- as it should be. One more invariant of the basis change is the trace of any operator, defined as the sum of the diagonal terms of its matrix in a certain basis:

Operator/
matrix trace

$$
\begin{equation*}
\operatorname{Tr} \hat{A} \equiv \operatorname{Tr} \mathrm{~A} \equiv \sum_{j} A_{i j} \tag{4.96}
\end{equation*}
$$

The (easy) proof of this fact, using the relations we have already discussed, is left for reader's exercise.
So far, I have implied that both state bases $\{u\}$ and $\{v\}$ are known, and the natural question is where does this information comes from in quantum mechanics of actual physical systems. To get a partial answer to this question, let us return to Eq. (68) that defines eigenstates and eigenvalues of an
operator. Let us assume that the eigenstates $a_{j}$ of a certain operator $\hat{A}$ form a full and orthonormal set, and find the matrix elements of the operator in the basis of these states. For that, it is sufficient to innermultiply both sides of Eq. (68), written for index $j^{\prime}$, by the bra-vector of an arbitrary state $a_{j}$ of the same set:

$$
\begin{equation*}
\left\langle a_{j}\right| \hat{A}\left|a_{j^{\prime}}\right\rangle=\left\langle a_{j}\right| A_{j^{\prime}}\left|a_{j^{\prime}}\right\rangle . \tag{4.97}
\end{equation*}
$$

The left-hand part is just the matrix element $A_{j j}$, we are looking for, while the right hand part is just $A_{j} \cdot \delta_{j j}$. As a result, we see that the matrix is diagonal, with the diagonal consisting of eigenvalues:

$$
\begin{equation*}
A_{i j^{\prime}}=A_{j} \delta_{j j^{\prime}} \tag{4.98}
\end{equation*}
$$

In particular, in the eigenstate basis (but not necessarily in an arbitrary basis!), $A_{j j}$ means the same as $A_{j}$. Thus the most important problem of finding the eigenvalues and eigenstates of an operator is equivalent to the diagonalization of its matrix, ${ }^{18}$ i.e. finding the basis in which the corresponding operator acquires the diagonal form (98); then the diagonal elements are the eigenvalues, and the basis itself is the desirable set of eigenstates.

Let us modify the above calculation by inner-multiplying Eq. (68) by a bra-vector of a different basis - say, the one, denoted $\{u\}$, in which we know the matrix elements $A_{j j}$. The multiplication gives

$$
\begin{equation*}
\left\langle u_{k}\right| \hat{A}\left|a_{j}\right\rangle=\left\langle u_{k}\right| A_{j}\left|a_{j}\right\rangle . \tag{4.99}
\end{equation*}
$$

In the left-hand part we can (as usual :-) insert the identity operator, between the operator and the ketvector, and then use the closure relation (44), while in the right-hand part, we can move the eigenvalue $A_{j}$ out of the bra-ket, and then insert a summation over a new index, compensating it with the proper Kronecker delta symbol:

$$
\begin{equation*}
\left\langle u_{k}\right| \hat{A} \sum_{k^{\prime}}\left|u_{k^{\prime}}\right\rangle\left\langle u_{k^{\prime}} \mid a_{j}\right\rangle=A_{j} \sum_{k^{\prime}}\left\langle u_{k^{\prime}} \mid a_{j}\right\rangle \delta_{k k^{\prime}} \tag{4.100}
\end{equation*}
$$

Moving out the sign of summation over $k$ ', and using definition (47) of the matrix elements, we get

$$
\begin{equation*}
\sum_{k^{\prime}}\left(A_{k k^{\prime}}-A_{j} \delta_{k k^{\prime}}\right)\left\langle u_{k^{\prime}} \mid a_{j}\right\rangle=0 . \tag{4.101}
\end{equation*}
$$

But the set of such equalities, for all $N$ possible values of index $k$, is just a system of linear, homogeneous equations for unknown $c$-numbers $\left\langle u_{k} \mid a_{j}\right\rangle$. But according to Eqs. (82)-(84), these numbers are nothing else than the matrix elements $U_{k^{\prime} j}$ of a unitary matrix providing the required transformation from the initial basis $\{u\}$ to the basis $\{a\}$ that diagonalizes matrix A. The system may be presented in the matrix form:

$$
\left(\begin{array}{ccc}
A_{11}-A_{j} & A_{12} & \ldots  \tag{4.102}\\
A_{21} & A_{22}-A_{j} & \ldots \\
\ldots & \ldots & \ldots
\end{array}\right)\left(\begin{array}{c}
U_{1 j} \\
U_{2 j} \\
\ldots
\end{array}\right)=0
$$

$\qquad$

and the usual condition of its consistency,

$$
\left|\begin{array}{ccc}
A_{11}-A_{j} & A_{12} & \ldots  \tag{4.103}\\
A_{21} & A_{22}-A_{j} & \ldots \\
\ldots & \ldots & \ldots
\end{array}\right|=0,
$$

plays the role of the characteristic equation of the system. This equation has $N$ roots $A_{j} ;$; plugging each of them back into system (102), we can use it to find $N$ matrix elements $U_{k j}(k=1,2, \ldots N)$ corresponding to this particular eigenvalue. However, since equations (103) are homogeneous, they allow finding $U_{k j}$ only to a constant multiplier. In order to ensure their normalization, i.e. the unitary character of matrix $U$, we may use the condition that all eigenvectors are normalized (just as the basis vectors are):

$$
\begin{equation*}
\left\langle a_{j} \mid a_{j}\right\rangle=\sum_{k}\left\langle a_{j} \mid u_{k}\right\rangle\left\langle u_{k} \mid a_{j}\right\rangle=\sum_{k}\left|U_{k j}\right|^{2}=1, \tag{4.104}
\end{equation*}
$$

for each $j$. This normalization completes the diagonalization. ${ }^{19}$
Now (at last!) I can give the reader some examples. As a simple but very important case, let us diagonalize the operators described (in a certain 2-function basis $\{u\}$ ) by the so-called Pauli matrices

Pauli

$$
\sigma_{x} \equiv\left(\begin{array}{ll}
0 & 1  \tag{4.105}\\
1 & 0
\end{array}\right), \quad \sigma_{y} \equiv\left(\begin{array}{cc}
0 & -i \\
i & 0
\end{array}\right), \quad \sigma_{z} \equiv\left(\begin{array}{cc}
1 & 0 \\
0 & -1
\end{array}\right) .
$$

Though introduced by a physicist, with a specific purpose to describe electron's spin, these matrices have a general mathematical significance, because together with the $2 \times 2$ identity matrix I, they provide a full, linearly-independent $2 \times 2$ basis - meaning that an arbitrary $2 \times 2$ matrix may be presented as

$$
\left(\begin{array}{ll}
A_{11} & A_{12}  \tag{4.106}\\
A_{21} & A_{22}
\end{array}\right)=a_{0} \mathrm{I}+a_{x} \sigma_{x}+a_{y} \sigma_{y}+a_{z} \sigma_{z},
$$

with a unique set of 4 coefficients $a$.
Let us start with diagonalizing matrix $\sigma_{x}$. For it, the characteristic equation (103) is evidently

$$
\left|\begin{array}{cc}
-A_{j} & 1  \tag{4.107}\\
1 & -A_{j}
\end{array}\right|=0
$$

and has two roots, $A_{1,2}= \pm 1$. (Again, the numbering is arbitrary!) The reader may readily check that the eigenvalues of matrices $\sigma_{y}$ and $\sigma_{z}$ are similar. However, the eigenvectors of the operators corresponding to all these matrices are different. To find them for $\sigma_{x}$, let us plug its first eigenvalue, $A_{1}=+1$, back into equations (101), written for this particular case:

$$
\begin{array}{r}
-\left\langle u_{1} \mid a_{1}\right\rangle+\left\langle u_{2} \mid a_{1}\right\rangle=0  \tag{4.108}\\
\left\langle u_{1} \mid a_{1}\right\rangle-\left\langle u_{2} \mid a_{1}\right\rangle=0 .
\end{array}
$$

[^585]The equations are compatible (of course, because the used eigenvalue $A_{1}=+1$ satisfies the characteristic equation), and any of them gives

$$
\begin{equation*}
\left\langle u_{1} \mid a_{1}\right\rangle=\left\langle u_{2} \mid a_{1}\right\rangle, \text { i. e. } \quad U_{11}=U_{21} . \tag{4.109}
\end{equation*}
$$

With that, the normalization condition (104) yields

$$
\begin{equation*}
\left|U_{11}\right|^{2}=\left|U_{21}\right|^{2}=\frac{1}{2} . \tag{4.110}
\end{equation*}
$$

Although the normalization is insensitive to the simultaneous multiplication of $U_{11}$ and $U_{21}$ by the same phase factor $\exp \{i \varphi\}$ with any real $\varphi$, it is convenient to keep the coefficients real, for example taking $\varphi$ $=0$, i.e. to get

$$
\begin{equation*}
U_{11}=U_{21}=\frac{1}{\sqrt{2}} . \tag{4.111}
\end{equation*}
$$

Performing an absolutely similar calculation for the second characteristic value, $A_{2}=-1$, we get $U_{12}=-U_{22}$, and we may choose the common phase to get

$$
\begin{equation*}
U_{12}=-U_{22}=\frac{1}{\sqrt{2}}, \tag{4.112}
\end{equation*}
$$

so that the whole unitary matrix for diagonalization of the operator corresponding to $\sigma_{x}$ is ${ }^{20}$

$$
\mathrm{U}_{x}=\mathrm{U}_{x}^{\dagger}=\frac{1}{\sqrt{2}}\left(\begin{array}{cc}
1 & 1  \tag{4.113}\\
1 & -1
\end{array}\right)
$$

For what follows, it will be convenient to have this result expressed in the ket-relation form - see Eqs. (85)-(86):

$$
\begin{array}{ll}
\left|a_{1}\right\rangle=U_{11}\left|u_{1}\right\rangle+U_{21}\left|u_{2}\right\rangle=\frac{1}{\sqrt{2}}\left(\left|u_{1}\right\rangle+\left|u_{2}\right\rangle\right), & \left|a_{2}\right\rangle=U_{12}\left|u_{1}\right\rangle+U_{22}\left|u_{2}\right\rangle=\frac{1}{\sqrt{2}}\left(\left|u_{1}\right\rangle-\left|u_{2}\right\rangle\right), \\
\left|u_{1}\right\rangle=U_{11}^{\dagger}\left|a_{1}\right\rangle+U_{21}^{\dagger}\left|a_{2}\right\rangle=\frac{1}{\sqrt{2}}\left(\left|a_{1}\right\rangle+\left|a_{2}\right\rangle\right), & \left|u_{2}\right\rangle=U_{12}^{\dagger}\left|a_{1}\right\rangle+U_{22}^{\dagger}\left|a_{2}\right\rangle=\frac{1}{\sqrt{2}}\left(\left|a_{1}\right\rangle-\left|a_{2}\right\rangle\right), \tag{4.115}
\end{array}
$$

These results are already sufficient to understand the Stern-Gerlach experiments described in Sec. 1 - with two additional postulates. The first of them is that particle's interaction with external magnetic field may be described by the following vector operator of the dipole magnetic moment: ${ }^{21}$

$$
\begin{equation*}
\hat{\mathbf{m}}=\gamma \hat{\mathbf{S}} \tag{4.116}
\end{equation*}
$$

where the coefficient $\gamma$, specific for every particle type, is called the gyromagnetic ratio, ${ }^{22}$ and $\hat{\mathbf{S}}$ is the vector operator of spin. For the so-called spin- $1 / 2$ particles (including the electron), this operator may be represented, in the so-called $z$-basis, by the following 3D vector of the Pauli matrices (105):

[^586]\[

\mathbf{S}=\frac{\hbar}{2}\left(\mathbf{n}_{x} \sigma_{x}+\mathbf{n}_{y} \sigma_{y}+\mathbf{n}_{z} \sigma_{z}\right)=\frac{\hbar}{2}\left($$
\begin{array}{cc}
\mathbf{n}_{z} & \mathbf{n}_{x}-i \mathbf{n}_{y}  \tag{4.117}\\
\mathbf{n}_{x}+i \mathbf{n}_{y} & -\mathbf{n}_{z}
\end{array}
$$\right),
\]

and $\mathbf{n}_{x, y, z}$ are the usual Cartesian unit vectors in 3D space. (In the quantum-mechanics sense, they are just $c$-numbers, or rather " $c$-vectors".) The $z$-basis, in which Eq. (177) is valid, is defined as an orthonormal basis of two states, frequently denoted $\uparrow$ an $\downarrow$, in which the $z$-component of the vector operator of spin is diagonal, with eigenvalues $+\hbar / 2$ and $-\hbar / 2$. Note that we do not "understand" what exactly these states are, ${ }^{23}$ but loosely associate them with a certain internal rotation of the electron about $z$-axis, with either positive or negative angular momentum component $S_{z}$. However, any attempt to use such classical interpretation for quantitative predictions runs into fundamental difficulties - see Sec. 5.7 below.

The second new postulate describes the general relation between the bra-ket formalism and experiment. ${ }^{24}$ Namely, in quantum mechanics, each real observable $A$ is represented by a Hermitian operator $\hat{A}=\hat{A}^{\dagger}$, and a result of its measurement in a quantum state $\alpha$, described by a linear superposition of the eigenstates $a_{j}$ of the operator,

$$
\begin{equation*}
|\alpha\rangle=\sum_{j} \alpha_{j}\left|a_{j}\right\rangle, \quad \text { with } \alpha_{j}=\left\langle a_{j} \mid \alpha\right\rangle, \tag{4.118}
\end{equation*}
$$

may be only one of corresponding eigenvalues $A_{j} \cdot{ }^{25}$ If state (118) and all eigenstates $\alpha_{j}$ are normalized to unity,

$$
\begin{equation*}
\langle\alpha \mid \alpha\rangle=1, \quad\left\langle a_{j} \mid a_{j}\right\rangle=1 \tag{4.119}
\end{equation*}
$$

then the probability of outcome $A_{j}$ is ${ }^{26}$

Quantum measurement potulate

$$
\begin{equation*}
W_{j}=\left|\alpha_{j}\right|^{2}=\alpha_{j}^{*} \alpha_{j}=\left\langle\alpha \mid a_{j}\right\rangle\left\langle a_{j} \mid \alpha\right\rangle, \tag{4.120}
\end{equation*}
$$

This relation is evidently a generalization of Eq. (1.22) in wave mechanics. As a sanity check, let us assume that the set of eigenstates $a_{j}$ is full, and calculate the sum of all the probabilities:

$$
\begin{equation*}
\sum_{j} W_{j}=\sum_{j}\left\langle\alpha \mid a_{j}\right\rangle\left\langle a_{j} \mid \alpha\right\rangle=\langle\alpha| \hat{I}|\alpha\rangle=1 . \tag{4.121}
\end{equation*}
$$

Now returning to the Stern-Gerlach experiment, conceptually the description of the first ( $z$ oriented) experiment shown in Fig. 1 is the hardest for us, because the statistical ensemble describing the unpolarized electron beam at its input is mixed ("incoherent"), and cannot be described by a pure

[^587]("coherent") superposition of the type (6) that have been the subject of our studies so far. (We will discuss the mixed ensembles in Chapter 7.) However, it is intuitively clear that its results, and in particular Eq. (6), are compatible with the description of its two output beams as sets of electrons in pure states $\uparrow$ and $\downarrow$, respectively. The absorber following that first stage (Fig. 2) just takes all spin-down electrons out of the picture, producing an output beam of polarized electrons in a pure $\uparrow$ state. For such beam, probabilities (120) are $W_{\uparrow}=1$ and $W_{\downarrow}=0$. This is certainly compatible with the result of the "control" experiment shown on the bottom panel of Fig. 2: the repeated SG $(z)$ stage does not split such a beam, keeping the probabilities the same.

Now let us discuss the double Stern-Gerlach experiment shown on the top panel of Fig. 2. For that, let us present the $z$-polarized beam in another basis of two states (I will denote them as $\rightarrow$ and $\leftarrow$ ) in which, by definition, the matrix of operator $\hat{S}_{x}$ is diagonal. But this is exactly the set we called $a_{1,2}$ in the $\sigma_{x}$ matrix diagonalization problem solved above. On the other hand, states $\uparrow$ and $\downarrow$ are exactly what we called $u_{1,2}$ in that problem, because in this basis, matrices $\sigma_{z}$ and hence $\mathrm{S}_{z}$ are diagonal. Hence, in application to the electron spin problem, we may rewrite Eqs. (114)-(115) as

$$
\begin{array}{ll}
|\rightarrow\rangle=\frac{1}{\sqrt{2}}(|\uparrow\rangle+|\downarrow\rangle), & |\leftarrow\rangle=\frac{1}{\sqrt{2}}(|\uparrow\rangle-|\downarrow\rangle), \\
|\uparrow\rangle=\frac{1}{\sqrt{2}}(|\rightarrow\rangle+|\leftarrow\rangle), & |\downarrow\rangle=\frac{1}{\sqrt{2}}(|\rightarrow\rangle-|\leftarrow\rangle), \tag{4.123}
\end{array}
$$

Relation between eigenvectors of operators $S_{x}$ and $S_{z}$

Currently, for us the first of Eqs. (123) is most important, because it shows that the quantum state of electrons entering the $\mathrm{SG}(x)$ stage may be presented as a coherent superposition of electrons with $S_{x}=+\hbar / 2$ and $S_{x}=-\hbar / 2$. Notice that the beams have equal probability amplitude moduli, so that according to Eq. (122), the split beams $\rightarrow$ and $\leftarrow$ have equal intensities, in accordance with experiment. (The minus sign before the second ket-vector is of no consequence here, though it may have an impact on outcome of other experiments - for example if the $\rightarrow$ and $\leftarrow$ beams are brought together again.)

Now, let us discuss the most mysterious (from the classical point of view) multi-stage SG experiment shown on the middle panel of Fig. 2. After the second absorber has taken out all electrons in, say, the $\leftarrow$ state, the remaining electrons in state $\rightarrow$ are passed to the final, SG (z), stage. But according to the first of Eqs. (122), this state may be presented as a (coherent) linear superposition of the $\uparrow$ and $\downarrow$ states, with equal amplitudes. The stage separates these two states into separate beams, with equal probabilities $W_{\uparrow}=W_{\downarrow}=1 / 2$ to find an electron in each of them, thus explaining the experimental results.

To conclude our discussion of the multistage Stern-Gerlach experiment, let me note that though it cannot be explained in terms of wave mechanics (which operates with scalar de Broglie waves), it has an analogy in classical theories of vector fields, such as the classical electrodynamics. Let a plane electromagnetic wave propagate perpendicular to the plane of drawing in Fig. 5, and pass through linear polarizer 1. Similarly to the initial SG (z) stages (including the following absorbers) shown in Fig. 2, the polarizer produces a wave linearly polarized in one direction - the vertical direction in Fig. 5. Its electric field vector has no horizontal component, as may be revealed by wave's full absorption in a perpendicular polarizer 3. However, let us pass the wave through polarizer 2 first. In this case, the output wave does acquire a horizontal component, as can be, again, revealed by passing it through polarizer 3. If angles between polarization direction 1 and 2 , and between 2 and 3 , are both equal $\pi / 4$, each polarizer reduces the wave amplitude by a factor of $\sqrt{ } 2$, and hence intensity by a factor of 2 , exactly
like in the multistage SG experiment, with polarizer 2 playing the role of the $\mathrm{SG}(x)$ stage. The "only" difference is that the necessary angle is $\pi / 4$, rather than by $\pi / 2$ for the Stern-Gerlach experiment. In quantum electrodynamics (see Chapter 9 below), which confirms the classical predictions for this experiment, this difference is explained by that between the integer spin of the electromagnetic field quanta, photons, and the half-integer spin of electrons.

Fig. 4.5. Light polarization sequence similar to the 3 -stage Stern-Gerlach experiment shown on the middle panel of Fig. 2.

### 4.5. Observables: Expectation values and uncertainties

After this particular (and hopefully very inspiring) example, let us discuss the general relation between the Dirac formalism and experiment in more detail. The expectation value of an observable over any statistical ensemble (not necessarily coherent) may be always calculated using the general rule (1.37). For the particular case of a coherent superposition (118), we can combine that definition with Eq. (120) and the second of Eqs. (118), and then use Eqs. (59) and (98) to write

$$
\begin{equation*}
\langle A\rangle=\sum_{j} A_{j} W_{j}=\sum_{j} \alpha_{j}^{*} A_{j} \alpha_{j}=\sum_{j}\left\langle\alpha \mid a_{j}\right\rangle A_{j}\left\langle a_{j} \mid \alpha\right\rangle=\sum_{j, j^{\prime}}\left\langle\alpha \mid a_{j}\right\rangle\left\langle a_{j}\right| \hat{A}\left|a_{j^{\prime}}\right\rangle\left\langle a_{j^{\prime}} \mid \alpha\right\rangle . \tag{4.124}
\end{equation*}
$$

Now using the completeness relation (44) twice, with indices $j$ and $j^{\prime}$, we arrive at a very simple and important formula ${ }^{27}$

This is a clear analog of the wave-mechanics formula (1.23) - and as we will see in the next chapter, may be used to derive it. A huge advantage of Eq. (125) is that it does not explicitly involve the eigenvector set of the corresponding operator, and allows the calculation to be performed in any convenient basis. ${ }^{28}$

For example, let us consider an arbitrary state $\alpha$ of spin- $1 / 2$, and calculate the expectation values of its components. The calculations are easiest in the $z$-basis, because we know the operators of the components in that basis - see Eq. (117). Representing the ket- and bra-vectors of our state as linear superpositions of vectors of the basis states $\uparrow$ and $\downarrow$,

$$
\begin{equation*}
|\alpha\rangle=\alpha_{\uparrow}|\uparrow\rangle+\alpha_{\downarrow}|\downarrow\rangle, \quad\langle\alpha|=\langle\uparrow| \alpha_{\uparrow}^{*}+\langle\downarrow| \alpha_{\downarrow}^{*} . \tag{4.126}
\end{equation*}
$$

[^588]and plugging these expressions to Eq. (125) written for observable $S_{z}$, we get
\[

$$
\begin{align*}
\left\langle S_{z}\right\rangle & =\left(\langle\uparrow| \alpha_{\uparrow}^{*}+\langle\downarrow| \alpha_{\downarrow}^{*}\right) \hat{S}_{z}\left(\alpha_{\uparrow}|\uparrow\rangle+\alpha_{\downarrow}|\downarrow\rangle\right)  \tag{4.127}\\
& =\alpha_{\uparrow} \alpha_{\uparrow}^{*}\langle\uparrow| \hat{S}_{z}|\uparrow\rangle+\alpha_{\downarrow} \alpha_{\downarrow}^{*}\langle\downarrow| \hat{S}_{z}|\downarrow\rangle+\alpha_{\uparrow} \alpha_{\downarrow}^{*}\langle\downarrow| \hat{S}_{z}|\uparrow\rangle+\alpha_{\downarrow} \alpha_{\uparrow}^{*}\langle\uparrow| \hat{S}_{z}|\downarrow\rangle .
\end{align*}
$$
\]

Now there are two equivalent ways (both very simple :-) to calculate the bra-kets in this expression. The first one is to represent each of them in the matrix form in the $z$-basis, in which bra- and ket-vectors of states $\uparrow$ and $\downarrow$ are, respectively, matrix-rows $(1,0)$ and $(0,1)$, or the similar matrixcolumns. Another (perhaps more elegant) way is to use the general Eq. (59), for the $z$-basis, to write

$$
\begin{equation*}
\hat{S}_{x}=\frac{\hbar}{2}(|\uparrow\rangle\langle\downarrow|+|\downarrow\rangle\langle\uparrow|), \quad \hat{S}_{y}=-i \frac{\hbar}{2}(|\uparrow\rangle\langle\downarrow|-|\downarrow\rangle\langle\uparrow|), \quad \hat{S}_{z}=\frac{\hbar}{2}(|\uparrow\rangle\langle\uparrow|-|\downarrow\rangle\langle\downarrow|) \tag{4.128}
\end{equation*}
$$

For our particular calculation, we may plug the last of these expressions into Eq. (127), and to use the orthonormality conditions (119):

$$
\begin{equation*}
\langle\uparrow \mid \uparrow\rangle=\langle\downarrow \mid \downarrow\rangle=1, \quad\langle\uparrow \mid \downarrow\rangle=\langle\downarrow \mid \uparrow\rangle=0 . \tag{4.129}
\end{equation*}
$$

Both calculations give (of course) the same result:

$$
\begin{equation*}
\left\langle S_{z}\right\rangle=\frac{\hbar}{2}\left(\alpha_{\uparrow} \alpha_{\uparrow}^{*}-\alpha_{\downarrow} \alpha_{\downarrow}^{*}\right) . \tag{4.130}
\end{equation*}
$$

This particular result might be also obtained using Eq. (120) for probabilities $W_{\uparrow}=\alpha \uparrow \alpha \uparrow^{*}$ and $W_{\downarrow}=$ $\alpha \downarrow \downarrow_{\downarrow}{ }^{*}$ :

$$
\begin{equation*}
\left\langle S_{z}\right\rangle=W_{\uparrow}\left(+\frac{\hbar}{2}\right)+W_{\downarrow}\left(-\frac{\hbar}{2}\right)=\alpha_{\uparrow} \alpha_{\uparrow}^{*}\left(+\frac{\hbar}{2}\right)+\alpha_{\downarrow} \alpha_{\downarrow}^{*}\left(-\frac{\hbar}{2}\right) . \tag{4.131}
\end{equation*}
$$

The formal way (127), based on using Eq. (125), has, however, an advantage of being applicable, without any change, to finding the observables whose operators are not diagonal in the $z$-basis, as well. In particular, absolutely similar calculations give

$$
\begin{align*}
& \left\langle S_{x}\right\rangle=\alpha_{\uparrow} \alpha_{\uparrow}^{*}\langle\uparrow| \hat{S}_{x}|\uparrow\rangle+\alpha_{\downarrow} \alpha_{\downarrow}^{*}\langle\downarrow| \hat{S}_{x}|\downarrow\rangle+\alpha_{\uparrow} \alpha_{\downarrow}^{*}\langle\downarrow| \hat{S}_{x}|\uparrow\rangle+\alpha_{\downarrow} \alpha_{\uparrow}^{*}\langle\uparrow| \hat{S}_{x}|\downarrow\rangle=\frac{\hbar}{2}\left(\alpha_{\uparrow} \alpha_{\downarrow}^{*}+\alpha_{\downarrow} \alpha_{\uparrow}^{*}\right),  \tag{4.132}\\
& \left\langle S_{y}\right\rangle=\alpha_{\uparrow} \alpha_{\uparrow}^{*}\langle\uparrow| \hat{S}_{y}|\uparrow\rangle+\alpha_{\downarrow} \alpha_{\downarrow}^{*}\langle\downarrow| \hat{S}_{y}|\downarrow\rangle+\alpha_{\uparrow} \alpha_{\downarrow}^{*}\langle\downarrow| \hat{S}_{y}|\uparrow\rangle+\alpha_{\downarrow} \alpha_{\uparrow}^{*}\langle\uparrow| \hat{S}_{y}|\downarrow\rangle=i \frac{\hbar}{2}\left(\alpha_{\uparrow} \alpha_{\downarrow}^{*}-\alpha_{\downarrow} \alpha_{\uparrow}^{*}\right), \tag{4.133}
\end{align*}
$$

Similarly, we can express, via the same coefficients $\alpha \uparrow$ and $\alpha \downarrow$, the r.m.s. fluctuations of all spin components. For example, let us have a good look at the spin state $\uparrow$. According to Eq. (126), in this state $\alpha \uparrow=1$ and $\alpha_{\downarrow}=0$, so that Eqs. (130)-(133) yield:

$$
\begin{equation*}
\left\langle S_{z}\right\rangle=\frac{\hbar}{2}, \quad\left\langle S_{x}\right\rangle=\left\langle S_{y}\right\rangle=0 . \tag{4.134}
\end{equation*}
$$

Now let us use the same Eq. (125) to calculate the spin component uncertainties. According to Eqs. (105) and (117), operators of spin component squared are equal to $(\hbar / 2)^{2} \hat{I}$, so that the general Eq. (1.33) yields

$$
\begin{gather*}
\left(\delta S_{z}\right)^{2}=\left\langle S_{z}^{2}\right\rangle-\left\langle S_{z}\right\rangle^{2}=\langle\uparrow| \hat{S}_{z}^{2}|\uparrow\rangle-\left(\frac{\hbar}{2}\right)^{2}=\left(\frac{\hbar}{2}\right)^{2}\langle\uparrow| \hat{I}|\uparrow\rangle-\left(\frac{\hbar}{2}\right)^{2}=0,  \tag{4.135a}\\
\left(\delta S_{x}\right)^{2}=\left\langle S_{x}^{2}\right\rangle-\left\langle S_{x}\right\rangle^{2}=\langle\uparrow| \hat{S}_{x}^{2}|\uparrow\rangle-0=\left(\frac{\hbar}{2}\right)^{2}\langle\uparrow| \hat{I}|\uparrow\rangle=\left(\frac{\hbar}{2}\right)^{2},  \tag{4.135b}\\
\left(\delta S_{y}\right)^{2}=\left\langle S_{y}^{2}\right\rangle-\left\langle S_{y}\right\rangle^{2}=\langle\uparrow| \hat{S}_{y}^{2}|\uparrow\rangle-0=\left(\frac{\hbar}{2}\right)^{2}\langle\uparrow| \hat{I}|\uparrow\rangle=\left(\frac{\hbar}{2}\right)^{2} . \tag{4.135c}
\end{gather*}
$$

While Eqs. (134) and (135a) are compatible with the classical notion of the spin being "definitely in the $\uparrow$ state", this correspondence should not be overstretched to the interpretation of this state as a certain $(z)$ orientation of electron's magnetic moment $\mathbf{m}$, because such classical picture cannot explain Eqs. (135b) and (135c). The best (but still imprecise!) classical image I can offer is the magnetic moment $\mathbf{m}$ oriented, on the average, in the $z$-direction, but still having $x$ - and $y$-components strongly "wobbling" about their zero average values.

It is straightforward to verify that in the $x$-polarized and $y$-polarized states the situation is similar, with the corresponding change of indices. Thus, in neither state may all 3 components of the spin have exact values. Let me show that this is not just an occasional fact, but reflects the most profound property of quantum mechanics, the uncertainty relations. Consider 2 observables, $A$ and $B$, that may be measured in the same quantum state. There are two possibilities here. If operators corresponding to the observables commute,

$$
\begin{equation*}
[\hat{A}, \hat{B}]=0 \tag{4.136}
\end{equation*}
$$

then all the matrix elements of the commutator in any orthogonal basis (in particular, in the basis of eigenstates $a_{j}$ of operator $A$ ) are also zero. From here, we get

$$
\begin{equation*}
\left\langle a_{j}\right|[\hat{A}, \hat{B}]\left|a_{j^{\prime}}\right\rangle=\left\langle a_{j}\right| \hat{A} \hat{B}\left|a_{j^{\prime}}\right\rangle-\left\langle a_{j}\right| \hat{B} \hat{A}\left|a_{j^{\prime}}\right\rangle=0 . \tag{4.137}
\end{equation*}
$$

In the first bra-ket of the middle expression, let us act by operator $\hat{A}$ on the bra-vector, while in the second one, on the ket-vector. According to Eq. (68), such action turns operators into the corresponding eigenvalues, so that we get

$$
\begin{equation*}
A_{j}\left\langle a_{j}\right| \hat{B}\left|a_{j^{\prime}}\right\rangle-A_{j^{\prime}}\left\langle a_{j}\right| \hat{B}\left|a_{j^{\prime}}\right\rangle=\left(A_{j}-A_{j^{\prime}}\right)\left\langle a_{j}\right| \hat{B}\left|a_{j^{\prime}}\right\rangle=0 \tag{4.138}
\end{equation*}
$$

This means that if eigenstates of operator $\hat{A}$ are non-degenerate (i.e. $A_{j} \neq A_{j}$, if $j \neq j$ '), the matrix of operator $\hat{B}$ has to be diagonal in basis $a_{j}$, i.e., the eigenstate sets of operators $\hat{A}$ and $\hat{B}$ coincide. Such pairs of observables, that share their eigenstates, are called compatible. For example, in wave mechanics of a particle, momentum (1.26) and the kinetic energy (1.27) are compatible, sharing eigenfunctions (1.29). Now we see that this is not occasional, because each Cartesian component of the kinetic energy is proportional to the square of the corresponding component of the momentum, and any operator commutes with an arbitrary power of itself:

$$
\begin{equation*}
\left[\hat{A}, \hat{A}^{n}\right] \equiv[\hat{A}, \underbrace{\hat{A} \hat{A} \ldots \hat{A}}_{n}]=\hat{A} \underbrace{\hat{A} \hat{A} \ldots}_{n} \hat{A}-\underbrace{\hat{A} \hat{A} \ldots \hat{A}}_{n} \hat{A}=0 . \tag{4.139}
\end{equation*}
$$

Now, what if operators $\hat{A}$ and $\hat{B}$ do not commute? Then the following general uncertainty relation is valid: ${ }^{29}$

$$
\delta A \delta B \geq \frac{1}{2}|\langle[\hat{A}, \hat{B}]\rangle| .
$$

General uncertainty relation

Schwartz inequality

The proof may be started by using postulate (16) - that the norm of any legitimate state of the system cannot be negative. Let us apply this postulate to the state with the following ket-vector:

$$
\begin{equation*}
|\delta\rangle \equiv|\alpha\rangle-\frac{\langle\beta \mid \alpha\rangle}{\langle\beta \mid \beta\rangle}|\beta\rangle \tag{4.142}
\end{equation*}
$$

where $\alpha$ and $\beta$ are possible, non-null states of the system, so that the denominator in Eq. (142) is not equal to zero. For this case, Eq. (16) gives

$$
\begin{equation*}
\left(\langle\alpha|-\frac{\langle\alpha \mid \beta\rangle}{\langle\beta \mid \beta\rangle}\langle\beta|\right)\left(|\alpha\rangle-\frac{\langle\beta \mid \alpha\rangle}{\langle\beta \mid \beta\rangle}|\beta\rangle\right) \geq 0 \tag{4.143}
\end{equation*}
$$

Opening the parentheses, we get

$$
\begin{equation*}
\langle\alpha \mid \alpha\rangle-\frac{\langle\alpha \mid \beta\rangle}{\langle\beta \mid \beta\rangle}\langle\beta \mid \alpha\rangle-\frac{\langle\beta \mid \alpha\rangle}{\langle\beta \mid \beta\rangle}\langle\alpha \mid \beta\rangle+\frac{\langle\alpha \mid \beta\rangle\langle\beta \mid \alpha\rangle}{\langle\beta \mid \beta\rangle^{2}}\langle\beta \mid \beta\rangle \geq 0 \tag{4.144}
\end{equation*}
$$

After the cancellation of one inner product $\langle\beta \mid \beta\rangle$ in the numerator and denominator of the last term, it cancels with the $2^{\text {rd }}$ (or $3^{\text {rd }}$ ) term, proving the Schwartz inequality (141).

Now let us apply this inequality to states

$$
\begin{equation*}
|\alpha\rangle \equiv \hat{\widetilde{A}}|\gamma\rangle \text { and }|\beta\rangle \equiv \hat{\widetilde{B}}|\gamma\rangle \tag{4.145}
\end{equation*}
$$

where, in both relations, $\gamma$ is the same (but otherwise arbitrary) possible state of the system, and the deviations operators are defined similarly to observable deviations (see Sec. 1.2), for example,

$$
\begin{equation*}
\hat{\tilde{A}} \equiv \hat{A}-\langle A\rangle \tag{4.146}
\end{equation*}
$$

With this substitution, and taking into account that the observable operators $\hat{A}$ and $\hat{B}$ are Hermitian, Eq. (141) yields

$$
\begin{equation*}
\left.\langle\gamma| \hat{\tilde{A}}^{2}|\gamma\rangle\langle\gamma| \hat{\widetilde{B}}^{2}|\gamma\rangle \geq|\langle\gamma| \hat{\tilde{A}} \hat{\tilde{B}}| \gamma\right\rangle\left.\right|^{2} \tag{4.147}
\end{equation*}
$$

[^589]Since state $\gamma$ is arbitrary, we may use Eq. (125) to rewrite this relation as an operator inequality:

$$
\begin{equation*}
\delta A \delta B \geq|\langle\hat{\tilde{A}} \hat{\tilde{B}}\rangle| . \tag{4.148}
\end{equation*}
$$

Actually, this is already an uncertainty relation, even "better" (stronger) than its standard form (140); moreover, it is more convenient in some cases. In order to proceed to Eq. (140), we need a couple more steps. First, let us notice that the operator product in Eq. (148) may be recast as

$$
\begin{equation*}
\hat{\widetilde{A}} \hat{\widetilde{B}}=\frac{1}{2}\{\hat{\widetilde{A}}, \hat{\widetilde{B}}\}-\frac{i}{2} \hat{C}, \quad \text { where } \hat{C} \equiv i[\hat{\widetilde{A}}, \hat{\widetilde{B}}] \tag{4.149}
\end{equation*}
$$

Any anticommutator of Hermitian operators, including that in Eq. (149), is a Hermitian operator, and its eigenvalues are purely real, so that its expectation value (in any state) is also purely real. On the other hand, the commutator part of Eq. (149) is just

$$
\begin{equation*}
\hat{C} \equiv i[\hat{\tilde{A}}, \hat{\widetilde{B}}]=i(\hat{A}-\langle A\rangle)(\hat{B}-\langle B\rangle)-i(\hat{B}-\langle B\rangle)(\hat{A}-\langle A\rangle)=i(\hat{A} \hat{B}-\hat{B} \hat{A})=i[\hat{A}, \hat{B}] . \tag{4.150}
\end{equation*}
$$

Second, according to Eqs. (52) and (65), the Hermitian conjugate of any product of Hermitian operators $\hat{A}$ and $\hat{B}$ is just the product of swapped operators. Using the fact, we may write

$$
\begin{equation*}
\hat{C}^{\dagger}=(i[\hat{A}, \hat{B}])^{\dagger}=-i(\hat{A} \hat{B})^{\dagger}+i(\hat{B} \hat{A})^{\dagger}=-i \hat{B} \hat{A}+i \hat{A} \hat{B}=i[\hat{A}, \hat{B}]=\hat{C} \tag{4.151}
\end{equation*}
$$

so that operator $\hat{C}$ is also Hermitian, i.e. its eigenvalues are also real, and thus its average is purely real as well. As a result, the square of the average of the operator product (149) may be presented as

$$
\begin{equation*}
\langle\hat{\tilde{A}} \hat{\tilde{B}}\rangle^{2}=\left\langle\frac{1}{2}\{\hat{\tilde{A}}, \hat{\tilde{B}}\}\right\rangle^{2}+\left\langle\frac{1}{2} \hat{C}\right\rangle^{2} . \tag{4.152}
\end{equation*}
$$

Since the first term in the right-hand part of this equality cannot be negative,

$$
\begin{equation*}
\langle\hat{\widetilde{A}} \hat{\tilde{B}}\rangle^{2} \geq\left\langle\frac{1}{2} \hat{C}\right\rangle^{2}=\left\langle\frac{i}{2}[\hat{A}, \hat{B}]\right\rangle^{2} \tag{4.153}
\end{equation*}
$$

and we can continue Eq. (148) as

$$
\begin{equation*}
\delta A \delta B \geq|\langle\hat{\tilde{A}} \hat{\tilde{B}}\rangle| \geq \frac{1}{2}|\langle[\hat{A}, \hat{B}]\rangle|, \tag{4.154}
\end{equation*}
$$

thus proving Eq. (140).
For the particular case of operators $\hat{x}$ and $\hat{p}_{x}$ (or a similar pair of operators for another Cartesian coordinate), we can readily combine Eq. (140) with Eq. (2.14b) and to prove the original Heisenberg's uncertainty relation (2.13). For the spin-1/2 operators defined by Eq. (117), it is straightforward (and highly recommended to the reader) to show that

$$
\begin{equation*}
\left[\hat{S}_{x}, \hat{S}_{y}\right]=i \hbar \hat{S}_{z} \tag{4.155}
\end{equation*}
$$

with similar relations for other pairs of indices taken in the "correct" order (from $x$ to $y$ to $z$ to $x$, etc.). As a result, the uncertainty relations (140) for spin- $1 / 2$ particles, notably including electrons, are

$$
\begin{equation*}
\delta S_{x} \delta S_{y} \geq \frac{\hbar}{2}\left|\left\langle S_{z}\right\rangle\right|, \text { etc. } \tag{4.156}
\end{equation*}
$$

In particular, in the $\uparrow$ state, the right-hand part of this relation equals $(\hbar / 2)^{2}$, and neither of the uncertainties $\delta S_{x}, \delta S_{y}$ can equal zero. As a reminder, our direct calculation earlier in this section has shown that each of these uncertainties is equal to $\hbar / 2$, i.e. their product equals to the lowest value allowed by the uncertainty relation (156). In this aspect, the spin-polarized states are similar to the Gaussian wave packets studied in Sec. 2.2.

### 4.6. Quantum dynamics: Three pictures

So far in this chapter, I shied away from the discussion of system dynamics, implying that the bra- and ket-vectors of the system are their "snapshots" at a certain instant $t$. Now we are sufficiently prepared to examine their time dependence. One of the most beautiful features of quantum mechanics is that the time evolution may be described using either of three alternative "pictures", giving exactly the same final results for expectation values of all observables.

From the standpoint of our wave mechanics experience, the Schrödinger picture is the most natural. In this picture, the operators corresponding to time-independent observables (e.g., to the Hamiltonian function $H$ of an isolated system) are also constant, while the bra- and ket-vectors of the quantum state of the system evolve in time as

$$
\begin{equation*}
\langle\alpha(t)|=\left\langle\alpha\left(t_{0}\right)\right| \hat{u}^{\dagger}\left(t, t_{0}\right), \quad|\alpha(t)\rangle=\hat{u}\left(t, t_{0}\right)\left|\alpha\left(t_{0}\right)\right\rangle, \tag{4.157}
\end{equation*}
$$

where $\hat{u}\left(t, t_{0}\right)$ is the time-evolution operator, which obeys the following differential equation:

$$
\begin{equation*}
i \hbar \dot{\hat{u}}=\hat{H} \hat{u} \tag{4.158}
\end{equation*}
$$

where $\hat{H}$ is the Hamiltonian operator of the system (that is always Hermitian, $\hat{H}^{\dagger}=\hat{H}$ ), and the dot means the differentiation is over argument $t$, but not $t_{0}$. While this equation is a very natural replacement of the wave-mechanical equation (1.25), and is also frequently called the Schrödinger equation, ${ }^{31}$ it still should be considered as a new, more general postulate, which finds its final justification (as it is usual in physics) in the agreement between its corollaries with experiment - more exactly, in having not a single credible contradiction with experiment.

Starting the discussion of Eqs. (157)-(158), let us first consider the case of a system described by a time-independent Hamiltonian, whose eigenstates $a_{n}$ and eigenvalues $E_{n}$ obey Eq. (68), ${ }^{32}$

$$
\begin{equation*}
\hat{H}\left|a_{n}\right\rangle=E_{n}\left|a_{n}\right\rangle, \tag{4.159}
\end{equation*}
$$

and hence are also time-independent. (Similarly to the wavefunctions $\psi_{n}$ defined by Eq. (1.60), $a_{n}$ are called the stationary states of the system.) Let us use Eqs. (157)-(159) to calculate the law of time evolution of the expansion coefficients $\alpha_{n}$, defined by Eq. (118), in the stationary state basis:

[^590]\[

$$
\begin{align*}
\dot{\alpha}_{n}(t) & =\frac{d}{d t}\left\langle a_{n} \mid \alpha(t)\right\rangle=\frac{d}{d t}\left\langle a_{n}\right| \hat{u}\left(t, t_{0}\right)\left|\alpha\left(t_{0}\right)\right\rangle=\left\langle a_{n}\right| \dot{\hat{u}}\left(t, t_{0}\right)\left|\alpha\left(t_{0}\right)\right\rangle  \tag{4.160}\\
& =\left\langle a_{n}\right| \frac{1}{i \hbar} \hat{H} \hat{u}\left(t, t_{0}\right)\left|\alpha\left(t_{0}\right)\right\rangle=\frac{E_{n}}{i \hbar}\left\langle a_{n}\right| \hat{u}\left(t, t_{0}\right)\left|\alpha\left(t_{0}\right)\right\rangle=\frac{E_{n}}{i \hbar}\left\langle a_{n} \mid \alpha(t)\right\rangle=-\frac{i}{\hbar} E_{n} \alpha_{n} .
\end{align*}
$$
\]

This is the same simple equation as Eq. (1.59), and its integration yields a similar result - cf. Eq. (1.61), just with the initial time $t_{0}$ rather than 0 :

Pauli
Hamiltonian: operator

$$
\begin{equation*}
\alpha_{n}(t)=\alpha_{n}\left(t_{0}\right) \exp \left\{-\frac{i}{\hbar} E_{n}\left(t-t_{0}\right)\right\} \tag{4.161}
\end{equation*}
$$

In order to illustrate how does this result work, let us consider spin- $1 / 2$ dynamics in a timeindependent, uniform external magnetic field $B$, taking its direction for axis $z$. To construct the system's Hamiltonian, we may apply the correspondence principle to the classical expression for the energy of a magnetic moment $\mathbf{m}$ in the external magnetic field $\mathcal{B}, 33$

$$
\begin{equation*}
U=-\mathbf{m} \cdot \boldsymbol{B} . \tag{4.162}
\end{equation*}
$$

In quantum mechanics, the operator corresponding to the moment $\mathbf{m}$ is given by Eq. (116) (suggested by W. Pauli), so that the spin-field interaction is described by the so-called Pauli Hamiltonian:

$$
\begin{equation*}
\hat{H}=-\hat{\mathbf{m}} \cdot \boldsymbol{B}=-\hat{\boldsymbol{S}} \cdot \boldsymbol{B}=-\gamma \boldsymbol{B} \hat{S}_{z} \tag{4.163}
\end{equation*}
$$

where $\hat{S}_{z}$ is the operator of the $z$-component of electron's spin. According to Eq. (117), in the $z$-basis of states $\uparrow$ and $\downarrow$, the matrix of operator (163) is

$$
\begin{equation*}
\mathrm{H}=-\frac{\gamma \hbar B}{2} \sigma_{z}=\frac{\hbar \Omega}{2} \sigma_{z}, \quad \text { with } \Omega \equiv-\gamma B \text {. } \tag{4.164}
\end{equation*}
$$

The constant $\Omega$ so defined coincides with the classical frequency of the precession of a symmetric top, with an angular momentum $\mathbf{S}$ and magnetic moment $\mathbf{m}=\gamma \mathbf{S}$, about axis $z$, induced by external torque $\tau$ $=\mathbf{m} \times$ B: 34

$$
\begin{equation*}
\Omega=-\frac{\tau}{S}=-\frac{m B}{S}=-\gamma B . \tag{4.165a}
\end{equation*}
$$

For an electron, with its negative gyromagnetic ratio $\gamma_{e}=-g_{e} e / 2 m_{e}$, neglecting the minor difference between factors $g_{e}$ and 2 , we get

$$
\begin{equation*}
\Omega=\frac{e}{m_{e}} \mathcal{B}, \tag{4.165b}
\end{equation*}
$$

i.e. the frequency's magnitude coincides with that of the cyclotron frequency $\omega_{c}$ - see Eq. (3.48).

In order to apply the general Eq. (161), at this stage we would need to find the eigenstates $a_{n}$ and eigenenergies $E_{n}$ of our Hamiltonian. However, with our (smart :-) choice of the direction of axis $z$, the Hamiltonian matrix is already diagonal:

[^591]\[

\mathrm{H}=-\frac{\hbar \Omega}{2} \sigma_{z}=\frac{\hbar \Omega}{2}\left($$
\begin{array}{cc}
1 & 0  \tag{4.166}\\
0 & -1
\end{array}
$$\right)
\]

meaning that $\uparrow$ and $\downarrow$ are the eigenstates of the system, with eigenenergies, respectively,

$$
\begin{equation*}
E_{\uparrow}=+\frac{\hbar \Omega}{2} \quad \text { and } \quad E_{\downarrow}=-\frac{\hbar \Omega}{2} . \tag{4.167}
\end{equation*}
$$

(Note that their difference,

$$
\begin{equation*}
\Delta E \equiv\left|E_{\uparrow}-E_{\downarrow}\right|=\hbar|\Omega|=\hbar|\gamma \mathcal{B}|, \tag{4.168}
\end{equation*}
$$

corresponds to the classical energy $2 \mid m$ 耳 of flipping the magnetic dipole with moment $m=\gamma \hbar / 2$, oriented along the direction of field B. ${ }^{35}$ ) With that, Eq. (161) immediately yields following expressions for the time evolution of the expansion coefficients:

$$
\begin{equation*}
\alpha_{\uparrow}(t)=\alpha_{\uparrow}\left(t_{0}\right) \exp \left\{-\frac{i}{2} \Omega\left(t-t_{0}\right)\right\}, \quad \alpha_{\downarrow}(t)=\alpha_{\downarrow}\left(t_{0}\right) \exp \left\{\frac{i}{2} \Omega\left(t-t_{0}\right)\right\}, \tag{4.169}
\end{equation*}
$$

allowing a ready calculation of time evolution of the expectation values of any observable.
In particular, we can calculate the expectation value of $S_{z}$ as a function of time by applying Eq. (130) to an arbitrary time moment $t$ :

$$
\begin{equation*}
\left\langle S_{z}\right\rangle(t)=\frac{\hbar}{2}\left[\alpha_{\uparrow}(t) \alpha_{\uparrow}^{*}(t)-\alpha_{\downarrow}(t) \alpha_{\downarrow}^{*}(t)\right]=\frac{\hbar}{2}\left[\alpha_{\uparrow}(0) \alpha_{\uparrow}^{*}(0)-\alpha_{\downarrow}(0) \alpha_{\downarrow}^{*}(0)\right]=\left\langle S_{z}\right\rangle(0) . \tag{4.170}
\end{equation*}
$$

Thus the expectation value of the spin component parallel to the applied magnetic field remains constant, regardless of the initial state of the system. However, this is not true for the components perpendicular to the field. For example, Eq. (132), applied to moment $t$, gives

$$
\begin{equation*}
\left\langle S_{x}\right\rangle(t)=\frac{\hbar}{2}\left[\alpha_{\uparrow}(t) \alpha_{\downarrow}^{*}(t)+\alpha_{\downarrow}(t) \alpha_{\uparrow}^{*}(t)\right]=\frac{\hbar}{2}\left[\alpha_{\uparrow}(0) \alpha_{\downarrow}^{*}(0) e^{-i \Omega\left(t-t_{0}\right)}+\alpha_{\downarrow}(0) \alpha_{\uparrow}^{*}(0) e^{i \Omega\left(t-t_{0}\right)}\right] . \tag{4.171}
\end{equation*}
$$

Clearly, this expression describes sinusoidal oscillations with frequency (165). The amplitude and phase of these oscillations depend on initial conditions. Indeed, solving Eqs. (132)-(133) for the expansion coefficient products, we get relations

$$
\begin{equation*}
\hbar \alpha_{\downarrow}(t) \alpha_{\uparrow}^{*}(t)=\left\langle S_{x}\right\rangle(t)+i\left\langle S_{y}\right\rangle(t), \quad \hbar \alpha_{\uparrow}(t) \alpha_{\downarrow}^{*}(t)=\left\langle S_{x}\right\rangle(t)-i\left\langle S_{y}\right\rangle(t) \tag{4.172}
\end{equation*}
$$

valid for any time $t$. Plugging their values for $t=0$ into Eq. (171), we get

$$
\begin{align*}
\left\langle S_{x}\right\rangle(t) & =\frac{1}{2}\left[\left\langle S_{x}\right\rangle(0)+i\left\langle S_{y}\right\rangle(0)\right] e^{i \Omega\left(t-t_{0}\right)}+\frac{1}{2}\left[\left\langle S_{x}\right\rangle(0)-i\left\langle S_{y}\right\rangle(0)\right] e^{-i \Omega\left(t-t_{0}\right)}  \tag{4.173}\\
& \equiv\left\langle S_{x}\right\rangle(0) \cos \Omega t-\left\langle S_{y}\right\rangle(0) \sin \Omega t
\end{align*}
$$

An absolutely similar calculation using Eq. (133) gives

[^592]\[

$$
\begin{equation*}
\left\langle S_{y}\right\rangle(t)=\left\langle S_{y}\right\rangle(0) \cos \Omega t+\left\langle S_{x}\right\rangle(0) \sin \Omega t . \tag{4.174}
\end{equation*}
$$

\]

These formulas show, for example, if at moment $t=0$ the spin's state was $\uparrow$, i.e. $\left\langle S_{x}\right\rangle(0)=\left\langle S_{y}\right\rangle(0)$ $=0$, then the amplitude of oscillation of the both "lateral" component of spin vanishes. On the other hand, if the spin was initially in state $\rightarrow$, i.e. had the definite, maximum possible value of $S_{x}$, equal to $\hbar / 2$ (in classics, we would say "the spin $\hbar / 2$ was oriented in direction $x$ "), then both expectation values $\left\langle S_{x}\right\rangle$ and $\left\langle S_{y}\right\rangle$ oscillate in time ${ }^{36}$ with this amplitude, with the phase shift $\pi / 2$ between them. These formulas may be interpreted as the torque-induced precession of the Cartesian components of the spin vector of length $S=\hbar / 2$, confined in plane $[x, y]$, with classical frequency $\Omega=\gamma B$ about axis $z$ (counterclockwise if $\gamma \mathcal{B}>0$ ).

Thus, the gyromagnetic ratio is just the angular frequency of the torque-induced precession of spin (about field's direction) per unit magnetic field; for electrons, $\left|\gamma_{e}\right| \approx 1.761 \times 10^{11} \mathrm{~s}^{-1} \mathrm{~T}^{-1}$; for protons, the ratio is much smaller because of their larger mass: $\gamma_{p} \approx 2.675 \times 10^{8} \mathrm{~s}^{-1} \mathrm{~T}^{-1}$, and for larger spin- $1 / 2$ nuclei, $\gamma$ may be much smaller still - e.g., $8.681 \times 10^{6} \mathrm{~s}^{-1} \mathrm{~T}^{-1}$ for the ${ }^{57} \mathrm{Fe}$ nucleus. ${ }^{37}$

Note, however, that this classical language does not describe large quantum-mechanical uncertainties of these observables, which are absent in the classical picture of the precession - at least when it starts from a definite orientation of the angular momentum vector.

Now let us return to the discussion of the general Schrödinger equation (158) and prove the following fascinating fact: it is possible to write the general solution of this operator equation. In the easiest case when the Hamiltonian is time-independent, this solution is an exact analog of Eq. (161),

$$
\begin{equation*}
\hat{u}\left(t, t_{0}\right)=\hat{u}\left(t_{0}, t_{0}\right) \exp \left\{-\frac{i}{\hbar} \hat{H}\left(t-t_{0}\right)\right\}=\hat{I} \exp \left\{-\frac{i}{\hbar} \hat{H}\left(t-t_{0}\right)\right\} . \tag{4.175}
\end{equation*}
$$

To start its proof we should, first of all, understand what does a function (in this case, the exponent) of an operator mean. In the operator (and matrix) algebra, such functions are defined by their Taylor expansions; in particular, Eq. (175) means that

$$
\begin{align*}
\hat{u}\left(t, t_{0}\right) & =\hat{I}+\sum_{k=1}^{\infty} \frac{1}{k!}\left(-\frac{i}{\hbar} \hat{H} t\right)^{k} \\
& =\hat{I}+\frac{1}{1!}\left(-\frac{i}{\hbar}\right) \hat{H}\left(t-t_{0}\right)+\frac{1}{2!}\left(-\frac{i}{\hbar}\right)^{2} \hat{H}^{2}\left(t-t_{0}\right)^{2}+\frac{1}{3!}\left(-\frac{i}{\hbar}\right)^{3} \hat{H}^{3}\left(t-t_{0}\right)^{3}+\ldots \tag{4.176}
\end{align*}
$$

where $\hat{H}^{2} \equiv \hat{H} \hat{H}, \hat{H}^{3} \equiv \hat{H} \hat{H} \hat{H}$, etc. Working with such series of operator products is not as hard as one could imagine, due to their regular structure. For example, let us differentiate Eq. (176) over $t$ :

[^593]\[

$$
\begin{align*}
\dot{\hat{u}}\left(t, t_{0}\right) & =\hat{0}+\frac{1}{1!}\left(-\frac{i}{\hbar}\right) \hat{H}+\frac{1}{2!}\left(-\frac{i}{\hbar}\right)^{2} \hat{H}^{2} 2\left(t-t_{0}\right)+\frac{1}{3!}\left(-\frac{i}{\hbar}\right)^{2} \hat{H}^{3} 3\left(t-t_{0}\right)^{2}+\ldots \\
& =\left(-\frac{i}{\hbar}\right) \hat{H}\left[\hat{I}+\frac{1}{1!}\left(-\frac{i}{\hbar}\right) \hat{H}\left(t-t_{0}\right)+\frac{1}{2!}\left(-\frac{i}{\hbar}\right)^{2} \hat{H}^{2}\left(t-t_{0}\right)^{2}\right]+\ldots=-\frac{i}{\hbar} \hat{H} \hat{u}\left(t, t_{0}\right), \tag{4.177}
\end{align*}
$$
\]

so that the differential equation (158) is indeed satisfied. On the other hand, Eq. (175) also satisfies the initial condition

$$
\begin{equation*}
\hat{u}\left(t_{0}, t_{0}\right)=\hat{u}^{\dagger}\left(t_{0}, t_{0}\right)=\hat{I}, \tag{4.178}
\end{equation*}
$$

which immediately follows from the definition (157) of the evolution operator, so it is indeed the (unique) solution for the time evolution operator - in the Schrödinger picture.

Now let us allow operator $\hat{H}$ to be a function of time, but with the condition that its "values" (in fact, operators) at different instants commute with each other:

$$
\begin{equation*}
\left\lfloor\hat{H}\left(t^{\prime}\right), \hat{H}\left(t^{\prime \prime}\right)\right\rfloor=0, \quad \text { for any } t^{\prime}, t^{\prime \prime} \tag{4.179}
\end{equation*}
$$

(An important example of such a Hamiltonian is that of a particle under the effect of a classical, timedependent force $\mathbf{F}(t)$ :

$$
\begin{equation*}
\hat{H}_{F}=-\mathbf{F}(t) \cdot \hat{\mathbf{r}} . \tag{4.180}
\end{equation*}
$$

Indeed, the radius-vector operator $\hat{\mathbf{r}}$ does not depend explicitly on time and hence commutes with itself, as well as with $c$-numbers $\mathbf{F}\left(t^{\prime}\right)$ and $\mathbf{F}\left(t^{\prime \prime}\right)$.) In this case it is sufficient to replace, in all above formulas, product $\hat{H}\left(t-t_{0}\right)$ with the corresponding integral over time; in particular, Eq. (175) is generalized as

$$
\begin{equation*}
\hat{u}\left(t, t_{0}\right)=\hat{I} \exp \left\{-\frac{i}{\hbar} \int_{t_{0}}^{t} \hat{H}\left(t^{\prime}\right) d t^{\prime}\right\} \tag{4.181}
\end{equation*}
$$

Evolution operator: expression

This replacement means that the first form of Eq. (176) should be replaced with

$$
\begin{equation*}
\hat{u}\left(t, t_{0}\right)=\hat{I}+\sum_{k=1}^{\infty} \frac{1}{k!}\left(-\frac{i}{\hbar}\right)^{k}\left(\int_{t_{0}}^{t} \hat{H}\left(t^{\prime}\right) d t^{\prime}\right)^{k}=\hat{I}+\sum_{k=1}^{\infty}\left(-\frac{i}{\hbar}\right)^{k} \int_{t_{0}}^{t} d t_{1} \int_{t_{0}}^{t} d t_{2} \ldots \int_{t_{0}}^{t} d t_{k} \hat{H}\left(t_{1}\right) \hat{H}\left(t_{2}\right) \ldots \hat{H}\left(t_{k}\right) . \tag{4.182}
\end{equation*}
$$

The proof that the first form of Eq. (182) satisfies Eq. (158) is absolutely similar to the one carried out above.

We may now use Eq. (181) to show that the time-evolution operator is unitary at any moment, even for the time-dependent Hamiltonian. Indeed, from that formula,

$$
\begin{equation*}
\hat{u}\left(t, t_{0}\right) \hat{u}^{\dagger}\left(t, t_{0}\right)=\hat{I} \exp \left\{-\frac{i}{\hbar} \int_{t_{0}}^{t} \hat{H}\left(t^{\prime}\right) d t^{\prime}\right\} \hat{I} \exp \left\{+\frac{i}{\hbar} \int_{t_{0}}^{t} \hat{H}\left(t^{\prime \prime}\right) d t^{\prime \prime}\right\} . \tag{4.183}
\end{equation*}
$$

Since each of the exponents may be presented with the Taylor series (182), and, thanks to Eq. (179), different components of these sums may be swapped at will, expression (183) may be manipulated exactly as the product of $c$-number exponents, in particular rewritten it as

$$
\begin{equation*}
\hat{u}\left(t, t_{0}\right) \hat{u}^{\dagger}\left(t, t_{0}\right)=\hat{I} \exp \left\{-\frac{i}{\hbar}\left[\int_{t_{0}}^{t} \hat{H}\left(t^{\prime}\right) d t^{\prime}-\int_{t_{0}}^{t} \hat{H}\left(t^{\prime \prime}\right) d t^{\prime \prime}\right]\right\}=\hat{I} \exp \{\hat{0}\}=\hat{I} . \tag{4.184}
\end{equation*}
$$

This property ensures, in particular, that the system state's normalization does not depend on time:

$$
\begin{equation*}
\langle\alpha(t) \mid \alpha(t)\rangle=\left\langle\alpha\left(t_{0}\right)\right| \hat{u}^{\dagger}\left(t, t_{0}\right) \hat{u}\left(t, t_{0}\right)\left|\alpha\left(t_{0}\right)\right\rangle=\left\langle\alpha\left(t_{0}\right) \mid \alpha\left(t_{0}\right)\right\rangle . \tag{4.185}
\end{equation*}
$$

The most difficult cases for the explicit solution of Eq. (158) are those when Eq. (179) is violated. ${ }^{38}$ It may be proven that in these cases the integral limits in the last form of Eq. (182) should be truncated, giving the so-called Dyson series

$$
\begin{equation*}
\hat{u}\left(t, t_{0}\right)=\hat{I}+\sum_{k=1}^{\infty}\left(-\frac{i}{\hbar}\right)^{k} \int_{t_{0}}^{t} d t_{1} \int_{t_{0}}^{t_{1}} d t_{2} \ldots \int_{t_{0}}^{t_{k-1}} d t_{k} \hat{H}\left(t_{1}\right) \hat{H}\left(t_{2}\right) \ldots \hat{H}\left(t_{k}\right) . \tag{4.186}
\end{equation*}
$$

Since we would not have time to use this relation in our course, I will skip its proof. ${ }^{39}$
Let me now return to the general discussion of quantum dynamics to outline its alternative, Heisenberg picture. For that, let us recall that according to Eq. (125), in quantum mechanics the expectation value of any observable $A$ is a long bra-ket. Below we will see that other quantities (say, the rates of quantum transitions between pairs of different states, say $\alpha$ and $\beta$ ) may also be measured in experiment; the most general form for all such measurable quantities is the following long bracket:

$$
\begin{equation*}
\langle\alpha| \hat{A}|\beta\rangle \tag{4.187}
\end{equation*}
$$

As has been discussed above, in the Schrödinger picture the bra- and ket-vectors of the states are timedependent, while the variable operators stay constant (if the corresponding variables do not explicitly depend on time), so that Eq. (187), applied to moment $t$, may be presented as

$$
\begin{equation*}
\langle\alpha(t)| \hat{A}_{\mathrm{s}}|\beta(t)\rangle \tag{4.188}
\end{equation*}
$$

where index "S" emphasizes the Schrödinger picture. Let us apply to the bra- and ket-vectors in this expression the evolution law (157):

$$
\begin{equation*}
\langle\alpha| \hat{A}|\beta\rangle=\left\langle\alpha\left(t_{0}\right)\right| \hat{u}^{\dagger}\left(t, t_{0}\right) \hat{A}_{\mathrm{s}} \hat{u}\left(t, t_{0}\right)\left|\beta\left(t_{0}\right)\right\rangle . \tag{4.189}
\end{equation*}
$$

This equality means that if we form a long bracket with bra- and ket-vectors of the initial-time states, together with the following time-dependent Heisenberg operator ${ }^{40}$

$$
\begin{equation*}
\hat{A}_{\mathrm{H}}(t) \equiv \hat{u}^{\dagger}\left(t, t_{0}\right) \hat{A}_{\mathrm{S}} \hat{u}\left(t, t_{0}\right)=\hat{u}^{\dagger}\left(t, t_{0}\right) \hat{A}_{\mathrm{H}}\left(t_{0}\right) \hat{u}\left(t, t_{0}\right), \tag{4.190}
\end{equation*}
$$

all experimentally measurable results will remain the same as in the Schrödinger picture:

[^594]Let us see how does the Heisenberg picture work for the same simple (but very important!) problem of the spin- $1 / 2$ precession in a $z$-oriented magnetic field, described (in the $z$-basis) by the Hamiltonian matrix (164). In that basis, Eq. (158) for the time-evolution operator reads

$$
i \hbar\left(\begin{array}{cc}
\dot{u}_{11} & \dot{u}_{12}  \tag{4.192}\\
\dot{u}_{21} & \dot{u}_{22}
\end{array}\right)=\frac{\hbar \Omega}{2}\left(\begin{array}{cc}
1 & 0 \\
0 & -1
\end{array}\right)\left(\begin{array}{ll}
u_{11} & u_{12} \\
u_{21} & u_{22}
\end{array}\right)=\frac{\hbar \Omega}{2}\left(\begin{array}{cc}
u_{11} & u_{12} \\
-u_{21} & -u_{22}
\end{array}\right) \text {. }
$$

We see that in this simple case the equations for different matrix elements of the evolution operator matrix are decoupled, and readily solvable, using the universal initial condition (178):41

$$
\mathrm{u}(t, 0)=\left(\begin{array}{cc}
e^{i \Omega t / 2} & 0  \tag{4.193}\\
0 & e^{-i \Omega t / 2}
\end{array}\right) \equiv \mathrm{I} \cos \frac{\Omega t}{2}-i \sigma_{z} \sin \frac{\Omega t}{2} .
$$

Now we can use Eq. (190) to find the Heisenberg-picture operators of spin components. Dropping index "H" for brevity (the Heisenberg-picture operators are clearly marked by their dependence on time anyway, we get

$$
\begin{align*}
\mathrm{S}_{x}(t) & =\mathrm{u}^{\dagger}(t, 0) \mathrm{S}_{x}(0) \mathrm{u}(t, 0)=\frac{\hbar}{2} \mathrm{u}^{\dagger}(t, 0) \sigma_{x} \mathrm{u}(t, 0) \\
& =\frac{\hbar}{2}\left(\begin{array}{cc}
e^{i \Omega t / 2} & 0 \\
0 & e^{-i \Omega t / 2}
\end{array}\right)\left(\begin{array}{ll}
0 & 1 \\
1 & 0
\end{array}\right)\left(\begin{array}{cc}
e^{i-\Omega t / 2} & 0 \\
0 & e^{i \Omega t / 2}
\end{array}\right)  \tag{4.194}\\
& =\frac{\hbar}{2}\left(\begin{array}{cc}
0 & e^{i \Omega t} \\
e^{-i \Omega t} & 0
\end{array}\right)=\frac{\hbar}{2}\left[\sigma_{x} \cos \Omega t-\sigma_{y} \sin \Omega t\right] \equiv \mathrm{S}_{x}(0) \cos \Omega t-\mathrm{S}_{\mathrm{y}}(0) \sin \Omega t .
\end{align*}
$$

Absolutely similar calculations of the other spin components yield

$$
\begin{align*}
\mathrm{S}_{y}(t)=\frac{\hbar}{2}\left(\begin{array}{cc}
0 & -i e^{i \Omega t} \\
i e^{-i \Omega t} & 0
\end{array}\right) & =\frac{\hbar}{2}\left[\sigma_{y} \cos \Omega t+\sigma_{x} \sin \Omega t\right] \equiv \mathrm{S}_{y}(0) \cos \Omega t+\mathrm{S}_{x}(0) \sin \Omega t  \tag{4.195}\\
\mathrm{~S}_{z}(t) & =\frac{\hbar}{2}\left(\begin{array}{cc}
1 & 0 \\
0 & -1
\end{array}\right)=\frac{\hbar}{2} \sigma_{z}=S_{z}(0) . \tag{4.196}
\end{align*}
$$

A practical advantage of these formulas is that they describe system's evolution for arbitrary initial conditions, thus making the analysis of the initial state effects very simple. Indeed, since in the Heisenberg picture the expectation values of observables are calculated using Eq. (191) (with $\beta=\alpha$ ), with time-independent bra- and ket vectors, such averaging of Eqs. (194)-(196) immediately returns us to Eqs. (170), (173), and (174), obtained in the Schrödinger picture. Moreover, these equations for the Heisenberg operators formally coincide with the classical equations of the torque-induced precession for $c$-number variables. (In the next chapter, we will see that the same exact mapping is valid for the Heisenberg picture of the orbital motion.)

[^595]In order to see that the last fact is by no means a coincidence, let us combine Eqs. (158) and (190) to form an explicit differential equation of the Heisenberg operator evolution. For that, let us differentiate Eq. (190) over time:

$$
\begin{equation*}
\frac{d}{d t} \hat{A}_{\mathrm{H}}=\frac{\partial \hat{u}^{\dagger}}{\partial t} \hat{A}_{\mathrm{s}} \hat{u}+\hat{u}^{\dagger} \frac{\partial \hat{A}_{\mathrm{S}}}{\partial t} \hat{u}+\hat{u}^{\dagger} \hat{A}_{\mathrm{s}} \frac{\partial \hat{u}}{\partial t} . \tag{4.197}
\end{equation*}
$$

Plugging in the derivatives of the time evolution operator from Eq. (158) and its Hermitian conjugate, and multiplying both parts of the equation by $i \hbar$, we get

$$
\begin{equation*}
i \hbar \frac{d}{d t} \hat{A}_{\mathrm{H}}=-\hat{u}^{\dagger} \hat{H} \hat{A}_{\mathrm{s}} \hat{u}+\hat{u}^{\dagger} \frac{\partial \hat{A}_{\mathrm{S}}}{\partial t} \hat{u}+\hat{u}^{\dagger} \hat{A}_{\mathrm{S}} \hat{H} \hat{u} \tag{4.198a}
\end{equation*}
$$

If for the Schrödinger-picture Hamiltonian the condition similar to Eq. (179) is satisfied, then, according to Eqs. (177) or (182), the Hamiltonian commutes with the time evolution operator and its Hermitian conjugate, and may be swapped with any of them. ${ }^{42}$ Hence, we may rewrite Eq. (198a) as

$$
\begin{equation*}
i \hbar \frac{d}{d t} \hat{A}_{\mathrm{H}}=-\hat{H} \hat{u}^{\dagger} \hat{A}_{\mathrm{s}} \hat{u}+i \hbar \hat{u}^{\dagger} \frac{\partial \hat{A}_{\mathrm{S}}}{\partial t} \hat{u}+\hat{u}^{\dagger} \hat{A}_{\mathrm{s}} \hat{u} \hat{H}=i \hbar \hat{u}^{\dagger} \frac{\partial \hat{A}_{\mathrm{S}}}{\partial t} \hat{u}+\left[\hat{u}{ }^{\dagger} \hat{A}_{\mathrm{S}} \hat{u}, \hat{H}\right] . \tag{4.198b}
\end{equation*}
$$

Now using the definition (190) again, for both terms in the right-hand part, we may write

Heisenberg equation of motion

$$
\begin{equation*}
i \hbar \frac{d}{d t} \hat{A}_{\mathrm{H}}=i \hbar\left(\frac{\partial \hat{A}}{\partial t}\right)_{\mathrm{H}}+\left[\hat{A}_{\mathrm{H}}, \hat{H}\right] . \tag{4.199}
\end{equation*}
$$

This is the so-called Heisenberg equation of motion. ${ }^{43}$
Let us see how does this equation look for the same problem of spin- $1 / 2$ precession in a $z$ oriented, time-independent magnetic field, described in the $z$-basis by the Hamiltonian matrix (164), which does not depend on time. In this basis, Eq. (199) for the vector operator of spin reads ${ }^{44}$

$$
i \hbar\left(\begin{array}{ll}
\dot{\mathbf{S}}_{11} & \dot{\mathbf{S}}_{12}  \tag{4.200}\\
\dot{\mathbf{S}}_{21} & \dot{\mathbf{S}}_{22}
\end{array}\right)=\frac{\hbar \Omega}{2}\left[\left(\begin{array}{ll}
\mathbf{S}_{11} & \mathbf{S}_{12} \\
\mathbf{S}_{21} & \mathbf{S}_{22}
\end{array}\right),\left(\begin{array}{cc}
1 & 0 \\
0 & -1
\end{array}\right)\right]=\hbar \Omega\left(\begin{array}{cc}
0 & -\mathbf{S}_{12} \\
\mathbf{S}_{21} & 0
\end{array}\right) .
$$

Once again, the equations for different matrix elements are decoupled, and their solution is elementary:

$$
\begin{align*}
& \mathbf{S}_{11}(t)=\mathbf{S}_{11}(0)=\text { const }, \quad \mathbf{S}_{22}(t)=\mathbf{S}_{22}(0)=\text { const }, \\
& \mathbf{S}_{12}(t)=\mathbf{S}_{12}(0) e^{i \Omega t}, \quad \mathbf{S}_{21}(t)=\mathbf{S}_{21}(0) e^{-i \Omega t} \tag{4.201}
\end{align*}
$$

[^596]According to Eq. (190), the initial "values" of the Heisenberg-picture matrix elements are just the Schrödinger-picture ones, so that using Eq. (117) we may rewrite this solution in either of two forms:

$$
\begin{gather*}
\mathbf{S}(t)=\frac{\hbar}{2}\left[\mathbf{n}_{x}\left(\begin{array}{cc}
0 & e^{i \Omega t} \\
e^{-i \Omega t} & 0
\end{array}\right)+\mathbf{n}_{y}\left(\begin{array}{cc}
0 & -i e^{i \Omega t} \\
i e^{-i \Omega t} & 0
\end{array}\right)+\mathbf{n}_{z}\left(\begin{array}{cc}
1 & 0 \\
0 & -1
\end{array}\right)\right] \\
=\frac{\hbar}{2}\left(\begin{array}{cc}
\mathbf{n}_{z} & \mathbf{n}_{-} e^{i \Omega t} \\
\mathbf{n}_{+} e^{-i \Omega} & -\mathbf{n}_{z}
\end{array}\right), \quad \text { with } \mathbf{n}_{ \pm} \equiv \mathbf{n}_{x} \pm i \mathbf{n}_{y} . \tag{4.202}
\end{gather*}
$$

The simplicity of the last expression is spectacular. (Remember, it covers any initial conditions, and all 3 spatial components of spin!) On the other hand, for some purposes the former expression may be more convenient; in particular, its Cartesian components immediately give our earlier results (194)(196).

One of advantages is that the Heisenberg picture is that it provides a more clear link between the classical and quantum mechanics. Indeed, analytical classical mechanics may be used to derive the following equation of time evolution of an arbitrary function $A\left(q_{j}, p_{j}, t\right)$ of generalized coordinates and momenta of the system, and time: ${ }^{45}$

$$
\begin{equation*}
\frac{d A}{d t}=\frac{\partial A}{\partial t}-\{A, H\} \tag{4.203}
\end{equation*}
$$

where $H$ is the classical Hamiltonian function of the system, and $\{. ., .$.$\} is the so-called Poisson bracket$ defined, for two arbitrary functions $A\left(q_{j}, p_{j}, t\right)$ and $B\left(q_{j}, p_{j}, t\right)$, as

$$
\begin{equation*}
\{A, B\} \equiv \sum_{j}\left(\frac{\partial A}{\partial p_{j}} \frac{\partial B}{\partial q_{j}}-\frac{\partial A}{\partial q_{j}} \frac{\partial B}{\partial p_{j}}\right) \tag{4.204}
\end{equation*}
$$

Comparing Eq. (203) with Eq. (199), we see that the correspondence between the classical and quantum mechanics (in the Heisenberg picture) is provided by the following symbolic relation ${ }^{46}$

$$
\begin{equation*}
\{A, B\} \leftrightarrow \frac{i}{\hbar}[\hat{A}, \hat{B}] . \tag{4.205}
\end{equation*}
$$

[^597]This relation may be used, in particular, for finding appropriate operators for system's observables, if their form is not immediately evident from the correspondence principle. We will develop this argumentation further in the next chapter where we revisit the wave mechanics, and also in Chapter 9.

Finally, let us discuss one more alternative picture of quantum dynamics. It is also attributed to P. A. M. Dirac, and is called either the "Dirac picture", or (more frequently) the interaction picture. The last name stems from the fact that this picture is very useful for the perturbative (approximate) approaches to systems whose Hamiltonians may be partitioned into two parts,

$$
\begin{equation*}
\hat{H}=\hat{H}_{0}+\hat{H}_{\mathrm{int}} \tag{4.206}
\end{equation*}
$$

where $\hat{H}_{0}$ is the sum of relatively simple Hamiltonians of non-interacting component sub-systems, while their second term in Eq. (206) represents their weak interaction. (Note, however, that the relations in the balance of this section are exact and not based on these assumptions.) In this case, it is natural to consider, together with the genuine unitary operator $\hat{u}\left(t, t_{0}\right)$ of the time evolution of the system, which obeys Eq. (158), a similarly defined unitary operator of evolution of the "unperturbed system" described by Hamiltonian $\hat{H}_{0}$ alone:

$$
\begin{equation*}
i \hbar \dot{\hat{u}}_{0}=\hat{H}_{0} \hat{u}_{0} \tag{4.207}
\end{equation*}
$$

and also the following interaction evolution operator,

Interaction evolution operator

$$
\begin{equation*}
\hat{u}_{I} \equiv \hat{u}_{0}^{\dagger} \hat{u} \tag{4.208}
\end{equation*}
$$

The sense of this definition becomes more clear if we insert the reciprocal relation,

$$
\begin{equation*}
\hat{u} \equiv \hat{u}_{0} \hat{u}_{0}^{\dagger} \hat{u}=\hat{u}_{0} \hat{u}_{I} \tag{4.209}
\end{equation*}
$$

and its Hermitian conjugate,

$$
\begin{equation*}
\hat{u}^{\dagger}=\left(\hat{u}_{0} \hat{u}_{I}\right)^{\dagger}=\hat{u}_{I}^{\dagger} \hat{u}_{0}^{\dagger}, \tag{4.210}
\end{equation*}
$$

into the basic Eq. (190) - which is valid in any picture:

$$
\begin{equation*}
\langle\alpha| \hat{A}|\beta\rangle=\left\langle\alpha\left(t_{0}\right)\right| \hat{u}^{\dagger}\left(t, t_{0}\right) \hat{A}_{\mathrm{s}} \hat{u}\left(t, t_{0}\right)\left|\beta\left(t_{0}\right)\right\rangle=\left\langle\alpha\left(t_{0}\right)\right| \hat{u}_{I}^{\dagger}\left(t, t_{0}\right) \hat{u}_{0}^{\dagger}\left(t, t_{0}\right) \hat{A}_{\mathrm{s}} \hat{u}_{0}\left(t, t_{0}\right) \hat{u}_{I}\left(t, t_{0}\right)\left|\beta\left(t_{0}\right)\right\rangle . \tag{4.211}
\end{equation*}
$$

This relation shows that all calculations of the observable expectation values and transition rates (i.e. all the results of quantum mechanics that may be experimentally verified) are expressed by the following formula, with the standard bra-ket structure (187),

$$
\begin{equation*}
\langle\alpha| \hat{A}|\beta\rangle=\left\langle\alpha_{I}(t)\right| \hat{A}_{I}(t)\left|\beta_{I}(t)\right\rangle \tag{4.212}
\end{equation*}
$$

if we assume that both the state vectors and operators evolve in time, with the vectors evolving due to the interaction operator $\hat{u}_{I}$,

$$
\begin{equation*}
\left\langle\alpha_{I}(t)\right| \equiv\left\langle\alpha\left(t_{0}\right)\right| \hat{u}_{I}^{\dagger}\left(t, t_{0}\right), \quad\left|\beta_{I}(t)\right\rangle \equiv \hat{u}_{I}\left(t, t_{0}\right)\left|\beta\left(t_{0}\right)\right\rangle \tag{4.213}
\end{equation*}
$$

while the operators' evolution being governed by the unperturbed operator $\hat{u}_{0}$ :

$$
\begin{equation*}
\hat{A}_{I}(t) \equiv \hat{u}_{0}^{\dagger}\left(t, t_{0}\right) \hat{A}_{\mathrm{s}} \hat{u}_{0}\left(t, t_{0}\right) \tag{4.214}
\end{equation*}
$$

These relations describe the interaction picture of quantum dynamics. Let me defer an example of its convenience until the perturbative analysis of open quantum systems in Sec. 7.6, and here end the discussion with a proof that the interaction evolution operator satisfies the Schrödinger equation,

$$
\begin{equation*}
i \hbar \dot{\hat{u}}_{I}=\hat{H}_{I} \hat{u}_{I} \tag{4.215}
\end{equation*}
$$

in which $\hat{H}_{I}$ is the interaction Hamiltonian transformed in accordance with rule (214):

$$
\begin{equation*}
\hat{H}_{I}(t) \equiv \hat{u}_{0}^{\dagger}\left(t, t_{0}\right) \hat{H}_{\mathrm{int}} \hat{u}_{0}\left(t, t_{0}\right) . \tag{4.216}
\end{equation*}
$$

The proof is very straightforward: first using definition (208), and then Eqs. (158) and the Hermitian conjugate of Eq. (207), we may write

$$
\begin{align*}
i \hbar \dot{\hat{u}}_{I} & =i \hbar \frac{d}{d t}\left(\hat{u}_{0}^{\dagger} \hat{u}\right)=i \hbar\left(\dot{\hat{u}}_{0}^{\dagger} \hat{u}+\hat{u}_{0}^{\dagger} \dot{\hat{u}}\right)=-\hat{H}_{0} \hat{u}_{0}^{\dagger} \hat{u}+\hat{u}_{0}^{\dagger} \hat{H} \hat{u}=-\hat{H}_{0} \hat{u}_{0}^{\dagger} \hat{u}+\hat{u}_{0}^{\dagger}\left(\hat{H}_{0}+\hat{H}_{\mathrm{int}}\right) \hat{u}  \tag{4.217}\\
& =-\hat{H}_{0} \hat{u}_{0}^{\dagger} \hat{u}+\hat{u}_{0}^{\dagger} \hat{H}_{0} \hat{u}+\hat{u}_{0}^{\dagger} \hat{H}_{\mathrm{int}} \hat{u}=\left(-\hat{H}_{0} \hat{u}_{0}^{\dagger}+\hat{u}_{0}^{\dagger} \hat{H}_{0}\right) \hat{u}+\hat{u}_{0}^{\dagger} \hat{H}_{\mathrm{int}} \hat{u} .
\end{align*}
$$

Since $\hat{u}_{0}^{\dagger}$ may be presented as an integral of $\hat{H}_{0}$ (similar to Eq. (181) relating $\hat{u}$ and $\hat{H}$ ), these operators commute, so that the parentheses in the last form of Eq. (217) vanish. Now plugging $\hat{u}$ from Eq. (209), we get the equation,

$$
\begin{equation*}
i \hbar \dot{\hat{u}}_{I}=\hat{u}_{0}^{\dagger} \hat{H}_{\mathrm{int}} \hat{u}_{0} u_{I}=\left(\hat{u}_{0}^{\dagger} \hat{H}_{\mathrm{int}} \hat{u}_{0}\right) \hat{u}_{I} \tag{4.218}
\end{equation*}
$$

that is equivalent to the combination of Eqs. (215) and (216).
Equation (215) shows that if the energy scale of interaction $H_{\text {int }}$ is much weaker than the background energy $H_{0}$, operators $\hat{u}_{I}$ and $\hat{u}_{I}^{\dagger}$, and hence the state vectors (213) evolve relatively slowly. Such an exclusion of fast background oscillations is especially convenient for the perturbative approaches to complex interacting systems, in particular to the open quantum systems that weakly interact with their environment - see Sec. 7.6.

### 4.7. Exercise problems

4.1. Let $\alpha$ and $\beta$ be two possible quantum states of the same system, and $\hat{A}$ be a linear operator. Which of the following expressions are legitimate (i. e. have a well-defined meaning) within the bra-ket formalism?

1. $\langle\alpha\rangle$
2. $\langle\alpha \mid \beta\rangle^{2}$
3. $|\alpha\rangle\langle\beta|$
4. $\hat{A}^{*}$
5. $\langle\hat{A}|$
6. $\langle\alpha| \hat{A}$
7. $\alpha|\hat{A}\rangle$
8. $|\alpha\rangle^{2}$
9. $\hat{A}^{2}$
10. $\left\langle\left.\alpha\right|^{\dagger}\right.$
4.2. Prove that if $\hat{A}$ and $\hat{B}$ are linear operators, then:
(i) $\left(\hat{A}^{\dagger}\right)^{\dagger}=\hat{A}$;
(ii) $(i \hat{A})^{\dagger}=-i \hat{A}^{\dagger}$;
(iii) $(\hat{A} \hat{B})^{\dagger}=\hat{B}^{\dagger} \hat{A}^{\dagger}$;
(iv) operators $\hat{A} \hat{A}^{\dagger}$ and $\hat{A}^{\dagger} \hat{A}$ are Hermitian.
4.3. Prove that for any linear operators $\hat{A}, \hat{B}, \hat{C}, \hat{D}$,

$$
[\hat{A} \hat{B}, \hat{C} \hat{D}]=\hat{A}\{\hat{B}, \hat{C}\} \hat{D}-\hat{A} \hat{C}\{\hat{B}, \hat{D}\}+\{\hat{A}, \hat{C}\} \hat{D} \hat{B}-\hat{C}\{\hat{A}, \hat{D}\} \hat{B}
$$

4.4. Calculate all possible binary products $\sigma_{j} \sigma_{j^{\prime}}$ (for $j, j^{\prime}=x, y, z$ ) of the Pauli matrices (105),

$$
\sigma_{x} \equiv\left(\begin{array}{ll}
0 & 1 \\
1 & 0
\end{array}\right), \quad \sigma_{y} \equiv\left(\begin{array}{cc}
0 & -i \\
i & 0
\end{array}\right), \quad \sigma_{z} \equiv\left(\begin{array}{cc}
1 & 0 \\
0 & -1
\end{array}\right),
$$

and their commutators and anticommutators (defined similarly to those of the corresponding operators). Present the results using the Kronecker delta and Levi-Civita permutation symbols. ${ }^{47}$
4.5. Calculate the following expressions,
(i) $(\mathbf{c} \cdot \sigma)^{n}$, and then
(ii) $(\mathrm{bI}+\mathbf{c} \cdot \sigma)^{n}$,
for the scalar product $\mathbf{c} \cdot \sigma$ of the Pauli matrix vector $\sigma \equiv \mathbf{n}_{x} \sigma_{x}+\mathbf{n}_{y} \sigma_{y}+\mathbf{n}_{z} \sigma_{z}$ by an arbitrary $c$-number vector $\mathbf{c}$, where $n \geq 0$ is an integer, and $b$ is an arbitrary scalar $c$-number.

Hint: For task (ii), you may like to use the binomial theorem, ${ }^{48}$ and then transform the result in a way enabling you to use the same theorem backwards.
4.6. Use the results of the previous problem to derive Eqs. (2.165)-(2.166) for the transparency $T$ of a system of $N$ similar, equidistant, delta-functional tunnel barriers.
4.7. Use result of Problem 5 to spell out the following the following matrix: $\exp \{i \theta \mathbf{n} \cdot \sigma\}$, where $\sigma$ is the vector of Pauli matrices, $\mathbf{n}$ is a $c$-number vector of unit length, and $\theta$ is a $c$-number scalar.
4.8. Use the result of Problem 5(ii) to calculate $\exp \{A\}$, where $A$ is an arbitrary $2 \times 2$ matrix.
4.9. Express elements of matrix $B=\exp \{A\}$ explicitly via those of the $2 \times 2$ matrix $A$. Spell out your result for the following matrices:

$$
\mathrm{A}=\left(\begin{array}{ll}
a & a \\
a & a
\end{array}\right), \quad \mathrm{A}^{\prime}=\left(\begin{array}{ll}
i \varphi & i \varphi \\
i \varphi & i \varphi
\end{array}\right)
$$

with real $a$ and $\varphi$.
4.10. Prove that for arbitrary square matrices A and B ,

$$
\operatorname{Tr}(\mathrm{AB})=\operatorname{Tr}(\mathrm{BA}) .
$$

Is each diagonal element $(A B)_{j j}$ necessarily equal to $(B A)_{j j}$ ?

[^598]4.11. Prove that the matrix trace of an arbitrary operator does not change at an arbitrary unitary transformation.
4.12. Prove that for any two full and orthonormal bases $u_{j}, v_{j}$ of the same Hilbert space,
$$
\operatorname{Tr}\left(\left|u_{j}\right\rangle\left\langle v_{j^{\prime}}\right|\right)=\left\langle v_{j^{\prime}} \mid u_{j}\right\rangle .
$$
4.13. Is the 1D scattering matrix S, defined by Eq. (133), unitary? What about the 1D transfer matrix T defined by Eq. (134)?
4.14. Calculate the trace of the following matrix:
$$
\exp \{\mathbf{i} \cdot \boldsymbol{\sigma}\} \exp \{i \mathbf{b} \cdot \boldsymbol{\sigma}\}
$$
where $\boldsymbol{\sigma}$ is the Pauli matrix vector, while $\mathbf{a}$ and $\mathbf{b}$ are usual ( $c$-number) geometric vectors.
4.15. Let $A_{j}$ be eigenvalues of some operator $\hat{A}$. Express the following two sums,
$$
\Sigma_{1}=\sum_{j} A_{j}, \quad \Sigma_{2}=\sum_{j} A_{j}^{2}
$$
via the matrix elements $A_{j j}$, of this operator in an arbitrary basis.
4.16. Calculate $\left\langle\sigma_{z}\right\rangle$ of a two-level system in a quantum state with the following ket-vector:
$$
|\alpha\rangle=\operatorname{const} \times|\uparrow\rangle+|\downarrow\rangle+|\rightarrow\rangle+|\leftarrow\rangle),
$$
where $(\uparrow, \downarrow)$ and $(\rightarrow, \leftarrow)$ are eigenstates of the Pauli matrices $\sigma_{z}$ and $\sigma_{x}$, respectively.
Hint: Double-check whether the solution you are giving is general.
4.17. An electron is fully polarized in the positive $z$-direction. Calculate the probabilities of the alternative outcomes of a perfect Stern-Gerlach experiment with the magnetic field $\mathbf{B}$ oriented in the direction of some axis $\mathbf{n}$, performed on this electron.
4.18. A perfect Stern-Gerlach instrument makes a single-shot measurement of the following combination, $\left(S_{x}+S_{z}\right) / \sqrt{ } 2$, of two spin components of a $z$-polarized electron; after that, component $S_{z}$ of the same particle is measured. What are the possible outcomes of these measurements and their probabilities?
4.19. In a certain basis, the Hamiltonian of a spin- $1 / 2$ (two-level) system is described by matrix
\[

\mathrm{H}=\left($$
\begin{array}{cc}
E_{1} & 0 \\
0 & E_{2}
\end{array}
$$\right), \quad with E_{1} \neq E_{2},
\]

and the operator of some observable $A$, by matrix

$$
\mathrm{A}=\left(\begin{array}{ll}
1 & 1 \\
1 & 1
\end{array}\right)
$$

For the system's state with the energy equal exactly to $E_{1}$, find the possible results of measurements of observable $A$ and the probabilities of the corresponding measurement outcomes.
4.20. ${ }^{*}$ States $u_{1,2,3}$ form an orthonormal basis of a system with Hamiltonian

$$
\hat{H}=-\delta\left(\left|u_{1}\right\rangle\left\langle u_{2}\right|+\left|u_{2}\right\rangle\left\langle u_{3}\right|+\left|u_{3}\right\rangle\left\langle u_{1}\right|\right)+\text { h.c. }
$$

where $\delta$ is a real constant, and h.c. means the Hermitian conjugate of the previous expression. Calculate its stationary states and energy levels. Can you relate this system with any other(s) discussed earlier in the course?
4.21. Suggest a Hamiltonian describing particle's dynamics in an infinite 1D set of similar quantum wells in the tight-binding approximation, in the bra-ket formalism, and verify that is yields the correct dispersion relation (2.206).
4.22. Calculate eigenvectors and eigenvalues of the following matrices:

$$
A=\left(\begin{array}{lll}
0 & 1 & 0 \\
1 & 0 & 1 \\
0 & 1 & 0
\end{array}\right), \quad B=\left(\begin{array}{llll}
0 & 0 & 0 & 1 \\
0 & 0 & 1 & 0 \\
0 & 1 & 0 & 0 \\
1 & 0 & 0 & 0
\end{array}\right)
$$

4.23. Find eigenvalues of the following matrix:

$$
\mathrm{A}=\mathbf{a} \cdot \boldsymbol{\sigma} \equiv a_{x} \sigma_{x}+a_{y} \sigma_{y}+a_{z} \sigma_{z},
$$

where $a_{x, y, z}$ are real $c$-numbers (scalars), and $\sigma_{x, y, z}$ are the Pauli matrices. Sketch the dependence of the eigenvalues on parameter $a_{z}$, with $a_{x}$ and $a_{y}$ fixed. Compare the result with Fig. 29.
4.24. Derive a differential equation for the time evolution of the expectation value of an observable, using both the Schrödinger picture and the Heisenberg picture of quantum mechanics.
4.25. At $t=0$, a spin $-1 / 2$ particle, whose interaction with an external field is described by Hamiltonian

$$
\hat{H}=\mathbf{a} \cdot \hat{\boldsymbol{\sigma}} \equiv a_{x} \hat{\sigma}_{x}+a_{y} \hat{\sigma}_{y}+a_{z} \hat{\sigma}_{z},
$$

(where $a_{x, y, z}$ are real and constant $c$-numbers, and $\hat{\sigma}_{x, y, z}$ are the operators that, in the $z$-basis, are represented by the Pauli matrices $\sigma_{x, y, z}$ ), was in state $\uparrow$, one of two eigenstates of operator $\hat{\sigma}_{z}$. Use the Schrödinger picture equations to calculate the time evolution of:
(i) the ket-vector $|\alpha\rangle$ of the system (in any stationary basis you like),
(ii) the probabilities to find the system in states $\uparrow$ and $\downarrow$, and
(iii) the expectation values of all 3 spatial components ( $\hat{S}_{x}$, etc.) of the spin vector operator $\hat{\mathbf{S}}=(\hbar / 2) \hat{\boldsymbol{\sigma}}$.

Analyze and interpret the results for the particular case $a_{y}=a_{z}=0$.
4.26. For the same system as in the previous problem, use the Heisenberg picture equations to calculate the time evolution of:
(i) all three spatial components ( $\hat{S}_{x}$, etc.) of the spin operator $\hat{\mathbf{S}}_{\mathrm{H}}(\mathrm{t})$,
(ii) the expectation values of the spin components.

Compare the latter results with those of the previous problem.
4.27. For the same system as in two last problems, calculate the matrix elements of operator $\hat{\sigma}_{z}$ in the basis of eigenstates $a_{1}, a_{2}$.

Hint: In contrast to the cited problems, the answer evidently does not depend on the initial conditions.
4.28. In the Schrödinger picture of quantum mechanics, three operators satisfy the following commutation relation:

$$
[\hat{A}, \hat{B}]=\hat{C}
$$

What is their relation in the Heisenberg picture (at the same time instant)?
4.29. A spin $-1 / 2$ particle is placed into a magnetic field $B(t)$, which is an arbitrary function of time. Derive the differential equations describing the time evolution of:
(i) the vector operator $\hat{\mathbf{S}}$ of particle's spin (in the Heisenberg picture), and
(ii) the expectation value $\langle\mathbf{S}\rangle$ of spin's vector.

Contemplate the relative merits of the latter equation for the description of a single spin and of a large collection of similar, non-interacting spins.
4.30.* Prove the Bloch theorem given by either Eq. (3.107) or Eq. (3.108).

Hint: Consider the translation operator $\hat{\tau}_{\mathrm{R}}$, defined by the following result of its action on an arbitrary function $f(\mathbf{r})$ :

$$
\hat{\tau}_{\mathbf{R}} f(\mathbf{r})=f(\mathbf{r}+\mathbf{R}),
$$

where $\mathbf{R}$ is an arbitrary vector of the Bravais lattice (3.106). In particular, analyze the commutation properties of the operator, and apply them to an eigenfunction $\psi(\mathbf{r})$ of the stationary Schrödinger equation for a particle in a 3D periodic potential described by Eq. (3.105).

## Chapter 5. Some Exactly Solvable Problems

This describes several simplest but important applications of the bra-ket formalism, notably including a few wave-mechanics problems we have already started to discuss in Chapters 2 and 3.

### 5.1. Two-level systems

In the course of discussion of the bra-ket formalism in the last chapter, we have already considered several examples of how it works for electron's spin. We have seen, in particular, that in magnetic field the electron has eigenenergies (4.167), i.e. two energy levels. As will be shown later in the course, such two-energy-level picture is valid not only for electrons and other spin- $1 / 2$ elementary particles (such as muons and neutrinos), but also may give a good approximation for other important quantum systems. For example, as was already mentioned in Chapter 2, two energy levels are sufficient for an approximate description of dynamics of two weakly coupled quantum wells (Sec. 2.6), and of level anticrossing in the weak-potential approximation of the band theory (Sec. 2.7). Such two-level systems (alternatively called "spin- $1 / 2$-like" systems) are nowadays the focus of additional attention in the view of prospects of their possible use for information processing and encryption. (In the last context, to be discussed in Sec. 8.5, a two-level system is usually called a qubit.)

This is why before proceeding to other problems, let us summarize in brief what we have already learned about properties and dynamics of two-level systems, in a more convenient language. According to the general Eq. (4.6), a ket- (or bra-) vector of an arbitrary pure (coherent) state $\alpha$ of such a system may be presented, at any instant, as a linear combination of two basis vectors, for example

$$
\begin{equation*}
|\alpha\rangle=\alpha_{\uparrow}|\uparrow\rangle+\alpha_{\downarrow}|\downarrow\rangle, \tag{5.1}
\end{equation*}
$$

and hence is completely described by two complex coefficients (c-numbers) - say, $\alpha \uparrow$ and $\alpha \downarrow$. These two numbers are not completely arbitrary; they are restricted by the normalization condition. If the basis vectors are normalized, then to have the system in some basis state with a $100 \%$ probability, we need

$$
\begin{equation*}
W_{\Sigma}=\langle\alpha \mid \alpha\rangle=\left(\langle\uparrow| \alpha_{\uparrow}^{*}+\langle\downarrow| \alpha_{\downarrow}^{*}\right)\left(\alpha_{\uparrow}|\uparrow\rangle+\alpha_{\downarrow}|\downarrow\rangle\right)=\alpha_{\uparrow}^{*} \alpha_{\uparrow}+\alpha_{\downarrow}^{*} \alpha_{\downarrow}=\left|\alpha_{\uparrow}\right|^{2}+\left|\alpha_{\downarrow}\right|^{2}=1 \tag{5.2}
\end{equation*}
$$

This requirement is automatically satisfied if we take the moduli of $\alpha \uparrow$ and $\alpha \downarrow$ equal to the sine and cosine of the same (real) angle. Thus we can write, for example,

$$
\begin{equation*}
\alpha_{\uparrow}=\cos \frac{\theta}{2} e^{i \gamma}, \quad \alpha_{\downarrow}=\sin \frac{\theta}{2} e^{i(\gamma+\varphi)} \tag{5.3}
\end{equation*}
$$

Moreover, according to the general Eq. (4.125), if we deal with just one system, ${ }^{1}$ the common phase factor $\exp \{i \gamma\}$ is unimportant for calculation of any expectation values, and we can take $\gamma=0$, so that Eq. (3) is reduced to

[^599]\[

$$
\begin{equation*}
\alpha_{\uparrow}=\cos \frac{\theta}{2}, \quad \alpha_{\downarrow}=\sin \frac{\theta}{2} e^{i \varphi} \tag{5.4}
\end{equation*}
$$

\]

Bloch sphere representation of state

The reason why the argument of sine and cosine functions is usually taken in the form $\theta / 2$, becomes clear from Fig. 1a: Eq. (4) conveniently maps each state $\alpha$ on a certain representation point of a unit-radius Bloch sphere, ${ }^{2}$ with polar angle $\theta$ and azimuthal angle $\varphi$. In particular, state $\uparrow$ (with $\alpha \uparrow=1$ and $\alpha \downarrow=0$ ) corresponds to the North Pole of the sphere $(\theta=0$ ), while state $\downarrow$ (with $\alpha \uparrow=0$ and $\alpha \downarrow=1$ ), to its South pole $(\theta=\pi) .{ }^{3}$ Similarly, states $\rightarrow$ and $\leftarrow$, described by Eqs. (4.122), i.e. having $\alpha \uparrow=1 / \sqrt{ } 2$ and $\alpha \downarrow= \pm 1 / \sqrt{2}$, correspond to points with $\theta=\pi / 2$ and to, respectively, $\varphi=0$ and $\varphi=\pi$. Two more special points (denoted in Fig. 1a as $\odot$ and $\otimes$ ) are also located on sphere's equator (at $\theta=\pi / 2$ and $\varphi=$ $\pm \pi / 2$ ); it is easy to check that they correspond to the eigenstates of matrix $\sigma_{y}$ (in the same $z$-basis).

In order to understand why such mutually perpendicular location of these three special point pairs on the Bloch sphere is not occasional, let us plug Eqs. (4) into Eqs. (4.131)-(4.133) for the expectation values of spin components. The result is

$$
\begin{equation*}
\left\langle S_{x}\right\rangle=\frac{\hbar}{2} \sin \theta \cos \varphi, \quad\left\langle S_{y}\right\rangle=\frac{\hbar}{2} \sin \theta \sin \varphi, \quad\left\langle S_{z}\right\rangle=\frac{\hbar}{2} \cos \theta \tag{5.5}
\end{equation*}
$$

showing that the radius-vector of the representation point on the sphere is (after multiplication by $\hbar / 2$ ) just the expectation value of the spin vector $\mathbf{S}$.

Fig. 5.1. Bloch sphere: (a) notation, and presentation of spin precession in magnetic fields directed along: (b) axis $z$, and (c) axis $x$.

Now let us see how does the representation point moves in various cases. First of all, according to Eqs. (4.157)-(4.158), in the absence of an external field (when the Hamiltonian operator is equal to zero and hence the time-evolution operator is constant) the point does not move at all. Now, if we apply to an electron a magnetic field directed along axis $z$, then, according to Eqs. (4.202), the Heisenberg operator of $S_{z}$ (and hence the expectation value $\left\langle S_{z}\right\rangle$ ) remains constant, while angle $\varphi$ in Eq. (5) evolves

[^600]in time as $\Omega t+$ const. This means that the torque-induced precession of the spin in a constant field $\boldsymbol{B}=$ $\mathbf{n}_{z} B$ is described by a circular rotation of the representation point about axis $z$ (in Fig. 1b, in the horizontal plane) with the classical precession frequency $\Omega$. This is essentially the classical picture of rotation of the angular momentum vector about the precession axis $z$, with both its length and the $z$ component conserved. ${ }^{4}$

It is straightforward to repeat all calculations of Sec. 4.6 for a field of a different orientation and prove the (virtually evident) result that the representation point performs a similar rotation about the field direction. (Fig. 1c shows such rotation for an $x$-directed field.) Finally, note that it is sufficient to turn off the field to stop the precession instantly. (Since Eq. (4.158) is the first-order differential equation, the representation point has no effective inertia. ${ }^{5}$ ) Hence changing the direction and magnitude of the external field, it is possible to move spin's representation point to any position on the Bloch sphere. (In Chapter 6 we will examine another method of manipulating the point position, that is based on external rf field and is more convenient for some two-level systems.)

In the context of quantum information, this means that in the absence of uncontrollable interaction with environment, it is possible to prepare a qubit in any pure quantum state, and then keep it unchanged. From here it is clear that a qubit is very much different from and a classical bistable system used to store single bits of information - such as the voltage state of a usual SRAM cell (a positivefeedback loop of two transistor-based inverters). As Eq. (4) shows, qubit's state is determined by two independent, continuous parameters $\theta$ and $\varphi$, so it may store much more information than one bit. (The difference is even more spectacular in qubit systems, to be discussed in Sec. 8.5.) However, classical bistable systems, due to their nonlinearity, are stable with respect to small perturbations, so that their operation is rather robust with respect to unintentional interaction with their environment. In contrast, qubit's state may be readily disturbed (i.e. its representation point on the Bloch sphere shifted) by even minor perturbations, and does not have an internal state stabilization mechanism. ${ }^{6}$ Due to this reason, qubit-based systems are rather vulnerable to environment-induced drifts, including dephasing and relaxation effects, which will be discussed in Chapter 7.

### 5.2. Revisiting wave mechanics

In order to use the bra-ket formalism for the description of the "orbital" motion of a particle as a whole, we have to either rewrite or even modify some of its formulas for the case of observables with continuous spectrum of eigenvalues. (One example we already know well are the momentum and kinetic energy of a free particle.) In that case, all the above expressions for states, their bra- and ket-vectors, and eigenvalues, should be stripped of discrete indices, like the index $j$ in the key equation (4.68), which determines eigenstates and eigenvalues of observable $A$. For that, Eq. (4.68) may be rewritten in the form

[^601]\[

$$
\begin{equation*}
\hat{A}\left|a_{A}\right\rangle=A\left|a_{A}\right\rangle . \tag{5.6}
\end{equation*}
$$

\]

More essentially, all sums over such continuous eigenstate sets should be replaced by integrals. For example, for a full and orthonormal set of eigenstates (6), the closure relation (4.44) should be replaced with

$$
\begin{equation*}
\int d A\left|a_{A}\right\rangle\left\langle a_{A}\right|=\hat{I} \tag{5.7}
\end{equation*}
$$

where the integral should be taken over the whole interval of possible values of observable $A$. Applying this relation to the ket-vector of an arbitrary state $\alpha$ (generally, not an eigenstate of operator $\hat{A}$ ), we get

$$
\begin{equation*}
|\alpha\rangle=\hat{I}|\alpha\rangle=\int d A\left|a_{A}\right\rangle\left\langle a_{A} \mid \alpha\right\rangle=\int d A\left\langle a_{A} \mid \alpha\right\rangle\left|a_{A}\right\rangle . \tag{5.8}
\end{equation*}
$$

This integral replaces sum (4.37) for the representation of an arbitrary ket-vector as an expansion over eigenstates of an operator. For the particular case when $|\alpha\rangle=\left|a_{A}{ }^{\prime}\right\rangle$, this relation requires ${ }^{7}$

$$
\begin{equation*}
\left\langle a_{A} \mid a_{A^{\prime}}\right\rangle=\delta\left(A-A^{\prime}\right) ; \tag{5.9}
\end{equation*}
$$

According to Eq. (8), in the continuous case the bra-ket $\left\langle a_{A} \mid \alpha\right\rangle$ still plays the role of the coefficient whose modulus squared determines state $a_{A}$ 's probability - see the last form of Eq. (4.120). However, in the continuous spectrum case the probability to find the system exactly in a particular state is infinitesimal. Instead we should speak about the probability density $w(A) \propto\left|\left\langle a_{A} \mid \alpha\right\rangle\right|^{2}$ to find the observable within a small interval $d A$ about a certain value $A$. The coefficient in that relation may be found by making the similar change from summation to integration (without any additional coefficients) in the normalization condition (4.121):

$$
\begin{equation*}
\int d A\left\langle\alpha \mid a_{A}\right\rangle\left\langle a_{A} \mid \alpha\right\rangle=1 \tag{5.10}
\end{equation*}
$$

Since the total probability of the system to be in some state should also equal $\int w(A) d A$, this means that

$$
\begin{equation*}
w(A)=\left\langle\alpha \mid a_{A}\right\rangle\left\langle a_{A} \mid \alpha\right\rangle=\left|\left\langle\alpha \mid a_{A}\right\rangle\right|^{2} \tag{5.11}
\end{equation*}
$$

Now let us see how we can calculate expectation values of continuous observables, i.e. their ensemble averages. If we speak about the same observable $A$ whose eigenstates are used as the basis (or any compatible observable), everything is simple. Inserting Eq. (11) into the general statistical relation

$$
\begin{equation*}
\langle A\rangle=\int w(A) A d A, \tag{5.12}
\end{equation*}
$$

which is just the evident continuous version of Eq. (1.37), we get

$$
\begin{equation*}
\langle A\rangle=\int\left\langle\alpha \mid a_{A}\right\rangle A\left\langle a_{A} \mid \alpha\right\rangle d A \tag{5.13}
\end{equation*}
$$

Presenting this expression as a double integral,

$$
\begin{equation*}
\langle A\rangle=\int d A \int d A^{\prime}\left\langle\alpha \mid a_{A}\right\rangle A \delta\left(A-A^{\prime}\right)\left\langle a_{A^{\prime}} \mid \alpha\right\rangle, \tag{5.14}
\end{equation*}
$$

[^602]and using the continuous-spectrum version of Eq. (4.98),
\[

$$
\begin{equation*}
\left\langle a_{A}\right| \hat{A}\left|a_{A^{\prime}}\right\rangle=A \delta\left(A-A^{\prime}\right), \tag{5.15}
\end{equation*}
$$

\]

we may write

$$
\begin{equation*}
\langle A\rangle=\int d A \int d A^{\prime}\left\langle\alpha \mid a_{A}\right\rangle\left\langle a_{A}\right| \hat{A}\left|a_{A^{\prime}}\right\rangle\left\langle a_{A^{\prime}} \mid \alpha\right\rangle=\langle\alpha| \hat{A}|\alpha\rangle, \tag{5.16}
\end{equation*}
$$

so that Eq. (4.125) remains valid in the continuous-spectrum case without any changes.
The situation is a bit more complicated for the expectation values of operators that do not commute with the base-creating operator, because the matrix of such an operators in that may not be diagonal. We will consider (and overcome :-) this technical difficulty very soon, but otherwise we are ready for the discussion of wave mechanics. (For the notation simplicity I will discuss its 1D version; the generalization to the 2D and 3D cases is straightforward.)

Let us consider what is called the coordinate representation, postulating the (intuitively almost evident) existence of a quantum state basis, whose with ket-vectors will be called $|x\rangle$, corresponding to a certain, exactly defined value $x$ of particle's coordinate. Writing the following evident identity:

$$
\begin{equation*}
x|x\rangle=x|x\rangle, \tag{5.17}
\end{equation*}
$$

and comparing this relation with Eq. (6), we see that they do not contradict each other if we assume that $x$ in the left-hand part of this equation is considered as the coordinate operator $\hat{x}$ whose action on a ket(or bra-) vector is just its multiplication by c-number $x$. (This looks like a proof, but is actually a separate, independent postulate, no matter how plausible.)

In this coordinate representation, the inner product $\left\langle a_{A} \mid \alpha(t)\right\rangle$ becomes $\langle x \mid \alpha(t)\rangle$, and Eq. (11) takes the form

$$
\begin{equation*}
w(x, t)=\langle\alpha(t) \mid x\rangle\langle x \mid \alpha(t)\rangle=\langle x \mid \alpha(t)\rangle^{*}\langle x \mid \alpha(t)\rangle . \tag{5.18}
\end{equation*}
$$

Comparing this formula with the basic postulate (1.22) of wave mechanics, we see that they coincide if the Schrödinger's wavefunction of time-evolving state $\alpha(t)$ is identified with that bra-ket: ${ }^{8}$

$$
\begin{equation*}
\Psi_{\alpha}(x, t)=\langle x \mid \alpha(t)\rangle \tag{5.19}
\end{equation*}
$$

This key formula provides the connection between the bra-ket formalism and wave mechanics, and should not be too surprising for the (thoughtful :-) reader. Indeed, Eqs. (4.45) shows that any inner product of vectors describing two states is a measure of their coincidence - just as the scalar product of two geometric vectors. (The orthonormality condition (4.38) is a particular manifestation of this fact.) In this language, value (19) of wavefunction $\Psi_{\alpha}$ at point $x$ and moment $t$ characterizes "how much of a particular coordinate $x$ " does the state $\alpha$ contain at that particular instance. (Of course this informal language is too crude to describe the fact that $\Psi_{\alpha}(x, t)$ is a complex function, which has not only a modulus, but also a phase.)

[^603]Let us rewrite the most important formulas of the bra-ket formalism (so far, in the Schrödinger picture) in the wave mechanics notation. In particular, let us use Eq. (19) to calculate the (partial) time derivative of the wavefunction, multiplied by the usual coefficient $i \hbar$ :

$$
\begin{equation*}
i \hbar \frac{\partial \Psi_{\alpha}}{\partial t}=i \hbar \frac{\partial}{\partial t}\langle x \mid \alpha(t)\rangle \tag{5.20}
\end{equation*}
$$

Since the coordinate operator $\hat{x}$ does not depend on time explicitly, its eigenstates $x$ are stationary, and we can swap the time derivative and the time-independent ket-vector and hence $\langle x|$. Making use of the Schrödinger-picture equations (4.157) and (4.158), and then inserting the identity operator in the continuous form (7) of the closure relation, written for the coordinate eigenstates,

$$
\begin{equation*}
\int d x^{\prime}\left|x^{\prime}\right\rangle\left\langle x^{\prime}\right|=\hat{I} \tag{5.21}
\end{equation*}
$$

we may continue to develop the right-hand part of Eq. (20) as

$$
\begin{align*}
\langle x| i \hbar \frac{\partial}{\partial t}|\alpha(t)\rangle & =\langle x| i \hbar \frac{\partial}{\partial t} \hat{u}\left(t, t_{0}\right)\left|\alpha\left(t_{0}\right)\right\rangle=\langle x| \hat{H} \hat{u}\left(t, t_{0}\right)\left|\alpha\left(t_{0}\right)\right\rangle=\langle x| \hat{H}|\alpha(t)\rangle  \tag{5.22}\\
& =\int d x^{\prime}\langle x| \hat{H}\left|x^{\prime}\right\rangle\left\langle x^{\prime} \mid \alpha(t)\right\rangle=\int d x^{\prime}\langle x| \hat{H}\left|x^{\prime}\right\rangle \Psi_{\alpha}\left(x^{\prime}, t\right) .
\end{align*}
$$

For a general Hamiltonian operator, we have to stop here, because if it does not commute with the coordinate operator, its matrix in the $x$-basis is not diagonal, and integral (22) cannot be worked out explicitly. However, there exists a broad set of space-local operators ${ }^{9}$ whose arguments include just one value of the spatial coordinate, for which we can move ket-vector $\langle x|$ to the right ${ }^{10}$

$$
\begin{equation*}
\langle x| \hat{A}\left|x^{\prime}\right\rangle \Psi\left(x^{\prime}, t\right)=\hat{A} \Psi\left(x^{\prime}, t\right)\left\langle x \mid x^{\prime}\right\rangle=\hat{A} \Psi(x, t) \delta\left(x-x^{\prime}\right) \tag{5.23}
\end{equation*}
$$

[^604]where operator $\hat{A}$ in the last two forms should be understood as its coordinate representation that is defined by Eq. (23) - if it is valid for a particular operator. For example, consider the 1 D version of operator (1.40),
\[

$$
\begin{equation*}
\hat{H}=\frac{\hat{p}_{x}^{2}}{2 m}+U(\hat{x}, t), \tag{5.24}
\end{equation*}
$$

\]

which was the basis of all our discussions in Chapter 2. Its potential-energy part commutes with operator $\hat{x}$, so its matrix in the $x$-basis is diagonal, meaning that this part of Hamiltonian (24) is clearly local, with its coordinate representation given merely by the $c$-number function $U(x, t)$. The situation with the kinetic energy, which is a function of momentum operator $\hat{p}_{x}$, not commuting with $\hat{x}$, is less evident. Let me show that this operator is also local, and in the same shot derive (the 1D version of Eq. (1.26), if we postulate the commutation relation (2.14):

$$
\begin{equation*}
\hat{x} \hat{p}_{x}-\hat{p}_{x} \hat{x}=i \hbar \hat{I} \tag{5.25}
\end{equation*}
$$

[^605]For that, let us consider the following matrix element, $\langle x| \hat{x} \hat{p}_{x}-\hat{p}_{x} \hat{x}\left|x^{\prime}\right\rangle$. On one hand, we may use Eq. (25) to write

$$
\begin{equation*}
\langle x| \hat{x} \hat{p}_{x}-\hat{p}_{x} \hat{x}\left|x^{\prime}\right\rangle=\langle x| i \hbar \hat{I}\left|x^{\prime}\right\rangle=i \hbar\left\langle x \mid x^{\prime}\right\rangle=i \hbar \delta\left(x-x^{\prime}\right) . \tag{5.26}
\end{equation*}
$$

On the other hand, since $\hat{x}\left|x^{\prime}\right\rangle=x^{\prime}\left|x^{\prime}\right\rangle$ and $\langle x| \hat{x}=\langle x| x$, we can write

$$
\begin{equation*}
\langle x| \hat{x} \hat{p}_{x}-\hat{p}_{x} \hat{x}\left|x^{\prime}\right\rangle=\langle x| x \hat{p}_{x}-\hat{p}_{x} x^{\prime}\left|x^{\prime}\right\rangle=\left(x-x^{\prime}\right)\langle x| \hat{p}_{x}\left|x^{\prime}\right\rangle . \tag{5.27}
\end{equation*}
$$

Comparing Eqs. (26) and (27), we may write

$$
\begin{equation*}
\langle x| \hat{p}_{x}\left|x^{\prime}\right\rangle=i \hbar \frac{\delta\left(x-x^{\prime}\right)}{\left(x-x^{\prime}\right)} \tag{5.28a}
\end{equation*}
$$

Thus $\hat{p}_{x}$ is a local operator. Since Eq. (28a) may be rewritten as ${ }^{11}$

$$
\begin{equation*}
\langle x| \hat{p}_{x}\left|x^{\prime}\right\rangle=-i \hbar \frac{\partial}{\partial x} \delta\left(x-x^{\prime}\right) \tag{5.28b}
\end{equation*}
$$

its comparison with Eq. (23) shows that the formula used so much in Chapter 2,

$$
\begin{equation*}
\hat{p}_{x}=-i \hbar \frac{\partial}{\partial x} \tag{5.29}
\end{equation*}
$$

is indeed valid, but only for the coordinate representation of the momentum operator. (Later in this section we will see that in an alternative, momentum representation, this operator looks completely differently.)

It is straightforward to show (and virtually evident) that any operator $f(\hat{p})$ is local as well, with its coordinate representation being

$$
\begin{equation*}
f\left(-i \hbar \frac{\partial}{\partial x}\right) \tag{5.30}
\end{equation*}
$$

In particular, this pertains to the kinetic energy operator in Eq. (24), so that Eq. (20) is reduced to the Schrödinger equation in its familiar wave-mechanics form (1.28), if by $\hat{H}$ we mean its coordinate representation:

$$
\begin{equation*}
\hat{H}=\frac{1}{2 m}\left(-i \hbar \frac{\partial}{\partial x}\right)^{2}+U(x, t)=-\frac{\hbar^{2}}{2 m} \frac{\partial^{2}}{\partial x^{2}}+U(x, t) \tag{5.31}
\end{equation*}
$$

Now let us return, as was promised, to operators that do not commute with operator $\hat{x}$, and hence do not have to share its continuous spectrum. Inner-multiplying both parts of the general Eq. (4.68) by ket-vector $\langle x|$, and inserting into the left-hand part the identity operator in form (21), we get

$$
\begin{equation*}
\int d x^{\prime}\langle x| \hat{A}\left|x^{\prime}\right\rangle\left\langle x^{\prime} \mid a_{j}\right\rangle=A_{j}\left\langle x \mid a_{j}\right\rangle, \tag{5.32}
\end{equation*}
$$

[^606]i.e., using the wavefunction definition (19),
\[

$$
\begin{equation*}
\int d x^{\prime}\langle x| \hat{A}\left|x^{\prime}\right\rangle \Psi_{j}\left(x^{\prime}, t\right)=A_{j} \Psi_{j}(x, t) . \tag{5.33}
\end{equation*}
$$

\]

If the operator $A$ is space-local, i.e. satisfies Eq. (23), then this result is immediately reduced to

$$
\begin{equation*}
\hat{A} \Psi_{j}(x, t)=A_{j} \Psi_{j}(x, t) \tag{5.34}
\end{equation*}
$$

Operator's eigenstates and eigenvalues
(where the left-hand part implies the coordinate representation of the operator), even if the operator does not commute with operator $\hat{x} .{ }^{12}$ The most important case of this coordinate-representation form of the eigenproblem (4.68) is the familiar Eq. (1.60) for eigenvalues $E_{n}$ of energy. Hence, the energy spectrum of a system (that, as we know very well from the first chapters of the course, may be discrete) is nothing more than the set of eigenvalues of its Hamiltonian operator - a very important conclusion indeed.

The operator locality also simplifies the expression for its expectation value. Indeed, plugging the completeness relation in the form (21) into the general Eq. (4.125) twice (written in the first case for $x$ and in the second case for $x$ '), we get

$$
\begin{equation*}
\langle A\rangle=\int d x \int d x^{\prime}\langle\alpha(t) \mid x\rangle\langle x| \hat{A}\left|x^{\prime}\right\rangle\left\langle x^{\prime} \mid \alpha(t)\right\rangle=\int d x \int d x^{\prime} \Psi_{\alpha}^{*}(x, t)\langle x| \hat{A}\left|x^{\prime}\right\rangle \Psi_{\alpha}\left(x^{\prime}, t\right) \tag{5.35}
\end{equation*}
$$

Now, Eq. (23) reduces this result to just

$$
\begin{equation*}
\langle A\rangle=\int d x \int d x \Psi_{\alpha}^{*}(x, t) \hat{A} \Psi_{\alpha}(x, t) \delta\left(x-x^{\prime}\right)=\int \Psi_{\alpha}^{*}(x, t) \hat{A} \Psi_{\alpha}(x, t) d x \tag{5.36}
\end{equation*}
$$

i.e. to Eq. (1.23), which we had to postulate in Chapter 1.

So, we have essentially derived all basic relations of wave mechanics from the bra-ket formalism, which will also allow us to get some important new results in that area. Before doing that, let us have a look at a pair of very interesting relations, together called the Ehrenfest theorem. In order to derive them, let us calculate the following commutator: ${ }^{13}$

$$
\begin{equation*}
\left[\hat{x}, \hat{p}_{x}^{2}\right] \equiv \hat{x} \hat{p}_{x} \hat{p}_{x}-\hat{p}_{x} \hat{p}_{x} \hat{x} . \tag{5.37}
\end{equation*}
$$

Rewriting Heisenberg's commutation relation (25) as

$$
\begin{equation*}
\hat{x} \hat{p}_{x}=\hat{p}_{x} \hat{x}+i \hbar \tag{5.38}
\end{equation*}
$$

we can use it twice in the first term of the right-hand part of Eq. (37) to sequentially move the momentum operators to the left:

$$
\begin{equation*}
\hat{x} \hat{p}_{x} \hat{p}_{x}=\left(\hat{p}_{x} \hat{x}+i \hbar\right) \hat{p}_{x}=\hat{p}_{x} \hat{x} \hat{p}_{x}+i \hbar \hat{p}_{x}=\hat{p}_{x}\left(\hat{p}_{x} \hat{x}+i \hbar\right)+i \hbar \hat{p}_{x}=\hat{p}_{x} \hat{p}_{x} \hat{x}+2 i \hbar \hat{p}_{x} . \tag{5.39}
\end{equation*}
$$

[^607]The first term of the result cancels with the second term of Eq. (37), so that the commutator is rather simple:

$$
\begin{equation*}
\left[\hat{x}, \hat{p}_{x}^{2}\right]=2 i \hbar \hat{p}_{x} \tag{5.40}
\end{equation*}
$$

Let us use this equality to calculate the Heisenberg-picture equation of motion for operator $\hat{x}$, applying the general Heisenberg equation (4.199) to the orbital motion, when the Hamiltonian has the form (31), with time-independent potential $U(x):^{14}$

$$
\begin{equation*}
\frac{d \hat{x}}{d t}=\frac{1}{i \hbar}[\hat{x}, \hat{H}]=\frac{1}{i \hbar}\left[\hat{x}, \frac{\hat{p}_{x}^{2}}{2 m}+U(\hat{x})\right] . \tag{5.41}
\end{equation*}
$$

The potential energy operator commutes with the coordinate operator. Thus, the right-hand part of Eq. (41) is proportional to commutator (40):

$$
\begin{equation*}
\frac{d \hat{x}}{d t}=\frac{\hat{p}_{x}}{m} \tag{5.42}
\end{equation*}
$$

In that operator equality, we readily recognize the classical relation between particle's momentum and is velocity.

Now let us see what does a similar procedure give for the momentum's derivative:

$$
\begin{equation*}
\frac{d \hat{p}_{x}}{d t}=\frac{1}{i \hbar}\left[\hat{p}_{x}, \hat{H}\right]=\frac{1}{i \hbar}\left[\hat{p}_{x}, \frac{\hat{p}_{x}^{2}}{2 m}+U(\hat{x})\right] . \tag{5.43}
\end{equation*}
$$

The kinetic energy operator commutes with the momentum operator, and hence may be dropped from the right-hand part of this equation. In order to calculate the remaining commutator of the momentum and potential energy, let us use the fact that any smooth potential profile may be represented by its Taylor expansion:

$$
\begin{equation*}
U(\hat{x})=\sum_{k=0}^{\infty} \frac{1}{k!} \frac{\partial^{k} U}{\partial \hat{x}^{k}} \hat{x}^{k}, \tag{5.44}
\end{equation*}
$$

where the derivatives of $U$ should be understood as $c$-numbers (evaluated at $x=0$ ), so that we may write

$$
\begin{equation*}
\left[\hat{p}_{x}, U(\hat{x})\right]=\sum_{k=0}^{\infty} \frac{1}{k!} \frac{\partial^{k} U}{\partial \hat{x}^{k}}\left[\hat{p}_{x}, \hat{x}^{k}\right]=\sum_{k=0}^{\infty} \frac{1}{k!} \frac{\partial^{k} U}{\partial \hat{x}^{k}}(\hat{p}_{x} \underbrace{\hat{x} \hat{x} . \hat{x}}_{k \text { times }}-\underbrace{\left.\hat{x} \hat{x} \ldots \hat{x} \hat{p}_{x}\right) . ~ . ~ . ~}_{k \text { times }} \tag{5.45}
\end{equation*}
$$

Applying Eq. (38) $k$ times to the last term in the parentheses, exactly as we did it in Eq. (39), we get

$$
\begin{equation*}
\left[\hat{p}_{x}, U(\hat{x})\right]=-\sum_{k=1}^{\infty} \frac{1}{k!} \frac{\partial^{k} U}{\partial \hat{x}^{k}} i k \hbar \hat{x}^{k-1}=-i \hbar \sum_{k=1}^{\infty} \frac{1}{(k-1)!} \frac{\partial^{k} U}{\partial \hat{x}^{k}} \hat{x}^{k-1} . \tag{5.46}
\end{equation*}
$$

But the last sum is just the Taylor expansion of the derivative $\partial U / \partial x$. Indeed,

$$
\begin{equation*}
\frac{\partial U}{\partial \hat{x}}=\sum_{k^{\prime}=0}^{\infty} \frac{1}{k^{\prime}!} \frac{\partial^{k^{\prime}}}{\partial \hat{x}^{k^{\prime}}}\left(\frac{\partial U}{\partial \hat{x}}\right) \hat{x}^{k^{\prime}}=\sum_{k^{\prime}=0}^{\infty} \frac{1}{k^{\prime}!} \frac{\partial^{k^{\prime}+1} U}{\partial \hat{x}^{k^{\prime}+1}} \hat{x}^{k^{\prime}}=\sum_{k=1}^{\infty} \frac{1}{(k-1)!} \frac{\partial^{k} U}{\partial \hat{x}^{k}} \hat{x}^{k-1}, \tag{5.47}
\end{equation*}
$$

[^608]where at the last step I have replaced the notation of the summation index from $k$ ' to $k-1$. As a result, Eq. (43) yields:
\[

$$
\begin{equation*}
\frac{d \hat{p}_{x}}{d t}=-\frac{\partial}{\partial \hat{x}} U(\hat{x}) . \tag{5.48}
\end{equation*}
$$

\]

This equation again coincides with the classical equation of motion! Discussing spin dynamics in Sec. 4.6 and 5.1 , we have already seen that this is very typical of the Heisenberg picture. Moreover, averaging Eqs. (42) and (48) over the initial state (as Eq. (4.191) prescribes ${ }^{15}$ ), we get similar results for the expectation values: ${ }^{16}$

$$
\begin{equation*}
\frac{d\langle x\rangle}{d t}=\frac{\left\langle p_{x}\right\rangle}{m}, \quad \frac{d\left\langle p_{x}\right\rangle}{d t}=-\left\langle\frac{\partial U}{\partial x}\right\rangle . \tag{5.49}
\end{equation*}
$$

However, it is important to remember that the equivalence between these quantum-mechanical equations and similar equations of classical mechanics is superficial, and the degree of the similarity between the two mechanics very much depends on the problem. As one extreme, let us consider the case when a particle's state, at any moment between $t_{0}$ and $t$, may be accurately represented by one, relatively narrow wave packet. Then we may interpret Eqs. (49) as equations of essentially classical motion for the wave packet's center, in accordance with the correspondence principle. However, even in this case it is important to remember about the purely quantum mechanical effects of nonvanishing wave packet width and its spreading in time, which were discussed in Sec. 2.2.

In the opposite extreme, Eqs. (49), though valid, may tell almost nothing about system's dynamics. Maybe the most apparent example is the "leaky" quantum well that was discussed in Sec. 2.5 - see Fig. 2.18 and its discussion. Since both the potential $U(x)$ and the initial state are symmetric relative to point $x=0$, the right-hand parts of both Eqs. (49) identically equal zero. Of course, the result (that average values of both momentum and coordinate stay equal zero at all times) is correct, but it does not tell us too much about the rich dynamics of the system (the finite lifetime of the metastable state, the formation of two wave packets, their waveform and propagation speed), and about the important insight the solution gives for the quantum measurement theory. Another similar example is the band theory (Sec. 2.7), with its purely quantum effect of the allowed energy bands and forbidden gaps, of which Eq. (49) gives no clue.

To summarize, the Ehrenfest theorem is important as an illustration of the correspondence principle, but its predictive power should not be exaggerated.

Now we are ready to patch some holes left during our studies of wave mechanics in Chapters 13. First of all, I have promised you to develop a more balanced view at the monochromatic de Broglie waves (4.1), which would be more respectful to the evident $\mathbf{r} \leftrightarrow \mathbf{p}$ symmetry of the coordinate and momentum. Let us do this for the 1D case when the wave may be presented as ${ }^{17}$

[^609]\[

$$
\begin{equation*}
\psi_{p}(x)=a_{p} \exp \left\{i \frac{p x}{\hbar}\right\}, \quad \text { for all }-\infty<x<+\infty \tag{5.50}
\end{equation*}
$$

\]

Let us have a good look at this function. Since it satisfies equation (34) for the 1D momentum operator $\hat{p}=-i \hbar \partial / \partial x$,

$$
\begin{equation*}
\hat{p} \psi_{p}=p \psi_{p} \tag{5.51}
\end{equation*}
$$

$\psi_{p}$ is an eigenfunction of the momentum operator. But this means that we can also write Eq. (6) for the corresponding ket-vector:

$$
\begin{equation*}
\hat{p}|p\rangle=p|p\rangle, \tag{5.52}
\end{equation*}
$$

and according to Eq. (19) the wavefunction may be presented as

$$
\begin{equation*}
\psi_{p}(x)=\langle x \mid p\rangle . \tag{5.53}
\end{equation*}
$$

Expression (53) is quite remarkable in its $x \leftrightarrow p$ symmetry - which may be pursued further on. Before doing that, however, we have to discuss normalization of such functions. Indeed, in this case, the probability density $w(x)(18)$ is constant, so that its integral

$$
\begin{equation*}
\int_{-\infty}^{+\infty} w(x) d x=\int_{-\infty}^{+\infty} \psi_{p}(x) \psi_{p}^{*}(x) d x \tag{5.54}
\end{equation*}
$$

diverges if $a_{p} \neq 0$. Earlier in the course, we discussed two ways to avoid this divergence. One is to use a very large but finite integration volume - see Eq. (1.31). Another way to avoid the divergence is to form a wave packet of the type (2.20), possibly of a very large length and very narrow spread of momenta $p$. Then integral (54) may be required to equal 1 without any conceptual problem.

However, both these methods violate the $x \leftrightarrow p$ symmetry, and hence are inconvenient for our current purposes. Instead, let us continue to identify the bra- and ket-vectors $\left\langle a_{A}\right|$ and $\left|a_{A}\right\rangle$ of the general theory, developed in the beginning of this section, with eigenvectors $\langle p|$ and $|p\rangle$ of momentum - just as we have already done in Eq. (52). Then the normalization condition (9) becomes

$$
\begin{equation*}
\left\langle p \mid p^{\prime}\right\rangle=\delta\left(p-p^{\prime}\right) \tag{5.55}
\end{equation*}
$$

Inserting the identity operator in the form (21) (with the integration variable $x$ ' replaced by $x$ ) into the left-hand side of this equation, we can translate this normalization rule to the wavefunction language:

$$
\begin{equation*}
\int d x\langle p \mid x\rangle\left\langle x \mid p^{\prime}\right\rangle \equiv \int d x \psi_{p}^{*}(x) \psi_{p^{\prime}}(x)=\delta\left(p-p^{\prime}\right) \tag{5.56}
\end{equation*}
$$

Now using Eq. (50), this requirement turns into the following condition:

$$
\begin{equation*}
a_{p}^{*} a_{p^{\prime}}^{+\infty} \exp \left\{i \frac{\left(p-p^{\prime}\right) x}{\hbar}\right\} d x \equiv\left|a_{p}\right|^{2} 2 \pi \hbar \delta\left(p-p^{\prime}\right)=\delta\left(p-p^{\prime}\right) \tag{5.57}
\end{equation*}
$$

so that, finally, $a_{p}=\exp \{i \varphi\} /(2 \pi \hbar)^{1 / 2}$, where $\phi$ is an arbitrary (real) phase, and Eq. (50) becomes ${ }^{18}$

[^610]\[

$$
\begin{equation*}
\psi_{p}(x)=\frac{1}{(2 \pi \hbar)^{1 / 2}} \exp \left\{i\left(\frac{p x}{\hbar}+\phi\right)\right\}, \tag{5.58}
\end{equation*}
$$

\]

As was mentioned above, for finite-length wave packets such normalization is not really necessary. However, frequently it makes sense to keep the pre-exponential coefficient in Eq. (58) even for wave packets, because of the following reason. Let us form a wave packet of the type (2.20), based on wavefunctions (58) - taking $\phi=0$ for the notation brevity, because it may be incorporated into function $\varphi(p)$ :

$$
\begin{equation*}
\psi(x)=\frac{1}{(2 \pi \hbar)^{1 / 2}} \int \varphi(p) \exp \left\{i \frac{p x}{\hbar}\right\} d p \tag{5.59}
\end{equation*}
$$

From the mathematical point of view, this is just the equation of a 1D Fourier spatial transform, and its reciprocal is

$$
\begin{equation*}
\varphi(p) \equiv \frac{1}{(2 \pi \hbar)^{1 / 2}} \int \psi(x) \exp \left\{-i \frac{p x}{\hbar}\right\} d x \tag{5.60}
\end{equation*}
$$

These expressions are completely symmetrical, and present the same wave packet; this is why functions $\psi(x)$ and $\varphi(p)$ are frequently called, respectively, the coordinate ( $x-$ ) and momentum ( $p-$ ) representations of the (same) state of the particle. Using Eqs. (53) and (58), they may be presented in an even more manifestly symmetric form,

$$
\begin{equation*}
\psi(x)=\int \varphi(p)\langle x \mid p\rangle d p, \quad \varphi(p)=\int \psi(x)\langle p \mid x\rangle d x \tag{5.61}
\end{equation*}
$$

in which the scalar products satisfy the basic postulate (4.14) of the bra-ket formalism:

$$
\begin{equation*}
\langle p \mid x\rangle=\frac{1}{(2 \pi \hbar)^{1 / 2}} \exp \left\{-i \frac{p x}{\hbar}\right\}=\langle x \mid p\rangle^{*} \tag{5.62}
\end{equation*}
$$

We already know that in the $x$-representation, i.e. in the usual wave mechanics, the coordinate operator $\hat{x}$ is reduced to the multiplication by $x$, and the momentum operator is proportional to a derivative over $x$ :

$$
\begin{equation*}
\left.\hat{x}\right|_{\operatorname{in} x}=x,\left.\quad \hat{p}\right|_{\operatorname{in} x}=-i \hbar \frac{\partial}{\partial x} . \tag{5.63}
\end{equation*}
$$

It is natural to guess that in the $p$-representation, the expressions for operators would be reciprocal:

$$
\begin{equation*}
\left.\hat{x}\right|_{\text {in } p}=i \hbar \frac{\partial}{\partial p},\left.\quad \hat{p}\right|_{\text {in } p}=p \tag{5.64}
\end{equation*}
$$

with the difference in one sign only, due to the opposite signs of the Fourier exponents in Eqs. (59) and (60). The proof of Eqs. (64) is straightforward; for example, acting by the momentum operator to wavefunction (59), we get

$$
\begin{align*}
\hat{p} \psi(x) & =-i \hbar \frac{\partial}{\partial x} \psi(x)=\frac{1}{(2 \pi \hbar)^{1 / 2}} \int \varphi(p)\left(-i \hbar \frac{\partial}{\partial x} \exp \left\{i \frac{p x}{\hbar}\right\}\right) d p  \tag{5.65}\\
& =\frac{1}{(2 \pi \hbar)^{1 / 2}} \int p \varphi(p) \exp \left\{i \frac{p x}{\hbar}\right\} d p,
\end{align*}
$$

and similarly for operator $\hat{x}$ acting on function $\varphi(p)$. Hence, the action of the operators (63) on wavefunction $\psi$ (i.e. state's $x$-representation) gives the same results as the action of operators (64) on function $\varphi$ (i.e. its $p$-representation).

It is interesting to have one more, different look at this coordinate-to-momentum duality. For that, notice that according to Eqs. (4.82)-(4.84), we may consider the bra-ket $\langle x \mid p\rangle$ as an element of the (infinite-size) matrix $U_{x p}$ of the unitary transform from the $x$-basis to $p$-basis. Now let us derive the operator transform rule that would be a continuous version of Eq. (4.92). Say, we want to calculate a matrix element of some operator in the $p$-representation:

$$
\begin{equation*}
\langle p| \hat{A}\left|p^{\prime}\right\rangle \tag{5.66}
\end{equation*}
$$

Inserting two identity operators (21) into this bra-ket, and then using Eq. (53) and its complex conjugate, and also Eq. (23) (again, valid only for space-local operators!), we get

$$
\begin{align*}
& \langle p| \hat{A}\left|p^{\prime}\right\rangle=\int d x \int d x^{\prime}\langle p \mid x\rangle\langle x| \hat{A}\left|x^{\prime}\right\rangle\left\langle x^{\prime} \mid p^{\prime}\right\rangle=\int d x \int d x^{\prime} \psi_{p}^{*}(x)\langle x| \hat{A}\left|x^{\prime}\right\rangle \psi_{p^{\prime}}\left(x^{\prime}\right) \\
& =\frac{1}{2 \pi \hbar} \int d x \int d x^{\prime} \exp \left\{-i \frac{p x}{\hbar}\right\} \delta\left(x-x^{\prime}\right) \hat{A} \exp \left\{i \frac{p^{\prime} x^{\prime}}{\hbar}\right\}=\frac{1}{2 \pi \hbar} \int d x \exp \left\{-i \frac{p x}{\hbar}\right\} \hat{A} \exp \left\{i \frac{p^{\prime} x}{\hbar}\right\} . \tag{5.67}
\end{align*}
$$

For example, for the momentum operator itself, this relation yields:

$$
\begin{equation*}
\langle p| \hat{p}\left|p^{\prime}\right\rangle=\frac{1}{2 \pi \hbar} \int d x \exp \left\{-i \frac{p x}{\hbar}\right\}\left(-i \hbar \frac{\partial}{\partial x}\right) \exp \left\{i \frac{p^{\prime} x}{\hbar}\right\}=\frac{p^{\prime}}{2 \pi \hbar} \int_{-\infty}^{+\infty} \exp \left\{i \frac{\left(p^{\prime}-p\right) x}{\hbar}\right\} d x=p^{\prime} \delta\left(p^{\prime}-p\right) \tag{5.68}
\end{equation*}
$$

Due to Eq. (52), this result is equivalent to the second of Eqs. (64).
A natural question arises: why is the momentum representation used much less frequently than the coordinate representation - i.e., the wave mechanics? The answer is purely practical: besides the special case of the harmonic oscillator (to be revisited in Sec. 4 below), the orbital motion Hamiltonian (31) is not $x \leftrightarrow p$ symmetric, with the potential energy $U(x)$ being typically a more complex function than the kinetic energy, which is quadratic in momentum. Because of that, it is easier for problem solution to keep the potential energy operator just a wavefunction multiplier, as it is in the coordinate representation.

The most significant exception of this rule is the motion in a periodic potential, especially in the presence of additional external force $F(t)$, which may result in the effects discussed in Secs. 2.8 and 2.9 (the Bloch oscillations, Landau-Zener tunneling etc.). Indeed, in this case the dispersion relation $E_{n}(q)$, typically rather involved, plays the role of the effective kinetic energy, while the effective potential energy $U_{\mathrm{ef}}=-F(t) x$ in the field of the additional force is a simple function of $x$. This is why discussions of the listed and more complex issues of the band theory (such as quasiparticle scattering, mobility, diffusion, etc.) in solid state physics theory are most typically based on the momentum representation.

### 5.3. Feynman's path integrals

As has been already mentioned, even within the realm of wave mechanics, the bra-ket language allows to streamline some calculations that would be very bulky using the notation used in Chapters 1-3. Probably the best example in the famous alternative, path integral formulation of quantum mechanics,
developed in 1948 by R. Feynman. ${ }^{19}$ I will review this important concept - admittedly cutting one math corner for brevity. ${ }^{20}$ (This shortcut will be clearly marked.)

Let us inner-multiply both parts of Eq. (4.157), which is essentially the definition of the timeevolution operator, by the bra-vector of state $x$,

$$
\begin{equation*}
\langle x \mid \alpha(t)\rangle=\langle x| \hat{u}\left(t, t_{0}\right)\left|\alpha\left(t_{0}\right)\right\rangle, \tag{5.69}
\end{equation*}
$$

insert the identity operator before the ket-vector in the right-hand part, and then use the closure condition in the form of Eq. (21), with $x$ ' replaced with $x_{0}$ :

$$
\begin{equation*}
\langle x \mid \alpha(t)\rangle=\int d x_{0}\langle x| \hat{u}\left(t, t_{0}\right)\left|x_{0}\right\rangle\left\langle x_{0} \mid \alpha\left(t_{0}\right)\right\rangle . \tag{5.70}
\end{equation*}
$$

According to Eq. (19), this equality may be presented as

$$
\begin{equation*}
\Psi_{\alpha}(x, t)=\int d x_{0}\langle x| \hat{u}\left(t, t_{0}\right)\left|x_{0}\right\rangle \Psi_{\alpha}\left(x_{0}, t_{0}\right) . \tag{5.71}
\end{equation*}
$$

Comparing this expression with Eq. (2.44), we see that the bra-ket in this relation is nothing else than the 1D propagator, which was discussed in Sec. 2.2:

$$
\begin{equation*}
\langle x| \hat{u}\left(t, t_{0}\right)\left|x_{0}\right\rangle=G\left(x, t ; x_{0}, t_{0}\right) . \tag{5.72}
\end{equation*}
$$

As a reminder, we have already calculated the propagator for a free particle - see Eq. (2.49).
Now let us break the time segment $\left[t_{0}, t\right]$ into $N$ (for the time being, not necessarily equal) parts by inserting ( $N-1$ ) intermediate points (Fig. 2)

$$
\begin{equation*}
t_{0}<t_{1}<\ldots<t_{k}<\ldots<t_{N-1}<t \tag{5.73}
\end{equation*}
$$

and rewrite the time evolution operator in the form

$$
\begin{equation*}
\hat{u}\left(t, t_{0}\right)=\hat{u}\left(t, t_{N-1}\right) \hat{u}\left(t_{N-1}, t_{N-2}\right) \ldots \hat{u}\left(t_{2}, t_{1}\right) \hat{u}\left(t_{1}, t_{0}\right), \tag{5.74}
\end{equation*}
$$

whose correctness is evident from the very definition (4.157) of the operator. Plugging Eq. (74) into Eq. (72), let us insert the identity operator, again in the form (21) but written for $x_{k}$ rather than $x^{\prime}$, between each two partial evolution operators including time argument $t_{k}$. The result is

$$
\begin{equation*}
G\left(x, t ; x_{0}, t_{0}\right)=\int d x_{N-1} \int d x_{N-2} \ldots \int d x_{1}\langle x| \hat{u}\left(t, t_{N-1}\right)\left|x_{N-1}\right\rangle\left\langle x_{N-1}\right| \hat{u}\left(t_{N-1}, t_{N-2}\right)\left|x_{N-2}\right\rangle \ldots\left\langle x_{1}\right| \hat{u}\left(t_{1}, t_{0}\right)\left|x_{0}\right\rangle . \tag{5.75}
\end{equation*}
$$

Fig. 5.2. Time partition and coordinate notation at the initial stage of the Feynman's path integral derivation.

[^611]The physical sense of each integration variable $x_{k}$ is the wavefunction's argument at time $t_{k}$ - see Fig. 2. The key Feynman's breakthrough was the realization that if all intervals are similar and sufficiently small, $t_{k}-t_{k-1}=d \tau \rightarrow 0$, all the partial bra-kets participating in Eq. (75) may be readily expressed via Eq. (2.49), even if the particle is not free, but moves in a stationary potential profile $U(x)$. To show that, let us use either Eq. (4.175) or Eq. (4.181), which, for a small time interval $d \tau$, give the same result:

$$
\begin{equation*}
\hat{u}(\tau+d \tau, \tau)=\exp \left\{-\frac{i}{\hbar} \hat{H} d \tau\right\}=\exp \left\{-\frac{i}{\hbar}\left(\frac{\hat{p}^{2}}{2 m} d \tau+U(\hat{x}) d \tau\right)\right\} . \tag{5.76}
\end{equation*}
$$

Generally, an exponent of a sum of two operators may be treated as that of $c$-number arguments, and in particular factored into a product of two exponents, only if the operators commute. (Indeed, in this case we can use all the standard algebra for exponents of $c$-number arguments.) In our case, this is not so, because operator $\hat{p}$ does not commute with $\hat{x}$, and hence with $U(\hat{x})$. However, it may be shown ${ }^{21}$ that for an infinitesimal time interval $d \tau$, the nonvanishing commutator

$$
\begin{equation*}
\left[\frac{\hat{p}^{2}}{2 m} d \tau, U(\hat{x}) d \tau\right] \neq 0 \tag{5.77}
\end{equation*}
$$

proportional to $(d \tau)^{2}$, is so small that in the first approximation in $d \tau$ its effects may be ignored. As a result, we may factor the right-hand part in Eq. (76) by writing

$$
\begin{equation*}
\hat{u}(\tau+d \tau, \tau)_{d \tau \rightarrow 0} \rightarrow \exp \left\{-\frac{i}{\hbar} \frac{\hat{p}^{2}}{2 m} d \tau\right\} \exp \left\{-\frac{i}{\hbar} U(\hat{x}) d \tau\right\} \tag{5.78}
\end{equation*}
$$

(This approximation is very much similar in spirit to the rectangle-formula approximation for a usual 1D integral, which in also asymptotically impeachable.)

Since the second exponential function in the right-hand part of Eq. (78) commutes with the coordinate operator, we can move it out of each partial bra-ket participating in Eq. (75), with $U(x)$ turning into a $c$-number function:

$$
\begin{equation*}
\left\langle x_{\tau+d \tau}\right| \hat{u}(\tau+d \tau, \tau)\left|x_{\tau}\right\rangle=\left\langle x_{\tau+d \tau}\right| \exp \left\{-\frac{i}{\hbar} \frac{\hat{p}^{2}}{2 m} d \tau\right\}\left|x_{\tau}\right\rangle \exp \left\{-\frac{i}{\hbar} U(x) d \tau\right\} . \tag{5.79}
\end{equation*}
$$

But the remaining bra-ket is just the propagator of a free particle, and we can use Eq. (2.49) for it:

$$
\begin{equation*}
\left\langle x_{\tau+d \tau}\right| \exp \left\{-\frac{i}{\hbar} \frac{\hat{p}^{2}}{2 m} d \tau\right\}\left|x_{\tau}\right\rangle=\left(\frac{m}{2 \pi i \hbar d \tau}\right)^{1 / 2} \exp \left\{i \frac{m(d x)^{2}}{2 \hbar d \tau}\right\} \tag{5.80}
\end{equation*}
$$

As the result, the full propagator (75) takes the form

$$
\begin{equation*}
G\left(x, t ; x_{0} t_{0}\right)=\lim _{\substack{d \tau \rightarrow 0 \\ N \rightarrow \infty}} \int d x_{N-1} \int d x_{N-2} . . \int d x_{1}\left(\frac{m}{2 \pi i \hbar d \tau}\right)^{N / 2} \exp \left\{\sum_{k=1}^{N}\left[i \frac{m(d x)^{2}}{2 \hbar d \tau}-i \frac{U(x)}{\hbar} d \tau\right]\right\} . \tag{5.81}
\end{equation*}
$$

[^612]At $N \rightarrow \infty$ and hence $d \tau \equiv\left(t-t_{0}\right) / N \rightarrow 0$, the sum under the exponent in this expression tends to an integral:

$$
\begin{equation*}
\sum_{k=1}^{N} \frac{i}{\hbar}\left[\frac{m}{2}\left(\frac{d x}{d \tau}\right)^{2}-U(x)\right]_{\tau=t_{k}} d \tau \rightarrow \frac{i}{\hbar} \int_{t_{0}}^{t}\left[\frac{m}{2}\left(\frac{d x}{d \tau}\right)^{2}-U(x)\right] d \tau \tag{5.82}
\end{equation*}
$$

and the expression in square brackets is just the particle's Lagrangian function $L .{ }^{22}$ The integral of the function over time is the classical action $S$ calculated along a particular "path" $x(\tau) .{ }^{23}$ As a result, defining the (1D) path integral as

$$
\begin{equation*}
\int(\ldots) D[x(\tau)] \equiv \lim _{\substack{d \tau \rightarrow 0 \\ N \rightarrow \infty}}\left(\frac{m}{2 \pi i \hbar d \tau}\right)^{N / 2} \int d x_{N-1} \int d x_{N-2} . . \int d x_{1}(\ldots) \tag{5.83a}
\end{equation*}
$$

we can bring our result to a superficially simple form

$$
\begin{equation*}
G\left(x, t ; x_{0}, t_{0}\right)=\int \exp \left\{\frac{i}{\hbar} \varsigma[x(\tau)]\right\} D[x(\tau)] \tag{5.83b}
\end{equation*}
$$

1D path
integral: definition

The name "path integral" for the mathematical construct (83a) may be readily explained if we keep the number $N$ of time intervals large but finite, and also approximate each of the enclosed integrals by a sum over $M \gg 1$ discrete points along the coordinate axis (Fig. 3a).

Fig. 5.3. Several 1D classical paths in (a) the discrete approximation and (b) the continuous limit.

Then the path integral is a product of $(N-1)$ sums corresponding to different values of time $\tau$, each of them with $M$ terms, each of the terms representing the function under the integral at a particular spatial point. Multiplying those $(N-1)$ sums, we get a sum of $(N-1) M$ terms, each evaluating the function at a specific spatial-temporal point $[x, \tau]$. These terms may be now grouped to represent all possible different continuous classical paths $x[\tau]$ from the initial point $\left[x_{0}, t_{0}\right]$ to the finite point $[x, t]$. It is evident that the last interpretation remains true even in the continuous limit $N, M \rightarrow \infty-$ see Fig. 3b.

Why does such representation of the sum has sense? This is because in the classical limit the particle follows just a certain path, corresponding to the minimum of action $S^{22}$ Hence, for all close trajectories, the difference $\left(S-S_{\mathrm{cl}}\right)$ is proportional to the square of the deviation from the classical trajectory. Hence, for a quasiclassical motion, with $S_{\mathrm{cl}} \gg \hbar$, there is a substantial bunch of close trajectories, with $\left(S-S_{\mathrm{cl}}\right) \ll \hbar$, that give similar contributions to the path integral. On the other hand,

[^613]strongly non-classical trajectories, with $\left(S-S_{\mathrm{cl}}\right) \gg \hbar$, give phases $S \hbar$ rapidly oscillating from one trajectory to the next one, and their contributions to the path integral are averaged out. ${ }^{24}$ As a result, for the quasiclassical motion, the propagator's exponent may be evaluated on the classical path:
\[

$$
\begin{equation*}
G_{\mathrm{cl}} \propto \exp \left\{\frac{i}{\hbar} S_{\mathrm{cl}}\right\}=\exp \left\{\frac{i}{\hbar} \int_{t_{0}}^{t}\left[\frac{m}{2}\left(\frac{d x}{d \tau}\right)^{2}-U(x)\right] d \tau\right\} . \tag{5.84}
\end{equation*}
$$

\]

The sum of the kinetic and potential energies is the full energy $E$ of the particle, that remains constant for motion in a stationary potential $U(x)$, so that we may rewrite the expression under the integral as ${ }^{25}$

$$
\begin{equation*}
\left[\frac{m}{2}\left(\frac{d x}{d \tau}\right)^{2}-U(x)\right] d \tau=\left[m\left(\frac{d x}{d \tau}\right)^{2}-E\right] d \tau=m \frac{d x}{d \tau} d x-E d \tau \tag{5.85}
\end{equation*}
$$

With that replacement, Eq. (83b) yields

$$
\begin{equation*}
G_{\mathrm{cl}} \propto \exp \left\{\frac{i}{\hbar} \int_{x_{0}}^{x} m \frac{d x}{d \tau} d x\right\} \exp \left\{-\frac{i}{\hbar} E\left(t-t_{0}\right)\right\}=\exp \left\{\frac{i}{\hbar} \int_{x_{0}}^{x} p(x) d x\right\} \exp \left\{-\frac{i}{\hbar} E\left(t-t_{0}\right)\right\}, \tag{5.86}
\end{equation*}
$$

where $p$ is the classical momentum of the particle. But (at least, leaving the pre-exponential factor alone) this is exactly the WKB approximation result that was derived and studied in detail in Chapter 2!

One may question the value of a calculation that yields the results that could be readily obtained from Schrödinger's wave mechanics. The Feynman's approach, is indeed not used too often, but it has its merits. First, it has an important philosophical (and hence heuristic) value. Indeed, Eq. (83) may be interpreted by saying that the essence of quantum mechanics is the exploration, by the system, of all possible paths $x(\tau)$, each of them classical-like in the sense that the particle's coordinate $x$ and velocity $d x / d \tau$ (and hence its momentum) are exactly defined simultaneously at each point. The resulting contributions to the path integral are added up coherently to form the final propagator $G$, and via it, the final probability $W \propto|G|^{2}$ of the particle propagation from $\left[x_{0}, t_{0}\right]$ to $[x, t]$. Of course, as the scale of action (i.e. of the energy-by-time product) of the motion decreases and becomes comparable to $\hbar$, more and more paths produce substantial contribution to this sum, and hence to $W$, ensuring a larger and larger difference between the quantum and classical properties of the system.

Second, the path integral provides a justification for some simple explanations of quantum phenomena. A typical example is the quantum interference effects discussed in Sec. 3.1 - see, e.g., Fig. 3.1 and the corresponding text. At that discussion, we used the Huygens principle to argue that at the two-slit interference, the WKB approximation might be restricted of effects by two paths that pass through different slits, but otherwise consisting of straight-line segments. To have another look at that assumption, let us generalize the path integral to multi-dimensional geometries. Fortunately, the simple structure of Eq. (83b) makes such generalization virtually evident:

[^614]\[

$$
\begin{gather*}
G\left(\mathbf{r}, t ; \mathbf{r}_{0}, t_{0}\right)=\int \exp \left\{\frac{i}{\hbar} S[\mathbf{r}(\tau)]\right\} D[\mathbf{r}(\tau)] \\
S \equiv \int_{t_{0}}^{t} L\left(\mathbf{r}, \frac{d \mathbf{r}}{d \tau}\right) d \tau=\int_{t_{0}}^{t}\left[\frac{m}{2}\left(\frac{d \mathbf{r}}{d \tau}\right)^{2}-U(\mathbf{r})\right] d \tau \tag{5.87}
\end{gather*}
$$
\]

SD propagator via the path integral
where definition (83a) of the path integral should be also modified correspondingly. (I will not go into these technical details.) For the Young-type experiment (Fig. 3.1), where a classical particle could reach the detector only after passing through one of the slits, the classical paths are the straight-line segments shown in Fig. 3.1, and if they are much longer than the de Broglie wavelength, the propagator may be well approximated by the sum of two integrals of $L d \tau=i \mathbf{p}(\mathbf{r}) \cdot d \mathbf{r} / \hbar$ - as it was done in Sec. 3.1.

Last but not least, the path integral allows simple solutions of some problems that would be hard to get by other methods. As the simplest example, let us consider the problem of tunneling in multidimensional space, sketched in Fig. 4 for the 2D case - just for graphics' simplicity. Here, potential $U(x$, $y$ ) has the "saddle" shape. (Another helpful image is a mountain path between two summits, in Fig. 4 located on the top and at the bottom of the drawing.) A particle of energy $E$ may move classically in the left and right regions with $U(x, y)<E$, but can pass from one of these regions to another one only via the quantum-mechanical tunneling under the pass. Let us calculate the transparency of this tunnel barrier in the WKB approximation, ignoring the possible pre-exponential factor.

Fig. 5.4. Saddle-type 2D potential profile and the instanton trajectory of a particle of energy $E$ (dashed line, schematically).

According to the evident multi-dimensional generalization Eq. (86), for the classically forbidden region, where $E<U(x, y)$, the contributions to propagator (87) are proportional to

$$
\begin{equation*}
\exp \left\{-\int_{\mathrm{r}_{0}}^{\mathbf{r}} \boldsymbol{\kappa}(\mathbf{r}) \cdot d \mathbf{r}\right\} \exp \left\{-\frac{i}{\hbar} E\left(t-t_{0}\right)\right\}, \tag{5.88}
\end{equation*}
$$

where the magnitude of vector $\kappa$ at each point may be calculated just in the 1 D case - see, egg., Eq. (2.97),

$$
\begin{equation*}
\frac{\hbar^{2} \kappa^{2}(\mathbf{r})}{2 m}=U(\mathbf{r})-E, \tag{5.89}
\end{equation*}
$$

while its direction should be tangential to the path trajectory in space. Now the path integral is actually much simpler than in the classically-allowed region, because the spatial exponents are purely real and there is no complex interference between them. Because of the minus sign in the exponent, the largest
contribution to $G$ evidently comes from the trajectory (or rather a narrow bundle of trajectories) for which the functional

$$
\begin{equation*}
\int_{\mathbf{r}_{0}}^{\mathbf{r}} \boldsymbol{\kappa}\left(\mathbf{r}^{\prime}\right) \cdot d \mathbf{r}^{\prime} \tag{5.90}
\end{equation*}
$$

has the smallest value, and the barrier transmission coefficient may be calculated as

$$
\begin{equation*}
T \approx|G|^{2} \approx \exp \left\{-2 \int_{\mathbf{r}_{0}}^{\mathbf{r}} \boldsymbol{\kappa}\left(\mathbf{r}^{\prime}\right) \cdot d \mathbf{r}^{\prime}\right\} \tag{5.91}
\end{equation*}
$$

where $\mathbf{r}$ and $\mathbf{r}_{0}$ are certain points on the opposite classical turning-point surfaces: $U(\mathbf{r})=U\left(\mathbf{r}_{0}\right)=E .{ }^{26}$
Thus the tunneling problem is reduced to finding the trajectory (including points $\mathbf{r}$ and $\mathbf{r}_{0}$ ) that connects the two surfaces and minimizes functional (90). This is of course a well-known problem of the calculus of variations, ${ }^{27}$ but it is interesting that the path integral provides a simple alternative way of solving it. Let us consider an auxiliary problem of particle's motion in a potential profile $U_{\mathrm{inv}}(\mathbf{r})$ that is inverted relative to particle's energy $E$, i.e. is defined by the following equality:

$$
\begin{equation*}
U_{\mathrm{inv}}(\mathbf{r})-E \equiv E-U(\mathbf{r}) \tag{5.92}
\end{equation*}
$$

As was discussed above, at fixed energy $E$, the path integral for the WKB motion in the classically allowed region of potential $U_{\mathrm{inv}}(x, y)$ (that coincides with the classically forbidden region of the original problem) is dominated by the classical trajectory corresponding to the minimum of

$$
\begin{equation*}
\boldsymbol{S}_{\text {inv }}=\int_{\mathbf{r}_{0}}^{\mathbf{r}} \mathbf{p}_{\text {inv }}\left(\mathbf{r}^{\prime}\right) \cdot d \mathbf{r}^{\prime}=\hbar \int_{\mathbf{r}_{0}}^{\mathbf{r}} \mathbf{k}_{\text {inv }}\left(\mathbf{r}^{\prime}\right) \cdot d \mathbf{r}, \tag{5.93}
\end{equation*}
$$

where $\mathbf{k}_{\text {inv }}$ should be determined from the relation

$$
\begin{equation*}
\frac{\hbar^{2} k_{\mathrm{inv}}^{2}(\mathbf{r})}{2 m} \equiv E-U_{\mathrm{inv}}(\mathbf{r}) \tag{5.94}
\end{equation*}
$$

But comparing Eqs. (89), (92), and (94), we see that $\mathbf{k}_{\text {inv }}=\boldsymbol{\kappa}$ at each point of space! This means that the tunneling path (in the WKB limit) corresponds to the classical (so-called instanton) ${ }^{28}$ trajectory of the same particle in the inverted potential $U_{\text {inv }}(\mathbf{r})$. If the initial point $\mathbf{r}_{0}$ is fixed, this trajectory may be readily found by the means of classical mechanics. (Note that the initial velocity of the instanton launched from point $\mathbf{r}_{0}$ should be zero, because by the classical turning point definition: $U_{\mathrm{inv}}\left(\mathbf{r}_{0}\right)=U\left(\mathbf{r}_{0}\right)$ $=E$.) Thus the problem is reduced to a simpler task of maximizing the transparency (91) over the position of $\mathbf{r}_{0}$ on the equipotential surface $U\left(\mathbf{r}_{0}\right)=E$. Moreover, for many symmetric potentials, the position of this point may be readily guessed without calculations.

[^615]Note that besides the calculation of barrier transparency, the instanton trajectory has one more important implication: the so-called traversal time $\tau_{t}$ of the classical motion along it, in the inverted potential, defined by Eq. (94), plays the role of the most important (though not the only one) time scale of particle's tunneling under the potential barrier. ${ }^{29}$

### 5.4. Revisiting harmonic oscillator

Let us return to the 1D harmonic oscillator, i.e. any system described by Hamiltonian (2.50) with potential energy (2.111):

$$
\begin{equation*}
\hat{H}=\frac{\hat{p}^{2}}{2 m}+\frac{m \omega_{0}^{2} \hat{x}^{2}}{2} \tag{5.95}
\end{equation*}
$$

In Sec. 2.10 we have used the "brute-force" (wave-mechanics) approach to analyze the eigenfunctions $\psi_{n}(x)$ and eigenvalues $E_{n}$ of this Hamiltonian, and found that, unfortunately, that approach required relatively complex math that obscures the physics of these stationary ("Fock") states. Now let us use the bra-ket formalism to make the properties of these states much more transparent, using very simple calculations.

First, introducing normalized (dimensionless) operators of coordinates and momentum: ${ }^{30}$

$$
\begin{equation*}
\hat{\xi} \equiv \frac{\hat{x}}{x_{0}}, \quad \hat{\zeta} \equiv \frac{\hat{p}}{m \omega_{0} x_{0}}, \tag{5.96}
\end{equation*}
$$

where $x_{0} \equiv\left(\hbar / m \omega_{0}\right)^{1 / 2}$ is the natural coordinate scale ( $\sqrt{ } 2$ the r.m.s. spread of ground-state wavefunction) which was discussed in detail in Sec. 2.10, we can present Hamiltonian (95) in a very simple and $x \leftrightarrow p$ symmetric form:

$$
\begin{equation*}
\hat{H}=\frac{\hbar \omega_{0}}{2}\left(\hat{\xi}^{2}+\hat{\zeta}^{2}\right) . \tag{5.97}
\end{equation*}
$$

Now, let us introduce a new operator

$$
\begin{equation*}
\hat{a} \equiv \frac{1}{\sqrt{2}}(\hat{\xi}+i \hat{\zeta})=\left(\frac{m \omega_{0}}{2 \hbar}\right)^{1 / 2}\left(\hat{x}+i \frac{\hat{p}}{m \omega_{0}}\right) . \tag{5.98a}
\end{equation*}
$$

Since both operators $\hat{\xi}$ and $\hat{\zeta}$ correspond to real observables, i.e. have real eigenvalues and hence are Hermitian (self-adjoint), the Hermitian conjugate of operator $\hat{a}$ is simply its complex conjugate:

$$
\begin{equation*}
\hat{a}^{\dagger}=\frac{1}{\sqrt{2}}(\hat{\xi}-i \hat{\zeta})=\left(\frac{m \omega_{0}}{2 \hbar}\right)^{1 / 2}\left(\hat{x}-i \frac{\hat{p}}{m \omega_{0}}\right) \tag{5.98b}
\end{equation*}
$$

Solving the system of two equations (98) for $\hat{\xi}$ and $\hat{\zeta}$, we may readily get reciprocal relations

[^616]\[

$$
\begin{equation*}
\hat{\xi}=\frac{1}{\sqrt{2}}\left(\hat{a}+\hat{a}^{\dagger}\right), \quad \hat{\zeta}=\frac{1}{\sqrt{2} i}\left(\hat{a}-\hat{a}^{\dagger}\right) . \tag{5.99}
\end{equation*}
$$

\]

Our Hamiltonian (97) includes squares of these operators. Calculating them, we have to be careful to avoid swapping the new operators, because they do not commute. Indeed, for the normalized operators (96), Eq. (2.14) gives

$$
\begin{equation*}
[\hat{\xi}, \hat{\zeta}]=\frac{1}{x_{0}^{2} m \omega_{0}}[\hat{x}, \hat{p}]=i \hat{I}, \tag{5.100}
\end{equation*}
$$

Creationannihilation operators: commutation relation
so that Eqs. (98) yield

$$
\begin{equation*}
\left[\hat{a}, \hat{a}^{\dagger}\right]=\frac{1}{2}[(\hat{\xi}+i \hat{\zeta}),(\hat{\xi}-i \hat{\zeta})]=-\frac{i}{2}([\hat{\xi}, \hat{\zeta}]-[\hat{\zeta}, \hat{\xi})=\hat{I} . \tag{5.101}
\end{equation*}
$$

With such due caution, Eq. (99) gives

$$
\begin{equation*}
\hat{\xi}^{2}=\frac{1}{2}\left(\hat{a}^{2}+\hat{a}^{\dagger^{2}}+\hat{a} \hat{a}^{\dagger}+\hat{a}^{\dagger} \hat{a}\right), \quad \hat{\zeta}^{2}=-\frac{1}{2}\left(\hat{a}^{2}+\hat{a}^{\dagger^{2}}-\hat{a} \hat{a}^{\dagger}-\hat{a}^{\dagger} \hat{a}\right) . \tag{5.102}
\end{equation*}
$$

Plugging these expressions back into Eq. (97), we get

$$
\begin{equation*}
\hat{H}=\frac{\hbar \omega_{0}}{2}\left(\hat{a} \hat{a}^{\dagger}+\hat{a}^{\dagger} \hat{a}\right) \tag{5.103}
\end{equation*}
$$

This expression is elegant enough, but may be recast into an even more convenient form. For that, let us rewrite the commutation relation (100) as

$$
\begin{equation*}
\hat{a} \hat{a}^{\dagger}=\hat{a}^{\dagger} \hat{a}+\hat{I} \tag{5.104}
\end{equation*}
$$

and plug it into Eq. (103). The result is

$$
\begin{equation*}
\hat{H}=\frac{\hbar \omega_{0}}{2}\left(2 \hat{a}^{\dagger} \hat{a}+\hat{I}\right)=\hbar \omega_{0}\left(\hat{N}+\frac{1}{2} \hat{I}\right) \tag{5.105}
\end{equation*}
$$

where, in the last form, one more (evidently, Hermitian) operator,

$$
\begin{equation*}
\hat{N} \equiv \hat{a}^{\dagger} \hat{a} \tag{5.106}
\end{equation*}
$$

has been introduced. Since, according to Eq. (105), operators $\hat{H}$ and $\hat{N}$ differ only by the addition of an identity operator and the multiplication by a $c$-number, these operators commute. Hence, according to the general arguments of Sec. 4.5, they share the set of stationary (Fock) eigenstates $n$, and we can write the eigenproblem for the new operator as

$$
\begin{equation*}
\hat{N}|n\rangle=N_{n}|n\rangle \tag{5.107}
\end{equation*}
$$

where $N_{n}$ are some eigenvalues that, according to Eq. (105), determine also the energy spectrum of the oscillator:

$$
\begin{equation*}
E_{n}=\hbar \omega_{0}\left(N_{n}+\frac{1}{2}\right) \tag{5.108}
\end{equation*}
$$

So far, we know only that all eigenvalues $N_{n}$ are real, but not much more. In order to calculate them, let us carry out the following calculation - splendid in its simplicity and efficiency. Consider the result of action of operator $\hat{N}$ on the ket-vector $\hat{a}^{\dagger}|n\rangle$. Using the definition (106) and the associative rule, we may write

$$
\begin{equation*}
\hat{N}\left(\hat{a}^{\dagger}|n\rangle\right)=\left(\hat{a}^{\dagger} \hat{a}\right)\left(\hat{a}^{\dagger}|n\rangle\right)=\hat{a}^{\dagger}\left(\hat{a} \hat{a}^{\dagger}\right)|n\rangle . \tag{5.109}
\end{equation*}
$$

Now using the commutation relation (104), and then Eq. (107), we may continue as

$$
\begin{equation*}
\hat{a}^{\dagger}\left(\hat{a} \hat{a}^{\dagger}\right)|n\rangle=\hat{a}^{\dagger}\left(\hat{a}^{\dagger} \hat{a}+\hat{I}\right)|n\rangle=\hat{a}^{\dagger}(\hat{N}+\hat{I})|n\rangle=\hat{a}^{\dagger}\left(N_{n}+1\right)|n\rangle=\left(N_{n}+1\right)\left(\hat{a}^{\dagger}|n\rangle\right) . \tag{5.110}
\end{equation*}
$$

Let us summarize the result of this calculation:

$$
\begin{equation*}
\hat{N}\left(\hat{a}^{\dagger}|n\rangle\right)=\left(N_{n}+1\right)\left(\hat{a}^{\dagger}|n\rangle\right) . \tag{5.111}
\end{equation*}
$$

Performing an absolutely similar calculation with operator $\hat{a}$, we can also get another formula:

$$
\begin{equation*}
\hat{N}(\hat{a}|n\rangle)=\left(N_{n}-1\right)(\hat{a}|n\rangle) . \tag{5.112}
\end{equation*}
$$

It is time to stop calculations and translate these results into plain English: if $|n\rangle$ is an eigenket of operator $\hat{N}$ with eigenvalue $N_{n}$, then $\hat{a}^{\dagger}|n\rangle$ and $\hat{a}|n\rangle$ are also eigenkets of that operator, with eigenvalues $\left(N_{n}+1\right)$, and $\left(N_{n}-1\right)$, respectively. This statement may be presented with the ladder diagram shown in Fig. 5.

Fig. 5.5. Hierarchy (the "ladder diagram") of eigenstates of a 1D harmonic oscillator. Arrows show the actions of the creation and annihilation operators on the eigenstates.

Operator $\hat{a}^{\dagger}$ moves the system a step up the ladder, while operator $\hat{a}$ brings it one step down. In other words, the former operator creates a new excitation of the system, ${ }^{31}$ while the latter operator kills ("annihilates") such excitation. This is why $\hat{a}^{\dagger}$ is called the creation operator, and $\hat{a}$, the annihilation operator. In its turn, according to Eq. (107), operator $\hat{N}$ does not change the state of the system, but "counts" its position on the ladder:

$$
\begin{equation*}
\langle n| \hat{N}|n\rangle=\langle n| N_{n}|n\rangle=N_{n} . \tag{5.113}
\end{equation*}
$$

[^617]This is why $\hat{N}$ is called the number operator, in our current context meaning the number of the elementary excitations of the oscillator.

This calculation still needs a completion. Indeed, we still do not know whether the ladder shown in Fig. 5 shows all eigenstates of the oscillator, and what exactly the numbers $N_{n}$ are. Fascinating enough, both questions may be answered by exploring a single paradox. Let us start with some state (step of the ladder), and keep going down it, applying operator $\hat{a}$ again and again. Each time, eigenvalue $N_{n}$ is decreased by one, so that eventually it should become negative. However, this cannot happen, because any real eigenstate, including the states presented by kets $|d\rangle \equiv \hat{a}|n\rangle$ and $|n\rangle$, should have a positive norm - see Eq. (4.16). Comparing the norms,

$$
\begin{equation*}
\|n\|^{2}=\langle n \mid n\rangle, \quad\|d\|^{2}=\langle n| \hat{a}^{\dagger} a|n\rangle=\langle n| \hat{N}|n\rangle=N_{n}\langle n \mid n\rangle, \tag{5.114}
\end{equation*}
$$

we see that the both of them cannot be positive simultaneously if $N_{n}$ is negative.
The way toward the resolution of this paradox is to notice that the action of the creation and annihilation operators on the stationary states may consist in not only their promotion to the next step of the ladder diagram, but also by their multiplication by some $c$-numbers:

$$
\begin{equation*}
\hat{a}|n\rangle=A_{n}|n-1\rangle, \quad \hat{a}^{\dagger}|n\rangle=A_{n}^{\prime}|n+1\rangle . \tag{5.115}
\end{equation*}
$$

(Linear relations (111) and (112) clearly allow that.) Let us calculate coefficients $A_{n}$ assuming, for convenience, that all eigenstates, including states $n$ and ( $n-1$ ), are normalized:

$$
\begin{equation*}
\langle n \mid n\rangle=1, \quad\langle n-1 \mid n-1\rangle=\langle n| \frac{\hat{a}^{\dagger}}{A_{n}^{*}} \frac{\hat{a}}{A_{n}}|n\rangle=\frac{1}{A_{n}^{*} A_{n}}\langle n| \hat{N}|n\rangle=\frac{N_{n}}{A_{n}^{*} A_{n}}\langle n \mid n\rangle=1 . \tag{5.116}
\end{equation*}
$$

From here, we get $\left|A_{n}\right|=\left(N_{n}\right)^{1 / 2}$, i.e.

$$
\begin{equation*}
\hat{a}|n\rangle=N_{n}^{1 / 2} e^{i \varphi_{n}}|n-1\rangle, \tag{5.117}
\end{equation*}
$$

where $\varphi_{n}$ is an arbitrary real phase. Now let us consider what happens if all numbers $N_{n}$ are integers. (Because of the definition of $N_{n}$, given by Eq. (107), it is convenient to call these integers $n$, i.e. by the same letter as the corresponding eigenstate.) Then when we have come down to state with $n=0$, an attempt to make one more step down gives

$$
\begin{equation*}
\hat{a}|0\rangle=0|-1\rangle . \tag{5.118}
\end{equation*}
$$

But in accordance with Eq. (4.9), the state in the right-hand part of this equation is the "null-state", i.e. does not exist. ${ }^{32}$ This gives the (only known :-) resolution of the state ladder paradox: the ladder has the lowest step with $N_{n}=n=0$.

As a by-product of our discussion, we have obtained a very important relation $N_{n}=n$, which means, in particular, that the state ladder includes all eigenstates of the oscillator. Plugging this relation into Eq. (108), we see that the full spectrum of eigenenergies of the harmonic oscillator is described by the simple formula

[^618]\[

$$
\begin{equation*}
E_{n}=\hbar \omega_{0}\left(n+\frac{1}{2}\right), \quad n=0,1,2 \ldots \tag{5.119}
\end{equation*}
$$

\]

which was already discussed in Sec. 2.10. It is rather remarkable that the bra-ket formalism has allowed us to derive it without calculation of the corresponding (rather cumbersome) wavefunctions $\psi_{n}(x)$ - see Eqs. (2.279).

Moreover, the formalism may be also used to calculate virtually any bra-ket pertaining to the oscillator, without using $\psi_{n}(x)$. In order to illustrate that, let us first calculate $A_{n}{ }_{n}$ participating in the latter of relations (115). This can be done absolutely similarly to the above calculation of $A_{n}$; otherwise, since we already know that $\left|A_{n}\right|=\left(N_{n}\right)^{1 / 2}=n^{1 / 2}$, we may notice that according to Eqs. (106) and (115), the eigenproblem (107), that in our new notation for $N_{n}$ becomes

$$
\begin{equation*}
\hat{N}|n\rangle=n|n\rangle \tag{5.120}
\end{equation*}
$$

may be rewritten as

$$
\begin{equation*}
n|n\rangle=\hat{a}^{\dagger} \hat{a}|n\rangle=\hat{a}^{\dagger} A_{n}|n-1\rangle=A_{n} A_{n-1}^{\prime}|n\rangle . \tag{5.121}
\end{equation*}
$$

Comparing the first and the last form of this equality, we see that $\left|A_{n-1}^{\prime}\right|=n /\left|A_{n}\right|=n^{1 / 2}$, i.e. $A^{\prime}{ }_{n}=(n+$ $1)^{1 / 2} \exp \left(i \varphi_{n}{ }^{\prime}\right)$. Taking all phases $\varphi_{n}$ and $\varphi_{n}{ }^{\prime}$ equal to zero for simplicity, we may reduce Eqs. (115) to their final, standard form ${ }^{33}$

$$
\begin{equation*}
\hat{a}^{\dagger}|n\rangle=(n+1)^{1 / 2}|n+1\rangle, \quad \hat{a}|n\rangle=n^{1 / 2}|n-1\rangle . \tag{5.122}
\end{equation*}
$$

Now we can use these formulas to calculate, for example, the matrix elements of operator $\hat{x}$ in the Fock state basis:

$$
\begin{equation*}
\left\langle n^{\prime}\right| \hat{x}|n\rangle=x_{0}\left\langle n^{\prime}\right| \hat{\xi}|n\rangle=\frac{x_{0}}{\sqrt{2}}\left\langle n^{\prime}\right|\left(\hat{a}+\hat{a}^{\dagger}\right)|n\rangle=\frac{x_{0}}{\sqrt{2}}\left(\left\langle n^{\prime}\right| \hat{a}|n\rangle+\left\langle n^{\prime}\right| \hat{a}^{\dagger}|n\rangle\right) . \tag{5.123}
\end{equation*}
$$

To complete the calculation, we may now use Eqs. (122) and the Fock state orthonormality:

$$
\begin{equation*}
\left\langle n^{\prime} \mid n\right\rangle=\delta_{n^{\prime} n} . \tag{5.124}
\end{equation*}
$$

The result is

$$
\begin{equation*}
\left\langle n^{\prime}\right| \hat{x}|n\rangle=\frac{x_{0}}{\sqrt{2}}\left(n^{1 / 2} \delta_{n^{\prime}, n-1}+(n+1)^{1 / 2} \delta_{n^{\prime}, n+1}\right)=\left(\frac{\hbar}{2 m \omega_{0}}\right)^{1 / 2}\left(n^{1 / 2} \delta_{n^{\prime}, n-1}+(n+1)^{1 / 2} \delta_{n^{\prime}, n+1}\right) \tag{5.125}
\end{equation*}
$$

Acting absolutely similarly, for the momentum bra-kets we get a similar expression:

$$
\begin{equation*}
\left\langle n^{\prime}\right| \hat{p}|n\rangle=i\left(\frac{\hbar m \omega_{0}}{2}\right)^{1 / 2}\left(-n^{1 / 2} \delta_{n^{\prime}, n-1}+(n+1)^{1 / 2} \delta_{n^{\prime}, n+1}\right) \tag{5.126}
\end{equation*}
$$

Hence the matrices of both operators in the Fock-state basis have only two diagonals, adjacent to the main diagonal; all other elements (including the diagonal ones) are zeros.

[^619]Matrix elements of higher powers of these operators, as well as their products, may be handled similarly, though the higher is the power, the bulkier is the result. For example, ${ }^{34}$

$$
\begin{align*}
\left\langle n^{\prime}\right| \hat{x}^{2}|n\rangle & =\left\langle n^{\prime}\right| \hat{x} \hat{x}|n\rangle=\sum_{n^{\prime \prime}=0}^{\infty}\left\langle n^{\prime}\right| \hat{x}\left|n^{\prime \prime}\right\rangle\left\langle n^{\prime \prime}\right| \hat{x}|n\rangle \\
& =\frac{x_{0}^{2}}{2} \sum_{n^{\prime \prime}=0}^{\infty}\left(\left(n^{\prime \prime}\right)^{1 / 2} \delta_{n^{\prime}, n^{\prime \prime}-1}+\left(n^{\prime \prime}+1\right)^{1 / 2} \delta_{n^{\prime}, n^{\prime \prime}+1}\right)\left(n^{1 / 2} \delta_{n^{\prime \prime}, n-1}+(n+1)^{1 / 2} \delta_{n^{\prime \prime}, n+1}\right)  \tag{5.127}\\
& =\frac{x_{0}^{2}}{2}\left\{[n(n-1)]^{1 / 2} \delta_{n^{\prime}, n-2}+[(n+1)(n+2)]^{1 / 2} \delta_{n^{\prime}, n+2}+(2 n+1) \delta_{n^{\prime}, n}\right\} .
\end{align*}
$$

For applications, the most important of these matrix elements are those on its main diagonal:

$$
\begin{equation*}
\left\langle x^{2}\right\rangle=\langle n| \hat{x}^{2}|n\rangle=\frac{x_{0}^{2}}{2}(2 n+1) \tag{5.128}
\end{equation*}
$$

This expression shows, in particular, that the expectation value of oscillator's potential energy in $n$-th Fock state is

$$
\begin{equation*}
\langle U\rangle=\frac{m \omega_{0}^{2}}{2}\left\langle x^{2}\right\rangle=\frac{\hbar \omega_{0}}{2}\left(n+\frac{1}{2}\right) . \tag{5.129}
\end{equation*}
$$

This is exactly $1 / 2$ of the total energy (119) of the oscillator. As a sanity check, an absolutely similar calculation of the kinetic energy shows that

$$
\begin{equation*}
\left\langle\frac{p^{2}}{2 m}\right\rangle=\frac{1}{2 m}\langle n| \hat{p}^{2}|n\rangle=\frac{\hbar \omega_{0}}{2}\left(n+\frac{1}{2}\right), \tag{5.130}
\end{equation*}
$$

i.e. both partial energies equal $E_{n} / 2$, just as in a classical oscillator. ${ }^{35}$

### 5.5. The Glauber and squeezed states

There is evidently a huge difference between a quantum stationary (Fock) state of the oscillator and its classical state. Indeed, let us write the classical Hamilton equations of motion of the oscillator (using capital letters to distinguish the classical variables from arguments of quantum wavefunctions):

$$
\begin{equation*}
\dot{X}=\frac{P}{m}, \quad \dot{P}=-\frac{\partial U}{\partial x}=-m \omega_{0}^{2} X \tag{5.131}
\end{equation*}
$$

On the "phase plane" with Cartesian coordinates $x$ and $p$ (Fig. 6), these equations describe clockwise rotation of the representation point $\{X(t), P(t)\}$ along an elliptic trajectory starting from the initial point $\{X(0), P(0)\}$. (The normalization of momentum by $m \omega_{0}$, similar to the one performed by the second of Eqs. (96), makes the trajectory pleasingly circular, with a constant radius equal to oscillation's amplitude $A$, reflecting the constant full energy

[^620]\[

$$
\begin{equation*}
E_{c}=\frac{m \omega_{0}^{2}}{2} A^{2}, \quad A^{2}=[X(t)]^{2}+\left[\frac{P(t)}{m \omega_{0}}\right]^{2}=\mathrm{const}=[X(0)]^{2}+\left[\frac{P(0)}{m \omega_{0}}\right]^{2}, \tag{5.132}
\end{equation*}
$$

\]

determined by the initial conditions.)
For the forthcoming comparison with quantum states, it is convenient to describe this classical solution by the following dimensionless complex variable

$$
\begin{equation*}
\alpha(t) \equiv \frac{1}{\sqrt{2} x_{0}}\left(X(t)+i \frac{P(t)}{m \omega_{0}}\right), \tag{5.133}
\end{equation*}
$$

which is essentially the standard complex-number representation of system's position on the 2D phase plane, with $|\alpha| \equiv A / \sqrt{ } 2 x_{0}$. With this definition, Eqs. (131) are conveniently merged into one equation,

$$
\begin{equation*}
\dot{\alpha}=-i \omega_{0} \alpha, \tag{5.134}
\end{equation*}
$$

with an evident, very simple solution

$$
\begin{equation*}
\alpha(t)=\alpha(0) e^{-i \omega_{0} t} \tag{5.135}
\end{equation*}
$$

where the constant $\alpha(0)$ may be complex, and is just the (normalized) classical complex amplitude of oscillations. ${ }^{36}$ This equation describes sinusoidal oscillations of both $X(t) \propto \operatorname{Re}[\alpha(t)]$ and $P \propto \operatorname{Im}[\alpha(t)]$, with a phase shift of $\pi / 2$ between them.

Fig. 5.6. Schematic representation of various states of a harmonic oscillator on the phase plane. The bold black point represents a classical state, with the dashed line showing its trajectory. (Very imperfect) classical images of the Fock states with $n=0,1$, and 2 are shown in blue, while the blurred red spot is the (equally schematic) Glauber state's image. Finally, the magenta elliptical spot is a classical image of a squeezed ground state. Arrows show the direction of states' evolution in time.

On the other hand, according to the basic Eqs. (4.157)-(4.158), the time dependence of a Fock state, as of a stationary state of the oscillator, is limited to the phase factor $\exp \left\{-i E_{n} t / \hbar\right\}$ not in observables, but rather in the wavefunction, and a result, gives time-independent expectation values of $x$, $p$, or of any function thereof. (Moreover, as Eqs. (125) and (126) show, $\langle x\rangle=\langle p\rangle=0$.) Taking into

[^621]account Eqs. (129) and (130), the closest (though very imperfect) geometric image ${ }^{37}$ for such a state on the phase plane is a blurred circle of radius $A_{n}=x_{0}(2 n+1)^{1 / 2}$, along which the wavefunction is uniformly spread as a wave - see the blue rings in Fig. 6. For the ground state $(n=0)$, with wavefunction (2.269), a better image is a blurred round spot, of radius $\sim x_{0}$, at the origin.

However, the Fock states $n$ are not the only possible quantum states of the oscillator: according to the basic Eq. (4.6), a state described by ket-vector

$$
\begin{equation*}
|\alpha\rangle=\sum_{n=0}^{\infty} \alpha_{n}|n\rangle \tag{5.136}
\end{equation*}
$$

with any set of (complex) $c$-numbers $\alpha_{n}$, is also its legitimate state, subject only to the normalization condition $\langle\alpha \mid \alpha\rangle=1$, giving

$$
\begin{equation*}
\sum_{n=0}^{\infty}\left|\alpha_{n}\right|^{2}=1 \tag{5.137}
\end{equation*}
$$

It is natural to ask: can we select coefficients $\alpha_{n}$ in such a special way that the state properties would be closer to the classical ones; in particular the expectation values $\langle x\rangle$ and $\langle p\rangle$ of coordinate and momentum would evolve in time just as the classical values $X(t)$ and $P(t)$, while the uncertainties of these observables would be time-independent and the same as in the ground state:

$$
\begin{equation*}
\delta x=\frac{x_{0}}{\sqrt{2}}=\left(\frac{\hbar}{2 m \omega_{0}}\right)^{1 / 2}, \quad \delta p=\frac{m \omega_{0} x_{0}}{\sqrt{2}}=\left(\frac{\hbar m \omega_{0}}{2}\right)^{1 / 2} \tag{5.138}
\end{equation*}
$$

with the smallest possible value of the uncertainty product, $\delta x \delta p=\hbar / 2 .{ }^{38}$ Let me show that such a Glauber state, ${ }^{39}$ which is schematically represented in Fig. 6 by a blurred red spot around the classical point $\{X(t), P(t)\}$, is indeed possible.

Conceptually the simplest way to find the corresponding coefficients $\alpha_{n}$ would be to calculate $\langle x\rangle,\langle p\rangle, \delta x$ and $\delta p$ for an arbitrary set of $\alpha_{n}$, and then try to optimize these coefficients to reach our goal. However, this problem may be solved much easier using wave mechanics. Indeed, let us consider the following wavefunction

$$
\begin{equation*}
\Psi_{\alpha}(x, t)=C_{0} \exp \left\{-\frac{m \omega_{0}}{2 \hbar}[x-X(t)]^{2}+i \frac{P(t) x}{\hbar}\right\} \tag{5.139}
\end{equation*}
$$

Its comparison with Eqs. (2.16) and (2.269) shows that this is just a Gaussian wave packet with the average momentum $P$ and the coordinate width $\delta x$ given by Eq. (138), but shifted along axis $x$ by $X$.

[^622]Hence, this wavefunction satisfies all the above requirements, and a straightforward (though a bit bulky) differentiation over $x$ and $t$ shows it also satisfies oscillator's Schrödinger equation, provided that that functions $X(t)$ and $P(t)$ satisfy classical Eqs. (131).

This fact is true even for a more general situation when the oscillator, initially in its ground state ${ }^{40}$ comes under effect of a classical force $F(t)$. (Evidently, for its description its is sufficient to add this function to the right-hand part of the second of Eqs. (131).) Moreover, the electromagnetic radiation formed in "good" (single-mode) lasers is also in the Glauber state. (As will be discussed in Chapter 9, the experimental formation of Fock states $n$, with the only exception of $n=0$, i.e. the ground state, is much harder.) This is why the Glauber states are so important.

Though Eq. (139) gives the full wave-mechanics description of a Glauber state, there is a substantial place for the bra-ket formalism here too. For example, in order to calculate the corresponding coefficients in expansion (136),

$$
\begin{equation*}
\alpha_{n}=\langle n \mid \alpha\rangle=\int d x\langle n \mid x\rangle\langle x \mid \alpha\rangle=\int \psi_{n}^{*}(x) \psi_{\alpha}(x) d x \tag{5.140}
\end{equation*}
$$

we would need to use not only the simple Eq. (139), but also the Fock state wavefunctions $\psi_{n}(x)$, which are not very appealing - see Eq. (2.279). Instead, this calculation may be readily done in the bra-ket formalism, giving us one important byproduct result.

Let us start from expressing the double shift of the ground state (by $X$ and $P$ ), that has led us to Eq. (139), in the operator language. Forgetting about the $P$ for a minute, let us find a translation operator $\hat{\tau}_{X}$ that produces the desirable shift of coordinate by $X$ of an arbitrary wavefunction $\psi(x)$ - say represented as the standard wave packet (59). Evidently, the result of its action, in the coordinate representation, is

$$
\begin{equation*}
\hat{\tau}_{X} \psi(x)=\psi(x-X)=\frac{1}{(2 \pi \hbar)^{1 / 2}} \int \varphi(p) \exp \left\{i \frac{p(x-X)}{\hbar}\right\} d p \tag{5.141}
\end{equation*}
$$

Hence, the shift may be achieved by the multiplication of each Fourier component of the packet, with momentum $p$, by $\exp \{-i p X / \hbar\}$. This gives us a hint that the general form of the translation operator, valid in any representation, should be

$$
\begin{equation*}
\hat{\tau}_{X}=\exp \left\{-i \frac{\hat{p} X}{\hbar}\right\} \tag{5.142}
\end{equation*}
$$

The proof of this formula is provided by the fact that any operator is uniquely determined by the set of its matrix elements in any full and orthogonal basis, in particular the basis of momentum states $p$. According to Eq. (141), the analog of Eq. (23) for the $p$-representation, applied to the translation operator (which is evidently local), is

$$
\begin{equation*}
\langle p| \hat{\boldsymbol{T}}_{X}\left|p^{\prime}\right\rangle \varphi\left(p^{\prime}\right)=\delta\left(p-p^{\prime}\right) \exp \left\{-i \frac{p X}{\hbar}\right\} \varphi(p) \tag{5.143}
\end{equation*}
$$

so that operator (142) does exactly the job we need it to.

[^623]The operator that provides the shift of momentum by $P$ is absolutely similar - with the opposite sign under the exponent, due to the opposite sign of the exponent in the reciprocal Fourier transform, so that the simultaneous shift by both $X$ and $P$ may be achieved by the following translation operator:
$\alpha$-translation operator

$$
\begin{equation*}
\hat{\tau}_{\alpha}=\exp \left\{i \frac{P \hat{x}-\hat{p} X}{\hbar}\right\} \tag{5.144}
\end{equation*}
$$

As we already know, for a harmonic oscillator the creation-annihilation operators are more natural, so that we may use Eqs. (96) and (99) to recast Eq. (144) as

$$
\begin{equation*}
\hat{\tau}_{\alpha}=\exp \left\{\alpha \hat{a}^{\dagger}-\alpha^{*} \hat{a}\right\}, \text { with } \hat{\tau}_{\alpha}^{\dagger}=\exp \left\{\alpha^{*} \hat{a}-\alpha \hat{a}^{\dagger}\right\} \tag{5.145}
\end{equation*}
$$

where the $c$-number $\alpha$ (generally, a function of time) is defined by Eq. (133). Now, according to Eq.

Glauber state as ground state's translation (139), we may form the Glauber state's ket-vector just as

$$
\begin{equation*}
|\alpha\rangle=\hat{\tau}_{\alpha}|0\rangle \tag{5.146}
\end{equation*}
$$

This formula looks nice and simple, but making practical calculations (say, calculating expectation values of variables) with the translation operator (144) is not too easy because of its exponent-of-operators form. Fortunately, it turns out that a much simpler representation for the Glauber state is possible. To show than, let us start with the following general (and very useful) property of exponential functions of operators: if

$$
\begin{equation*}
[\hat{A}, \hat{B}]=\mu \hat{I} \tag{5.147}
\end{equation*}
$$

(where $\hat{A}$ and $\hat{B}$ are arbitrary operators, and $\mu$ is a $c$-number), then ${ }^{41}$

$$
\begin{equation*}
\exp \{+\hat{A}\} \hat{B} \exp \{-\hat{A}\}=\hat{B}+\mu \hat{I} \tag{5.148}
\end{equation*}
$$

Let us apply Eqs. (147)-(148) to two cases, both with

$$
\begin{equation*}
\hat{A}=\alpha^{*} \hat{a}-\alpha \hat{a}^{\dagger}, \quad \text { so that } \exp \{+\hat{A}\}=\hat{\tau}_{\alpha}^{\dagger}, \quad \exp \{-\hat{A}\}=\hat{\tau}_{\alpha} . \tag{5.149}
\end{equation*}
$$

First, let us take $\hat{B}=\hat{I}$, then Eq. (147) is valid with $\mu=0$, and Eq. (148) yields

$$
\begin{equation*}
\hat{\tau}_{\alpha}^{\dagger} \hat{\tau}_{\alpha}=\hat{I} \tag{5.150}
\end{equation*}
$$

This equality means that the translation operator is unitary - not a big surprise, because if we shift a classical point on the complex phase plane by $(+\alpha)$ and then by $(-\alpha)$, we certainly must come back to the initial position. Relation (150) means merely that this fact is also true for any quantum state as well.

Second, let us take $\hat{B}=\hat{a}$; in order to verify Eq. (147) and find the corresponding $\mu$, let us calculate the commutator. Using, at the due stage of calculation, Eq. (104), we get

$$
\begin{equation*}
[\hat{A}, \hat{B}]=\left[\alpha^{*} \hat{a}-\alpha \hat{a}^{\dagger}, \hat{a}\right]=-\alpha\left[\hat{a}^{\dagger}, \hat{a}\right]=\alpha \hat{I} \tag{5.151}
\end{equation*}
$$

[^624]so that in this case $\mu=\alpha$, and Eq. (148) yields
\[

$$
\begin{equation*}
\hat{\tau}_{\alpha}^{\dagger} \hat{a} \hat{\gamma}_{\alpha}=\hat{a}+\alpha \hat{I} \tag{5.152}
\end{equation*}
$$

\]

We have approached the summit of this beautiful calculation. Let us consider operator

$$
\begin{equation*}
\hat{\tau}_{\alpha} \hat{\sigma}_{\alpha}^{\dagger} \hat{a} \hat{\tau}_{\alpha} . \tag{5.153}
\end{equation*}
$$

Using Eq. (150), we may reduce this expression to $\hat{a} \hat{\gamma}_{\alpha}$, while the application of Eq. (151) to the same expression yields $\hat{\gamma}_{\alpha} \hat{a}+\alpha \hat{\gamma}_{\alpha}$. Hence, we get the following operator equality

$$
\begin{equation*}
\hat{a} \hat{\tau}_{\alpha}=\hat{\tau}_{\alpha} \hat{a}+\alpha \hat{\tau}_{\alpha}, \tag{5.154}
\end{equation*}
$$

which may be applied to any state. Now acting by these two operators on the ground state $|0\rangle$ and using the facts that $\hat{a}|0\rangle$ is the null-state, while $\hat{T}_{\alpha}|0\rangle \equiv|\alpha\rangle$, we finally get a very simple and elegant result: ${ }^{42}$

$$
\begin{equation*}
\hat{a}|\alpha\rangle=\alpha|\alpha\rangle \tag{5.155}
\end{equation*}
$$

Thus any Glauber state is just one of eigenstates of the annihilation operator, namely the one with the eigenvalue equal to parameter $\alpha$, i.e. to the complex representation (133) of the classical state which is the center of the Glauber state's distribution. ${ }^{43}$ This fact makes the calculations of the Glauber state properties much simpler. As the simplest example, let us use Eq. (155) to find $\langle x\rangle$ in the Glauber state:

$$
\begin{equation*}
\langle x\rangle=\langle\alpha| \hat{x}|\alpha\rangle=\frac{x_{0}}{\sqrt{2}}\langle\alpha|\left(\hat{a}+\hat{a}^{\dagger}\right)|\alpha\rangle=\frac{x_{0}}{\sqrt{2}}\left(\langle\alpha| \hat{a}|\alpha\rangle+\langle\alpha| \hat{a}^{\dagger}|\alpha\rangle\right) . \tag{5.156}
\end{equation*}
$$

In the first term in the parentheses, we can apply Eq. (155) directly, while in the second term, we can use the bra-counterpart of that relation, $\langle\alpha| \hat{a}^{\dagger}=\langle\alpha| \alpha^{*}$. Now assuming that the Glauber state is normalized, $\langle\alpha \mid \alpha\rangle=1$, and using Eq. (133), we get

$$
\begin{equation*}
\langle x\rangle=\frac{x_{0}}{\sqrt{2}}\left(\langle\alpha| \alpha|\alpha\rangle+\langle\alpha| \alpha^{*}|\alpha\rangle\right)=\frac{x_{0}}{\sqrt{2}}\left(\alpha+\alpha^{*}\right)=X, \tag{5.157}
\end{equation*}
$$

Acting absolutely similarly, we may readily extend this sanity check to verify that $\langle p\rangle=P$, and that $\delta x$ and $\delta p$ indeed obey Eq. (138).

As a more thorough sanity check, let us use Eq. (155) to re-calculate Glauber state's wavefunction (139). Inner-multiplying both sides of that relation by bra-vector $\langle x|$, and using definition (98a) of the annihilation operator, we get

[^625]\[

$$
\begin{equation*}
\frac{1}{\sqrt{2} x_{0}}\left\langle\left. x\left(\hat{x}+i \frac{\hat{p}}{m \omega_{0}}\right) \right\rvert\, \alpha\right\rangle=\alpha\langle x \mid \alpha\rangle . \tag{5.158}
\end{equation*}
$$

\]

Since $\langle x|$ is the bra-vector of the eigenstate of the Hermitian operator $\hat{x}$, they may be swapped, with the operator giving its eigenvalue $x$; acting on that bra-vector by the (local!) operator of momentum, we have to use it in the coordinate representation (63). As a result, we get

$$
\begin{equation*}
\frac{1}{\sqrt{2} x_{0}}\left(x\langle x \mid \alpha\rangle+\frac{\hbar}{m \omega_{0}} \frac{\partial}{\partial x}\langle x \mid \alpha\rangle\right)=\alpha\langle x \mid \alpha\rangle . \tag{5.159}
\end{equation*}
$$

But $\langle x \mid \alpha\rangle$ is nothing else than the Glauber state's wavefunction $\Psi_{\alpha}$, so that Eq. (153) gives for it a firstorder differential equation

$$
\begin{equation*}
\frac{1}{\sqrt{2} x_{0}}\left(x \Psi_{\alpha}+\frac{\hbar}{m \omega_{0}} \frac{\partial}{\partial x} \Psi_{\alpha}\right)=\alpha \Psi_{\alpha} \tag{5.160}
\end{equation*}
$$

Chasing $\Psi_{\alpha}$ and $x$ to the opposite sides of the equation, and using definition (133) of parameter $\alpha$, we may bring this equation to a form

$$
\begin{equation*}
\frac{\partial \Psi_{\alpha}}{\Psi_{\alpha}}=\frac{m \omega_{0}}{\hbar}\left[-x+\left(X+i \frac{P}{m \omega_{0}}\right)\right] \partial x . \tag{5.161}
\end{equation*}
$$

Integrating both parts, we return to Eq. (139) that had been derived by wave-mechanics means.
Now that we can use Eq. (155) for finding coefficients $\alpha_{n}$ in the expansion (136) of the Glauber state $\alpha$ in series over the Fock states $n$. Plugging Eq. (136) into each side of Eq. (155), using the first of Eq. (122) in the left-hand part, and requiring the coefficients at each ket-vector $|n\rangle$ in both parts to be equal, we get the following recurrence relation for the coefficients:

$$
\begin{equation*}
\alpha_{n+1}=\frac{\alpha}{(n+1)^{1 / 2}} \alpha_{n} \tag{5.162}
\end{equation*}
$$

Assuming some value of $\alpha_{0}$, and applying the relation sequentially for $n=1,2$, etc., we get

$$
\begin{equation*}
\alpha_{n}=\frac{\alpha^{n}}{(n!)^{1 / 2}} \alpha_{0} \tag{5.163}
\end{equation*}
$$

Now we can find $\alpha_{0}$ from the normalization requirement (137), getting

$$
\begin{equation*}
\left|\alpha_{0}\right|^{2} \sum_{n=0}^{\infty} \frac{|\alpha|^{2 n}}{n!}=1 \tag{5.164}
\end{equation*}
$$

In this sum, we may readily recognize the Taylor expansion of function $\exp \left\{|\alpha|^{2}\right\}$, so that the final result (besides an arbitrary common phase multiplier) is

Glauber
state as Fock states' superposition

$$
\begin{equation*}
|\alpha\rangle=\exp \left\{-\frac{|\alpha|^{2}}{2}\right\} \sum_{n=0}^{\infty} \frac{\alpha^{n}}{(n!)^{1 / 2}}|n\rangle . \tag{5.165}
\end{equation*}
$$

It means in particular that the probability $W_{n} \equiv \alpha_{n} \alpha_{n}{ }^{*}$ of finding the system energy on $n$-th energy level (119) obeys the well-known Poisson distribution (Fig. 7):

Fig. 5.7. The Poisson distribution for several values of $\langle n\rangle$. Note that $W_{n}$ are defined only for integer values of $n$; lines are only guides for the eye.

$$
\begin{equation*}
W_{n}=\frac{\langle n\rangle^{n}}{n!} e^{-\langle n\rangle} \tag{5.166}
\end{equation*}
$$

Poisson distribution
where in our particular case

$$
\begin{equation*}
\langle n\rangle=|\alpha|^{2} \tag{5.167}
\end{equation*}
$$

For applications, perhaps the most important mathematical property of this distribution is

$$
\begin{equation*}
\delta n=\langle n\rangle^{1 / 2} \tag{5.168}
\end{equation*}
$$

note also that at $\langle n\rangle \gg 1$, and hence $\delta n \ll\langle n\rangle$, the Poisson distribution approaches the Gaussian ("normal") one.

Now let us discuss the evolution of the Glauber state in time. In the Schrödinger language, it is completely described by dynamics (131) of the $c$-number shifts $X(t)$ and $P(t)$ participating in wavefunction (139). Note again that, in contrast to the spread of the wave packet of a free particle, discussed in Sec. 2.2, in the harmonic oscillator the Gaussian packet of special width (138) does not spread at all!

An alternative and equivalent way of dynamics description is to use the Heisenberg equation of motion. As Eqs. (42) and (48) tell us, such equations for Heisenberg operators of coordinate and momentum they have to be similar to the classical equation (131):

$$
\begin{equation*}
\dot{\hat{x}}_{\mathrm{H}}=\frac{\hat{p}_{\mathrm{H}}}{m}, \quad \dot{\hat{p}}_{\mathrm{H}}=-m \omega_{0}^{2} \hat{x}_{\mathrm{H}} . \tag{5.169}
\end{equation*}
$$

Now using Eqs. (98), for the Heisenberg-picture creation and annihilation operators we get equations

$$
\begin{equation*}
\dot{\hat{a}}_{\mathrm{H}}=-i \omega_{0} \hat{a}_{\mathrm{H}}, \quad \dot{\hat{a}}_{\mathrm{H}}^{\dagger}=+i \omega_{0} \hat{a}_{\mathrm{H}}^{\dagger}, \tag{5.170}
\end{equation*}
$$

that are completely similar for the classical equation (134) for the $c$-number parameter $\alpha$ and its complex conjugate, and hence have the solutions identical to Eq. (135):

$$
\begin{equation*}
\hat{a}_{\mathrm{H}}(t)=\hat{a}_{\mathrm{H}}(0) e^{-i \omega_{0} t}, \quad \hat{a}_{\mathrm{H}}^{\dagger}(t)=\hat{a}_{\mathrm{H}}^{\dagger}(0) e^{i \omega_{0} t} . \tag{5.171}
\end{equation*}
$$

As was discussed in Sec. 4.6, such equations are very convenient because they enable simple calculation of time evolution of observables for any initial state of the oscillator (Fock, Glauber, or any other) using Eq. (4.191). Applied to a Glauber state $\alpha(0)$, such calculation gives the same results as have already been derived earlier in this section, in particular confirms that the Gaussian wave packet of the special width (138) does not spread in time.

Now let us consider what happens if the initial wave packet is still Gaussian, but has a different width, say $\delta x<x_{0} / \sqrt{ } 2$. As we already know from Sec. 2.2, the momentum spread $\delta p$ will be correspondingly larger, still with the smallest uncertainty product: $\delta x \delta p=\hbar / 2$. Such squeezed ground state $\Sigma$, with zero expectation values of $x$ and $p$, may be generated from the Fock/Glauber ground state:

Squeezed ground state

$$
\begin{equation*}
|\nu\rangle=\hat{S}_{1}|0\rangle, \tag{5.172a}
\end{equation*}
$$

using the so-called squeezing operator,

Squeezing operator

$$
\begin{equation*}
\hat{S}_{\imath}=\exp \left\{\frac{1}{2}\left(s^{*} \hat{a} \hat{a}-s \hat{a}^{\dagger} \hat{a}^{\dagger}\right)\right\} \tag{5.172b}
\end{equation*}
$$

which depends on a complex $c$-number parameter $ュ=r e^{i \theta}$. Parameter's modulus $r$ determines the squeezing degree; it is straightforward to use Eq. (172) for checking that if $\lrcorner$ is real $(\theta=0, \xi=r)$, then

$$
\begin{equation*}
\delta x=\frac{x_{0}}{\sqrt{2}} e^{-r}=\left(\frac{\hbar}{2 m \omega_{0}}\right)^{1 / 2} e^{-r}, \quad \delta p=\frac{m \omega_{0} x_{0}}{\sqrt{2}} e^{r}=\left(\frac{\hbar m \omega_{0}}{2}\right)^{1 / 2} e^{r}, \quad \text { so that } \quad \delta x \delta p=\frac{\hbar}{2} . \tag{5.173}
\end{equation*}
$$

On the phase plane (Fig. 6), this state, with $r>0$, may be represented by an oval spot squeezed along axis $x$ (hence the state's name) and stretched along axis $p$; the same formulas but with $r<0$ describe the opposite squeezing. On the other hand, phase $\theta$ of the squeeze parameter $ュ$ determines the angle $\theta / 2$ of oval's turn about the phase plane origin - see the magenta ellipse in Fig. 6; if $\theta \neq 0$, Eqs. (173) are valid for variables $\left\{x^{\prime}, p^{\prime}\right\}$ obtained from $\{x, p\}$ via clockwise rotation by that angle. For any of such origin-centered squeezed states, time evolution is reduced to an increase of the angle with rate $\omega_{0}$, i.e. to the clockwise rotation of the ellipse, without its deformation, with angular velocity $\omega_{0}$ - see the magenta arrows in Fig. 6. As a result, uncertainties $\delta x$ and $\delta p$ oscillate in time with double frequency $2 \omega_{0}$, while their product is constant at its minimal possible value $\hbar / 2$.

Such squeezed ground states have important implications for quantum measurements (see Sec. 7.7 below) and may be formed, for example, by parametric excitation of the oscillator, ${ }^{44}$ with a parameter modulation depth close to, but still below the threshold of parametric oscillations excitation. Unfortunately, I do have time for a further discussion of this interesting topic, ${ }^{45}$ but still need to mention

[^626]a more general class of squeezed states, centered to an arbitrary point $\{X, P\}$ rather than the origin, that may be formed by an additional action of the displacement operator (144) on the squeezed ground state (172). Calculations similar to those that led us from Eq. (145) to Eq. (155), but now for the product operator $\hat{\gamma}_{\alpha} \hat{\mathcal{S}}_{s}$ rater than bare $\hat{\gamma}_{\alpha}$, show that such a general squeezed state is an eigenstate of the following mixed operator
\[

$$
\begin{equation*}
\hat{b} \equiv \hat{a} \cosh r+\hat{a}^{\dagger} e^{i \theta} \sinh r \tag{5.174a}
\end{equation*}
$$

\]

with eigenvalue

$$
\begin{equation*}
\beta=\alpha \cosh r+\alpha^{*} e^{i \theta} \sinh r \tag{5.174b}
\end{equation*}
$$

For the particular case $\alpha=0$, Eq. (174b) yields $\beta=0$, i.e. the action of operator (174a) on the squeezed ground state $=$ with the same $r$ and $\theta$ yields the null-state, thus generalizing Eq. (118), which is valid for the "usual" (non-squeezed) ground state.

### 5.6. Revisiting spherically-symmetric problems

One more blank spot to fill has been left in our study of wave mechanics of spherically-3D symmetric systems in Sec. 3.6. Indeed, while the eigenfunctions describing axially-symmetric 2D systems, and the azimuthal components of those in spherically-symmetric 3D systems, are very simple,

$$
\begin{equation*}
\psi_{m}=\frac{1}{(2 \pi)^{1 / 2}} e^{i m \varphi}, \quad m=0, \pm 1, \pm 2, \ldots \tag{5.175}
\end{equation*}
$$

the polar components of the eigenfunctions in the latter case (i.e., of spherical harmonics) include the associate Legendre functions $P_{l}^{m}(\cos \theta)$ that may be expressed via elementary functions only indirectly - see Eqs. (3.165) and (3.168). This makes all the calculations less than transparent and, in particular, does not allow a clear insight into the origin of the very simple eigenvalue spectrum - see, e.g., Eq. (3.163). The bra-ket formalism, applied to the angular momentum operator, allows one to get such insight, and also produces a very convenient tool for many calculations involving spherically-symmetric potentials.

Let us start from using the correspondence principle to spell out the quantum-mechanical operator of the orbital angular momentum $\mathbf{L} \equiv \mathbf{r} \times \mathbf{p}$ of a point particle:

$$
\hat{\mathbf{L}} \equiv \hat{\mathbf{r}} \times \hat{\mathbf{p}}=\left|\begin{array}{rrr}
\mathbf{n}_{x} & \mathbf{n}_{y} & \mathbf{n}_{z}  \tag{5.176}\\
\hat{x} & \hat{y} & \hat{z} \\
\hat{p}_{x} & \hat{p}_{y} & \hat{p}_{z}
\end{array}\right|, \quad \text { i.e. } \hat{L}_{x} \equiv \hat{y} \hat{p}_{z}-\hat{z} \hat{p}_{y}, \text { etc. }
$$

From this definition, we can readily calculate the commutation relations for all Cartesian components of operators $\hat{\mathbf{L}}, \hat{\mathbf{r}}$, and $\hat{\mathbf{p}}$; for example,

$$
\begin{equation*}
\left[\hat{L}_{x}, \hat{y}\right]=\left[\hat{y} \hat{p}_{z}-\hat{z} \hat{p}_{y}, \hat{y}\right]=-\hat{z}\left[\hat{p}_{y}, \hat{y}\right]=i \hbar \hat{z} \tag{5.177}
\end{equation*}
$$

etc. Using the sequential numbering of coordinate axes ( $x=r_{1}$, etc.), the summary of these calculations may be presented in similar, compact (and beautiful!) forms:
relations

$$
\begin{equation*}
\left[\hat{L}_{j}, \hat{r}_{j^{\prime}}\right]=i \hbar \hat{r}_{j^{\prime}} \varepsilon_{i j j^{\prime \prime}}, \quad\left[\hat{L}_{j}, \hat{p}_{j^{\prime}}\right]=i \hbar \hat{p}_{j^{\prime \prime}} \varepsilon_{i j j^{\prime \prime}}, \quad\left[\hat{L}_{j}, \hat{L}_{j^{\prime}}\right]=i \hbar \hat{L}_{j^{\prime \prime}} \varepsilon_{i j j^{\prime \prime}} \tag{5.178}
\end{equation*}
$$

where each of indices $j$ and $j$ ' and $j$ " may take any of values 1,2 , and $3, j$ " is the complementary index of the same set (not equal to either $j$ or $j$ '), and $\varepsilon_{j j} j^{\prime \prime}$ " is the Levi-Civita symbol (or "permutation symbol"). ${ }^{46}$ Also introducing in the natural way a (scalar!) operator of the observable $L^{2}=|\mathbf{L}|^{2}$,

$$
\begin{equation*}
\hat{L}^{2} \equiv \hat{L}_{x}^{2}+\hat{L}_{y}^{2}+\hat{L}_{z}^{2} \tag{5.179}
\end{equation*}
$$

it is straightforward to check that this operator commutes with each of the Cartesian components:

$$
\begin{equation*}
\left[\hat{L}^{2}, \hat{L}_{j}\right]=0 \tag{5.180}
\end{equation*}
$$

This result, at the first sight, may seem to contradict the last of Eqs. (178). Indeed, haven't we learned in Sec. 4.5 that commuting operators (e.g., $\hat{L}^{2}$ and any of $\hat{L}_{j}$ ) share their eigenstate sets? If yes, shouldn't that mean that this set has to be common for all 4 operators? ${ }^{47}$ The resolution in this paradox may be found in the condition that was mentioned just after Eq. (4.138), but (sorry!) not sufficiently emphasized there. According to that relation, if an operator has degenerate eigenstates (i.e. if $A_{j}=A_{j}$, even for $j \neq j^{\prime}$ ), they should not be necessarily shared by another compatible operator. This is exactly the situation with the orbital angular momentum operators, that may be schematically shown at a Venn diagram (Fig. 8):48 the set of eigenstates of operator $\hat{L}^{2}$ is highly degenerate, ${ }^{49}$ and is broader than those of the component operators $\hat{L}_{j}$ (that, as will be shown below, are non-degenerate until we consider particle's spin).

Fig. 5.8. Venn diagram showing (schematically) the partitioning of the set of eigenstates of operator $\hat{L}^{2}$. Each inner sector corresponds to the states shared with one of Cartesian component operators $\hat{L}_{j}$, while the outer (shaded) ring presents the eigenstates of $\hat{L}^{2}$ that are not shared with either of $\hat{L}_{j}$ - e.g., all linear combinations of eigenstates of different component operators.

[^627]Let us focus on just one of these 3 joint sets of eigenstates - by tradition, of operators $\hat{L}^{2}$ and $\hat{L}_{z}$. (This tradition is due to the canonical form of spherical coordinates, in which the polar angle is measured from axis $z$. Indeed, using Eqs. (63), in the coordinate representation we get the following expression,

$$
\begin{equation*}
\hat{L}_{z} \equiv \hat{x} p_{y}-\hat{y} p_{x}=x\left(-i \hbar \frac{\partial}{\partial y}\right)-y\left(-i \hbar \frac{\partial}{\partial x}\right)=-i \hbar \frac{\partial}{\partial \varphi} . \tag{5.181}
\end{equation*}
$$

Writing the standard eigenproblem for the operator in this representation, $\hat{L}_{z} \psi_{m}=L_{z} \psi_{m}$, we see that it is satisfied by eigenfunctions (175), with eigenvalues $L_{z}=\hbar m$ - at was already conjectured in Sec. 3.5.) More specifically, let us consider a set of eigenstates $\{l, m\}$ corresponding to a certain degenerate eigenvalue of operator $\hat{L}^{2}$ but all possible eigenvalues of operator $\hat{L}_{z}$, i.e. all possible quantum numbers $m$. (At this point, $l$ is just some parameter that determines the eigenvalue of $\hat{L}^{2}$; it will be defined more explicitly in a minute.) In order to analyze this set, it is instrumental to introduce the so-called ladder (also called, respectively, "raising" and "lowering") operators

$$
\begin{equation*}
\hat{L}_{ \pm} \equiv \hat{L}_{x} \pm i \hat{L}_{y} \tag{5.182}
\end{equation*}
$$

- note a substantial similarity between this definition and Eqs. (98). It is straightforward to use this definition and the last of Eqs. (178) to calculate the following commutators:

$$
\begin{equation*}
\left[\hat{L}_{+}, \hat{L}_{-}\right]=2 \hbar \hat{L}_{z}, \quad \text { and }\left[\hat{L}_{z}, \hat{L}_{ \pm}\right]= \pm \hbar \hat{L}_{ \pm}, \tag{5.183}
\end{equation*}
$$

and use Eq. (179) to prove another important relation:

$$
\begin{equation*}
\hat{L}^{2}=\hbar \hat{L}_{z}+\hat{L}_{z}^{2}+\hat{L}_{-} \hat{L}_{+} . \tag{5.184}
\end{equation*}
$$

Now let us rewrite the last of Eqs. (183) as

$$
\begin{equation*}
\hat{L}_{z} \hat{L}_{ \pm}=\hat{L}_{ \pm} \hat{L}_{z} \pm \hbar \hat{L}_{ \pm}, \tag{5.185}
\end{equation*}
$$

and act by its both parts on the ket-vector $|l, m\rangle$ of the set specified above:

$$
\begin{equation*}
\hat{L}_{z} \hat{L}_{ \pm}|l, m\rangle=\hat{L}_{ \pm} \hat{L}_{z}|l, m\rangle \pm \hbar \hat{L}_{ \pm}|l, m\rangle . \tag{5.186}
\end{equation*}
$$

Since eigenvalues of operator $\hat{L}_{z}$ are equal to $\hbar m$, in the first term of the right-hand part we may write

$$
\begin{equation*}
\hat{L}_{z}|l, m\rangle=\hbar m|l, m\rangle . \tag{5.187}
\end{equation*}
$$

With that, Eq. (186) may be recast as

$$
\begin{equation*}
\hat{L}_{z}\left(\hat{L}_{ \pm}|l, m\rangle\right)=\hbar(m \pm 1)\left(\hat{L}_{ \pm}|l, m\rangle\right) . \tag{5.188}
\end{equation*}
$$

In a spectacular similarity with Eqs. (111)-(112) for the harmonic oscillator, Eq. (188) means that states $\hat{L}_{ \pm}|l, m\rangle$ are also the eigenstates of operator $\hat{L}_{z}$, corresponding to eigenvalues ( $m \pm 1$ ). Thus the ladder operators act exactly as the creation and annihilation operators in the oscillator, moving the system up or down a ladder of eigenstates (Fig. 9). The most significant difference is that now the state
ladder must end in both directions, because an infinite increase of $|m|$, with whatever sign, would cause the expectation values of operator

$$
\begin{equation*}
\hat{L}_{x}^{2}+\hat{L}_{y}^{2}=\hat{L}^{2}-\hat{L}_{z}^{2}, \tag{5.189}
\end{equation*}
$$

which corresponds to a non-negative observable, to become negative. Hence there should be two states on both ends of the ladder, $\left|l, m_{\max }\right\rangle$ and $\left|l, m_{\min }\right\rangle$, for whom

$$
\begin{equation*}
\hat{L}_{+}\left|l, m_{\max }\right\rangle=0, \quad \hat{L}_{-}\left|l, m_{\min }\right\rangle=0 . \tag{5.190}
\end{equation*}
$$

Due to the symmetry of the whole problem with respect to the replacement $m \rightarrow-m$, we should have $m_{\min }=-m_{\max }$. This $m_{\max }$ is exactly the quantum number that is traditionally called $l$, so that

Fig. 5.9. Hierarchy (ladder diagram) of the common eigenstates of operators $\hat{L}^{2}$ and $\hat{L}_{z}$.

Evidently, this relation of quantum numbers $m$ and $l$ is compatible with the almost-classical image of various orientations of the angular momentum vector of the same length in various directions, with its $z$-component taking several $(2 l+1)$ possible values $\hbar m$. In this simple picture, however, $L^{2}$ would be equal to square of $\left(L_{z}\right)_{\max }$, i.e. to $(\hbar l)^{2}$; however, this is not so. Indeed, applying the operator equality (184) to the top state $\left|l, m_{\max }\right\rangle \equiv|l, l\rangle$, we get

$$
\begin{align*}
\hat{L}^{2}|l, l\rangle & =\hbar \hat{L}_{z}|l, l\rangle+\hat{L}_{z}^{2}|l, l\rangle+\hat{L}_{-} \hat{L}_{+}|l, l\rangle=\hbar^{2} l|l, l\rangle+\hbar^{2} l^{2}|l, l\rangle+0  \tag{5.192}\\
& =\hbar^{2} l(l+1)|l, l\rangle .
\end{align*}
$$

Since by our initial assumption, all eigenvectors $|l, m\rangle$ correspond to the same eigenvalue of operator $\hat{L}^{2}$, this result means that all these eigenvalues are equal to $\hbar^{2} l(l+1)$. Just as in case of the spin- $1 / 2$ vector operators, the deviation of this result from $\hbar^{2} l^{2}$ may be interpreted as the result of unavoidable uncertainties ("fluctuations") of the $x$ - and $y$-components of the angular momentum, that give a finite positive contribution to $L^{2}$ even if the angular momentum vector is aligned in the best possible way with the $z$-axis.

Now let us compare our results with those of Sec. 3.6. Using the expression of Cartesian coordinates via the spherical ones exactly as was done in Eq. (181), we get the following expressions for the ladder operators (182) in the coordinate representation:

$$
\begin{equation*}
\hat{L}_{ \pm}=\hbar e^{ \pm i \varphi}\left( \pm \frac{\partial}{\partial \theta}+i \cot \operatorname{an} \theta \frac{\partial}{\partial \varphi}\right) \tag{5.193}
\end{equation*}
$$

Now plugging this equation, together with Eq. (181), into Eq. (184), we get

$$
\begin{equation*}
\hat{L}^{2}=-\hbar^{2}\left[\frac{1}{\sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial}{\partial \theta}\right)+\frac{1}{\sin ^{2} \theta} \frac{\partial^{2}}{\partial \varphi^{2}}\right] . \tag{5.194}
\end{equation*}
$$

But this is exactly the operator (besides its division by constant parameter $2 m R^{2}$ ) that stands in the lefthand part of Eq. (3.156). Hence that equation, which was explored by the "brute-force" (wavemechanical) approach in Sec. 3.6, may be understood as the eigenproblem for operator $\hat{L}^{2}$ in the coordinate representation, with eigenfunctions $Y_{l}^{m}(\theta, \varphi)$ corresponding to eigenkets $\{l, m\}$, and eigenvalues $L^{2}=2 m R^{2} E$. As a reminder, the main result of that, rather involved analysis was expressed by Eq. (3.163), which now may be rewritten as

$$
\begin{equation*}
L_{l}^{2}=2 m R^{2} E_{l}=\hbar^{2} l(l+1), \tag{5.195}
\end{equation*}
$$

in a full agreement with what was obtained in this section by much more efficient means based on the bra-ket formalism. In particular, it is fascinating to see how easy are now many operations with eigenvectors $|l, m\rangle$, albeit wavefunctions of these states, spherical harmonics $Y_{l}^{m}(\theta, \varphi)$, have rather complex spatial behavior - please have one more look at Eq. (3.171) and Fig. 3.19. ${ }^{50}$

### 5.7. Spin and its addition to orbital angular momentum

Surprisingly, the theory described in the last section is useful for much more than orbital motion analysis. In particular, it helps to generalize the spin $-1 / 2$ results discussed in Chapter 4 to other values of spin $s$ - the parameter still has to be defined. For that, let us notice that the commutation relations that were derived, for $s=1 / 2$, from the Pauli matrix properties, may be rewritten in exactly the same form as Eqs. (178) and (180) for the orbital momentum:

$$
\begin{equation*}
\left[\hat{S}_{j}, \hat{S}_{j^{\prime}}\right]=i \hbar \hat{S}_{j^{\prime \prime}} \varepsilon_{j j^{\prime \prime \prime} j^{\prime \prime}}, \quad\left[\hat{S}^{2}, \hat{S}_{j}\right]=0 \tag{5.196}
\end{equation*}
$$

[^628]It has been postulated (and confirmed by numerous experiments) that these relations hold true for any quantum particle. Now note that all the calculations of the last section have been based almost exclusively on such relations - the exception will be discussed imminently. Hence, we may repeat them for spin operators, and get the relations similar to Eq. (187) and (192):

[^629]Spin operators: eigenstates eigenvalues

$$
\begin{equation*}
\hat{S}_{z}\left|s, m_{s}\right\rangle=\hbar m_{s}\left|s, m_{s}\right\rangle, \quad \hat{S}^{2}\left|s, m_{s}\right\rangle=\hbar^{2} s(s+1)\left|s, m_{s}\right\rangle, \quad 0 \leq s, \quad-s \leq m_{s} \leq+s \tag{5.197}
\end{equation*}
$$

where $m_{s}$ is a quantum number similar to the orbital number $m$, and the non-negative constant $s$ is defined as the maximum value of $\left|m_{s}\right|$. This parameter is exactly what is called particle's spin - in the narrow sense of the word.

Now let us return to the only part of our orbital moment calculations that has not been derived from the commutation relations. This was the fact, based on solution (175) of the orbital motion problems, that quantum numbers $m$ (the analog of $m_{s}$ ) are integer. For spin, we do not have such a solution, so that the spectrum of numbers $m_{s}$ (and hence its limits $\pm s$ ) should be found from the more loose requirement that the eigenstate ladder, extending from $-s$ to $+s$, has an integer number of steps. Hence, $2 s$ has to be integer, i.e. spin $s$ of a quantum particle may be either integer (as it is, for example, for photons and gluons), or half-integer (e.g., for all quarks and leptons including electrons). ${ }^{51}$

For $s=1 / 2$, this picture yields all spin properties of electron that were derived in Chapter 4 from postulate (4.117). In particular, operators $\hat{S}^{2}$ and $\hat{S}_{z}$ have only 2 common eigenstates, with $S_{z}=\hbar m_{s}=$ $\pm \hbar / 2$, and both with $S^{2}=s(s+1) \hbar^{2}=(3 / 4) \hbar^{2}$. Note that this analogy with the angular momentum sheds a new light on the symmetry properties of electrons. Indeed, the fact that $m$ in Eq. (175) is integer was derived in Sec. 3.5 from the requirement that making a full circle around axis $z$, we should find a similar value of wavefunction $\psi_{m}$, which differs from the initial one by an inconsequential factor $\exp \{2 \pi i m\}$. With the replacement $m \rightarrow m_{s}= \pm 1 / 2$, such operation would multiply the wavefunction by $\exp \{ \pm \pi i\}$, i.e. reverse its sign. On course, spin cannot be described by a usual wavefunction, but this odd parity of electrons (and all other spin- $1 / 2$ particles) is clearly revealed in multiparticle systems - see Chapter 8.

Now we are sufficiently equipped to analyze particles that have both the orbital momentum and the spin. In classical mechanics, such a particle would be characterized by the total angular momentum vector $\mathbf{J}=\mathbf{L}+\mathbf{S}$. Following the correspondence principle, we may make an assumption that quantummechanical properties of this observable may be analyzed using the similarly defined vector operator:

$$
\begin{equation*}
\hat{\mathbf{J}} \equiv \hat{\mathbf{L}}+\hat{\mathbf{S}}, \tag{5.198}
\end{equation*}
$$

with Cartesian components

$$
\begin{equation*}
\hat{J}_{z} \equiv \hat{L}_{z}+\hat{S}_{z} \tag{5.199}
\end{equation*}
$$

etc, and the magnitude squared equal to

$$
\begin{equation*}
\hat{J}^{2} \equiv \hat{J}_{x}^{2}+\hat{J}_{y}^{2}+\hat{J}_{z}^{2} \tag{5.200}
\end{equation*}
$$

Let us examine the properties of this vector operator. Since its two components describe different degrees of freedom of the particle (again, you may say "belong to different Hilbert spaces"), they may be considered as completely commuting:

$$
\begin{equation*}
\left[\hat{L}_{j}, \hat{S}_{j^{\prime}}\right]=0, \quad\left[\hat{L}^{2}, \hat{S}^{2}\right]=0 \tag{5.201}
\end{equation*}
$$

[^630]These above equalities are sufficient to derive the commutation rules of the total angular momentum, and, not surprisingly, they turn out to be absolutely similar to those of its components:

$$
\begin{equation*}
\left[\hat{J}_{j}, \hat{J}_{j^{\prime}}\right]=i \hbar \hat{J}_{j^{\prime \prime}} \varepsilon_{i j j^{\prime \prime}}, \quad\left[\hat{J}^{2}, \hat{J}_{j}\right]=0 \tag{5.202}
\end{equation*}
$$

Now repeating all arguments of the last section, we may derive the following expressions for the common eigenstates of operators $\hat{J}^{2}$ and $\hat{J}_{z}$ :

$$
\begin{equation*}
J_{z}\left|j, m_{j}\right\rangle=\hbar m_{j}\left|j, m_{j}\right\rangle, \quad \hat{J}^{2}\left|j, m_{j}\right\rangle=\hbar^{2} j(j+1)\left|j, m_{j}\right\rangle, \quad 0 \leq j, \quad-j \leq m_{j} \leq+j \tag{5.203}
\end{equation*}
$$

Total momentum: eigenstates, and eigenvalues
where $j$ and $m_{j}$ are new quantum numbers. Repeating the arguments made for $m_{s}$, we may conclude that $j$ and $m_{j}$ may be either integer or half-integer.

Before we proceed, one remark on notation: it is very convenient to use the same letter $m$ for numbering eigenstates of all momentum components participating in Eq. (199), with corresponding indices $(j, l$, and $s)$, in particular, to replace what we called $m$ with $m_{l}$. With this replacement, the main results of the last section may be summarized in the form similar to Eqs. (197) and (203):

$$
\begin{equation*}
\hat{L}_{z}\left|l, m_{l}\right\rangle=\hbar m_{l}\left|l, m_{l}\right\rangle, \quad \hat{L}^{2}\left|l, m_{l}\right\rangle=\hbar^{2} l(l+1)\left|l, m_{l}\right\rangle, \quad 0 \leq l, \quad-l \leq m_{l} \leq+l . \tag{5.204}
\end{equation*}
$$

In order to understand which eigenstates used is Eqs. (197), (203), and (204) are compatible with each other, let us use Eqs. (198)-(202) to calculate the mutual commutators of the operators squared and their $z$-components. The result is

$$
\begin{array}{ll}
{\left[\hat{J}^{2}, \hat{L}^{2}\right]=0,} & {\left[\hat{J}^{2}, \hat{S}^{2}\right]=0} \\
{\left[\hat{J}^{2}, \hat{L}_{z}\right] \neq 0,} & {\left[\hat{J}^{2}, \hat{S}_{z}\right] \neq 0} \tag{5.206}
\end{array}
$$

This result may be presented schematically on the following Venn diagram (Fig. 10), in which the crossed arrows indicate the only non-commuting pairs of operators.

operators diagonal in
the coupled
representation

Fig. 5.10. Venn diagram for angular momentum operators, and their mutually-commuting groups.

This means that just as for each component angular momentum ( $\mathbf{J}, \mathbf{L}$, and $\mathbf{S}$ ) considered separately we could select a group of common eigenstates for its magnitude squared and the $z$ component, we also may find eigenstates shared by two broader groups of operators, encircled with colored lines in Fig. 10. The first group (within the red circle), consists of all operators but $\hat{J}^{2}$. This means that there are eigenstates shared by 5 remaining operators, and they may be characterized by certain values of the corresponding quantum numbers: $l, m_{l}, s, m_{s}$, and $m_{j}$. Actually, only 4 of these
numbers are independent, because due to Eq. (199) for these compatible operators, for each eigenstate of the group, their "magnetic" quantum numbers $m$ have to satisfy the following relation:

$$
\begin{equation*}
m_{j}=m_{l}+m_{s} . \tag{5.207}
\end{equation*}
$$

Hence the common eigenstates of the operators of this group are fully defined by just 4 quantum numbers, for example, $l, m_{l}, s$, and $m_{s}$. For some calculations, especially those for systems whose Hamiltonians include only operators of this group, it is convenient to the use this set of eigenstates as the basis; frequently this is called the uncoupled representation.

However, in some situations we cannot ignore interactions between the orbital and spin degrees of freedom (in the common jargon, the spin-orbit coupling), which leads in particular to splitting (called the fine structure) of atomic energy levels even in the absence of external magnetic field. I will discuss these effects in detail in the next chapter, and now will only note that they may be described by a separate term, proportional to product $\hat{\mathbf{L}} \cdot \hat{\mathbf{S}}$, in the system's Hamiltonian. If this term is not negligible, the uncoupled representation becomes inconvenient. Indeed, writing

$$
\begin{equation*}
\hat{J}^{2}=(\hat{\mathbf{L}}+\hat{\mathbf{S}})^{2}=\hat{L}^{2}+\hat{S}^{2}+2 \hat{\mathbf{L}} \cdot \hat{\mathbf{S}} \tag{5.208}
\end{equation*}
$$

and looking at Fig. 10 again, we see that the operator $\hat{\mathbf{L}} \cdot \hat{\mathbf{S}}$, describing the spin-orbit coupling, does not commute with operators $\hat{L}_{z}$ and $\hat{S}_{z}$. This means that stationary states of the system with such term in the Hamiltonian do not belong to the uncoupled representation basis. On the other hand, Eq. (208) shows that operator $\hat{\mathbf{L}} \cdot \hat{\mathbf{S}}$ does commute with all 4 operators of another group, encircled with the blue line in Fig. 10. According to Eqs. (201), (202), and (205), all operators of that group also commute to each other, so that they have common eigenstates that may be marked by the corresponding quantum numbers, $l, s, j$, and $m_{j}$. This group is the basis for the coupled representation of particle's state.

Excluding the quantum numbers $l$ and $s$, common for both groups, from notation, it is convenient to denote the common ket-vectors of each group as, respectively,

Coupled and uncoupled bases

$$
\begin{array}{ll}
\left|m_{l}, m_{s}\right\rangle, & \text { for the uncolpled representation's basis, } \\
\left|j, m_{j}\right\rangle, & \text { for the coupled representation's basis. } \tag{5.209}
\end{array}
$$

As we will see in the next chapter, for solution of some important problems (e.g., the fine structure of atomic spectra and the Zeeman effect), we will need the relation between the kets $\left|j, m_{j}\right\rangle$ and the kets $\mid m_{l}$, $\left.m_{s}\right\rangle$. This relation may be represented as the usual linear superposition,

$$
\begin{equation*}
\left|j, m_{j}\right\rangle=\sum_{m_{l}, m_{s}}\left|m_{l}, m_{s}\right\rangle\left\langle m_{l}, m_{s} \mid j, m_{j}\right\rangle, \tag{5.210}
\end{equation*}
$$

whose bra-kets (c-numbers), essentially the elements of the unitary matrix of the transformation between two eigenstate bases (209), are called the Clebsch-Gordan coefficients.

The best (though imperfect) classical interpretation of Eq. (210) I can offer is as follows. If the lengths of vectors $\mathbf{L}$ and $\mathbf{S}$ (in quantum mechanics associated with numbers $l$ and $s$, respectively), and also their scalar product $\mathbf{L} \cdot \mathbf{S}$, are all fixed, then so is the length of vector $\mathbf{J}=\mathbf{L}+\mathbf{S}$ (whose length in quantum mechanics is described by quantum number $j$ ). Hence, the classical image of a specific eigenket $\left|j, m_{j}\right\rangle$, in which $l, s, j$, and $m_{j}$ are all fixed, is a state in which $L^{2}, S^{2}, J^{2}$, and $J_{z}$ are fixed.

However, this fixation still allows for an arbitrary rotation of the pair of vectors $\mathbf{L}$ and $\mathbf{S}$ (with a fixed angle between them, and hence fixed $\mathbf{L} \cdot \mathbf{S}$ and $J^{2}$ ) about the direction of vector $\mathbf{J}$ - see Fig. 11.

Fig. 5.11. Classical image of two quantum states with the same $l, s, j$, and $m_{j}$, but different $m_{l}$ and $m_{s}$.

Hence the components $L_{z}$ and $S_{z}$ in these conditions are not fixed, and in classical mechanics may take a continuum of values, two of which (with the largest and smallest possible values of $S_{z}$ ) are shown in Fig. 11. In quantum mechanics, these components are quantized, with their states represented by eigenkets $\left|m_{l}, m_{s}\right\rangle$, so that a linear combination of such kets is necessary to represent ket $\left|j, m_{j}\right\rangle$. This is exactly what Eq. (210) does.

Some of properties of the Clebsch-Gordan coefficients $\left\langle m_{l}, m_{s} \mid j, m_{j}\right\rangle$ may be readily established. For example, the coefficients do not vanish only if the involved magnetic quantum numbers satisfy Eq. (207); let us prove this fact. ${ }^{52}$ All matrix elements of the null-operator

$$
\begin{equation*}
\hat{J}_{z}-\left(\hat{L}_{z}+\hat{S}_{z}\right)=\hat{0} \tag{5.211}
\end{equation*}
$$

should equal zero in any basis; in particular

$$
\begin{equation*}
\left\langle j, m_{j}\right| \hat{J}_{z}-\left(\hat{L}_{z}+\hat{S}_{z}\right)\left|m_{l}, m_{s}\right\rangle=0 \tag{5.212}
\end{equation*}
$$

Acting by operator $\hat{J}_{z}$ on the bra-vector, and by the sum $\left(\hat{L}_{z}+\hat{S}_{z}\right)$ on the ket-vector, we get

$$
\begin{equation*}
\left[m_{j}-\left(m_{l}+m_{s}\right)\right]\left\langle j, m_{j} \mid m_{l}, m_{s}\right\rangle=0 \tag{5.213}
\end{equation*}
$$

thus proving that $\left\langle m_{l}, m_{s} \mid j, m_{j}\right\rangle \equiv\left\langle j, m_{j} \mid m_{l}, m_{s}\right\rangle^{*}=0$, if $m_{j}-\left(m_{l}+m_{s}\right) \neq 0$.
For the most important case of spin- $1 / 2$ particles ( $s=1 / 2$, and hence $m_{s}= \pm 1 / 2$ ), whose uncoupled representation basis includes $2 \times(2 l+1)$ states, restriction (207) enables the representation of all nonvanishing Clebsch-Gordan coefficients on the simple diagram shown in Fig. 12. Indeed, each coupled-representation eigenket $\left|j, m_{j}\right\rangle$, with $m_{j}=m_{l}+m_{s}=m_{l} \pm 1 / 2$, may be related with non-zero Clebsch-Gordan coefficients to at most two uncoupled-representation eigenstates $\left|m_{l}, m_{s}\right\rangle$. Since $m_{l}$ may only take integer values from $-l$ to $+l, m_{j}$ may only take semi-integer values on the interval $[-l-1 / 2, l+$ $1 / 2]$. Hence, by the definition of $j$ as $\left(m_{j}\right)_{\max }$, its maximum value has to be $l+1 / 2$, and for $m_{j}=l+1 / 2$, this is the only possible value. This means that the uncoupled state with $m_{l}=l$ and $m_{s}=1 / 2$ should be identical to the coupled-representation state with $j=l+1 / 2$ and $m_{j}=l+1 / 2$ :

$$
\begin{equation*}
\left|j=l+\frac{1}{2}, m_{j}=l+\frac{1}{2}\right\rangle=\left|m_{l}=m_{j}-\frac{1}{2}, m_{s}=+\frac{1}{2}\right\rangle . \tag{5.214}
\end{equation*}
$$

[^631]

Fig. 5.12. All possible sets of eigenvalues $m_{l}, m_{s}$ for a particle with fixed $l$, and $s=1 / 2$. Each uncoupled-representation state is represented by a dot, while each the coupled-representation state, by a single sloped line connecting the dots.

However, already for the next value, $m_{j}=l-1 / 2$, we need to have two values of $j$, so that two $\mid m_{l}$, $\left.m_{s}\right\rangle$ kets is to be related to two $\left|j, m_{j}\right\rangle$ kets by two Clebsch-Gordan coefficients. Since $l$ changes in unit steps, these values of $j$ have to be $l \pm 1 / 2$. This choice,

$$
\begin{equation*}
j=l \pm 1 / 2 \tag{5.215}
\end{equation*}
$$

evidently satisfies all lower values of $m_{j}$ (again, with only one value, $j=l+1 / 2$, necessary for the lowest $\left.m_{j}=-l-1 / 2\right)-$ see Fig. 12. Note that the total number of the coupled-representation states is $1+2 \times 2 l+1$ $=2(2 l+1)$, i.e. the same as in the uncoupled representation. So, each sum (210), for fixed $j, m_{j}$ (and fixed common parameter $l$ ), has at most 2 terms, i.e. involves at most 2 Clebsch-Gordan coefficients.

These coefficients may be calculated in a few steps, all but the last one rather simple even for arbitrary spin $s$. First, the matrix elements of ladder operators $\hat{L}_{ \pm}$in the standard $z$-basis (i.e. in the basis of kets $\left|m_{l}\right\rangle$ ) may be calculated from Eq. (184). Next, the similarity of vector operators $\hat{\mathbf{J}}$ and $\hat{\mathbf{S}}$ to operators $\hat{\mathbf{L}}$, expressed by Eqs. (197), (203), and (204), may be used to argue that the matrix elements of operators $\hat{S}_{ \pm}$and $\hat{J}_{ \pm}$, defined absolutely similarly to $\hat{L}_{ \pm}$, have similar matrix elements in the bases of kets $\left|m_{s}\right\rangle$ and $\left|m_{j}\right\rangle$, respectively. After that, acting by operator $\hat{J}_{ \pm}=\hat{L}_{ \pm}+\hat{S}_{ \pm}$upon both parts of Eq. (210), and then inner-multiplying the result by the bra vector $\left\langle m_{l}, m_{s}\right|$ and using the above matrix elements, we get recurrence relations for the Clebsch-Gordan coefficients. Finally, these relations may be recurrently applied to the adjacent states in both representations, starting from any of the two states common for them - for example, from state with ket-vectors (214), corresponding to the top right point in Fig. 12. Let me leave these straightforward but a bit tedious calculations for reader's exercise and just cite the final result of this procedure for $s=1 / 2: 53$

Clebsch Gordan coefficients for $s=1 / 2$

$$
\begin{align*}
& \left\langle m_{l}=m_{j}-\frac{1}{2}, \left.m_{s}=+\frac{1}{2} \right\rvert\, j=l \pm \frac{1}{2}, m_{j}\right\rangle= \pm\left(\frac{l \pm m_{j}+1 / 2}{2 l+1}\right)^{1 / 2},  \tag{5.216a}\\
& \left\langle m_{l}=m_{j}+\frac{1}{2}, \left.m_{s}=-\frac{1}{2} \right\rvert\, j=l \pm \frac{1}{2}, m_{j}\right\rangle=+\left(\frac{l \mp m_{j}+1 / 2}{2 l+1}\right)^{1 / 2}
\end{align*}
$$

[^632]For applications, it may be more convenient to use this result in the following equivalent form:

$$
\begin{align*}
& \left|j=l \pm \frac{1}{2}, m_{j}\right\rangle \\
& = \pm\left(\frac{l \pm m_{j}+1 / 2}{2 l+1}\right)^{1 / 2}\left|m_{l}=m_{j}-\frac{1}{2}, m_{s}=+\frac{1}{2}\right\rangle+\left(\frac{l \mp m_{j}+1 / 2}{2 l+1}\right)^{1 / 2}\left|m_{l}=m_{j}+\frac{1}{2}, m_{s}=-\frac{1}{2}\right\rangle \tag{5.216b}
\end{align*}
$$

We will use this relation in Sec. 6.4 for an analysis of the anomalous Zeeman effect, based on the perturbation theory. Moreover, most of the angular momentum addition theory described above is immediately applicable to the addition of angular momenta in multiparticle systems, so we will revisit it in Chapter 8.

To conclude this section, I have to note that the Clebsch-Gordan coefficients (for arbitrary $s$ ) participate also in the so-called Wigner-Eckart theorem that expresses matrix elements of certain spherical tensors, in the coupled-representation basis $\left|j, m_{j}\right\rangle$, via a reduced set of matrix elements. Unfortunately, a discussion of this theorem and its applications would require a higher mathematical background than I can expect from my readers, and more time/space than I can afford. ${ }^{54}$

### 5.8. Exercise problems

5.1. Use the discussion of Sec. 1 to find an alternative solution of Problem 4.17.
5.2. A two-level system is in a quantum state $\alpha$, described by ket-vector $|\alpha\rangle=\alpha_{\uparrow}|\uparrow\rangle+\alpha_{\downarrow}|\downarrow\rangle$, with given (generally, complex) c-number coefficients $\alpha \uparrow \downarrow$. Prove that we can always select a 3-component vector $\mathbf{a}=\left\{a_{x}, a_{y}, a_{z}\right\}$ of real $c$-numbers, such that $\alpha$ is an eigenstate of operator $\mathbf{a} \cdot \hat{\boldsymbol{\sigma}}$, where $\hat{\boldsymbol{\sigma}}$ is the operator described, in $z$-basis, by the Pauli matrix vector. Find all possible values of a satisfying this condition, and the second eigenstate of operator $\mathbf{a} \cdot \hat{\boldsymbol{\sigma}}$, orthogonal to the given $\alpha$. Give a Bloch-sphere interpretation of your result.
5.3. A spin $-1 / 2$ particle is in a constant vertical field, so that its Hamiltonian

$$
\hat{H}=\frac{\hbar \Omega}{2} \hat{\sigma}_{z}
$$

but its spin's initial state is an eigenstate of a different Hamiltonian: ${ }^{55}$

$$
\hat{H}_{i n i}=\mathbf{a} \cdot \hat{\boldsymbol{\sigma}} \equiv a_{x} \hat{\sigma}_{x}+a_{y} \hat{\sigma}_{y}+a_{z} \hat{\sigma}_{z} .
$$

Use any approach you like to calculate the time evolution of the expectation values of the spin components. Interpret the results.
5.4. For any periodic motion of a single particle in a confining potential $U(\mathbf{r})$, the virial theorem of non-relativistic classical mechanics ${ }^{56}$ is reduced to the following equality:

[^633]$$
\bar{T}=\frac{1}{2} \overline{\mathbf{r} \cdot \nabla U},
$$
where $T$ is particle's kinetic energy, and the top bar means averaging over the period of motion. Prove the quantum-mechanical version of the theorem for an arbitrary stationary quantum state, in the absence of spin effects:
$$
\langle T\rangle=\frac{1}{2}\langle\mathbf{r} \cdot \nabla U\rangle,
$$
where the angular brackets mean, as everywhere in these notes, the expectation value of the variable inside them.

Hint: Mimicking the proof of the classical virial theorem, consider the time evolution of operator

$$
\hat{G} \equiv \hat{\mathbf{r}} \cdot \hat{\mathbf{p}} .
$$

5.5. A constant force $F$ is applied to an (otherwise free) 1D particle of mass $m$. Calculate the eigenfunctions of the problem, using
(i) the coordinate representation, and
(ii) the momentum representation.

Discuss the relation between the results.
5.6. The momentum representation of an operator, defined in the Hilbert space of 1D orbital states of a particle, equals $p^{-1}$. Find its coordinate representation.
5.7.* For a particle moving in a 3D periodic potential, develop the bra-ket formalism for the $\mathbf{q}$ representation, in which a complex amplitude similar to $a_{q}$ in Eq. (2.234) (but generalized to 3D and all energy bands) plays the role of the wavefunction. In particular, calculate operators $\mathbf{r}$ and $\mathbf{v}$ in this representation, and use the result to prove Eq. (2.237) for 1D motion in the low-field limit.

Hint: Try to generalize the analysis of the momentum representation in Sec. 5.2.
5.8. In the Heisenberg picture of quantum dynamics, find the operator of velocity and acceleration,

$$
\hat{\mathbf{v}} \equiv \frac{d \hat{\mathbf{r}}}{d t} \quad \text { and } \hat{\mathbf{a}} \equiv \frac{d \hat{\mathbf{v}}}{d t},
$$

of an electron moving in an arbitrary electromagnetic field. Compare the results with the corresponding classical expressions.
5.9. Calculate, in the WKB approximation, the transmission coefficient $T$ for tunneling of a 2D particle with energy $E<U_{0}$ through a saddle-shaped potential "pass"

$$
U(x, y)=U_{0}\left(1+\frac{x y}{a^{2}}\right),
$$

where $U_{0}$ and $a$ are real constants.
5.10. Calculate the so-called Gamow factor ${ }^{57}$ for the alpha decay of atomic nuclei, i.e. the exponential factor in the transparency of the tunnel barrier, resulting from the following simple model of the particle's potential energy as a function of its distance from the nuclear center:

$$
U(r)= \begin{cases}U_{0}<0, & \text { for } r<R \\ \frac{Z Z^{\prime} e^{2}}{4 \pi \varepsilon_{0} r}, & \text { for } R<r,\end{cases}
$$

(where $Z e=2 e>0$ is the charge of the alpha-particle, $Z^{\prime} e>0$ is that of the nucleus after the decay, and $R$ is the nucleus' radius), in the WKB approximation.
5.11. For a 1D harmonic oscillator with mass $m$ and frequency $\omega_{0}$, calculate:
(i) all matrix elements $\langle n| \hat{x}^{3}\left|n^{\prime}\right\rangle$, and
(ii) diagonal matrix elements $\langle n| \hat{x}^{4}|n\rangle$,
where $n$ are the Fock states.
5.12. Calculate the sum (over all $n>0$ ) of the so-called oscillator strengths,

$$
\left.f_{n} \equiv \frac{2 m}{\hbar^{2}}\left(E_{n}-E_{0}\right)|\langle n| \hat{x}| 0\right\rangle\left.\right|^{2},
$$

of quantum transitions between the $n^{\text {th }}$ energy level and the ground state, for
(i) a 1 D harmonic oscillator, and
(ii) a 1D particle confined in an arbitrary stationary potential.
5.13.* Prove the so-called the Bethe sum rule,

$$
\left.\sum_{n^{\prime}}\left(E_{n^{\prime}}-E_{n}\right)\left|\langle n| e^{i k x}\right| n^{\prime}\right\rangle\left.\right|^{2}=\frac{\hbar^{2} k^{2}}{2 m}
$$

(where $k$ is a $c$-number), valid for a 1D particle moving in an arbitrary time-independent potential $U(x)$, and discuss its relation with the Thomas-Reiche-Kuhn sum rule, whose derivation was the subject of the previous problem.

Hint: Calculate the expectation value, in a stationary state $n$, of the following double commutator,

$$
\left.\hat{D} \equiv\left[\hat{H}, e^{i k x}\right], e^{-i k x}\right],
$$

in two ways - first, just spelling out both commutators, and, second, using the commutation relations between operators $\hat{p}$ and $e^{ \pm i k x}$, and compare the results.
5.14. Simplify the following operators:
(i) $\exp \{+i a \hat{x}\} \hat{p}_{x} \exp \{-i a \hat{x}\}$, and

[^634](ii) $\exp \left\{+i a \hat{p}_{x}\right\} \hat{x} \exp \left\{-i a \hat{p}_{x}\right\}$,
where $a$ is a $c$-number.
5.15. Use the Heisenberg equation of motion for a direct derivation of time evolution law (5.171) of the creation and annihilation operators of a harmonic oscillator.

### 5.16. Calculate:

(i) the expectation value of energy, and
(ii) the laws of time evolution of expectation values of the coordinate and momentum for a 1D harmonic oscillator, provided that in the initial moment $(t=0)$ it was in state

$$
|\alpha\rangle=\frac{1}{\sqrt{2}}(|15\rangle+|16\rangle),
$$

where $|n\rangle$ are ket-vectors of the stationary (Fock) states of the oscillator.
5.17.* Re-derive the London dispersion force potential between two 3D harmonic oscillators (already calculated in Problem 3.19), using the language of mutually-induced polarization.
5.18. The discussion of the Glauber state properties in Sec. 5 has used the following general statement: if

$$
[\hat{A}, \hat{B}]=\mu \hat{I}
$$

where $\hat{A}$ and $\hat{B}$ are arbitrary operators, and $\mu$ is an arbitrary $c$-number, then

$$
\exp \{+\hat{A}\} \hat{B} \exp \{-\hat{A}\}=\hat{B}+\mu \hat{I}
$$

Prove the statement.
Hint: One (of several) ways to prove the statement is to expand operator $\hat{f}(\lambda)=\exp \{\lambda \hat{A}\} \hat{B} \exp \{-\lambda \hat{A}\}$ into the Taylor series in c-number $\lambda$, and then evaluate it at $\lambda=1$.
5.19. An external force pulse $F(t)$, of a finite time duration $T$, is exerted on a 1D harmonic oscillator, initially in its ground state. Use the Heisenberg-picture equations of motion to calculate the expectation value of oscillator's energy at the end of the pulse.
5.20. Calculate the energy of the squeezed ground state $\perp$ of a harmonic oscillator, defined by Eq. (172).
5.21. Use Eqs. (5.178) of the lecture notes to prove that operators $\hat{L}_{j}$ and $\hat{L}^{2}$ commute with the Hamiltonian of a spinless particle placed in any central potential field.
5.22. Prove the following relations for the operators of the angular momentum:

$$
\hat{L}^{2}=\hat{L}_{z}^{2}+\hat{L}_{+} \hat{L}_{-}-\hbar \hat{L}_{z}=\hat{L}_{z}^{2}+\hat{L}_{-} \hat{L}_{+}+\hbar \hat{L}_{z} .
$$

(One of them, Eq. (184), was already used in Sec. 6.)
5.23. According to Eqs. (188) and their discussion, action of the ladder operators on the common eigenkets $|l, m\rangle$ of operators $\hat{L}^{2}$ and $\hat{L}_{z}$ may be described as

$$
\hat{L}_{ \pm}|l, m\rangle=L_{ \pm}^{(m)}|l, m \pm 1\rangle .
$$

Calculate coefficients $L_{ \pm}{ }^{(m)}$, assuming that the eigenstates are normalized: $\langle l, m \mid l, m\rangle=1$.
5.24. In the basis of common eigenstates of operators $\hat{L}_{z}$ and $\hat{L}^{2}$, described by eigenkets $|l, m\rangle$ :
(i) calculate matrix elements $\left\langle l, m_{1}\right| \hat{L}_{x}\left|l, m_{2}\right\rangle$ and $\left\langle l, m_{1}\right| \hat{L}_{x}^{2}\left|l, m_{2}\right\rangle$;
(ii) spell out your results for diagonal matrix elements (with $m_{1}=m_{2}$ ) and their $y$-axis counterparts; and
(iii) calculate diagonal matrix elements $\langle l, m| \hat{L}_{x} \hat{L}_{y}|l, m\rangle$ and $\langle l, m| \hat{L}_{y} \hat{L}_{x}|l, m\rangle$.
5.25. For the state described by the common eigenket $|l, m\rangle$ of operators $\hat{L}_{z}$ and $\hat{L}^{2}$ in a reference frame $\{x, y, z\}$, calculate the expectation values $\left\langle L_{z^{\prime}}\right\rangle$ and $\left\langle L_{z^{\prime}}{ }^{2}\right\rangle$ in the reference frame whose axis $z^{\prime}$ forms angle $\theta$ with axis $z$.
5.26. Write down the matrices of the following angular momentum operators: $\hat{L}_{x}, \hat{L}_{y}, \hat{L}_{z}$, and $\hat{L}_{ \pm}$, in the $z$-basis of states with $l=1$.
5.27. Find the angular part of the orbital wavefunction of a particle with a definite value of $L^{2}$, equal to $6 \hbar^{2}$, and the largest possible value of $L_{x}$. What is this value?
5.28. ${ }^{*}$ A charged 2D particle is trapped in a soft in-plane potential well $U(x, y)=m \omega_{0}^{2}\left(x^{2}+y^{2}\right) / 2$. Calculate its energy spectrum in the presence of an additional uniform magnetic field $\mathcal{B}$, normal to the plane.
5.29. Calculate the spectrum of rotational energies of an axially-symmetric, rigid molecule.
5.30. For the state with wavefunction $\psi=C x y e^{-\lambda r}$, with a real, positive $\lambda$, calculate:
(i) the expectation values of observables $L_{x}, L_{y}, L_{z}$ and $L^{2}$, and
(ii) the normalization constant $C$.
5.31. An angular state of a spinless particle is described by the following ket-vector:

$$
\left.|\alpha\rangle=\frac{1}{\sqrt{2}}(l=3, m=0\rangle+|l=3, m=1\rangle\right) .
$$

Find the expectation values of the $x$ - and $y$-components of its angular momentum. Is it sensitive to a possible phase shift between two component eigenkets?
5.32. ${ }^{*}$ Simplify the following double commutator: $\hat{A}_{i j^{\prime}} \equiv\left[\hat{r}_{j},\left[\hat{L}^{2}, \hat{r}_{j^{\prime}}\right]\right.$.
5.33. Express the commutators listed in Eq. (206), $\left[\hat{J}^{2}, \hat{L}_{z}\right]$ and $\left[\hat{J}^{2}, \hat{S}_{z}\right]$, via $\hat{L}_{j}$ and $\hat{S}_{j}$.
5.34. Find the operator $\hat{\tau}_{\phi}$ describing the state rotation by angle $\phi$ about a certain axis, using the similarity of this operation with the shift of a Cartesian coordinate, discussed in Sec. 5. Then use it to calculate the probabilities of measurements of a beam of particles with $z$-polarized spin- $1 / 2$, by a SternGerlach instrument turned by angle $\theta$ within the $[z, x]$ plane (where $y$ is the axis of particle propagation - see Fig. 4.1). ${ }^{58}$
5.35. The rotation ("angle translation") operators $\hat{\tau}_{\phi}$, analyzed in the previous problem, and the coordinate translation operator $\hat{\tau}_{X}$, discussed in Sec. 5.5 of the lecture notes, have a similar structure:

$$
\hat{\tau}_{\lambda}=\exp \left\{-i \frac{\hat{C} \lambda}{\hbar}\right\}
$$

where $\lambda$ is a real $c$-number, characterizing shift's magnitude, and $\hat{C}$ is a Hermitian operator that does not explicitly depend on time.
(i) Prove that all such operators $\hat{\tau}_{\lambda}$ are unitary.
(ii) Prove that if the shift by $\lambda$, induced by operator $\hat{\tau}_{\lambda}$, leaves the Hamiltonian of some system unchanged for any $\lambda$, then the variable $C$, corresponding to the operator $\hat{C}$, is a constant of motion.
(iii) Discuss what does the last conclusion give for the particular operators $\hat{\gamma}_{X}$ and $\hat{\tau}_{\phi}$.
5.36. A particle is in a state $\alpha$ with the orbital wavefunction proportional to the spherical harmonic $Y_{1}^{1}(\theta, \varphi)$. Find the angular dependence of the wavefunctions corresponding to the following ket-vectors:
(i) $\hat{L}_{x}|\alpha\rangle$,
(ii) $\hat{L}_{y}|\alpha\rangle$,
(iii) $\hat{L}_{z}|\alpha\rangle$,
(iv) $\hat{L}_{+} \hat{L}_{-}|\alpha\rangle$, and (v) $\hat{L}^{2}|\alpha\rangle$.
5.37. For a state with definite quantum numbers $l$ and $j$, prove that observable $\mathbf{L} \cdot \mathbf{S}$ also has a definite value, and calculate this value.
5.38.* Derive the general recurrence relations for the Clebsh-Gordan coefficients.

Hint: Using the similarity of commutation relations, discussed in Sec. 7, generalize the solution of Problem 19 to all angular momentum operators, and apply them to Eq. (198).
5.39. The byproduct of the solution of the previous problem is the general relation for the spin operators (valid for any spin $s$ ), which may be rewritten as

[^635]$$
\left\langle m_{s} \pm 1\right| \hat{S}_{ \pm}\left|m_{s}\right\rangle=\hbar\left[\left(s \pm m_{s}+1\right)\left(s \mp m_{s}\right)\right]^{1 / 2}
$$
provided that all other quantum numbers are fixed. Use this result to spell out the matrices $\mathrm{S}_{x}, \mathrm{~S}_{y}, \mathrm{~S}_{z}$, and $\mathrm{S}^{2}$ of a particle with $s=1$, in the $z$-basis - defined as the basis in which the matrix $\mathrm{S}_{z}$ is diagonal.
5.40.* For a particle with spin $s$, moving in a spherically-symmetric field, find the ranges of possible values of quantum numbers $m_{j}$ and $j$, necessary to describe, in the coupled representation basis:
(i) all states with a definite quantum number $l$, and
(ii) a state with definite value of not only $l$, but also $m_{l}$ and $m_{s}$.

Give an interpretation of your results in terms of the classical geometric vector diagram (see Fig. 11).
5.41. A spin- $1 / 2$ particle moves in a centrally-symmetric potential $U(r)$. Using Eqs. (216) for the Clebsch-Gordan coefficients,
(i) write explicit expressions for the ket vectors for states that would be simultaneously the eigenstates of operators $\hat{L}^{2}, \hat{J}^{2}$, and $\hat{J}_{z}$, via spin eigenkets $|\uparrow\rangle$ and $|\downarrow\rangle$;
(ii) for each such state, find all the possible values of observables $L^{2}, L_{z}, S^{2}$, and $S_{z}$, the probability of each listed value, and the expectation value for each of the observables.
5.42. Taking into account electron's spin, find the energy spectrum of an electron, free to move within a plane, besides being placed into a uniform magnetic field $\mathbf{B}$, normal to the plane. Compare the result with the Landau level picture discussed in Sec. 3.2.

## Chapter 6. Perturbation Theories

This chapter discusses several perturbative approaches to problems of quantum mechanics, and their simplest applications including the Stark effect, the fine structure of atomic levels, and the Zeeman effect. Moreover, the discussion of the perturbation theory of transitions to continuous spectrum and the Golden Rule of quantum mechanics in the end of this chapter will naturally bring us to the issue of open quantum systems - to be discussed in more detail in the next chapter.

### 6.1. Eigenvalue/eigenstate problems

Unfortunately, only a few problems of quantum mechanics may be solved exactly in the analytical form. Actually, in the previous chapters we have solved a substantial fraction of such problems for a single particle, and for multi-particle problems the exactly solvable cases are even more rare. However, most practical problems of physics feature a certain small parameter, and this smallness may be exploited by various approximate analytical methods. Earlier in the course, we have explored one of them, the WKB approximation, which is adequate for a particle moving through a slowly changing potential profile. Now I will discuss alternative approaches that are more suitable for other cases. The historic name for these approaches is the perturbation theory, but it is more fair to speak about several such theories, because they differ depending on the type of the problem.

The simplest perturbation theories address eigenproblems for systems described by timeindependent Hamiltonians of the type

$$
\begin{equation*}
\hat{H}=\hat{H}^{(0)}+\hat{H}^{(1)}, \tag{6.1a}
\end{equation*}
$$

where the perturbation operator $\hat{H}^{(1)}$ is "small" - in the sense its addition to the unperturbed operator $\hat{H}^{(0)}$ results in a relatively small change of eigenvalues $E_{n}$ of the system. A typical problem of this type is the 1D weakly anharmonic oscillator (Fig. 1) described by Hamiltonian (1a) with

Weakly
anharmonic oscillator

$$
\begin{equation*}
\hat{H}^{(0)}=\frac{\hat{p}^{2}}{2 m}+\frac{m \omega_{0}^{2}}{2} \hat{x}^{2}, \quad \hat{H}^{(1)}=\alpha \hat{x}^{3}+\beta \hat{x}^{4}+\ldots \tag{6.1b}
\end{equation*}
$$

with small coefficients $\alpha, \beta, \ldots$
I will use the anharmonic oscillator as our first particular example, but let me start from describing the perturbative approach to the general time-independent Hamiltonian (1a). In the bra-ket formalism, the eigenproblem for the perturbed system is

$$
\begin{equation*}
\left(\hat{H}^{(0)}+\hat{H}^{(1)}\right)|n\rangle=E_{n}|n\rangle . \tag{6.2}
\end{equation*}
$$

Let the eigenstates and eigenvalues of the unperturbed Hamiltonian, which satisfy equation

$$
\begin{equation*}
\hat{H}^{(0)}\left|n^{(0)}\right\rangle=E_{n}^{(0)}\left|n^{(0)}\right\rangle \tag{6.3}
\end{equation*}
$$

be known. In this case, to solve problem (2) means to find, first, its perturbed eigenvalues $E_{n}$ and, second, coefficients $\left\langle n^{,(0)} \mid n\right\rangle$ of the expansion of perturbed state vectors $|n\rangle$ in series over the unperturbed ones, $\left|n^{,(0)}\right\rangle$ :

Fig. 6.1. The simplest problem for the perturbation theory application: a 1D weakly anharmonic oscillator. (Dashed lines characterize the unperturbed, harmonic oscillator.)

Let us plug Eq. (4), with the summation index $n$ ' replaced with $n$ ", into both parts of Eq. (2):

$$
\begin{equation*}
\sum_{n^{\prime \prime}}\left\langle n^{\prime \prime}(0) \mid n\right\rangle \hat{H}^{(0)}\left|n^{\prime \prime}(0)\right\rangle+\sum_{n^{\prime \prime}}\left\langle n^{\prime \prime}(0) \mid n\right\rangle \hat{H}^{(1)}\left|n^{\prime \prime}(0)\right\rangle=\sum_{n^{\prime \prime}}\left\langle n^{\prime \prime}(0) \mid n\right\rangle E_{n}\left|n^{\prime \prime(0)}\right\rangle, \tag{6.5}
\end{equation*}
$$

and then inner-multiply all terms by an arbitrary unperturbed bra-vector $\left\langle n^{,(0)}\right|$. Assuming that the system of unperturbed eigenstates is orthonormal, $\left\langle n^{,(0)} \mid n^{\prime(0)}\right\rangle=\delta_{n^{\prime} n^{\prime \prime}, \text {, and using Eq. (3) in the first term of the }}$ left-hand part, we get the following system of linear equations

$$
\begin{equation*}
\sum_{n^{\prime \prime}}\left\langle n^{\prime \prime(0)} \mid n\right\rangle H_{n^{\prime} n^{\prime \prime}}^{(1)}=\left\langle n^{\prime(0)} \mid n\right\rangle\left(E_{n}-E_{n^{\prime}}^{(0)}\right), \tag{6.6}
\end{equation*}
$$

where the matrix elements of the perturbation are calculated in unperturbed bra-kets:

$$
\begin{equation*}
H_{n^{\prime} n^{\prime \prime}}^{(1)} \equiv\left\langle n^{\prime(0)}\right| \hat{H}^{(1)}\left|n^{\prime \prime(0)}\right\rangle \tag{6.7}
\end{equation*}
$$

The linear equation system (6) is still exact, ${ }^{1}$ and is frequently used for numerical calculations. (Since the matrix coefficients (7) typically decrease when $n$ ' and/or $n$ " become very large, the sum in the left-hand part of Eq. (6) may be typically truncated, still giving acceptable accuracy of the solution.) For getting analytical results we need to make more explicit approximations. In the simple perturbation theory we are discussing now, this is achieved by the expansion of both eigenenergies and coefficients into the Taylor series in a certain small parameter $\mu$ of the problem:

$$
\begin{gather*}
E_{n}=E_{n}^{(0)}+E_{n}^{(1)}+E_{n}^{(2)} \ldots  \tag{6.8}\\
\left\langle n^{\prime(0)} \mid n\right\rangle=\left\langle n^{\prime(0)} \mid n\right\rangle^{(0)}+\left\langle n^{(0)} \mid n\right\rangle^{(1)}+\left\langle n^{\prime(0)} \mid n\right\rangle^{(2)} \ldots \tag{6.9}
\end{gather*}
$$

where ${ }^{2}$

$$
\begin{equation*}
E_{n}^{(k)} \propto\left\langle n^{\prime(0)} \mid n\right\rangle^{(k)} \propto \mu^{k} . \tag{6.10}
\end{equation*}
$$

[^636]In order to explore the $1^{\text {st }}$-order approximation, which ignores all terms $O\left(\mu^{2}\right)$ and higher, let us plug only the two first terms of expansions (8) and (9) into the basic system of equations (6):

$$
\begin{equation*}
\sum_{n^{\prime \prime}} H_{n^{\prime} n^{\prime \prime}}^{(1)}\left(\delta_{n^{\prime \prime} n}+\left\langle n^{\prime \prime}(0) \mid n\right\rangle^{(1)}\right)=\left(\delta_{n^{\prime} n}+\left\langle n^{(0)} \mid n\right\rangle^{(1)}\right)\left(E_{n}^{(0)}+E_{n}^{(1)}-E_{n^{\prime}}^{(0)}\right) . \tag{6.11}
\end{equation*}
$$

Now let us open the parentheses, and disregard all the remaining terms $O\left(\mu^{2}\right)$. The result is

$$
\begin{equation*}
H_{n^{\prime} n}^{(1)}=\delta_{n^{\prime} n} E_{n}^{(1)}+\left\langle n^{\prime(0)} \mid n\right\rangle^{(1)}\left(E_{n}^{(0)}-E_{n^{\prime}}^{(0)}\right), \tag{6.12}
\end{equation*}
$$

This equation is valid for any set of indices $n$ and $n$ '; let us start from the case $n=n$ ' and immediately get a very simple (and the most important!) result:
$1^{\text {st }}$ - order correction energies

$$
\begin{equation*}
E_{n}^{(1)}=H_{n n}^{(1)} \equiv\left\langle n^{(0)}\right| \hat{H}^{(1)}\left|n^{(0)}\right\rangle . \tag{6.13}
\end{equation*}
$$

For example, let us see what does this result give for two first perturbation terms in the weakly anharmonic oscillator (1b)

$$
\begin{equation*}
E_{n}^{(1)}=\alpha\left\langle n^{(0)}\right| \hat{X}^{3}\left|n^{(0)}\right\rangle+\beta\left\langle n^{(0)}\right| \hat{X}^{4}\left|n^{(0)}\right\rangle . \tag{6.14}
\end{equation*}
$$

As the reader should know from the solution of Problem 5.6, the first term is zero, while the second one yields ${ }^{3}$

$$
\begin{equation*}
E_{n}^{(1)}=\frac{3}{4} \beta x_{0}^{4}\left(2 n^{2}+2 n+1\right) . \tag{6.15}
\end{equation*}
$$

Naturally, there should be some contribution from the (typically, larger) term proportional to $\alpha$, so we need to explore the $2^{\text {nd }}$ approximation of the perturbation theory. However, before doing that, let us complete our discussion of its $1^{\text {st }}$ order. For $n^{\prime} \neq n$, Eq. (12) may be used to calculate the eigenstates rather than the eigenvalues:

$$
\begin{equation*}
\left\langle n^{\prime(0)} \mid n\right\rangle^{(1)}=\frac{H_{n^{\prime} n}^{(1)}}{E_{n}^{(0)}-E_{n^{\prime}}^{(0)}}, \quad \text { for } n^{\prime} \neq n . \tag{6.16}
\end{equation*}
$$

This means that the eigenket's expansion (4), in the $1^{\text {st }}$ order, may be represented as
vectors

$$
\begin{equation*}
\left|n^{(1)}\right\rangle=\sum_{n^{\prime} \neq n} \frac{H_{n^{\prime} n}^{(1)}}{E_{n}^{(0)}-E_{n^{\prime}}^{(0)}}\left|n^{\prime(0)}\right\rangle+C\left|n^{(0)}\right\rangle . \tag{6.17}
\end{equation*}
$$

Coefficient $C$ cannot be found from Eq. (12), however, requiring the final state $n$ to be normalized, we see that other terms may provide only corrections $O\left(\mu^{2}\right)$, so in the $1^{\text {st }}$ order we should take $C=1$. The
${ }^{3}$ The result for $n=0$ may be readily calculated in the wave-mechanics style as well, using Eq. (2.269) for unperturbed ground state wavefunction, and the table integral MA Eq. (6.9d):

$$
\left\langle n^{(0)}\right| \hat{x}^{4}\left|n^{(0)}\right\rangle_{n=0}=\int\left(\psi_{0}^{(0)}\right)^{*} x^{4} \psi_{0}^{(0)} d x=\left(\frac{1}{\pi x_{0}}\right)^{1 / 2} \int_{-\infty}^{+\infty} x^{4} \exp \left\{-\frac{x^{2}}{x_{0}^{2}}\right\} d x=\frac{3}{4} x_{0}^{4},
$$

but for higher values of $n$, such calculations are much harder, because of more involved Eq. (2.279) for $\psi_{n}^{(0)}$. Note also that at $n \gg 1$, Eq. (15) gives predictions which coincide with those of the classical theory of weakly nonlinear oscillations - see, e.g., CM Sec. 4.2, in particular, Eq. (4.49).
most important feature of Eq. (17) is its denominator: the closer the (unperturbed) eigenenergies of two states, the larger is their mutual contribution (hybridization), created by the perturbation.

This feature also affects the $1^{\text {st }}$ approximation's validity condition that may be quantified using Eq. (16): the magnitudes of all the bra-kets it describes have to be much less then the unperturbed product $\langle n \mid n\rangle^{(0)}=1$, so that all elements of the perturbation matrix have to be much less that the difference between the corresponding unperturbed energies. For the anharmonic oscillator's energy correction (15), this requirement is reduced to $E_{n}{ }^{(1)} \ll \hbar \omega_{0}$.

Now we are ready for going after the $2^{\text {nd }}$ second order approximation to Eq. (6). Let us focus on the case $n^{\prime}=n$, because as we already know, only this term will give us a correction to eigenenergies. Moreover, we see that since the left-hand side of Eq. (6) already has the small factor $H^{(1)}{ }_{n^{\prime} n^{n}} \propto \mu$, the bra-ket coefficients in that part may be taken from the $1^{\text {st }}$ order result (16). As a result, we get

$$
\begin{equation*}
E_{n}^{(2)}=\sum_{n^{\prime \prime}}\left\langle n^{\prime \prime}(0) \mid n\right\rangle^{(1)} H_{n n^{\prime \prime}}^{(1)}=\sum_{n^{\prime \prime} \neq n} \frac{H_{n^{\prime \prime} n}^{(1)} H_{n n^{\prime \prime}}^{(1)}-E_{n^{\prime \prime}}^{(0)}}{E_{n}^{(0)} .} \tag{6.18}
\end{equation*}
$$

Since $\hat{H}^{(1)}$ represents an observable (energy), and hence has to be Hermitian, we may rewrite this expression as

$$
E_{n}^{(2)}=\sum_{n^{\prime} \neq n} \frac{\left|H_{n^{\prime} n}^{(1)}\right|^{2}}{E_{n}^{(0)}-E_{n^{\prime}}^{(0)}}=\sum_{n^{\prime} \neq n} \frac{\left.\left|\left\langle n^{\prime(0)}\right| \hat{H}^{(1)}\right| n^{(0)}\right\rangle\left.\right|^{2}}{E_{n}^{(0)}-E_{n^{\prime}}^{(0)}} .
$$

This is the much celebrated $2^{\text {nd }}$ order perturbation result that frequently (in sufficiently symmetric problems) is the first nonvanishing correction to the state energy - for example, from the cubic term (proportional to $\alpha$ ) in our weakly anharmonic oscillator problem (1). In order to calculate the corresponding correction, we may use another result of Problem 5.6:

$$
\begin{align*}
& \left\langle n^{\prime}\right| \hat{X}^{3}|n\rangle=\left(\frac{x_{0}}{\sqrt{2}}\right)^{3}  \tag{6.20}\\
& \times\left\{[n(n-1)(n-2)]^{1 / 2} \delta_{n^{\prime}, n-3}+3 n^{3 / 2} \delta_{n^{\prime}, n-1}+3(n+1)^{3 / 2} \delta_{n^{\prime}, n+1}+[(n+1)(n+2)(n+3)]^{1 / 2} \delta_{n^{\prime}, n+3}\right\} .
\end{align*}
$$

So, according to Eq. (19), we need to calculate

$$
\begin{align*}
& E_{n}^{(2)}=\alpha^{2}\left(\frac{x_{0}}{\sqrt{2}}\right)^{6} \\
& \times \sum_{n^{\prime} \neq n} \frac{\left[[n(n-1)(n-2)]^{1 / 2} \delta_{n^{\prime}, n-3}+3 n^{3 / 2} \delta_{n^{\prime}, n-1}+3(n+1)^{3 / 2} \delta_{n^{\prime}, n+1}+[(n+1)(n+2)(n+3)]^{1 / 2} \delta_{n^{\prime}, n+3}\right\}^{2}}{\hbar \omega_{0}\left(n-n^{\prime}\right)} \tag{6.21}
\end{align*}
$$

The summation is actually not as cumbersome as may look, because all mixed products are proportional to different Kronecker deltas and hence vanish, so that we need to sum up only the squares of each term:

$$
\begin{align*}
E_{n}^{(2)} & =\frac{\alpha^{2}}{\hbar \omega_{0}}\left(\frac{x_{0}}{\sqrt{2}}\right)^{6}\left[\frac{n(n-1)(n-2)}{3}+\frac{9 n^{3}}{1}+\frac{9(n+1)^{3}}{-1}+\frac{(n+1)(n+2)(n+3)}{-3}\right]  \tag{6.22}\\
& =-\frac{15}{4} \frac{\alpha^{2} x_{0}^{6}}{\hbar \omega_{0}}\left(n^{2}+n+\frac{11}{30}\right) .
\end{align*}
$$

Please notice that all energy level corrections are negative, regardless of the sign of $\alpha$. On the contrary, the $1^{\text {st }}$ order correction $E_{n}{ }^{(1)}(15)$ depends on the sign of parameter $\beta$, so that the net correction, $E_{n}{ }^{(1)}+E_{n}{ }^{(2)}$, may be of any sign.

Results (17) and (19) are clearly inapplicable to the degenerate case where, in the absence of perturbation, several states correspond to the same energy level, because of the divergence of their denominators. ${ }^{4}$ This divergence hints that the largest effect of the perturbation in that case is the degeneracy lifting, e.g., splitting of the initially degenerate energy level $E^{(0)}$ (Fig. 2), and that for the analysis of this case we can, to the first approximation, ignore the effect of all other energy levels. (A careful analysis shows that this is indeed the case until the level splitting becomes comparable with the distance to other energy levels.)

$$
\hat{H}=\hat{H}^{(0)} \quad \hat{H}=\hat{H}^{(0)}+\hat{H}^{(1)}
$$

Fig. 5.2. Lifting the energy level degeneracy by a perturbation (schematically).

Limiting the summation in Eq. (6) to the group of $N$ degenerate states with equal $E_{n}{ }^{(0)} \equiv E^{(0)}$, we reduce it to

$$
\begin{equation*}
\sum_{n^{\prime \prime}=1}^{N}\left\langle n^{\prime \prime(0)} \mid n\right\rangle H_{n^{\prime} n^{\prime \prime}}^{(1)}=\left\langle n^{\prime(0)} \mid n\right\rangle\left(E_{n}-E^{(0)}\right) . \tag{6.23}
\end{equation*}
$$

where $n$ ' and $n "$ number $N$ states of the degenerate group. ${ }^{5}$ For $n=n$ ', Eq. (23) may be rewritten as

$$
\begin{equation*}
\sum_{n^{\prime \prime}=1}^{N}\left\langle n^{\prime \prime}(0) \mid n^{\prime}\right\rangle\left(H_{n^{\prime} n^{\prime \prime}}^{(1)}-E_{n^{\prime \prime}}^{(1)} \delta_{n^{\prime} n^{\prime \prime}}\right)=0, \quad \text { where } E_{n}^{(1)} \equiv E_{n}-E^{(0)} \tag{6.24}
\end{equation*}
$$

For each $n=1,2, \ldots N$, this is a system of $N$ linear, homogenous equations (with $N$ terms each) for unknown coefficients $\left\langle n^{\prime(0)} \mid n^{\prime}\right\rangle$. In this problem, we readily recognize the problem of diagonalization of the perturbation matrix $\mathrm{H}^{(1)}$ - cf. Sec. 4.4 and in particular Eq. (4.101). As in the general case, in the condition of self-consistency of the system, we can change the notation of the lower index of $E^{(1)}$, for example to $n$ :

[^637]According to the definition (24) of $E_{n}{ }^{(1)}$, the resulting $N$ energy levels $E_{n}$ may be found as $E^{(0)}+E_{n}{ }^{(1)}$, where $E_{n}{ }^{(1)}$ are the $N$ roots of Eq. (25).

If the perturbation matrix is diagonal, the result is extremely simple,

$$
\begin{equation*}
E_{n}-E^{(0)} \equiv E_{n}^{(1)}=H_{n n}^{(1)}, \tag{6.26}
\end{equation*}
$$

and formally coincides with Eq. (13) for the non-degenerate case, but now may give a different result for each of $N$ previously degenerate states $n$.

Let us see what does this theory give for several important examples. First of all, let us consider a two-level system (or a system with two degenerate states with energy far from all others levels), with an arbitrary perturbation matrix ${ }^{6}$

$$
\mathrm{H}^{(1)}=\left(\begin{array}{ll}
H_{11} & H_{12}  \tag{6.27a}\\
H_{21} & H_{22}
\end{array}\right) .
$$

Since that both the unperturbed Hamiltonian and the operator of its perturbation are Hermitian, the diagonal elements of matrix $\mathrm{H}^{(1)}$ are real, and its off-diagonal elements are complex conjugates of each other. As a result, we can present the matrix in the same form as in Eq. (4.106):

$$
\mathrm{H}^{(1)}=\left(\begin{array}{cc}
a_{0}+a_{z} & a_{x}-i a_{y}  \tag{6.27b}\\
a_{x}+i a_{y} & a_{0}-a_{z}
\end{array}\right)=a_{0} \mathrm{I}+a_{x} \sigma_{x}+a_{y} \sigma_{y}+a_{z} \sigma_{z}=a_{0} \mathrm{I}+\mathbf{a} \cdot \boldsymbol{\sigma} .
$$

where scalar $a_{0}$ and the Cartesian components of vector a are real c-number coefficients. The corresponding characteristic equation,

$$
\left|\begin{array}{cc}
a_{0}+a_{z}-E_{n}^{(1)} & a_{x}-i a_{y}  \tag{6.28}\\
a_{x}+i a_{y} & a_{0}-a_{z}-E_{n}^{(1)}
\end{array}\right|=0
$$

has the solution that is familiar to the reader from Chapters 2 and 4:

$$
\begin{equation*}
E_{ \pm}^{(1)} \equiv E_{ \pm}-E^{(0)}=a_{0} \pm a=a_{0} \pm\left(a_{x}^{2}+a_{y}^{2}+a_{z}^{2}\right)^{1 / 2}=\frac{H_{11}+H_{22}}{2} \pm\left[\left(\frac{H_{11}-H_{22}}{2}\right)^{2}+H_{12} H_{21}\right]^{1 / 2} \tag{6.29}
\end{equation*}
$$

Let us discuss physics of this simple result. Parameter $a_{0}=\left(H_{11}+H_{22}\right) / 2$ is evidently the correction to the average energy of both states, that does not give any contribution to the level splitting. The splitting, $\Delta E=E_{+}-E_{-}$, is a hyperbolic function of coefficient $a_{z}=\left(\mathrm{H}_{11}-\mathrm{H}_{22}\right) / 2$ that describes the direct contributions (13) to the eigenstates due to the perturbation. A plot of this function is the famous level-anticrossing diagram (Fig. 3) that has already been discussed in Sec. 2.5 in a particular context of the weak potential limit of the 1D band theory - see Fig. 2.29.

Now we see that this is a general result for any two-level system. The examples of this behavior that we already know include the coupled quantum wells (see Fig. 2.29 and its discussion), band theory in the weak coupling limit (Sec. 2.5), and spin $-1 / 2$ systems discussed through Chapter 4 and in Sec. 5.1. By the way, from Sec. 4.4 we already know the perturbed states in the middle of the anticrossing

[^638]diagram (at $a_{z}=0$ ). For example, if $a_{y}=0$, then our perturbation Hamiltonian matrix (27), besides the trivial term proportional to $a_{0}$, is proportional to $\sigma_{x}$, and hence we can use the result (4.114) to write: ${ }^{7}$
where $1^{(0)}$ and $2^{(0)}$ are system's states in the absence of the perturbation.

Fig. 6.3. Level-anticrossing diagram for an arbitrary two-level system.

This analysis shows that other results of our discussions of particular two-level systems in Sec. 2.6 and 4.6 are also general. For example, if we put such any two-level system into an initial state different from one of the eigenstates $\pm$, the probability of its finding it in any of states $1^{(0)}$ or $2^{(0)}$ will oscillate with frequency

$$
\begin{equation*}
\Omega=\frac{\Delta E}{\hbar} \equiv \frac{E_{+}-E_{-}}{\hbar} . \tag{6.31}
\end{equation*}
$$

Hence, for a spin- $1 / 2$ particle in a $z$-oriented magnetic field, the periodic oscillations of the $x$ - and $y$ components of spin vector, described by Eqs. (4.196) and (4.202), may be interpreted not only as the torque-induced precession of spin within the $[x, y]$ plane, but alternatively as the quantum oscillations of the of the z-component of spin between states $\uparrow$ and $\downarrow$ with energies $E \uparrow$ and $E \downarrow$ given by Eq. (4.167).

Some other examples of such oscillations may be rather unexpected. For example, the ammonium molecule $\mathrm{NH}_{3}$ (Fig. 4) has two symmetric states which differ by the inversion of the nitrogen atom relative to the plane of the three hydrogen atoms, and are coupled due to quantummechanical tunneling of the nitrogen atom through the plane of hydrogen atoms. ${ }^{8}$ Since for this molecule, the level splitting $\Delta E$ corresponds to an experimentally convenient frequency $\Omega / 2 \pi \approx 24 \mathrm{GHz}$, it played an important historic role for the initial development of first atomic frequency standards and microwave quantum generators (masers) in the 1950s, ${ }^{9}$ which paved the way toward the development of the laser technology.

[^639]

Fig. 6.4. Ammonia molecule and its inversion.

### 6.2. The Stark effect

Another example of the level degeneracy lifted by a perturbation is the linear Stark effect atomic level splitting by an external electric field. Let us study this effect, in the linear approximation, for a hydrogen-like atom. Taking the direction of external electric field $\varepsilon$ (which is practically uniform on the atomic scale) for the $z$-axis, the perturbation may be represented by the following Hamiltonian: ${ }^{10}$

$$
\begin{equation*}
\hat{H}^{(1)}=-q \varepsilon \hat{\mathbf{z}}=-q \varepsilon r \cos \theta \tag{6.32}
\end{equation*}
$$

(Since we will work in the coordinate representation, we may skip the operator sign from this point on.)
As you (should :-) remember, energy levels of a hydrogen-like atom depend only on the main quantum number $n$ - see Eq. (3.191); hence all states but the ground state $n=1$ (" $1 s$ " in the spectroscopic nomenclature) in which $l=m=0$, have some degeneracy that grows rapidly with $n$. This is why I will carry out the calculations only for the lowest degenerate level with $n=2$. Since generally 0 $\leq l \leq n-1$, here $l$ may be equal either 0 (one $2 s$ state, with $m=0$ ) or 1 (three $2 p$ states, with $m=0, \pm 1$ ). Due to this 4 -fold degeneracy, $\mathrm{H}^{(1)}$ is a $4 \times 4$ matrix with 16 elements:

$$
\begin{align*}
& \overbrace{m=0}^{l=0} \overbrace{m=0 m=+1 m=-1}^{l=1} \\
& \mathrm{H}^{(1)}=  \tag{6.33}\\
&\left(\begin{array}{llll}
H_{11} & H_{12} & H_{13} & H_{14} \\
H_{21} & H_{22} & H_{23} & H_{24} \\
H_{31} & H_{32} & H_{33} & H_{34} \\
H_{41} & H_{42} & H_{43} & H_{44}
\end{array}\right) \begin{array}{l}
m=0, \\
m=0, \\
m=+1, \\
m=-1,
\end{array} \quad l=0,
\end{align*}
$$

However, please do not be scared. First, due to the Hermitian character of the operator, only 10 of the matrix elements ( 4 diagonal ones and 6 off-diagonal elements) may be substantially different. Moreover, due to a high symmetry of the problem, there are a lot of zeros even among these elements. Indeed, let us have a look at the angular components $Y_{l}^{m}$ of the corresponding wavefunctions, described by Eqs. (3.174)-(3.175). For states with $m= \pm 1$, the azimuthal parts of wavefunctions are proportional to $\exp \{ \pm i \varphi\}$; hence the off-diagonal elements $H_{34}$ and $H_{43}$ of matrix (33), relating these functions, are proportional to

[^640]\[

$$
\begin{equation*}
\oint d \Omega Y_{1}^{ \pm^{*}} \hat{H}^{(1)} Y_{1}^{\mp} \propto \int_{0}^{2 \pi} d \varphi\left(e^{ \pm i \varphi}\right)^{*}\left(e^{\mp i \varphi}\right)=0 . \tag{6.34}
\end{equation*}
$$

\]

The azimuthal-angle symmetry also kills the off-diagonal elements $H_{13}, H_{14}, H_{23}, H_{24}$ (and hence their complex conjugates $H_{31}, H_{41}, H_{32}$, and $H_{42}$ ), because they relate states with $m=0$ and $m \neq 0$, and are proportional to

$$
\begin{equation*}
\oint d \Omega Y_{1}^{0^{*}} \hat{H}^{(1)} Y_{1}^{ \pm 1} \propto \int_{0}^{2 \pi} d \varphi e^{ \pm i \varphi}=0 . \tag{6.35}
\end{equation*}
$$

For the diagonal elements $H_{33}$ and $H_{44}$, corresponding to $m= \pm 1$, the azimuthal-angle integral does not vanish, but since the spherical functions depend on the polar angle as $\sin \theta$, the matrix elements are proportional to

$$
\begin{equation*}
\oint d \Omega Y_{1}^{ \pm^{*}} \hat{H}^{(1)} Y_{1}^{ \pm} \propto \int_{0}^{\pi} \sin \theta d \theta \sin \theta \cos \theta \sin \theta=\int_{-1}^{+1} \cos \theta\left(1-\cos ^{2} \theta\right) d(\cos \theta) \tag{6.36}
\end{equation*}
$$

i.e. are equal to zero as any limit-symmetric integral of an odd function. Finally, for states $2 s$ and $2 p$ with $m=0$, the diagonal elements $H_{11}$ and $H_{22}$ are also killed by the polar-angle integration:

$$
\begin{align*}
& \oint d \Omega Y_{0}^{0^{*}} \hat{H}^{(1)} Y_{0}^{0} \propto \int_{0}^{\pi} \sin \theta d \theta \cos \theta=\int_{-1}^{1} \cos \theta d(\cos \theta)=0  \tag{6.37a}\\
& \oint d \Omega Y_{0}^{1^{*}} \hat{H}^{(1)} Y_{0}^{1} \propto \int_{0}^{\pi} \sin \theta d \theta \cos ^{3} \theta=\int_{-1}^{+1} \cos ^{3} \theta d(\cos \theta)=0 \tag{6.37b}
\end{align*}
$$

Hence, the only nonvanishing matrix elements are two off-diagonal elements $H_{12}$ and $H_{21}$ relating different states with $m=0$, because they are proportional to

$$
\begin{equation*}
\oint d \Omega Y_{0}^{0^{*}} \cos \theta Y_{1}^{0}=\frac{\sqrt{3}}{4 \pi} \int_{0}^{2 \pi} d \varphi \int_{0}^{\pi} \sin \theta d \theta \cos ^{2} \theta=\frac{1}{\sqrt{3}} \neq 0 . \tag{6.38}
\end{equation*}
$$

What remains is to use Eqs. (3.199) for the radial parts of these functions to finish the calculation of those two matrix elements:

$$
\begin{equation*}
H_{12}=H_{21}=-\frac{q \varepsilon}{\sqrt{3}} \int_{0}^{\infty} r^{2} d r R_{2,0}(r) r R_{2,1}(r) \tag{6.39}
\end{equation*}
$$

where the radial functions are given by Eqs. (3.199). Due to the structure of function $R_{2,0}(r)$, the integral falls into a sum of two parts, both of the type we have already met. ${ }^{11}$ The final result is

$$
\begin{equation*}
H_{12}=H_{21}=3 q \varepsilon r_{0}, \tag{6.40}
\end{equation*}
$$

where $r_{0}$ is the radius scale given by Eq. (3.183); for the hydrogen atom it is just the Bohr radius $r_{\mathrm{B}}$ (1.13).

Thus, for our case the perturbation matrix (33) is reduced to

[^641]\[

\mathrm{H}^{(1)}=\left($$
\begin{array}{cccc}
0 & 3 q \varepsilon r_{0} & 0 & 0  \tag{6.41}\\
3 q \varepsilon r_{0} & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0
\end{array}
$$\right)
\]

so that the condition (25) of self-consistency is

$$
\left|\begin{array}{cccc}
-E_{n}^{(1)} & 3 q \varepsilon r_{0} & 0 & 0  \tag{6.42}\\
3 q \varepsilon r_{0} & -E_{n}^{(1)} & 0 & 0 \\
0 & 0 & -E_{n}^{(1)} & 0 \\
0 & 0 & 0 & -E_{n}^{(1)}
\end{array}\right|=0
$$

giving a very simple characteristic equation

$$
\begin{equation*}
\left(E_{n}^{(1)}\right)^{2}\left[\left(E_{n}^{(1)}\right)^{2}-\left(3 q \varepsilon r_{0}\right)^{2}\right]=0 . \tag{6.43}
\end{equation*}
$$

with the roots

$$
\begin{equation*}
E_{1,2}^{(1)}=0, \quad E_{3,4}^{(1)}= \pm 3 q \varepsilon r_{0} \tag{6.44}
\end{equation*}
$$

Linear
Stark
effect
for $n=2$
so that the degeneracy is only partly lifted - see Fig. 5.

Fig. 6.5. Linear Stark effect for level $n$ $=2$ of a hydrogen-like atom.

Generally, in order to understand the nature of states corresponding to these levels, we should go back to Eq. (24) with each calculated value of $E_{n}{ }^{(1)}$, and calculate the corresponding expansion coefficients $\left\langle n "{ }^{(0)} \mid n\right\rangle$, which describe the perturbed states. However, in our simple case the outcome of the procedure is clear in advance. Indeed, since the states with $m= \pm 1$ are not affected by the perturbation (in the linear approximation in electric field), their degeneracy is not lifted, and energy unaffected - see the middle level in Fig. 5. On the other hand, the perturbation matrix connecting states $2 s$ and $2 p$, i.e. the top left $2 \times 2$ part of the full matrix (41), is proportional to the Pauli matrix $\sigma_{x}$, and we already know the result of its diagonalization - see Eqs. (4.114). This means that the upper and lower split levels correspond to very simple linear combinations of the previously degenerate states,
both with $m=0$.

Finally, let us estimate the magnitude of the linear Stark effect for a hydrogen atom. For a very high electric field of $\mathcal{E}=3 \times 10^{6} \mathrm{~V} / \mathrm{m},{ }^{12} q=e \approx 1.6 \times 10^{-19} \mathrm{C}$, and $r_{0}=r_{\mathrm{B}} \approx 0.5 \times 10^{-10} \mathrm{~m}$, we get a level splitting of $3 q \delta_{0} \approx 0.8 \times 10^{-22} \mathrm{~J} \approx 0.5 \mathrm{meV}$. This number is much lower than the unperturbed energy of the level, $E_{2}=-E_{H} / 2 \times 2^{2} \approx-3.4 \mathrm{eV}$, so that the perturbation result is quite valid. On the other hand, the splitting is much larger than the resolution limit imposed by the natural linewidth $\left(\sim 10^{-7} E_{2}\right.$, see Chapter 9 ), so that the effect is quite observable even in substantially lower electric fields.

### 6.3. Fine structure of atomic levels

Now let us analyze, for the simplest case of a hydrogen-like atom, the so-called fine structure of atomic levels - their degeneracy lifting even in the absence of external fields. In the limit when the effective speed $v$ of electron motion is much smaller than the speed of light $c$ (as it is in the hydrogen atom), the fine structure may be analyzed as a sum of two small relativistic effects. To analyze the first of these effects, let us expand the well-known classical relativistic expression ${ }^{13}$ for the kinetic energy $T$ $=E-m c^{2}$ of a free particle with the rest mass $m$,

$$
\begin{equation*}
T=\left(m^{2} c^{4}+p^{2} c^{2}\right)^{1 / 2}-m c^{2}=m c^{2}\left[\left(1+\frac{p^{2}}{m^{2} c^{2}}\right)^{1 / 2}-1\right], \tag{6.46}
\end{equation*}
$$

into the Taylor series with respect to the small ratio $(p / m c)^{2} \approx(v / c)^{2}$ :

$$
\begin{equation*}
T=m c^{2}\left[1+\frac{1}{2}\left(\frac{p}{m c}\right)^{2}-\frac{1}{8}\left(\frac{p}{m c}\right)^{4}+\ldots-1\right]=\frac{p^{2}}{2 m}-\frac{p^{4}}{8 m^{3} c^{2}}+\ldots \tag{6.47}
\end{equation*}
$$

and neglect all the terms besides the first (non-relativistic) one and the next term representing the first nonvanishing relativistic correction of $T$.

In accordance with the correspondence principle, the quantum-mechanical problem in this approximation may be described by the perturbative Hamiltonian (1a), where the unperturbed (nonrelativistic) Hamiltonian of the problem, whose eigenstates and eigenenergies were discussed in Sec. 3.5 , is

$$
\begin{equation*}
\hat{H}^{(0)}=\frac{\hat{p}^{2}}{2 m}+\hat{U}(r), \quad \hat{U}(r)=-\frac{C}{r}, \tag{6.48}
\end{equation*}
$$

while the small kinetic-relativistic perturbation is

Kineticrelativistic perturbation

$$
\begin{equation*}
\hat{H}^{(1)}=-\frac{\hat{p}^{4}}{8 m^{3} c^{2}}=-\frac{1}{2 m c^{2}}\left(\frac{\hat{p}^{2}}{2 m}\right)^{2} \tag{6.49a}
\end{equation*}
$$

Using Eq. (48), we may rewrite the last formula as

[^642]\[

$$
\begin{equation*}
\hat{H}^{(1)}=-\frac{1}{2 m c^{2}}\left(\hat{H}^{(0)}-\hat{U}(r)\right)^{2}, \tag{6.49b}
\end{equation*}
$$

\]

so that its matrix elements, participating in the characteristic equation (25) for a given degenerate energy level (3.191), i.e. a given principal quantum number $n$, are

$$
\begin{equation*}
\langle n \operatorname{lm}| \hat{H}^{(1)}\left|n l^{\prime} m^{\prime}\right\rangle=-\frac{1}{2 m c^{2}}\langle n \operatorname{lm}|\left(\hat{H}^{(0)}-\hat{U}(r)\right)\left(\hat{H}^{(0)}-\hat{U}(r)\right)\left|n l^{\prime} m^{\prime}\right\rangle, \tag{6.50}
\end{equation*}
$$

where the bra- and ket vectors describe the unperturbed eigenstates whose eigenfunctions (in the coordinate representation) are given by Eq. (3.190): $\psi_{n, l, m}=R_{n, l}(r) Y_{l}^{m}(\theta, \varphi)$.

It is straightforward (and hence left for the reader :-) to prove that all off-diagonal elements of the set (50) are equal to 0 . Thus we may use Eq. (26) for each set of quantum numbers $\{n, l, m\}$ :

$$
\begin{align*}
E_{n, l, m}^{(1)} & \equiv E_{n, l, m}-E_{n}^{(0)}=\langle n \operatorname{lm}| \hat{H}^{(1)}|n l m\rangle=-\frac{1}{2 m c^{2}}\left\langle\left(\hat{H}^{(0)}-\hat{U}(r)\right)^{2}\right\rangle_{n, l, m} \\
& =-\frac{1}{2 m c^{2}}\left(E_{n}^{2}-2 E_{n}\langle\hat{U}\rangle_{n, l}+\left\langle\hat{U}^{2}\right\rangle_{n, l}\right)=-\frac{1}{2 m c^{2}}\left[\frac{E_{0}^{2}}{4 n^{4}}-\frac{E_{0}}{n^{2}} C\left\langle\frac{1}{r}\right\rangle_{n, l}+C^{2}\left\langle\frac{1}{r^{2}}\right\rangle_{n, l}\right], \tag{6.51}
\end{align*}
$$

where index $m$ has been dropped, because the radial wavefunctions $R_{n, l}(r)$, which affect the averages, do not depend on that quantum number. Now using Eqs. (3.183), (3.191) and the first two of Eqs. (3.201), we finally get

$$
\begin{equation*}
E_{n, l}^{(1)}=-\frac{m C^{2}}{2 \hbar^{2} c^{2} n^{4}}\left(\frac{n}{l+1 / 2}-\frac{3}{4}\right)=-\frac{2 E_{n}^{2}}{m c^{2}}\left(\frac{n}{l+1 / 2}-\frac{3}{4}\right) . \tag{6.52}
\end{equation*}
$$

Let us discuss this result. First of all, its last form confirms that that correction (52) is indeed much smaller than the unperturbed energy $E_{n}$ (and hence the perturbation theory is solid) if the latter is much smaller than the relativistic rest energy $m c^{2}$ of the particle. Next, since in the Bohr problem $n \geq l+$ 1, the first fraction in the parentheses of Eq. (52) is always larger than 1, so that the relativistic correction to kinetic energy is negative for all $n$ and $l$. (This is already evident from Eqs. (6.49), which show that the correction Hamiltonian is a negatively defined form.) Finally, at a fixed principal number $n$, the negative correction's magnitude decreases with the growth of $l$. This fact may be classically interpreted using Eq. (3.200): the larger is $l$ (at fixed $n$ ), the smaller is particle's average distance from the center, and hence the smaller is its effective velocity, the smaller is the magnitude of the quantummechanical average of the negative relativistic correction (49a) to the kinetic energy.

Result (52) is conceptually valid for any physics of interaction $U(r)=-C / r$. However, if the interaction is Coulombic, say between an electron with charge $(-e)$ and a nucleus of charge $(+Z e)$, there is also another relativistic correction to energy, due to the so-called spin-orbit interaction. Its physics may be understood from the following semi-qualitative, classical reasoning: from the "the point of view" of an electron rotating about the nucleus at constant distance $r$ with velocity $v$, it is the nucleus, of charge $Z e$, that rotates about the electron with velocity $(-v)$ and hence time period $T=2 \pi r / v$. From the point of view of magnetostatics, such circular motion of electric charge $Q=Z e$ is equivalent to the
constant circular electric current $I=Q v=(Z e)(v / 2 \pi r)$ which creates, at electron's location, i.e. in the center of the current loop, a magnetic field with magnitude ${ }^{14}$

$$
\begin{equation*}
\mathcal{B}_{a}=\frac{\mu_{0}}{2 r} I=\frac{\mu_{0}}{2 r} \frac{Z e v}{2 \pi r}=\frac{\mu_{0} Z e v}{4 \pi r^{2}} . \tag{6.53}
\end{equation*}
$$

The field's direction $\mathbf{n}$ is perpendicular to the apparent plane of the nucleus' rotation (i.e. that of the real rotation of the electron), and hence its vector may be readily expressed via the similarly directed vector $\mathbf{L}$ of electron's angular (orbital) momentum:

$$
\begin{equation*}
\mathcal{B}_{a}=\frac{\mu_{0} Z e v}{4 \pi r^{2}} \mathbf{n}=\frac{\mu_{0} Z e}{4 \pi r^{3} m_{e}} m_{e} v r \mathbf{n}=\frac{\mu_{0} Z e}{4 \pi r^{3} m_{e}} \mathbf{L}=\frac{Z e}{4 \pi \varepsilon_{0} r^{3} m_{e} c^{2}} \mathbf{L} \tag{6.54}
\end{equation*}
$$

where the last transition is due to the basic relation between the SI unit constants: $\mu_{0} \equiv 1 / \varepsilon_{0} c^{2}$.
A more careful (but still classical) analysis of the problem ${ }^{15}$ brings both good and bad news. The bad news is that result (54) is wrong by a factor of 2 even for the circular motion, because the electron moves with acceleration, and the reference frame bound to its cannot be considered inertial (as was implied in the above reasoning), so that the actual magnetic field felt by the electron is

$$
\begin{equation*}
\boldsymbol{B}=\frac{Z e}{8 \pi \varepsilon_{0} r^{3} m_{e} c^{2}} \mathbf{L} . \tag{6.55}
\end{equation*}
$$

The good news is that, so corrected, the result is valid (on the average) for not only circular but arbitrary (elliptic ${ }^{16}$ ) orbital motion in the Coulomb field $U(r)$. Hence from the discussion in Sec. 4.1 and Sec. 4.4 we may expect that the quantum-mechanical description of the interaction between this apparent magnetic field and electron's spin moment (4.116) is given by the following perturbation Hamiltonian

$$
\begin{equation*}
\hat{H}^{(1)}=-\hat{\boldsymbol{\mu}} \cdot \hat{\boldsymbol{B}}=-\left(-\frac{e}{m_{e}} \hat{\mathbf{S}}\right) \cdot\left(\frac{Z e}{8 \pi \varepsilon_{0} r^{3} m_{e} c^{2}} \hat{\mathbf{L}}\right)=\frac{1}{2 m_{e}^{2} c^{2}} \frac{Z e^{2}}{4 \pi \varepsilon_{0}} \frac{1}{r^{3}} \hat{\mathbf{S}} \cdot \hat{\mathbf{L}}, \tag{6.56a}
\end{equation*}
$$

Spinorbit perturbation
where the small correction to value $g_{e}=2$ of electron's $g$-factor has been ignored, because Eq. (56) is already a small correction. This expression is confirmed by the fully-relativistic Dirac theory, to be discussed in Sec. 9.7 below: it yields, for an arbitrary central potential $U(r)$, the following Hamiltonian of the spin-orbit coupling:

$$
\begin{equation*}
\hat{H}^{(1)}=\frac{1}{2 m_{e}^{2} c^{2}} \frac{1}{r} \frac{d U(r)}{d r} \hat{\mathbf{S}} \cdot \hat{\mathbf{L}} . \tag{6.56b}
\end{equation*}
$$

For the Coulomb potential $U(r)=-Z e^{2} / 4 \pi \varepsilon_{0} r$, this formula is reduced to Eq. (56a).
As we already know from the discussion in Sec. 5.7, such Hamiltonian commutes with all operators diagonal in the coupled representation (inside the blue line in Fig. 5.10): $\hat{L}^{2}, \hat{S}^{2}, \hat{J}^{2}$, and $\hat{J}_{z}$. Hence, using Eq. (5.208) to rewrite the spin-orbit Hamiltonian as

[^643]\[

$$
\begin{equation*}
\hat{H}^{(1)}=\frac{1}{2 m_{e}^{2} c^{2}} \frac{Z e^{2}}{4 \pi \varepsilon_{0}} \frac{1}{r^{3}} \frac{1}{2}\left(\hat{J}^{2}-\hat{L}^{2}-\hat{S}^{2}\right), \tag{6.57}
\end{equation*}
$$

\]

we may conclude that this operator is diagonal in the coupled representation with fixed quantum numbers $l, s, j$, and $m_{j}$. As a result, in this representation, we may again use Eq. (26) for each set $\{l, j$, $\left.m_{j}\right\}:$

$$
\begin{equation*}
E_{n, j, l}^{(1)}=\frac{1}{2 m_{e}^{2} c^{2}} \frac{Z e^{2}}{4 \pi \varepsilon_{0}}\left\langle\frac{1}{r^{3}}\right\rangle_{n, l} \frac{1}{2}\left\langle\hat{J}^{2}-\hat{L}^{2}-\hat{S}^{2}\right\rangle_{j, s}, \tag{6.58}
\end{equation*}
$$

where the indices irrelevant for each particular term have been dropped. (As a reminder, the spin quantum number $s$ is fixed by particle's nature; for our case of an electron, $s=1 / 2$.) Now using the last of Eqs. (3.201), and similar expressions (5.192), (5.197), and (5.203), we get an explicit expression for the spin-orbit corrections ${ }^{17}$

$$
\begin{equation*}
E_{n, j, l}^{(1)}=\frac{1}{2 m_{e}^{2} c^{2}} \frac{Z e^{2}}{4 \pi \varepsilon_{0}} \frac{\hbar^{2}}{2 r_{0}^{3}} \frac{j(j+1)-l(l+1)-3 / 4}{n^{3} l(l+1 / 2)(l+1)}=\frac{E_{n}^{2}}{m_{e} c^{2}} n \frac{j(j+1)-l(l+1)-3 / 4}{l(l+1 / 2)(l+1)} . \tag{6.59}
\end{equation*}
$$

The last form of its right-hand part shows very clearly that this correction has the same scale as the kinetic correction (52), ${ }^{18}$ so that they should be considered together. In the first order of the perturbation they may be just added, giving a very simple formula for the net fine structure of level $n$ :

$$
\begin{equation*}
E_{\text {fine }}^{(1)}=\frac{E_{n}^{2}}{2 m_{e} c^{2}}\left(3-\frac{4 n}{j+1 / 2}\right) \tag{6.60}
\end{equation*}
$$

Fine structure of H-like atom's levels

This simplicity, as well as the independence of the result of the orbital quantum number $l$, will become less surprising when (in Sec. 9.7) we see that this formula follows in one shot from the Dirac theory, in which the Bohr atom's energy spectrum in numbered only with $n$ and $j$, but not $l$.

Let us recall (see Sec. 5.7) that for an electron ( $s=1 / 2$ ), the quantum number $j$ may take $n$ positive half-integer values, from $1 / 2$ to $n-1 / 2$. With the account of this fact, Eq. (60) shows that the fine structure of $n^{\text {th }}$ Bohr's energy level has $n$ sub-levels - see Fig. 6.

Fig. 6.6. Fine structure of a hydrogen-like atom's level.

[^644]Please note that according to Eq. (5.203), each of these sub-levels is still $(2 j+1)$-times degenerate in quantum number $m_{j}$. This degeneracy is very natural, because in the absence of external field the system is still isotropic. Moreover, on each fine-structure level, besides the lowest $(j=1 / 2)$ and the highest $(j=n-1 / 2)$ ones, each of the $m_{j}$-states is doubly-degenerate in the orbital quantum number $l=$ $j \mp 1 / 2$ - see the labels of $l$ in Fig. 6. (According to Eq. (5.215), each of these states, with fixed $j$ and $m_{j}$, may be represented as a linear combination of two states with adjacent values of $l$, and hence different electron spin orientations, $m_{s}= \pm 1 / 2$, weighed with the Clebsch-Gordan coefficients.)

These details aside, one may crudely say that the relativistic corrections make the total eigenenergy to grow with $l$, contributing to the effect already mentioned at our analysis of the periodic table of elements in Sec. 3.7. The relative scale of this increase may be evaluated from the largest deviation from the unperturbed energy $E_{n}$, reached for the state with $j=1 / 2($ and hence $l=0)$ :

$$
\begin{equation*}
\frac{\left|E_{\max }^{(1)}\right|}{E_{n}}=\frac{E_{n}}{m_{e} c^{2}}\left(2 n-\frac{3}{2}\right)=\left(\frac{Z e^{2}}{4 \pi \varepsilon_{0} \hbar c}\right)^{2}\left(\frac{1}{n}-\frac{3}{4 n^{2}}\right)=Z^{2} \alpha^{2}\left(\frac{1}{n}-\frac{3}{4 n^{2}}\right) . \tag{6.61}
\end{equation*}
$$

where $\alpha$ is the fine structure ("Sommerfeld") constant,

$$
\begin{equation*}
\alpha \equiv \frac{e^{2}}{4 \pi \varepsilon_{0} \hbar c} \approx \frac{1}{137}, \tag{6.62}
\end{equation*}
$$

that was already mentioned in Sec. 4.4. ${ }^{19}$ These expressions show that the fine structure is indeed a very small effect $\left(\sim \alpha^{2} \sim 10^{-6}\right.$ ) for the hydrogen atom, but it rapidly grows (as $Z^{2}$ ) with the nuclear charge (i.e. the atomic number) $Z$, and becomes rather substantial for the heaviest atoms with $Z \sim 100$.

### 6.4. The Zeeman effect

Now, we are ready to review the Zeeman effect - the lifting of atomic level degeneracy by an external magnetic field. ${ }^{20}$ Using Eq. (3.26) (with $q=-e$ ) for the description of electron's orbital motion in the field, and Eq. (4.116) for the operator of electron's magnetic moment due to its spin- $1 / 2$, we see that even for a hydrogen-like (i.e. single-electron) atom, neglecting the relativistic effects, the full Hamiltonian is rather bulky:

$$
\begin{equation*}
\hat{H}=\frac{1}{2 m_{e}}(\hat{\mathbf{p}}+e \hat{\mathbf{A}})^{2}-\frac{Z e^{2}}{4 \pi \varepsilon_{0} r}+\frac{e}{m_{e}} \boldsymbol{B} \cdot \hat{\mathbf{S}} . \tag{6.63}
\end{equation*}
$$

There are several simplifications we may make. First, let us assume that the external field is spatial-uniform on the atomic scale (which is a very good approximation for most cases), so that we can take the vector-potential in an axially-symmetric gauge - cf. Eq. (3.132):

[^645]\[

$$
\begin{equation*}
\mathbf{A}=\frac{1}{2} \boldsymbol{B} \times \mathbf{r} . \tag{6.64}
\end{equation*}
$$

\]

Second, let us neglect the terms proportional to $B^{2}$, which are small in practical magnetic fields of the order of a few Tesla. ${ }^{21}$ The remaining term in the effective kinetic energy, describing the interaction with the magnetic field, is linear in the momentum operator, so that we may repeat the standard classical calculation ${ }^{22}$ to reduce it to the product of $\mathcal{B}$ by the orbital magnetic moment's component $m_{z}=-$ $e L_{z} / 2 m_{e}$ - besides that both $m_{z}$ and $L_{z}$ should be understood as operators now. As a result, the Hamiltonian reduces to Eq. (1a), $\hat{H}^{(0)}+\hat{H}^{(1)}$, where $\hat{H}^{(0)}$ is that of the atom at $\mathcal{B}=0$, and

$$
\begin{equation*}
\hat{H}^{(1)}=\frac{e B}{2 m_{e}}\left(\hat{L}_{z}+2 \hat{S}_{z}\right) . \tag{6.65}
\end{equation*}
$$

The form of the perturbation immediately reveals the major complication with the Zeeman effect description. Namely, in comparison with its contribution (5.198) to the total angular momentum of the electron, its spin- $1 / 2$ produces a twice larger contribution into the magnetic moment, so that the righthand part of Eq. (65) is not proportional to the total angular moment. As a result, the effect description is simple only in two limits.

If the magnetic field is so high that its effects are much stronger than the relativistic (finestructure) effects discussed in the last section, we may treat two terms in Eq. (48) as independent perturbations of different (orbital and spin) degrees of freedom. Since in the $z$-basis each of the perturbation matrices is diagonal, we can again use Eq. (26):

$$
\begin{align*}
E-E^{(0)} & =\frac{e B}{2 m_{e}}\left(\left\langle n, l, m_{l}\right| \hat{L}_{z}\left|n, l, m_{l}\right\rangle+2\left\langle m_{s}\right| \hat{S}_{z}\left|m_{s}\right\rangle\right)=\frac{e B}{2 m_{e}}\left(\hbar m_{l}+2 \hbar m_{s}\right)  \tag{6.66}\\
& =\mu_{B} B\left(m_{l} \pm 1\right) .
\end{align*}
$$

This result describes splitting of each $2 \times(2 l+1)$-degenerate energy level, with certain $n$ and $l$, into ( $2 l$ +3 ) levels (Fig. 7), with the adjacent level splitting of $\mu_{\mathrm{B}} \mathcal{B}$, equal to $\sim 10^{-23} \mathrm{~J} \sim 10^{-4} \mathrm{eV} / \mathrm{T}$. Note that all levels, besides the top and bottom one, remain doubly degenerate. This limit of the Zeeman effect is sometimes called the Paschen-Back effect - which simplicity was recognized only in the 1920s, due to the need in very high magnetic fields for its observation.

Fig. 6.7. The Paschen-Back effect.

[^646]In the opposite limit of low magnetic field, the Zeeman effect takes place on the background of the fine structure splitting. As was discussed in Sec. 3, at $\mathcal{B}=0$ each split sub-level has a $2(2 l+1)$-fold degeneracy corresponding to $(2 l+1)$ different values of the half-integer quantum number $m_{j}$, ranging from $-j$ to $+j$, and 2 values of integer $l=j \mp 1 / 2$ - see Fig. 6. The magnetic field lifts this degeneracy. ${ }^{23}$ Indeed, in the coupled representation discussed in Sec. 5.7, perturbation (48) is described by the matrix with elements

$$
\begin{align*}
H^{(1)} & =\frac{e B}{2 m_{e}}\left\langle j, m_{j}\right| \hat{L}_{z}+2 \hat{S}_{z}\left|j^{\prime}, m_{j^{\prime}}\right\rangle=\frac{e B}{2 m_{e}}\left\langle j, m_{j}\right| \hat{J}_{z}+\hat{S}_{z}\left|j^{\prime}, m_{j^{\prime}}\right\rangle \\
& =\frac{e B}{2 m_{e}}\left(\hbar m_{j} \delta_{m_{j} m_{j^{\prime}}}+\left\langle j, m_{j}\right| \hat{S}_{z}\left|j^{\prime}, m_{j^{\prime}}\right\rangle\right) . \tag{6.67}
\end{align*}
$$

Now plugging into the last term the Clebsh-Gordan expansions (5.216a) for the bra- and ket-vectors, and taking into account that operator $\hat{S}_{z}$ gives non-zero bra-kets only for $m_{s}=m^{\prime}$, matrix (67) becomes diagonal, and may again use Eq. (26) to get

Anomalous
Zeeman
effect for $s=1 / 2$

$$
\begin{align*}
E-E^{(0)} & =\frac{e B}{2 m_{e}}\left[\hbar m_{j}+\frac{\hbar}{2} \frac{\left(l \pm m_{j}+1 / 2\right)}{2 l+1}-\frac{\hbar}{2} \frac{\left(l \mp m_{j}+1 / 2\right)}{2 l+1}\right]  \tag{6.68}\\
& =\frac{e B}{2 m_{e}} \hbar m_{j}\left(1 \pm \frac{1}{2 l+1}\right)=\mu_{\mathrm{B}} B m_{j}\left(1 \pm \frac{1}{2 l+1}\right), \quad \text { for }-j \leq m_{j} \leq+j
\end{align*}
$$

where two signs correspond to the two possible values of $l=j \mp 1 / 2-$ see Fig. 8 .

Fig. 6.8. Anomalous Zeeman effect in a hydrogen-like atom - schematically.

We see that the magnetic field splits each sub-level of the fine structure, with a given $l$, into $2 j+$ 1 levels, with the distance between the levels depending on l. In the end of the 1890 s, when the Zeeman effect was first observed, there was no notion of spin at all, so that this puzzling result was called the anomalous Zeeman effect. (In this terminology, the normal Zeeman effect is the one with no spin splitting, i.e. without the second terms in the parentheses of Eqs. (66)-(68); it may be observed experimentally in atoms with the net $\operatorname{spin} s=0$.)

[^647]The strict quantum-mechanical analysis of the anomalous Zeeman effect for arbitrary $s$ (which is important for applications to multi-electron atoms) is not that complex, but requires explicit expressions for the corresponding Clebsch-Gordan coefficients, which are rather bulky. Let me just cite the unexpectedly simple result of this analysis:

$$
\begin{equation*}
\Delta E=\mu_{\mathrm{B}} B m_{j} g, \tag{6.69}
\end{equation*}
$$

where $g$ is the so-called Lande factor: ${ }^{24}$

$$
\begin{equation*}
g=1+\frac{j(j+1)+s(s+1)-l(l+1)}{2 j(j+1)} \tag{6.70}
\end{equation*}
$$

For $s=1 / 2$ (and hence $j=l \pm 1 / 2$ ), this factor is reduced to the parentheses in the last form of Eq. (68).
It is remarkable that Eqs. (69)-(70) may be readily derived using very plausible classical arguments, similar to those used in Sec. 5.7-see Fig. 5.11 and its discussion. As we have seen above, in the absence of spin, the quantization of observable $L_{z}$ is an extension of the classical torque-induced precession of the corresponding vector (say, $\mathbf{L}$ ) about the magnetic field direction, so that the interaction energy, proportional to $B L_{z}=\boldsymbol{B} \cdot \mathbf{L}$, remains constant (Fig. 9a). At the spin-orbit interaction without external magnetic field, the Hamiltonian includes the operator of product $\mathbf{S} \cdot \mathbf{L}$, so that it has to be quantized, i.e. constant, together with $J^{2}, L^{2}$, and $S^{2}$. Hence, this system's classical image is a rapid precession of vectors $\mathbf{S}$ and $\mathbf{L}$ about the direction of vector $\mathbf{J}=\mathbf{L}+\mathbf{S}$, so that the spin-orbit interaction energy, proportional to product $\mathbf{L} \cdot \mathbf{S}$, remains constant (Fig. 9b). On this backdrop, the anomalous Zeeman effect in a relatively weak magnetic field $\boldsymbol{B}=\mathcal{B}_{\mathbf{z}}$ corresponds to a slow precession of vector $\mathbf{J}$ ("dragging" the rapidly rotating vectors $\mathbf{L}$ and $\mathbf{S}$ with it) about axis $z$.

Fig. 6.9. Classical images of (a) the orbital angular momentum's quantization in external magnetic field and (b) the fine-structure level splitting.

This picture allows us to conjecture that what is important for the slow precession rate are only the vectors $\mathbf{L}$ and $\mathbf{S}$ averaged over the period of the much faster precession about vector $\mathbf{J}$ - in other words, only their components $\mathbf{L}_{J}$ and $\mathbf{S}_{J}$ directed along vector $\mathbf{J}$. Classically, these components may be calculated as

$$
\begin{equation*}
\mathbf{L}_{J}=\frac{\mathbf{L} \cdot \mathbf{J}}{J^{2}} \mathbf{J}, \quad \mathbf{S}_{J}=\frac{\mathbf{S} \cdot \mathbf{J}}{J^{2}} \mathbf{J} \tag{6.71}
\end{equation*}
$$

The scalar products participating in these expressions may be readily expressed via the squared length of the vectors, using the following evident formulas:

[^648]\[

$$
\begin{equation*}
S^{2}=(\mathbf{J}-\mathbf{L})^{2}=J^{2}+L^{2}-2 \mathbf{L} \cdot \mathbf{J}, \quad L^{2}=(\mathbf{J}-\mathbf{S})^{2}=J^{2}+S^{2}-2 \mathbf{J} \cdot \mathbf{S} . \tag{6.72}
\end{equation*}
$$

\]

As a result, we get the following time average:

$$
\begin{align*}
\overline{L_{z}+2 S_{z}} & =\left(\mathbf{L}_{J}+2 \mathbf{S}_{J}\right)_{z}=\left(\frac{\mathbf{L} \cdot \mathbf{J}}{J^{2}} \mathbf{J}+2 \frac{\mathbf{S} \cdot \mathbf{J}}{J^{2}} \mathbf{J}\right)_{z}=\frac{J_{z}}{J^{2}}(\mathbf{L} \cdot \mathbf{J}+2 \mathbf{S} \cdot \mathbf{J}) \\
& =J_{z} \frac{\left(J^{2}+L^{2}-S^{2}\right)+2\left(J^{2}+S^{2}-L^{2}\right)}{2 J^{2}}=J_{z}\left(1+\frac{J^{2}+S^{2}-L^{2}}{2 J^{2}}\right) . \tag{6.73}
\end{align*}
$$

The last move is to smuggle in some quantum mechanics by using, instead of vector lengths squared, and the $z$-component of $J_{z}$, their eigenvalues given by Eqs. (5.197), (5.203), and (5.204). As a result, we immediately arrive at the exact result given by Eqs. (69)-(70). This coincidence encourages thinking about quantum mechanics of angular momenta in classical terms of torque-induced precession, and turns out to be very fruitful in more complex problems of atomic and molecular physics.

The high-field limit and low-field limits of the Zeeman effect, described respectively by Eqs. (66) and (68), are separated by a medium field strength range in which the Zeeman splitting is of the order of the fine-structure splitting analyzed in Sec. 3. There is no time in this course for a quantitative analysis of this crossover. ${ }^{25}$

### 6.5. Time-dependent perturbations

Now let us proceed to the case when perturbation $\hat{H}^{(1)}$ in Eq. (1a) is a function of time, while $\hat{H}^{(0)}$ is time-independent. The adequate perturbative approach to this problem, and its results, depend critically on the relation between the characteristic frequency (or the characteristic reciprocal time) $\omega$ of the perturbation and the distance between the initial system's energy levels:

$$
\begin{equation*}
\hbar \omega \leftrightarrow\left|E_{n}-E_{n^{\prime}}\right| . \tag{6.74}
\end{equation*}
$$

In the easiest case when all essential frequencies of a perturbation are very small in the sense of Eq. (74), we are dealing with the so-called adiabatic change of parameters, that may be treated essentially as a time-independent perturbation (see the previous sections of this chapter). The most interesting observation here is that the adiabatic perturbation does not allow any significant transfer of system's probability from one eigenstate to another. For example, in the WKB limit of the orbital motion, the Bohr-Sommerfeld quantization rule (2.110), and its multi-dimensional generalization, guarantee that integral

$$
\begin{equation*}
\oint_{C} \mathbf{p} \cdot d \mathbf{r}, \tag{6.75}
\end{equation*}
$$

taken along the particle's classical trajectory, is an adiabatic invariant, i.e. does not change at a slow change of system's parameters. (It is curious that classical mechanics also guarantees the invariance of integral (75), but its proof there ${ }^{26}$ is much harder than the quantum-mechanical derivation of this fact,

[^649]carried out in Sec. 2.4.) This is why even if the perturbation becomes large with time (while changing sufficiently slowly), we can expect the eigenstate and eigenvalue classification to persist.

Now let us proceed to the more important (and more complex) case when both sides of Eq. (74) are comparable, and use for its discussion the Schrödinger picture of quantum mechanics given by Eqs. (4.157) and (4.158). Combining these equations, we get the Schrödinger equation in the form

$$
\begin{equation*}
\left.i \hbar \frac{\partial}{\partial t}|\alpha(t)\rangle=\left(\hat{H}^{(0)}+H^{(1)}(t)\right) \alpha(t)\right\rangle . \tag{6.76}
\end{equation*}
$$

Very much in the spirit of our treatment of the time-independent case in Sec. 1, let us represent the timedependent ket-vector of the system with its expansion,

$$
\begin{equation*}
|\alpha(t)\rangle=\sum_{n}|n\rangle\langle n \mid \alpha(t)\rangle, \tag{6.77}
\end{equation*}
$$

over the full and orthonormal set of the unperturbed, stationary ket-vectors defined by equation

$$
\begin{equation*}
\hat{H}^{(0)}|n\rangle=E_{n}|n\rangle, \tag{6.78}
\end{equation*}
$$

where bra-kets $\langle n \mid \alpha(t)\rangle$ are time-dependent coefficients. Plugging expansion (77), with $n$ replaced with $n$ ', into both sides of Eq. (76), and then inner-multiplying both its parts by bra-vector $\langle n|$ of another unperturbed (and hence time-independent) state of the system, we get a set of linear, ordinary differential equations for the expansion coefficients:

$$
\begin{equation*}
i \hbar \frac{d}{d t}\langle n \mid \alpha(t)\rangle=E_{n}\langle n \mid \alpha(t)\rangle+\sum_{n^{\prime}} H_{n n^{\prime}}^{(1)}(t)\left\langle n^{\prime} \mid \alpha(t)\right\rangle, \tag{6.79}
\end{equation*}
$$

where the matrix elements of the perturbation in the unperturbed state basis, defined similarly to Eq. (7), are now functions of time:

$$
\begin{equation*}
H_{n n^{\prime}}^{(1)}(t) \equiv\langle n| \hat{H}^{(1)}(t)\left|n^{\prime}\right\rangle . \tag{6.80}
\end{equation*}
$$

The set of differential equations (79), which are still exact, may be useful for numerical calculations, because for virtually all practical problems the set of eigenstates $n$ ' may be restricted with an acceptable error in the final result. ${ }^{27}$ However, Eq. (79) has a certain technical inconvenience, which becomes clear if we consider its (evident) solution in the absence of perturbation: ${ }^{28}$

$$
\begin{equation*}
\langle n \mid \alpha(t)\rangle=\langle n \mid \alpha(0)\rangle \exp \left\{-i \frac{E_{n}}{\hbar} t\right\} . \tag{6.81}
\end{equation*}
$$

We see that the solution oscillates very fast, and its numerical modeling may present a challenge for even fastest computers. These spurious oscillations (whose frequency, in particular, depends of the energy reference level) may be partly tamed by looking for the general solution of Eqs. (79) in a form inspired by Eq. (81):

[^650]\[

$$
\begin{equation*}
\langle n \mid \alpha(t)\rangle \equiv a_{n}(t) \exp \left\{-i \frac{E_{n}}{\hbar} t\right\} . \tag{6.82}
\end{equation*}
$$

\]

Here $a_{n}(t)$ are new functions of time (essentially, the stationary states' probability amplitudes), which may be used, in particular, to calculate the time-dependent level occupancies, i.e. the probabilities $W_{n}$ to find the perturbed system on the corresponding energy levels of the unperturbed system:

$$
\begin{equation*}
W_{n}(t)=|\langle n \mid \alpha(t)\rangle|^{2}=\left|a_{n}(t)\right|^{2} \tag{6.83}
\end{equation*}
$$

Plugging Eq. (65) into Eq. (79), for these functions we readily get a slightly modified system of equations:

General equations probability amplitude evolution

$$
\begin{equation*}
i \hbar \dot{a}_{n}=\sum_{n^{\prime}} a_{n^{\prime}} H_{n n^{\prime}}^{(1)}(t) \exp \left\{i \frac{E_{n}-E_{n^{\prime}}}{\hbar} t\right\} \equiv \sum_{n^{\prime}} a_{n^{\prime}} H_{n n^{\prime}}^{(1)}(t) e^{i \omega_{n n^{\prime}} t} \tag{6.84}
\end{equation*}
$$

where factors $\omega_{n n^{\prime}}$, defined by relation

$$
\begin{equation*}
\hbar \omega_{n n^{\prime}} \equiv E_{n}-E_{n^{\prime}} \tag{6.85}
\end{equation*}
$$

have the physical sense of frequencies of potential quantum transitions between the $n$-th and $n$ '-th energy levels of the unperturbed system. (The conditions when such transitions indeed take place will be discussed later in this chapter.) An advantage of Eq. (84) over Eq. (79) for numerical calculations is the absence of any dependence on the energy reference selection, and lower frequencies of oscillations of the right hand part terms, especially when the energy levels of interest are close to each other.

In order to continue our analytical treatment, let us restrict ourselves to a particular but very important case of a sinusoidal perturbation turned on at some moment - for example, at $t=0$ :

Turning on sinusoidal perturbation

$$
\hat{H}^{(1)}(t)= \begin{cases}0, & \text { for } t<0  \tag{6.86}\\ \hat{A} e^{-i \omega t}+\hat{A}^{\dagger} e^{+i \omega t} & \text { for } t \geq 0\end{cases}
$$

where the perturbation amplitude operators $\hat{A}$ and $\hat{A}^{\dagger}$, and hence their matrix elements,

$$
\begin{equation*}
\langle n| \hat{A}\left|n^{\prime}\right\rangle \equiv A_{n n^{\prime}}, \quad\langle n| \hat{A}^{\dagger}\left|n^{\prime}\right\rangle=A_{n^{\prime} n}^{*}, \tag{6.87}
\end{equation*}
$$

are time-independent. ${ }^{29}$ In this case, for $t>0$, Eq. (84) yields

$$
\begin{equation*}
i \hbar \dot{a}_{n}=\sum_{n^{\prime}} a_{n^{\prime}}\left[A_{n n^{\prime}} e^{i\left(\omega_{n n^{\prime}}-\omega\right) t}+A_{n^{\prime} n}^{*} e^{i\left(\omega_{n n^{\prime}}+\omega\right) t}\right] . \tag{6.88}
\end{equation*}
$$

This is, generally, still a complex system of coupled differential equations; however, it allows simple and explicit solutions in two very important cases. First, let us assume that our system is initially in one eigenstate $n$ ' (say, on the ground energy level), and that the occupancies $W_{n}$ of all other levels stays very low all the time. (We will find the corresponding condition a posteriori - from the solution.) With the corresponding assumption

[^651]\[

$$
\begin{equation*}
a_{n^{\prime}}=1 ; \quad\left|a_{n}\right| \ll 1, \quad \text { for } n \neq n^{\prime}, \tag{6.89}
\end{equation*}
$$

\]

Eq. (88) may be readily integrated, giving

$$
\begin{equation*}
a_{n}=-\frac{A_{n n^{\prime}}}{\hbar\left(\omega_{n n^{\prime}}-\omega\right)}\left[e^{i\left(\omega_{n n^{\prime}}-\omega\right) t}-1\right]-\frac{A_{n^{\prime} n}^{*}}{\hbar\left(\omega_{n n^{\prime}}+\omega\right)}\left[e^{i\left(\omega_{n n^{\prime}}+\omega\right) t}-1\right], \quad \text { for } n \neq n^{\prime} \tag{6.90}
\end{equation*}
$$

We see that the probability $W_{n}$ (83) of finding the system on each energy level of the system oscillates in time, and that our assumption (89) is satisfied as soon as the excitation amplitude is not too large, ${ }^{30}$

$$
\begin{equation*}
\left|A_{n n^{\prime}}\right| \ll \hbar\left|\omega \pm \omega_{n n^{\prime}}\right| . \tag{6.91}
\end{equation*}
$$

Expression (90) also shows that this phenomenon has a clearly resonant character: the maximum occupancy $W_{n}$ of a level grows infinitely when the corresponding detuning, ${ }^{31}$

$$
\begin{equation*}
\Delta_{n n^{\prime}} \equiv \omega-\omega_{n n^{\prime}}, \tag{6.92}
\end{equation*}
$$

tends to zero. In this limit, our initial assumption (89) may become a liability; in order to overcome it we may perform the following trick - very similar to the one we used for transfer to the degenerate case in Sec. 1. Let us assume that for a certain level $n$,

$$
\begin{equation*}
\left|\Delta_{n n^{\prime}}\right| \ll \omega,\left|\omega \pm \omega_{n^{\prime \prime} n}\right|, \mid \omega \pm \omega_{n^{\prime \prime} n^{\prime}}, \quad \text { for all } n^{\prime \prime} \neq n, n^{\prime} \tag{6.93}
\end{equation*}
$$

- the condition illustrated in Fig. 10. Then, according to Eq. (90), we may ignore the occupancy of all but two levels, $n$ and $n^{\prime}$, and also the second, non-resonant terms with frequency $\omega_{n n^{\prime}}+\omega \approx 2 \omega \gg\left|\Delta_{n n^{\prime}}\right|$ in Eqs. (88) written for $a_{n}$ and $a_{n},{ }^{32}$

Fig. 6.10. Resonant excitation of one of the higher energy levels.

As a result, in this two-level approximation (that is of course not an approximation at all for twolevel systems, such as spin- $1 / 2$ - see Sec. 5.1 ), we get a simple system of two linear equations:

$$
\begin{align*}
& i \hbar \dot{a}_{n}=a_{n^{\prime}} A e^{-i \Delta t} \\
& i \hbar \dot{a}_{n^{\prime}}=a_{n} A^{*} e^{+i \Delta t} \tag{6.94}
\end{align*}
$$

[^652]where I have used shorthand notation $A \equiv A_{n n}$, and $\Delta \equiv \Delta_{n n}$, - and will use it for a while - until other energy levels become involved (in the beginning of the next section). This system of linear differential equations may be solved exactly by the introduction of a new variable (for one of the levels only!)
\[

$$
\begin{equation*}
b_{n} \equiv a_{n} e^{+i \Delta t} \tag{6.95}
\end{equation*}
$$

\]

According to this formula,

$$
\begin{equation*}
a_{n}=b_{n} e^{-i \Delta t}, \quad \dot{a}_{n}=\left(\dot{b}_{n}-i \Delta b_{n}\right) e^{-i \Delta t} \tag{6.96}
\end{equation*}
$$

Plugging these relations into Eq. (94), we see that both equations of the system loose their explicit time dependence:

$$
\begin{equation*}
i \hbar\left(\dot{b}_{n}-i \Delta b_{n}\right)=a_{n^{\prime}} A, \quad i \hbar \dot{a}_{n^{\prime}}=b_{n} A^{*} \tag{6.97}
\end{equation*}
$$

and now may be readily solved by regular methods. For example, we may differentiate the first equation, and then use the second one to eliminate variable $a_{n}$ :

$$
\begin{equation*}
i \hbar\left(\ddot{b}_{n}-i \Delta \dot{b}_{n}\right)=\dot{a}_{n^{\prime}} A=\frac{b_{n} A^{*}}{i \hbar} A=b_{n} \frac{|A|^{2}}{i \hbar} . \tag{6.98}
\end{equation*}
$$

From mathematics we know that the resulting linear, second-order differential equation, with time-independent coefficients, has the following general solution,

$$
\begin{equation*}
b_{n}(t)=b_{+} e^{\lambda_{+} t}+b_{-} e^{\lambda_{-} t} \tag{6.99}
\end{equation*}
$$

whose characteristic exponents $\lambda$ may be readily found by plugging any of the exponential functions into Eq. (98). In our case, both roots of the resulting characteristic equation,

$$
\begin{equation*}
\lambda^{2}-i \Delta \lambda+\frac{|A|^{2}}{\hbar^{2}}=0 \tag{6.100}
\end{equation*}
$$

are purely imaginary: $\lambda_{ \pm}=i(\Delta / 2 \pm \Omega)$, where

$$
\begin{equation*}
\Omega \equiv\left(\frac{\Delta^{2}}{4}+\frac{|A|^{2}}{\hbar^{2}}\right)^{1 / 2} \tag{6.101}
\end{equation*}
$$

The coefficients $b_{ \pm}$are determined by initial conditions. If, as before, the system was completely on level $n^{\prime}$ initially, i.e. $a_{n^{\prime}}(0)=1, a_{n}(0)=b_{n}(0)=0$; then Eq. (99) immediately yields $b_{-}=-b_{+}$, so that

$$
\begin{equation*}
b_{n}(t)=2 i b_{+} e^{i \Delta t / 2} \sin \Omega t, \quad a_{n}(t)=2 i b_{+} e^{-i \Delta t / 2} \sin \Omega t, \quad \dot{a}_{n}(0)=2 i b_{+} \Omega \tag{6.102}
\end{equation*}
$$

Now the coefficient $b_{+}$may be readily found from the comparison of the last equality in Eq. (102) with the first of Eqs. (94), taken for $t=0$, when $a_{n},=1$. This comparison yields $2 i b_{+} \Omega=A / i \hbar$, and hence

$$
\begin{equation*}
a_{n}(t)=-\frac{A}{\hbar \Omega} e^{-i \Delta t / 2} \sin \Omega t, \tag{6.103}
\end{equation*}
$$

so that the $n^{\text {th }}$ level occupancy is

$$
\begin{equation*}
W_{n}=\left|a_{n}\right|^{2}=\frac{|A|^{2}}{\hbar^{2} \Omega^{2}} \sin ^{2} \Omega t=\frac{|A|^{2}}{|A|^{2}+(\hbar \Delta / 2)^{2}} \sin ^{2} \Omega t \tag{6.104}
\end{equation*}
$$

This is the famous Rabi formula. ${ }^{33}$ It shows that an increase of the perturbation amplitude $|A|$ leads not only to an increase of the amplitude of the probability oscillations, but also of their frequency $2 \Omega$ described by Eq. (101) - see Fig. 11.

Fig. 6.11. Rabi oscillations.

Ultimately, at $|A| \gg \hbar|\Delta|$ (for example, at the exact resonance, $\Delta=0$ ) Eqs. (101)-(102) give $\Omega=$ $|A| / \hbar$ and $\left(W_{n}\right)_{\max }=1$, i.e. describe a periodic, full "repumping" of the system from one level to another and back, with a frequency proportional to the perturbation amplitude. This effect gives a very convenient tool for manipulating two-level-systems (qubits, in the quantum information context). For example, limiting the external excitation time to $\Delta t=\pi / 2 \Omega$ (or an odd number of such intervals) we may completely transfer the system from one eigenstate (say, $\downarrow$ ) to the opposite one ( $\uparrow$ ). ${ }^{34}$ On the Bloch sphere (Fig. 5.1), this transfer corresponds to the representing point's drive from the South Pole to the North Pole.

Note, however, that according to Eq. (90), if the system has energy levels other than $n$ and $n$ ', they also become occupied to some extent. Since the sum of occupancies should be 1 , this means that $\left(W_{n}\right)_{\text {max }}$ may approach 1 only if the excitation amplitude is very small, and hence the state switching time $\Delta t=\pi / 2 \Omega=\pi \hbar / 2|A|$ is very long. The ultimate limit in this sense is provided by the harmonic oscillator where all energy levels are equidistant, and probability repumping between all of them occurs with the same rate. Hence, in that particular system, the implementation of the full Rabi oscillations is impossible even at the exact resonance. ${ }^{35}$ In the opposite limit, when the detuning is large in comparison with $|A| / \hbar$, though still small in the sense of Eq. (93), the frequency of Rabi oscillations is completely determined by the detuning, and their amplitude is small:

[^653]\[

$$
\begin{equation*}
W_{n}(t)=4 \frac{|A|^{2}}{\hbar^{2} \Delta^{2}} \sin ^{2} \frac{\Delta t}{2} \ll 1, \text { for }|A|^{2} \ll(\hbar \Delta)^{2} \tag{6.105}
\end{equation*}
$$

\]

However, I would not like these quantitative details to obscure from the reader the most important qualitative (OK, maybe semi-quantitative :-) conclusion of this section's analysis: the resonant increase of interlevel transition intensity at $\omega \rightarrow \omega_{n n}$. Using the fundamental Kramer-Kronig dispersion relations, ${ }^{36}$ based essentially only on very general causality arguments, it is easy to show (and hence left for reader's exercise) that in a medium incorporating many similar quantum systems (e.g., atoms or molecules), this increase of quantum transitions is accompanied by a sharp increase of external field's absorption. This effect has numerous practical applications including systems based on the electron paramagnetic resonance (EPR) and nuclear magnetic resonance (NMR) spectroscopies, which are broadly used in material science, chemistry, and medicine. Unfortunately, I will not have time to discuss the related technical issues (in particular, interesting pulsing spectroscopy techniques) in detail, and have to refer the reader to special literature. ${ }^{37}$

### 6.6. Quantum-mechanical Golden Rule

The last result of the past section, Eq. (105), may be used to derive one of the most important results of quantum mechanics - its so-called Golden Rule. For that, let us consider the case when the perturbation causes quantum transitions from a discrete energy level $E_{n}$, into a group of eigenstates $E_{n}$ with a dense (virtually continuous) spectrum - see Fig. 12a. If, for all states $n$ of the group, the following conditions are satisfied

$$
\begin{equation*}
\left|A_{n n^{\prime}}\right|^{2} \ll\left(\hbar \Delta_{n n^{\prime}}\right)^{2} \ll\left(\hbar \omega_{n n^{\prime}}\right)^{2}, \tag{6.106}
\end{equation*}
$$

then Eq. (105) coincides with the result that would follow from Eq. (90). This means that we may apply Eq. (105), with indices $n$ and $n$ ' duly restored, to any level $n$ of our tight group. As a result, the total probability of having our system transferred from level $n$ ' to that group is

$$
\begin{equation*}
W_{\Sigma}(t)=\sum_{n} W_{n}(t)=\frac{4}{\hbar^{2}} \sum_{n} \frac{\left|A_{n n^{\prime}}\right|^{2}}{\Delta_{n n^{\prime}}^{2}} \sin ^{2} \frac{\Delta_{n n^{\prime}} t}{2} . \tag{6.107}
\end{equation*}
$$

(b)

Fig. 6.12. Deriving the Golden Rule: (a) the energy level scheme, and (b) the function under integral (108).

[^654]Now comes the main, absolutely beautiful trick: let us assume that the summation over $n$ will be limited to a tight group of very similar states for which the matrix elements $A_{n n}$, are virtually similar (we will check the validity of this assumption later on), so that we can take it out of the sum (107) and then replace the sum with the corresponding integral:

$$
\begin{equation*}
W_{\Sigma}(t)=\frac{4\left|A_{n n^{\prime}}\right|^{2}}{\hbar^{2}} \int \frac{1}{\Delta_{n n^{\prime}}^{2}} \sin ^{2} \frac{\Delta_{n n^{\prime}} t}{2} d n=\frac{4\left|A_{n n^{\prime}}\right|^{2} \rho_{n} t}{\hbar} \int \frac{1}{\left(\Delta_{n n^{\prime}} t\right)^{2}} \sin ^{2}\left(\frac{\Delta_{n n^{\prime}} t}{2}\right) d\left(-\Delta_{n n^{\prime}} t\right), \tag{6.108}
\end{equation*}
$$

where $\rho_{n}$ is the density of eigenstates $n$ on the energy axis:

$$
\begin{equation*}
\rho_{n} \equiv \frac{d n}{d E_{n}} \tag{6.109}
\end{equation*}
$$

This density, as well as the matrix element $A_{n n^{\prime}}$, have to be evaluated at $\Delta_{n n^{\prime}}=0$, i.e. at energy $E_{n}=E_{n},+$ $\hbar \omega$, and are assumed to be constant within the final state group. At fixed $E_{n^{\prime}}$, the function under integral (108) is even and decreases fast at $\left|\Delta_{n n}, t\right| \gg 1$ - see Fig. 12b. Hence we may introduce a dimensionless integration variable $\xi \equiv \Delta_{n n}$ t, and extend integration over this variable formally from $-\infty$ to $+\infty$. Then Eq. (108) is reduced to a table integral, ${ }^{38}$ and yields

$$
\begin{equation*}
W_{\Sigma}(t)=\frac{4\left|A_{n n^{\prime}}\right|^{2} \rho_{n}}{\hbar} \int_{-\infty}^{+\infty} \frac{1}{\xi^{2}} \sin ^{2} \frac{\xi}{2} d \xi=\frac{4\left|A_{n n^{\prime}}\right|^{2} \rho_{n} t}{\hbar} \frac{\pi}{2} \equiv \Gamma t \tag{6.110}
\end{equation*}
$$

where constant

$$
\begin{equation*}
\Gamma=\frac{2 \pi}{\hbar}\left|A_{n n^{\prime}}\right|^{2} \rho_{n} \tag{6.111}
\end{equation*}
$$

Density
of states
is the called the transition rate. ${ }^{39}$
This is one of the most famous and useful results of quantum mechanics, its Golden Rule (sometimes, rather unfairly, called the "Fermi Golden Rule" ${ }^{40}$ ), which deserves much discussion. First of all, let us reproduce the reasoning already used in Sec. 2.5 to show that the meaning of rate $\Gamma$ is much deeper than Eq. (110) seems to imply. Indeed, due to the conservation of the total probability, $W_{n},+W_{\Sigma}$ $=1$, we can rewrite that equation as

$$
\begin{equation*}
\left.\dot{W}_{n^{\prime}}\right|_{t=0}=-\Gamma . \tag{6.112}
\end{equation*}
$$

Evidently, this result cannot be true for $t \rightarrow \infty$, otherwise probability $W_{n}$, would become negative. The reason for that apparent contradiction is that result (110) was obtained in the assumption that initially the system was completely on level $n^{\prime}: W_{n^{\prime}}(0)=1$. Now, if in the initial moment the value of $W_{n^{\prime}}$, is
${ }^{38}$ See, e.g., MA Eq. (6.12).
${ }^{39}$ In some texts, the density of states in Eq. (111) is replaced with expression $\sum_{n} \delta\left(E_{n}-E_{n^{\prime}}-\hbar \omega\right)$. Indeed, the integration of this expression over any final energy interval $\Delta E_{n}$ gives the same result $\Delta n=\left(d n / d E_{n}\right) \Delta E_{n}=\rho_{n} \Delta E_{n}$ as Eq. (111). Such replacement may be useful in some cases, but should be used with utmost care, and for most applications the more explicit form (111) is preferable.
${ }^{40}$ Actually, this result was developed mostly by the same P. A. M. Dirac in 1927; E. Fermi's role was not much more than advertising it, under the name of "Golden Rule No. 2", in his lecture notes on nuclear physics, which were published much later, in 1950. (To be fair to Fermi, he has never tried to pose as the Golden Rule's author.)
different, result (110) has to be multiplied by that number, due to the linear relation (88) between $d a_{n} / d t$ and $a_{n}$. Hence, instead of Eq. (112) we get a differential equation similar to Eq. (2.159),

$$
\begin{equation*}
\dot{W}_{n^{\prime}}=-\Gamma W_{n^{\prime}}, \tag{6.113}
\end{equation*}
$$

Initial state's occupancy decay
which, for time-independent $\Gamma$, has the evident solution,

$$
\begin{equation*}
W_{n^{\prime}}(t)=W_{n^{\prime}}(0) e^{-\Gamma t} \tag{6.114}
\end{equation*}
$$

describing an exponential decay of the initial state's occupancy, with time constant $\tau=1 / \Gamma$.
I would ask the reader to think again about this fascinating mathematical result: by summation of periodic oscillations (105) over many levels $n$, we have got an exponential evolution (114) of the probability. The main trick here is of course that the effective range $\Delta E$ of states $E_{n}$, giving the dominating contribution into integral (108), shrinks with time: $\Delta E_{n} \sim \hbar / t .{ }^{41}$ By the way, since most of the decay takes place at times $t \sim \tau \equiv 1 / \Gamma$, the range of participating final energies may be estimated as

$$
\begin{equation*}
\Delta E_{n} \sim \frac{\hbar}{\tau}=\hbar \Gamma . \tag{6.115}
\end{equation*}
$$

This estimate is very instrumental for the formulation of conditions of validity of the Golden Rule (111). First, we have assumed that the matrix elements of the perturbation and the density of states do not depend on energy within interval (115). This gives the following requirement

$$
\begin{equation*}
\Delta E_{n} \sim \hbar \Gamma \ll E_{n}-E_{n^{\prime}} \sim \hbar \omega, \tag{6.116}
\end{equation*}
$$

Second, for the transfer from sum (107) to integral (108), we need the number of states within that energy interval, $\Delta N_{n}=\rho_{n} \Delta E_{n}$, to be much larger than 1. Merging Eq. (116) with Eq. (93) for all energy levels $n " \neq n, n$ ' not participating in the resonant transfer, we may summarize all conditions of the Golden Rule validity as

Golden
Rule's validity

$$
\begin{equation*}
\rho_{n}^{-1} \ll \hbar \Gamma \ll \hbar\left|\omega \pm \omega_{n^{\prime} n^{\prime \prime}}\right| \tag{6.117}
\end{equation*}
$$

(The reader may ask whether I have forgotten the condition expressed by the first of Eqs. (106). However, for $\Delta_{n n}, \sim \Delta E_{n} / \hbar \sim \Gamma$, this condition is just $\left|A_{n n}\right|^{2} \ll(\hbar \Gamma)^{2}$, so that plugging it into Eq. (111),

$$
\begin{equation*}
\Gamma \ll \frac{2 \pi}{\hbar}(\hbar \Gamma)^{2} \rho_{n}, \tag{6.118}
\end{equation*}
$$

and canceling one $\Gamma$ and one $\hbar$, we see that this requirement coincides with the left relation in Eq. (117) above.)

Let us have a look at whether these conditions may be satisfied in practice, at least in some cases. For example, let us consider the optical ionization of an atom, with the released electron confined in a volume of the order of $1 \mathrm{~cm}^{3}=10^{-6} \mathrm{~m}^{3}$. According to Eq. (1.82), with $E$ of the order of the atomic ionization energy $E_{n}-E_{m}=\hbar \omega \sim 1 \mathrm{eV}$, the density of electron states in that volume is of the order of $10^{17} 1 / \mathrm{eV}$. Thus conditions (117) provide an approximately 15 -orders-of magnitude range for acceptable

[^655]values of $\hbar \Gamma$. This illustration should give the reader a taste of why the Golden Rules is applicable to so many situations.

Finally, the physical picture of initial state's decay (which will also be the key for our discussion of quantum mechanics of "open" systems in the next chapter) is also very important. According to Eq. (114), the external excitation transfers the system onto the continuous spectrum of levels $n$, and it never comes back on the initial level $n$ '. However, it was derived from quantum mechanics of Hamiltonian systems, whose equations are invariant with respect to time reversal. This paradox is a result of the generalization (113) of the exact result (112), that breaks the time reversal symmetry, but is absolutely adequate for the physics under study. Some gut feeling of the physical sense of this irreversibility may be obtained from the following observation. From our wave-mechanics experience, we know that the distance between adjacent orbital energy levels tends to zero only if the system size goes to infinity. This means that the assumption of continuous energy spectrum of final states $n$ essentially requires these states to be infinitely extended in space - essentially being free de Broglie waves. The Golden Rule approach corresponds to the (physically justified) assumption that in an infinitely large system the traveling waves excited by a local source and propagating outward from it, would never come back, and even if they do, the unpredictable phase shifts introduced by the uncontrollable perturbations on their way would never allow them to sum up in the way necessary to bring the system back into the initial state $n^{\prime}$. ${ }^{42}$

Maybe the best illustration of this interpretation is given by the following problem - which is a toy model of the photoelectric effect that was briefly discussed in Sec. 1.1(iii). A 1D particle is initially trapped in the ground state of a narrow quantum well,

$$
\begin{equation*}
U(x)=-w \delta(x) \tag{6.119}
\end{equation*}
$$

Let us use the Golden Rule to find rate $\Gamma$ of particle's "ionization" (i.e. its excitation into an extended, delocalized state) by a weak classical sinusoidal force of amplitude $F_{0}$ and frequency $\omega$. As a reminder, finding the initial, localized state ( $n$ ') of such particle was the task of Problem 2.14, and its solution was

$$
\begin{equation*}
\psi_{n^{\prime}}(x)=\kappa^{1 / 2} \exp \{-\kappa|x|\}, \quad \kappa \equiv \frac{m w}{\hbar^{2}}, \quad E_{n^{\prime}}=-\frac{\hbar^{2} \kappa^{2}}{2 m}=-\frac{m w^{2}}{2 \hbar^{2}} . \tag{6.120}
\end{equation*}
$$

Extended states $n$ with continuous spectrum, for this problem exist only at energies $E_{n}>0$, so that the excitation rate is different from zero only for frequencies

$$
\begin{equation*}
\omega>\omega_{t} \equiv \frac{\left|E_{n^{\prime}}\right|}{\hbar}=\frac{m w^{2}}{2 \hbar^{3}} . \tag{6.121}
\end{equation*}
$$

The weak sinusoidal force may be described by the following perturbation Hamiltonian,

$$
\begin{equation*}
\hat{H}^{(1)}=-F(t) \hat{x}=-F_{0} \hat{x} \cos \omega t=-\frac{F_{0}}{2} \hat{x}\left(e^{i \omega t}+e^{-i \omega t}\right), \quad \text { for } t>0, \tag{6.122}
\end{equation*}
$$

so that according to Eq. (86), that serves as the amplitude operator definition, in this case

[^656]\[

$$
\begin{equation*}
\hat{A}=\hat{A}^{\dagger}=-\frac{F_{0}}{2} \hat{x} . \tag{6.123}
\end{equation*}
$$

\]

Now the matrix elements $A_{n n}$, that participate in Eq. (111) may be calculated in the coordinate representation:

$$
\begin{equation*}
A_{n n^{\prime}}=\int_{-\infty}^{+\infty} \psi_{n}^{*}(x) \hat{A}(x) \psi_{n^{\prime}}(x) d x=-\frac{F_{0}}{2} \int_{-\infty}^{+\infty} \psi_{n}^{*}(x) x \psi_{n^{\prime}}(x) d x \tag{6.124}
\end{equation*}
$$

Since, according to Eq. (120), the initial $\psi_{n}$, is a symmetric function of $x$, a nonvanishing contribution to this integral is given only by asymmetric functions $\psi_{n}(x)$, proportional to $\sin k_{n} x$, with wavenumber $k_{n}$ related to the final energy by the well-familiar equality (1.77):

$$
\begin{equation*}
\frac{\hbar^{2} k_{n}^{2}}{2 m}=E_{n} . \tag{6.125}
\end{equation*}
$$

As we know from Sec. 2.5 (see in particular Eq. (2.124) and its discussion), such asymmetric functions, with $\psi_{n}(0)=0$, are not affected by the zero-centered delta-functional potential (119), and their density $\rho_{n}$ is the same as in a completely free space, and we can use Eq. (1.94). (Actually, since that relation was derived for traveling waves, it is more prudent to repeat the calculation that has led to that result, confining the waves on an artificial segment $[-l / 2,+l / 2]$ - so long,

$$
\begin{equation*}
k_{n} l, k l \gg 1, \tag{6.126}
\end{equation*}
$$

that it does not affect the initial localized state and the excitation process. Then the confinement requirement $\psi_{n}( \pm l / 2)=0$ immediately yields the condition $k_{n} l / 2=n \pi$, so that Eq. (1.94) is indeed valid, but only for positive values of $k_{n}$, because $\sin k_{n} X$ with $k_{n} \rightarrow-k_{n}$ does not give an independent standingwave eigenstate.) Hence the final state density is

$$
\begin{equation*}
\rho_{n} \equiv \frac{d n}{d E_{n}}=\frac{d n}{d k_{n}} / \frac{d E_{n}}{d k_{n}}=\frac{l}{2 \pi} / \frac{\hbar^{2} k_{n}}{m}=\frac{l m}{2 \pi \hbar^{2} k_{n}} . \tag{6.127}
\end{equation*}
$$

It may look troubling that the density of states depends on artificial segment's length $l$, but the same $l$ also participates in the final wavefunction normalization factor, ${ }^{43}$

$$
\begin{equation*}
\psi_{n}=\left(\frac{2}{l}\right)^{1 / 2} \sin k_{n} x \tag{6.128}
\end{equation*}
$$

and hence the matrix element (124):

$$
\begin{equation*}
A_{n n^{\prime}}=-\frac{F_{0}}{2}\left(\frac{2 \kappa}{l}\right)^{1 / 2} \int_{-l}^{+l} \sin k_{n} x e^{-\kappa|x|} x d x .=-\frac{F_{0}}{2 i}\left(\frac{2 \kappa}{l}\right)^{1 / 2}\left(\int_{0}^{l} e^{\left(i k_{n}-\kappa\right) x} x d x-\int_{0}^{l} e^{-\left(i k_{n}+\kappa\right) x} x d x\right) \tag{6.129}
\end{equation*}
$$

These two integrals may be readily worked out by parts. Taking into account that, according to condition (126), their upper limits may be extended to $\infty$, the result is

[^657]\[

$$
\begin{equation*}
A_{n n^{\prime}}=-\left(\frac{2 \kappa}{l}\right)^{1 / 2} F_{0} \frac{2 k_{n} \kappa}{\left(k_{n}^{2}+\kappa^{2}\right)^{2}} \tag{6.130}
\end{equation*}
$$

\]

so that finally we get an expression for the rate, which is independent of the artificially introduced $l$ :

$$
\begin{equation*}
\Gamma=\frac{2 \pi}{\hbar}\left|A_{n n^{\prime}}\right|^{2} \rho_{n}=\frac{2 \pi}{\hbar}\left[\left(\frac{2 \kappa}{l}\right)^{1 / 2} F_{0} \frac{2 k_{n} \kappa}{\left(k_{n}^{2}+\kappa^{2}\right)^{2}}\right]^{2} \frac{l m}{2 \pi \hbar^{2} k_{n}}=\frac{8 F_{0}^{2} m k_{n} \kappa^{3}}{\hbar^{3}\left(k_{n}^{2}+\kappa^{2}\right)^{4}} \tag{6.131}
\end{equation*}
$$

Note that due to the above definitions of $k_{n}$ and $\kappa$, the expression in parentheses in the denominator of the last formula does not depend on the quantum well parameter $W$, and is a function of only the excitation frequency $\omega$ (and particle's mass):

$$
\begin{equation*}
\frac{\hbar^{2}\left(k_{n}^{2}+\kappa^{2}\right)}{2 m}=E_{n}-E_{n^{\prime}}=\hbar \omega . \tag{6.132}
\end{equation*}
$$

As a result, Eq. (131) may be recast simply as

$$
\begin{equation*}
\hbar \Gamma=\frac{F_{0}^{2} w^{3} k_{n}}{2(\hbar \omega)^{4}} . \tag{6.133}
\end{equation*}
$$

What is still hidden here is that $k_{n}$, defined by to Eq. (125) with $E_{n}=E_{n},+\hbar \omega$, is a function of frequency, changing as $\omega^{1 / 2}$ at $\omega \gg \omega_{t}$ (so that $\Gamma$ drops as $\omega^{-7 / 2}$ at $\omega \rightarrow \infty$ ), and as $\left(\omega-\omega_{t}\right)^{1 / 2}$ when $\omega$ approaches the "red boundary" $\omega_{t} \equiv\left|E_{n}\right| / \hbar=m \omega^{2} / 2 \hbar^{3}$ of the ionization effect, so that $\Gamma \propto\left(\omega-\omega_{t}\right)^{1 / 2} \rightarrow$ 0 in that limit as well. We see that our toy model does describe this main feature of the photoelectric effect, whose explanation by Einstein was essentially the starting point of quantum mechanics - see Sec. 1.1. The (very similar) analysis of this effect in a more realistic model, the hydrogen atom's ionization, is left for reader's exercise.

### 6.7. Golden Rule for step-like perturbations

Now let us reuse some of our results for a perturbation being turned on at $t=0$, but after that time-independent:

$$
\hat{H}^{(1)}(t)= \begin{cases}0, & t<0  \tag{6.134}\\ \hat{H}^{(1)}=\text { const }, & t \geq 0\end{cases}
$$

A superficial comparison of this equation and our former Eq. (69) seems to indicate that we may use all our previous results, taking $\omega=0$. However, that conclusion does not take into account the fact that analyzing both the two-level approximation and the Golden Rule for continuous spectrum, we have neglected the second (non-resonant) term in Eq. (90). This why it is more prudent to use the general Eq. (86),

$$
\begin{equation*}
i \hbar \dot{a}_{n}=\sum_{n^{\prime}} a_{n^{\prime}} \cdot H_{n n^{\prime}}^{(1)} e^{i \omega_{n n^{\prime}} t} \tag{6.135}
\end{equation*}
$$

in which the matrix element of the perturbation is now time-independent. We see that it is formally equivalent to Eq. (88) with only the first (resonant) term kept, if we make the following replacements:

Step-like perturbation

$$
\begin{equation*}
\hat{A} \rightarrow \hat{H}^{(1)}, \quad \Delta_{n n^{\prime}} \equiv \omega-\omega_{n n^{\prime}} \rightarrow-\omega_{n n^{\prime}} . \tag{6.136}
\end{equation*}
$$

As a sanity check, let us revisit a two-level system such as two quantum wells coupled by tunneling - see Fig. 13a. It is convenient to include the energy difference $E_{n}-E_{n}$, between the two levels into the unperturbed Hamiltonian, so that perturbation (134) describes only the localized state coupling due to tunneling through the energy barrier separating the wells. (The turning on of the coupling, described by Eq. (134), may be achieved, for example, by a rapid lowering of the barrier at $t=0$.) Then, after replacements (136), we are getting an analog of Eq. (104):

$$
\begin{equation*}
W_{n}=\left|a_{n}\right|^{2}=\frac{\left|H_{n n^{\prime}}^{(1)}\right|^{2}}{\hbar^{2} \Omega^{2}} \sin ^{2} \Omega t, \tag{6.137}
\end{equation*}
$$

where frequency $\Omega$ of the periodic "probability repumping" between levels $n$ ' and $n$ is now described, instead of Eq. (104), by relation

$$
\begin{equation*}
2 \Omega=\left(\omega_{n n^{\prime}}^{2}+4 \frac{\left|H_{n n^{\prime}}^{(1)}\right|^{2}}{\hbar^{2}}\right)^{1 / 2}=\frac{1}{\hbar}\left[\left(E_{n}-E_{n^{\prime}}\right)^{2}+4 H_{n n^{\prime}}^{(1)} H_{n^{\prime} n}^{(1)}\right]^{1 / 2} . \tag{6.138}
\end{equation*}
$$

But these are exactly the quantum oscillations that have already been discussed in Sec. 2.6 - now derived for an arbitrary quantum wells and tunnel barrier shape.
(a)
(b)

Fig. 6.13. Quantum-well implementation of coupling of a discrete-energy state $n$ ' to (a) another discrete-energy state, and (b) a state continuum, due to tunneling through a potential barrier.

The similarity of Eqs. (104) and (137) shows that the Rabi oscillations and the "usual" quantum oscillations have essentially the same physical nature, besides that in the former case the external rf signal quantum $\hbar \omega$ bridges over the state energy difference. We may also compare result (138) with our analysis of a two-level system, with a similar time-independent perturbation, in Sec. 1. According to Eq. (29), its eigenenergies differ by

$$
\begin{equation*}
E_{+}-E_{-}=\left[\left(H_{11}-H_{22}\right)^{2}+4 H_{12} H_{21}\right]^{1 / 2} . \tag{6.139}
\end{equation*}
$$

But this is exactly the result given by Eq. (138), provided that we consider $\left(H_{11}-H_{22}\right)$ as the difference ( $E_{n}-E_{n}$ ) of unperturbed state energies rather than as a perturbation, as we certainly have a right to do.

Now let us consider the effect of perturbation (134) in the case when it creates coupling between the initial (discrete) energy level and a dense group of states with a quasi-continuum spectrum, in the same energy range. Figure 13 b shows an example of such a system: a quantum well separated by a
penetrable tunnel barrier from an extended region with a quasi-continuous energy spectrum. Making replacements (136) in Eq. (111), we may present the Golden Rule for this case as

$$
\begin{equation*}
\Gamma=\frac{2 \pi}{\hbar}\left|H_{n n^{\prime}}^{(1)}\right|^{2} \rho_{n}, \tag{6.140}
\end{equation*}
$$

where states $n$ and $n$ ' now have the same energy. ${ }^{44}$
It is very informative to compare this result with Eq. (138) for a symmetric ( $E_{n}=E_{n^{\prime}}$ ) double quantum well using the same tunnel barrier - see Fig. 13. For the latter case, Eq. (138) yields

$$
\begin{equation*}
\Omega=\frac{1}{\hbar}\left|H_{n n^{\prime}}^{(1)}\right|_{\text {con }} . \tag{6.141}
\end{equation*}
$$

Here I have used index "con" (from "confinement") to emphasize that this matrix element is rather different from the one participating in Eq. (140). Indeed, in the latter case, the matrix element,

$$
\begin{equation*}
H_{n n^{\prime}}^{(1)}=\langle n| \hat{H}^{(1)}\left|n^{\prime}\right\rangle=\int \psi_{n^{\prime}}^{*} \hat{H}^{(1)} \psi_{n} d x, \tag{6.142}
\end{equation*}
$$

has to be calculated for two similar wavefunctions $\psi_{n}$ and $\psi_{n}$, confined to spatial intervals of the same scale $l_{\text {con }}$, while in Eq. (140), wavefunctions $\psi_{n}$ are extended to a much larger distance $l \gg l_{\text {con }}-$ see Fig. 13. As Eq. (129) tells us, in the 1D model we are considering now, this means an additional factor small factor of the order of $\left(l_{\text {con }} / l\right)^{1 / 2}$. Now using Eq. (128) as a crude but suitable model for the finalstate wavefunctions, we arrive at the following estimate:

$$
\begin{equation*}
\hbar \Gamma \sim 2 \pi\left|H_{n n^{\prime}}^{(1)}\right|_{\text {con }}^{2} \frac{l_{\text {con }}}{l} \rho_{n} \sim 2 \pi\left|H_{n n^{\prime}}^{(1)}\right|_{\text {con }}^{2} \frac{l_{\text {con }}}{l} \frac{l m}{2 \pi \hbar^{2} k_{n}} \sim \frac{\left|H_{n n^{\prime}}^{(1)}\right|_{\text {con }}^{2}}{\Delta E_{n^{\prime}}}=\frac{(\hbar \Omega)^{2}}{\Delta E_{n^{\prime}}} \tag{6.143}
\end{equation*}
$$

where $\Delta E_{n}, \sim \hbar^{2} / m l^{2}$ con is the scale of the differences between eigenenergies of the particle in an unperturbed quantum well. Since the condition of validity of the perturbative formula (140) is $\hbar \Omega \ll$ $\Delta E_{n}$, we see that ${ }^{45}$

$$
\begin{equation*}
\hbar \Gamma \sim \frac{\hbar \Omega}{\Delta E_{m}} \hbar \Omega \ll \hbar \Omega . \tag{6.144}
\end{equation*}
$$

Hence the rate of (irreversible) quantum tunneling into continuum is always much lower that the frequency of (reversible) quantum oscillations between states separated with the same potential barrier at least for the case when both are much lower than $\Delta E_{n^{\prime}} / \hbar$, so that the perturbation theory is valid. A handwaving interpretation of this result is that the confined particle wonders beyond the barrier and back many times before finally "deciding" to perform an irreversible transition into unconfined continuum. ${ }^{46}$

[^658]Let me conclude this section (and this chapter) with the application of Eq. (140) to an important case, which will provide us with a smooth transition to the next chapter's topics. Consider a composite system consisting of two parts, $a$ and $b$, with the energy spectra sketched in Fig. 14.

Fig. 6.14. Energy relaxation in system $a$ due to its coupling with system $b$ (which serves as the environment of $a$ ).

Let the systems be completely independent initially. The independence means that in the absence of perturbation, the total Hamiltonian of the system at $t<0$ may be presented as a sum

$$
\begin{equation*}
\hat{H}^{(0)}=\hat{H}_{a}(a)+\hat{H}_{b}(b), \tag{6.145}
\end{equation*}
$$

where arguments $a$ and $b$ symbolize the non-overlapping sets of variables of the two systems. Then eigenkets of the system may be naturally factored as ${ }^{47}$

$$
\begin{equation*}
|n\rangle=\left|n_{a}\right\rangle \otimes\left|n_{b}\right\rangle \tag{6.146}
\end{equation*}
$$

while its eigenenergies separate into a sum, just as the Hamiltonian (145) does:

$$
\begin{align*}
\hat{H}^{(0)}|n\rangle & \left.=\left(\hat{H}_{a}+\hat{H}_{b}\right) n_{a}\right\rangle \otimes\left|n_{b}\right\rangle=\left(\hat{H}_{a}\left|n_{a}\right\rangle\right) \otimes\left|n_{b}\right\rangle+\left(\hat{H}_{b}\left|n_{b}\right\rangle\right) \otimes\left|n_{a}\right\rangle  \tag{6.147}\\
& =\left(E_{n a}\left|n_{a}\right\rangle\right) \otimes\left|n_{b}\right\rangle+\left(E_{n b}\left|n_{b}\right\rangle\right) \otimes\left|n_{a}\right\rangle=\left(E_{n a}+E_{n b}\right)|n\rangle .
\end{align*}
$$

Analysis of such a composite system is much easier when the interaction of its components may be presented as a product of two Hermitian operators, each depending only on the degrees of freedom of only one component system:

$$
\begin{equation*}
\hat{H}^{(1)}=\hat{A}(a) \hat{B}(b) . \tag{6.148}
\end{equation*}
$$

A typical example of such a bilinear interaction Hamiltonian is the electric-dipole interaction between an atomic-scale electron system (with a size of the order of the Bohr radius $r_{\mathrm{B}} \sim 10^{-10} \mathrm{~m}$ ) and the electromagnetic field at optical frequencies $\omega \sim 10^{16} \mathrm{~s}^{-1}$, with wavelength $\lambda=2 \pi c / \omega \sim 10^{-6} \mathrm{~m} \gg r_{\mathrm{B}}$ : ${ }^{48}$

$$
\begin{equation*}
\hat{H}^{(1)}=-\hat{\mathbf{d}} \cdot \hat{\boldsymbol{\varepsilon}}, \quad \text { with } \hat{\mathbf{d}} \equiv \sum_{k} q_{k} \hat{\mathbf{r}}_{k}, \tag{6.149}
\end{equation*}
$$

where the dipole electric moment $\mathbf{d}$ depends only on positions $\mathbf{r}_{k}$ of charged particles (numbered with index $k$ ), while that of electric field $\varepsilon$ is a function of only the electromagnetic field's degrees of freedom - see Chapter 9 below.

[^659]Returning to the general situation shown in Fig. 14, if the component system $a$ was initially in an excited state $n^{\prime}{ }_{a}$, interaction (148) may bring it to another discrete state $n_{a}$ of a lower energy - for example, the ground state. In the process of this transition, the released energy, in the form of energy quantum

$$
\begin{equation*}
\hbar \omega \equiv E_{n^{\prime} a}-E_{n a}, \tag{6.150}
\end{equation*}
$$

is picked up by system $b$ :

$$
\begin{equation*}
E_{n b}-E_{n^{\prime} b}=\hbar \omega . \tag{6.151}
\end{equation*}
$$

(In typical applications, though not always, the initial state $n_{b}$ of that system is its ground state.) If the final state $n_{b}$ of the system is inside a state group with quasi-continuous energy spectrum (Fig. 14), the process has the exponential character (114) ${ }^{49}$ and may be interpreted as the effect of energy relaxation of system $a$, with the released energy quantum $\hbar \omega$ absorbed by system $b$. Note that since the quasicontinuous spectrum essentially requires a system of large spatial size, such model is very convenient for description of the environment of system $a$. (In physics, the "environment" typically means all the Universe less the system under consideration.)

The relaxation rate $\Gamma$ may be described by the Golden Rule. Since perturbation (148) does not depend on time explicitly, and the total energy of the composite system does not change, we may use Eq. (140) that, with the account of Eqs. (146) and (148), takes the form

$$
\begin{equation*}
\Gamma=\frac{2 \pi}{\hbar}\left|A_{n n^{\prime}}\right|^{2}\left|B_{n n^{\prime}}\right|^{2} \rho_{n}, \quad \text { where } A_{n n^{\prime}} \equiv\left\langle n_{a}\right| \hat{A}\left|n_{a}^{\prime}\right\rangle, B_{n n^{\prime}}=\left\langle n_{b}\right| \hat{B}\left|n_{b}^{\prime}\right\rangle, \tag{6.152}
\end{equation*}
$$

with $\rho_{n}$ being the density of the final states of system $b$, at the relevant energy $E_{n b}=E_{n^{\prime} b}+\hbar \omega=E_{n^{\prime} b}+$ $\left(E_{n}{ }^{\prime} a-E_{n a}\right)$. In particular, Eq. (152), with the dipole Hamiltonian (149), enables a very simple calculation of the natural linewidth of atomic electric dipole transitions. However, such calculation has to be postponed until Chapter 9 in which we will discuss the electromagnetic field quantization - i.e., the exact nature of states $n_{b}$ and $n^{\prime} b$ for this problem. Instead, I will proceed to a discussion of the effects of interaction of quantum systems with their environment, toward which the situation shown in Fig. 14 provides a clear path.

### 6.8. Exercise problems

6.1. Use Eq. (13) to prove the Hellmann-Feynman theorem: ${ }^{50}$

$$
\frac{\partial E_{n}}{\partial \lambda}=\langle n| \frac{\partial \hat{H}}{\partial \lambda}|n\rangle,
$$

where $\lambda$ is an arbitrary $c$-number parameter.
6.2. Analyze the relation between Eq. (15) and the results of classical analysis ${ }^{51}$ of a similar anharmonic ("nonlinear") oscillator.

[^660]6.3. A weak additional force $F$ is applied to a 1D particle that was placed into a hard-wall quantum well with
\[

U(x)= $$
\begin{cases}0, & \text { for } 0<x<a \\ +\infty, & \text { otherwise }\end{cases}
$$
\]

Calculate, sketch, and discuss the first-order perturbation of its ground-state wavefunction.
6.4. A 2 D quantum particle is confined in a square-shaped quantum well with infinitely high walls and slightly skewed floor:

$$
U=\left\{\begin{array}{lr}
\mu x y, & \text { for } 0<x<L \text { and } 0<y<L \\
+\infty, & \text { otherwise } .
\end{array}\right.
$$

In the first order in the small parameter $\mu$, find energies of the ground state and the lowest excited state of the system. Formulate the conditions of validity of your result.

Hint: To save reader's time on a straightforward but longish integration by parts, I can offer the following integral:

$$
\int_{0}^{1} \sin (\pi \xi) \sin (2 \pi \xi) \xi d \xi=-\frac{8}{9 \pi^{2}}
$$

6.5. Calculate the lowest-order relativistic correction to the ground-state energy of a 1D harmonic oscillator.
6.6. A 1 D particle of mass $m$ is localized at a narrow potential well which may be approximated with a delta-function:

$$
U(x)=-w \delta(x), \quad \text { with } w>0
$$

Calculate the change of its ground state energy by an additional weak, time-independent force $F$, in the first nonvanishing approximation of the perturbation theory. Discuss the limits of validity of this result, taking into account that at $F \neq 0$, the localized state of the particle is metastable.
6.7. Use the perturbation theory results to calculate the eigenvalues of the observable $L^{2}$, in the limit $l \approx|m| \gg 1$, by purely wave-mechanical means.

Hint: Try the following substitution: $\Theta(\theta)=f(\theta) / \sin ^{1 / 2} \theta$.
6.8. In the first nonvanishing order of the perturbation theory, calculate the shift of the groundstate energy of an electrically charged spherical rotator (i.e. a particle of mass $m$, free to move over a spherical surface of radius $R$ ) due to a weak, uniform, time-independent electric field $\boldsymbol{\varepsilon}$.
6.9. Use the perturbation theory to evaluate the effect of a constant electric field $\mathbf{E}$ on the ground state energy $E_{g}$ of a hydrogen atom. In particular:

[^661](i) calculate the $1^{\text {stt }}$-order shift of $E_{g}$,
(ii) bring the expression for the $2^{\text {nd }}$-order shift (neglecting the extended unperturbed states with $E$ $>0$ ) to the simplest possible analytical form,
(iii) find the lower and upper bounds on the result, and
(iv) discuss the simplest manifestations of the shift (called the quadratic Stark effect).
6.10.* A particle of mass $m$, with electric charge $q$, is in its ground $s$-state with known energy $E_{g}$ $<0$, being localized by a very short-range, spherically-symmetric potential well. Calculate its electric polarizability $\alpha$.
6.11. In the first nonvanishing order of the perturbation theory, calculate the correction to energies of the ground state and all lowest excited states of a hydrogen-like atom/ion, due to electron's penetration into its nucleus, modeling it as a spinless, uniformly charged sphere of radius $R \ll r_{\mathrm{B}} / Z$.
6.12. A spin $-1 / 2$ particle is placed into a magnetic field
$$
\boldsymbol{B}=\mathcal{B}_{z} \mathbf{n}_{z}+\mathcal{B}_{x} \mathbf{n}_{x}, \quad \text { with }\left|\mathcal{B}_{x}\right| \ll\left|\mathcal{B}_{z}\right| .
$$

Calculate its energy levels:
(i) exactly, and
(ii) in the first nonvanishing order of the perturbation theory in small $B_{x}$.

Compare the results of the two approaches.
6.13. Use the perturbation theory to analyze the orbital diamagnetism. Namely, calculate the magnetic susceptibility $\chi_{m}$ of a dilute gas due to the orbital motion of a single electron confined inside each gas particle.

Hint: You may like to use the well-known formula for the magnetic energy $u$ per unit volume of a linear medium:

$$
u=\mathcal{B}^{2} / 2 \mu
$$

where $\mathcal{B}$ is the applied magnetic field, and $\mu$ is the magnetic permeability, related to the susceptibility as $\mu \equiv \mu_{0}\left(1+\chi_{m}\right) .{ }^{52}$
6.14. ${ }^{*}$ Analyze the statistics of the spacing $S \equiv E_{+}-E$. between energy levels of a two-level system, assuming that all elements $H_{j j}$, of its Hamiltonian matrix (6.27) are independent random numbers, with equal and constant probability densities within the energy interval of interest. Compare the result with that for a purely diagonal matrix, with the similar probability distribution of the diagonal elements.
6.15. Discuss how to calculate the energy level degeneracy lifting in the second order of the perturbation theory, assuming that it is not lifted in the first order. Carry out such a calculation for a plane rotator of mass $m$ and radius $R$, carrying electric charge $q$, and placed into a weak, uniform, constant electric field $\varepsilon$.

[^662]6.16. Use the single-particle approximation to find the complex dielectric constant $\varepsilon(\omega)$ of a dilute gas of similar atoms, due to their induced electric polarization by a weak external ac field, for a field frequency $\omega$ very close to one of quantum transition frequencies $\omega_{n n}$, defined by Eq. (85).

Hint: In the single-particle approximation, atom's response to an external field is described as that of $Z$ similar, non-interacting electrons moving in an effective static attracting potential - generally induced not only by the nuclei but also by other electrons.
6.17. Use the solution of the previous problem to generalize the expression for the London dispersion force between two electroneutral molecules (whose calculation in the harmonic oscillator model was the subject of Problems 3.18 and 5.11) to the single-particle model with an arbitrary energy spectrum.
6.18. Use the solution of the previous problem to express the potential energy of interaction of two hydrogen atoms, both in their ground state and separated by distance $r \gg r_{\mathrm{B}}$, in the simplest analytical form, and use the result to estimate the energy.
6.19. In a certain quantum system, distances between three lowest energy levels are slightly different - see Fig. on the right $\left(|\xi| \ll \omega_{1,2}\right)$. Find the time necessary to populate the first excited level almost completely (with a given precision $\varepsilon \ll 1$ ), using the Rabi oscillation effect, if at $t=0$ the system is completely in its ground state.

Hint: Assume that all matrix elements of the perturbation Hamiltonian
 are known, and are all proportional to the external rf field amplitude.
6.20. A weak external force pulse $F(t)$, of a finite time duration, is applied to a 1 D harmonic oscillator that initially was in its ground state.
(i) Calculate, in the lowest nonvanishing order of the perturbation theory, the probability that the pulse drives the oscillator into an excited state.
(ii) Formulate the condition of validity of the result, and compare it with the exact solution of the problem.
(iii) Spell out the perturbative result for a Gaussian-shaped waveform,

$$
F(t)=F_{0} \exp \left\{-t^{2} / \tau^{2}\right\}
$$

and analyze its dependence on the effective duration $\tau$ of the pulse.
6.21. A charged plane rotator, initially in its ground state, is placed into a spatially-uniform, but time-dependent external field $\boldsymbol{\mathcal { E }}(t)$, applied at $t=0$.
(i) Calculate, in the lowest nonvanishing order in field's strength, the probability that the pulse drives the rotator oscillator into its $n^{\text {th }}$ excited state.
(ii) Spell out and analyze your results for a rotating field.
(iii) Same for an ac field with fixed polarization.
6.22 .
(i) Develop the general theory of excitations of the higher levels of a discrete-spectrum system, initially in the ground state, by a weak time-dependent perturbation, up to the $2^{\text {nd }}$ order.
(ii) Apply the theory to the system analyzed in the previous problem (a plane rotator driven by a time-dependent electric field) to find out what excitations, forbidden in the $1^{\text {st }}$ order of the perturbation theory, are allowed in its $2^{\text {nd }}$ order.
6.23. A heavy, relativistic particle, with the electric charge $q=Z e$, passes by a hydrogen atom, initially in its ground state, with the impact parameter (shortest distance) $b$ within the limits $r_{\mathrm{B}} \ll b \ll$ $r_{\mathrm{B}} / \alpha$, where $\alpha \approx 1 / 137$ is the fine structure constant. Calculate the probability of atom's transition to its lowest excited states.
6.24. ${ }^{*}$ A particle of mass $m$ is initially in the localized ground state, with the known energy $E_{g}<$ 0 , of a very small, spherically-symmetric potential well. Calculate the rate of its delocalization ("ionization") by an applied force $\mathbf{F}(t)=\mathbf{n}_{F} F_{0} \cos \omega t$, with a time-independent orientation $\mathbf{n}_{F}$, and discuss its dependence on frequency $\omega$.
6.25.* Calculate the rate of ionization of a hydrogen atom, initially in its ground state, by a classical, linearly polarized electromagnetic wave with electric field's amplitude $\varepsilon_{0}$, and frequency $\omega$ within the range

$$
\frac{\hbar}{m_{e} r_{\mathrm{B}}^{2}} \ll \omega \ll \frac{c}{r_{\mathrm{B}}},
$$

where $r_{\mathrm{B}}$ is the Bohr radius. Recast your result in terms of the cross-section of this electromagnetic wave absorption process. Discuss semi-quantitatively what changes would be necessary in the theory if either of the above conditions had been violated.
6.26. For the system of two weakly coupled quantum wells (see Fig. 13a), write the system of differential equations for the probability amplitudes $a_{n}$ defined by Eq. (2.199), and in particular prove Eqs. (2.201) - which were just guessed in Sec. 2.7.
6.27.* Use the quantum-mechanical Golden Rule to derive the general expression for the electric current $I$ through a weak tunnel junction between two conductors, biased with dc voltage $V$, treating the conduction electrons as a Fermi gas, in which the electron-electron interaction is limited to the Pauli exclusion principle. Simplify the result in the low-voltage limit.

Hint: The electric current flowing through a weak tunnel junction is so low that its perturbation of the electron states inside each conductor is negligible.
6.28. ${ }^{*}$ Generalize the result of the previous problem to the case when a weak tunnel junction is biased with voltage $V(t)=\bar{V}+A \cos \omega t$, with $\hbar \omega$ generally comparable with $e|\bar{V}|$ and $e A$.
6.29.* Use the quantum-mechanical Golden Rule to derive the Landau-Zener formula (2.266).
6.30. Calculate, in the $2^{\text {nd }}$ order of the perturbation theory, the rate $\Gamma$ of transitions between different states of a continuous group (of virtually the same energy $E_{n}$ ), induced by a monochromatic perturbation of frequency $\omega$, with $\hbar \omega$ comparable to the distances between other, discrete levels of the system.

## Chapter 7. Open Quantum Systems

This chapter discusses the effects of interaction of a quantum system with its environment, and in particular, with the instruments used for measurements. Some part of this material is on the fine line between quantum mechanics and (quantum) statistical physics. Here I will only cover those aspects of this field which are of key importance for the basic goals of this course, in particular for the discussion of quantum measurements in the end of the chapter. ${ }^{1}$

### 7.1. Open systems and the density matrix

All the way until the very end of the previous chapter, we have discussed quantum systems isolated from their environment. Indeed, from the very beginning we have assumed that we are dealing with the statistical ensembles of systems as similar to each other as only allowed by laws of quantum mechanics. Each member of such an ensemble, called pure or coherent, may be described by the same quantum state $\alpha$ - in the wave mechanics case, by the same wavefunction $\Psi_{\alpha}$. Even our discussion of the Golden Rule in the end of the last chapter, in particular its form in which one component system (in Fig. 6.13, system $b$ ) may be used as a model of the environment of another component ( $a$ ), was still based on the assumption of a pure initial state (6.146) of the system. Since the interaction of two component systems was described by a certain Hamiltonian (the one given by Eq. (6.145) for example), for the state $\alpha$ of the system as a whole at arbitrary instant we might write

$$
\begin{equation*}
|\alpha\rangle=\sum_{n} \alpha_{n}|n\rangle=\sum_{n} \alpha_{n}\left|n_{a}\right\rangle \otimes\left|n_{b}\right\rangle, \tag{7.1}
\end{equation*}
$$

with a unique correspondence between eigenstates states $n_{a}$ and $n_{b}$.
However, in many important cases our knowledge of quantum system's state is incomplete. This is especially unavoidable ${ }^{2}$ when a relatively simple quantum system $s$ of our interest (say, an electron or an atom) is in a contact with environment $e$ - here understood in a most general sense, say, as all the whole Universe less system $s-$ see Fig. 1. Then there is virtually no chance of making two or more experiments with exactly the same composite system, because it would imply a repeated preparation of the whole environment (including the experimenter :-) in a certain quantum state - a rather challenging task, to put it mildly. In this case, it makes much more sense to consider a statistical ensemble of another kind, with random quantum states of the environment, though possibly with known macroscopic parameters (e.g., temperature, pressure, etc.).

In classical physics, such mixed ensembles are the subject of statistical (classical) mechanics. ${ }^{3}$ Let us see how they may be described in quantum mechanics. For the beginning, we need to assume

[^663]again that the coupling between the system of interest and its environment is weak in the sense accepted in the perturbation theory. ${ }^{4}$ In this case we can still use the bra- and ket-vectors of unperturbed states, that depend on different sets of variables (again, "belonging to different Hilbert spaces"). Then the most general quantum state of the whole Universe, still assumed to be pure, ${ }^{5}$ may be described as the following linear superposition:
\[

$$
\begin{equation*}
|\alpha\rangle=\sum_{j, k} \alpha_{j k}\left|s_{j}\right\rangle \otimes\left|e_{k}\right\rangle . \tag{7.2}
\end{equation*}
$$

\]

Assumed quantum state of Universe

The "only" difference between the description of such an entangled state and the superposition of separable states, described by Eq. (1), is that coefficients $\alpha_{j k}$ in the right-hand part of Eq. (2) are numbered with two indices: index $j$ listing the quantum states of system $s$, and $k$ numbering the (enormously large) set of quantum states of the environment. So, in a mixed ensemble a certain state $s_{j}$ of the system of interest may coexist with different states of its environment. ${ }^{6}$ Of course, the enormity of the Hilbert space of the environment, i.e. the number of $k$-components in sum (2), strips us of any opportunity to make direct calculations using that sum. For example, according to the basic Eq. (4.125), in order to find the expectation value of an arbitrary observable $A$ in state (2), we would need to calculate

$$
\begin{equation*}
\langle A\rangle=\langle\alpha| \hat{A}|\alpha\rangle=\sum_{\substack{i, j^{\prime} \\ k, k^{\prime}}} \alpha_{j k}^{*} \alpha_{j^{\prime} k^{\prime}}\left\langle e_{k}\right| \otimes\left\langle s_{j}\right| \hat{A}\left|s_{j^{\prime}}\right\rangle \otimes\left|e_{k^{\prime}}\right\rangle \tag{7.3}
\end{equation*}
$$

Even if we assume that $\{s\}$ and $\{e\}$ are sets of the basis states of, respectively, the system and the environment, and that each is full and orthonormal, Eq. (3) still includes a double sum over the enormous basis state set of the environment!

However, let us consider a limited but the most important subset of operators - those of intrinsic observables, which depend only on the degrees of freedom of the system of interest $(s)$. These operators commute do not act on environment's degrees of freedom, and hence in Eq. (3) we may move the environment bra-vector $\left\langle e_{k}\right|$ over all the way to ket-vector $\left|e_{k^{\prime}}\right\rangle$. Assuming, again, that the set of environmental eigenstates is full and orthonormal, Eq. (3) is now reduced to

[^664]\[

$$
\begin{equation*}
\langle A\rangle=\sum_{\substack{j, j^{\prime} \\ k, k^{\prime}}} \alpha_{j k}^{*} \alpha_{j k^{\prime}}\left\langle s_{j}\right| \hat{A}\left|s_{j^{\prime}}\right\rangle\left\langle e_{k} \mid e_{k^{\prime}}\right\rangle=\sum_{i j^{\prime}} A_{j j^{\prime}} \sum_{k} \alpha_{j k}^{*} \alpha_{j^{\prime} k} . \tag{7.4}
\end{equation*}
$$

\]

This is already some relief, because we have "only" a single sum over $k$, but the main trick 7 is still ahead. After the summation over $k$, the second sum in the last form of Eq. (4) is some function $w$ of indices $j$ and $j$ ', so that, according to Eq. (4.96), this relation may be presented as

Expectation value of intrinsic observable

$$
\begin{equation*}
\langle A\rangle=\sum_{i j j^{\prime}} A_{i j j^{\prime}} w_{j^{\prime} j}=\operatorname{Tr}(\mathrm{Aw}) \tag{7.5}
\end{equation*}
$$

where matrix w , with elements

Density matrix: definition

$$
\begin{equation*}
w_{j^{\prime} j} \equiv \sum_{k} \alpha_{j k}^{*} \alpha_{j^{\prime} k}, \quad \text { i.e. } w_{j j^{\prime}} \equiv \sum_{k} \alpha_{j k} \alpha_{j^{\prime} k}^{*} \tag{7.6}
\end{equation*}
$$

is called the density matrix of the system. Most importantly, Eq. (5) shows that the knowledge of this matrix allows the calculation of the expectation value of any intrinsic observable $A$ (and, according to Eqs. (1.33)-(1.34), its r.m.s. fluctuation as well if necessary), even for the very general statistical ensemble of states (2). This is why let us have a very good look at the density matrix.

First of all, as we know very well by now that the expansion coefficients in superpositions of the type (2) may be always expressed as bra-kets; in our current case, we may write

$$
\begin{equation*}
\alpha_{j k}=\left\langle e_{k}\right| \otimes\left\langle s_{j} \| \alpha\right\rangle \tag{7.7}
\end{equation*}
$$

Plugging this expression into Eq. (6), we get

$$
\begin{equation*}
w_{j j^{\prime}}=\sum_{k} \alpha_{j k} \alpha_{j^{\prime k}}^{*}=\left\langle s_{j}\right| \otimes\left(\sum_{k}\left\langle e_{k} \mid \alpha\right\rangle\left\langle\alpha \mid e_{k}\right\rangle\right) \otimes\left|s_{j^{\prime}}\right\rangle=\left\langle s_{j}\right| \hat{w}\left|s_{j^{\prime}}\right\rangle . \tag{7.8}
\end{equation*}
$$

We see that from the point of our system (i.e. in its Hilbert space whose basis states may be numbered by indices $j$ only), the density matrix is indeed just the matrix of some construct, ${ }^{8}$

Statistical operator: definition

$$
\begin{equation*}
\hat{w} \equiv \sum_{k}\left\langle e_{k} \mid \alpha\right\rangle\left\langle\alpha \mid e_{k}\right\rangle, \tag{7.9}
\end{equation*}
$$

that is called the statistical (or "density") operator. As evident from its definition (9), in contrast to the density matrix this operator does not depend on the choice of a particular basis $s_{j}$ - just as all previous operators considered in this course, but in contrast to them, the statistical operator does depend on composite system's state $\alpha$, including the state of system $s$ as well. However, in the $j$-space it is mathematically still an operator whose matrix elements obey all formulas of the bra-ket formalism.

In particular, due to its definition (6), the density operator is Hermitian:

$$
\begin{equation*}
w_{i j^{\prime}}^{*}=\sum_{k} \alpha_{j k}^{*} \alpha_{j^{\prime} k}=\sum_{k} \alpha_{j^{\prime} k} \alpha_{j k}^{*}=w_{j j^{\prime}} \tag{7.10}
\end{equation*}
$$

[^665]so that according to the general analysis of Sec. 4.3, there should be a certain basis $\{w\}$ in which the matrix of this operator is diagonal:
\[

$$
\begin{equation*}
\left.w_{i j^{\prime}}\right|_{\text {in } w}=w_{j} \delta_{j j^{\prime}} . \tag{7.11}
\end{equation*}
$$

\]

Since any operator, in any basis may be presented in form (4.59), in basis $\{w\}$ we may write

$$
\begin{equation*}
\hat{w}=\sum_{j}\left|w_{j}\right\rangle w_{j}\left\langle w_{j}\right| . \tag{7.12}
\end{equation*}
$$

Statistical operator in diagonalizing
basis

This expression reminds, but is not equivalent to Eq. (4.44) for the identity operator, that has been used so many times in this course, and in the basis $w_{j}$ has the form

$$
\begin{equation*}
\hat{I}=\sum_{j}\left|w_{j}\right\rangle\left\langle w_{j}\right| . \tag{7.13}
\end{equation*}
$$

In order to comprehend the meaning of coefficients $w_{j}$ participating in Eq. (12), let us use Eq. (5) to calculate the expectation value of any observable $A$ whose eigenstates coincide with those of the special basis set $\{w\}$ :

$$
\begin{equation*}
\langle A\rangle=\operatorname{Tr}(\mathrm{Aw})=\sum_{i j j^{\prime}} A_{i j^{\prime}} w_{j} \delta_{i j^{\prime}}=\sum_{j} A_{j} w_{j} \tag{7.14}
\end{equation*}
$$

Expectation value of $w_{j}$-compatible variable
where $A_{j}$ is just the expectation value of observable $A$ in state $w_{j}$. Hence, in order to comply with the general Eq. (1.37), real $c$-numbers $w_{j}$ must have the physical sense of probabilities $W_{j}$ of finding the system in state $j$. As the result, we can rewrite Eq. (12) in the form

$$
\begin{equation*}
\hat{w}=\sum_{j}\left|w_{j}\right\rangle W_{j}\left\langle w_{j}\right| . \tag{7.15}
\end{equation*}
$$

In one ultimate case when only one of probabilities (say, $W_{j^{\prime \prime}}$ ) is different from zero,

$$
\begin{equation*}
W_{j}=\delta_{j j^{\prime \prime}}, \tag{7.16}
\end{equation*}
$$

the system is evidently in a coherent (pure) state $w_{j^{\prime \prime}}$. Indeed, it is fully described by one ket-vector $\left|w_{j^{\prime \prime}}\right\rangle$, and we can use the general rule (4.86) to present it in another (arbitrary) basis $\{s\}$ as a coherent superposition

$$
\begin{equation*}
\left|w_{j^{\prime \prime}}\right\rangle=\sum_{j^{\prime}}\left(U^{\dagger}\right)_{j j^{\prime}}\left|s_{j^{\prime}}\right\rangle=\sum_{j^{\prime}} U_{i j^{\prime}}^{*}\left|s_{j^{\prime}}\right\rangle, \tag{7.17}
\end{equation*}
$$

where U is the unitary matrix of transform from basis $\{w\}$ to basis $\{s\}$. According to Eqs. (11) and (16), in such a pure state the density matrix is diagonal in the $\{w\}$ basis,

$$
\begin{equation*}
\left.w_{i j^{\prime}}\right|_{\text {in } w}=\delta_{j, j^{\prime \prime}} \delta_{j^{\prime}, j^{\prime \prime}}, \tag{7.18a}
\end{equation*}
$$

but not in an arbitrary basis. Indeed, using the general rule (4.92), we get

$$
\begin{equation*}
\left.w_{i j^{\prime}}\right|_{\text {in } s}=\left.\sum_{l, l^{\prime}} U_{j l}^{\dagger} w_{l l^{\prime}}\right|_{\text {in } w} U_{l j^{\prime}}=U_{i j^{\prime}}^{\dagger} U_{j^{\prime \prime} j^{\prime}}=U_{j^{\prime \prime} j}^{*} U_{j^{\prime \prime} j^{\prime}} . \tag{7.18b}
\end{equation*}
$$

To make this result more transparent, let us denote matrix elements $U_{j^{\prime \prime} j}=\left\langle w_{j^{\prime}} \mid S_{j}\right\rangle$ (that, for fixed $j$ ', depend on just one index $j$ ) by $\alpha_{j}$; then

Density matrix in a pure state

$$
\begin{equation*}
\left.w_{i j^{\prime}}\right|_{\text {in } s}=\alpha_{j}^{*} \alpha_{j^{\prime}}, \tag{7.19}
\end{equation*}
$$

so that $N^{2}$ elements of the whole $N \times N$ matrix is determined by just one string of $N c$-numbers $\alpha_{j}$. For example, for a two-level system ( $N=2$ ),

$$
\left.\mathrm{w}\right|_{\mathrm{in} s}=\left(\begin{array}{ll}
\alpha_{1} \alpha_{1}^{*} & \alpha_{2} \alpha_{1}^{*}  \tag{7.20}\\
\alpha_{1} \alpha_{2}^{*} & \alpha_{2} \alpha_{2}^{*}
\end{array}\right) .
$$

We see that the off-diagonal terms are, colloquially, "as large as the diagonal ones", in the following sense:

$$
\begin{equation*}
w_{12} w_{21}=w_{11} w_{22} \tag{7.21}
\end{equation*}
$$

Since the diagonal terms have the sense of probabilities $W_{1,2}$ to find the system in the corresponding state, we may present Eq. (20) in the form

$$
\mathrm{w}=\left(\begin{array}{cc}
W_{1} & \left(W_{1} W_{2}\right)^{1 / 2} e^{i \varphi}  \tag{7.22}\\
\left(W_{1} W_{2}\right)^{1 / 2} e^{-i \varphi} & W_{2}
\end{array}\right) .
$$

The physical sense of the (real) constant $\varphi$ is the phase shift between the coefficients in the linear superposition (17) that presents the pure state $w_{j " \prime}$ in basis $s_{1,2}$.

Now let us consider a different statistical ensemble of two-level systems, that includes member states identical in all aspects (including similar probabilities $W_{1,2}$ in the same basis $s_{1,2}$ ), besides that the phase shifts $\varphi$ are random, with the phase probability uniformly distributed over the trigonometric circle. Then the ensemble averaging is equivalent to averaging over $\varphi$ from 0 to $2 \pi$, so that it kills the offdiagonal terms of the density matrix (22), and the matrix becomes diagonal. For a system with a timeindependent Hamiltonian, such averaging is especially plausible in the basis of stationary states $n$ of the system, in which phase $\varphi$ is just the difference of integration constants in Eq. (4.158), and randomness is naturally produced by minor fluctuations of the energy difference $E_{1}-E_{2}$. (In Sec. 3 we will study the dynamics of such dephasing process.) The mixed statistical ensemble of systems with the density matrix diagonal in the stationary state basis is called the classical mixture, and presents the limit opposite to the pure (coherent) state.

After that example, the reader should not be much shocked by the main claim ${ }^{9}$ of statistical mechanics that any large ensemble of similar systems in thermodynamic (or "thermal") equilibrium is exactly such a classical mixture. Moreover, for systems in the thermal equilibrium with a much larger environment with fixed temperature $T$ (such environment is usually called a heat bath or a thermostat) statistical physics gives ${ }^{10}$ a very simple expression, called the Gibbs distribution, for probabilities $W_{n}$ :

Gibbs distribution

$$
\begin{equation*}
W_{n}=\frac{1}{Z} \exp \left\{-\frac{E_{n}}{k_{\mathrm{B}} T}\right\} \tag{7.23a}
\end{equation*}
$$

[^666]where $E_{n}$ is the eigenenergy of the corresponding stationary state, and $Z$ is the normalization coefficient called the statistical sum
\[

$$
\begin{equation*}
Z \equiv \sum_{n} \exp \left\{-\frac{E_{n}}{k_{\mathrm{B}} T}\right\} . \tag{7.23b}
\end{equation*}
$$

\]

A detailed analysis of classical and quantum ensembles in thermodynamic equilibrium is the focus of statistical physics courses (such as my SM) rather than this course of quantum mechanics. However, I would still like to attract reader's attention to the key fact that, in contrast with the similarlylooking Boltzmann distribution for single particles, ${ }^{11}$ the Gibbs distribution is absolutely general and is not limited to classical statistics. In particular, for quantum gases of indistinguishable particles, it is absolutely compatible with quantum statistics (such as the Bose-Einstein or Fermi-Dirac distributions) of the component particles. For example, if we use Eq. (23) to calculate the average energy of a 1D harmonic oscillator of frequency $\omega_{0}$ in thermal equilibrium, we easily get ${ }^{12}$

$$
\begin{gather*}
W_{n}=\exp \left\{-n \frac{\hbar \omega_{0}}{k_{\mathrm{B}} T}\right\}\left(1-\exp \left\{-\frac{\hbar \omega_{0}}{k_{\mathrm{B}} T}\right\}\right),  \tag{7.24}\\
Z=\exp \left\{-\frac{\hbar \omega_{0}}{2 k_{\mathrm{B}} T}\right\} /\left(1-\exp \left\{-\frac{\hbar \omega_{0}}{k_{\mathrm{B}} T}\right\}\right),  \tag{7.25}\\
\langle E\rangle=\sum_{n=0}^{\infty} W_{n} E_{n}=\frac{\hbar \omega_{0}}{2} \operatorname{coth} \frac{\hbar \omega_{0}}{2 k_{\mathrm{B}} T}=\frac{\hbar \omega_{0}}{2}+\frac{\hbar \omega_{0}}{\exp \left\{\hbar \omega_{0} / k_{\mathrm{B}} T\right\}-1} . \tag{7.26a}
\end{gather*}
$$

An alternative way to present the last result is to write

$$
\begin{equation*}
\langle E\rangle=\frac{\hbar \omega_{0}}{2}+\hbar \omega_{0}\langle n\rangle, \quad \text { with }\langle n\rangle=\frac{1}{\exp \left\{\hbar \omega_{0} / k_{\mathrm{B}} T\right\}-1} \tag{7.26b}
\end{equation*}
$$

and to interpret it as the fact that in addition to the so-called zero-point energy $\hbar \omega_{0} / 2$ of the ground state, the oscillator (on the average) has $\langle n\rangle$ thermally-induced excitations, with energy $\hbar \omega_{0}$ each. In the harmonic oscillator, whose energy levels are equidistant, such a language is completely appropriate, because the transfer from any level to one just above it adds the same amount of energy, $\hbar \omega_{0}$, to the system. The above expression for $\langle n\rangle$ is actually the Bose-Einstein distribution (for the particular case of zero chemical potential); ${ }^{13}$ we see that it does not only contradict the Gibbs distribution (for the total energy of the system), but immediately follows from it. ${ }^{14}$

[^667]
### 7.2. Coordinate representation and the Wigner function

For many applications of the density matrix to wave mechanics, its coordinate representation is convenient. (I will only discuss it for 1D case; the generalization to multi-dimension case is straightforward.) Following Eq. (4.47), it is natural to define the following function of two arguments (frequently also called the density matrix):

$$
\begin{equation*}
w\left(x, x^{\prime}\right) \equiv\langle x| \hat{w}\left|x^{\prime}\right\rangle . \tag{7.27}
\end{equation*}
$$

Inserting, into the right-hand part of this definition, two closure conditions (4.44) for an arbitrary (full and orthonormal) basis $\{\mathrm{s}\}$, and then using Eq. (5.19), we get ${ }^{15}$

$$
\begin{equation*}
w\left(x, x^{\prime}\right)=\sum_{j, j^{\prime}}\left\langle x \mid s_{j}\right\rangle\left\langle s_{j}\right| \hat{w}\left|s_{j^{\prime}}\right\rangle\left\langle s_{j^{\prime}} \mid x^{\prime}\right\rangle=\sum_{j, j^{\prime}} \psi_{j}(x) w_{j j^{\prime}} \mid \text { ins } \psi_{j^{\prime}}^{*}\left(x^{\prime}\right) . \tag{7.28}
\end{equation*}
$$

In the special basis $\{w\}$, in which the density matrix is diagonal, this expression is reduced to

$$
\begin{equation*}
w\left(x, x^{\prime}\right)=\sum_{j} \psi_{j}(x) W_{j} \psi_{j}^{*}\left(x^{\prime}\right) \tag{7.29}
\end{equation*}
$$

Let us discuss the properties of this function. At coinciding arguments, $x=x$, this is just the probability density: ${ }^{16}$

$$
\begin{equation*}
w(x, x)=\sum_{j} \psi_{j}(x) W_{j} \psi_{j}^{*}(x)=\sum_{j} w_{j}(x) W_{j}=w(x) . \tag{7.30}
\end{equation*}
$$

However, the density matrix gives more information about the system than just the probability density. As the simplest example, let us consider a pure quantum state, with $W_{j}=\delta_{j, j}$, so that $\psi(x)=\psi_{j}(x)$, and

$$
\begin{equation*}
w\left(x, x^{\prime}\right)=\psi_{j^{\prime}}(x) \psi_{j^{\prime}}^{*}\left(x^{\prime}\right)=\psi(x) \psi^{*}\left(x^{\prime}\right) . \tag{7.31}
\end{equation*}
$$

We see that the density matrix carries the information not only about the modulus but also the phase of the wavefunction. (Of course one may argue rather convincingly that in this ultimate limit the densitymatrix description is redundant, because all this information is contained in the wavefunction itself.)

How may be the density matrix interpreted? In the simple case (31), we can write

$$
\begin{equation*}
\left|w\left(x, x^{\prime}\right)\right|^{2}=w\left(x, x^{\prime}\right) w^{*}\left(x, x^{\prime}\right)=\psi(x) \psi^{*}(x) \psi\left(x^{\prime}\right) \psi^{*}\left(x^{\prime}\right)=w(x) w\left(x^{\prime}\right), \tag{7.32}
\end{equation*}
$$

so that the modulus squared of the density matrix may is just as the joint probability density to find the system at point $x$ and point $x^{\prime}$. For example, for a simple wave packet with the spatial extent $\delta x, w\left(x, x^{\prime}\right)$ is appreciable only if the both points are not farther than $\delta x$ from the packet center, and hence from each other. The interpretation becomes more complex if we deal with an incoherent mixture of several wavefunctions, for example the classical mixture describing the thermodynamic equilibrium. In this case, we can use Eq. (23) to rewrite Eq. (29) as follows:

[^668]\[

$$
\begin{equation*}
w\left(x, x^{\prime}\right)=\sum_{n} \psi_{n}(x) W_{n} \psi_{n}^{*}\left(x^{\prime}\right)=\frac{1}{Z} \sum_{n} \psi_{n}(x) \exp \left\{-\frac{E_{n}}{k_{B} T}\right\} \psi_{n}^{*}\left(x^{\prime}\right) . \tag{7.33}
\end{equation*}
$$

\]

As the simplest example, let us see what is the density matrix of a free (1D) particle in the thermal equilibrium. As we know very well, in this case, the set of energies $E_{p}=p^{2} / 2 m$ of stationary states (monochromatic waves) forms a continuum, so that we need to replace sum (33) by an integral, taking "delta-normalized" traveling wavefunctions (5.59) as eigenstates:

$$
\begin{equation*}
w\left(x, x^{\prime}\right)=\frac{1}{2 \pi \hbar Z} \int_{-\infty}^{+\infty} \exp \left\{-\frac{i p x}{\hbar}\right\} \exp \left\{-\frac{p^{2}}{2 m k_{B} T}\right\} \exp \left\{\frac{i p x^{\prime}}{\hbar}\right\} d p \tag{7.34}
\end{equation*}
$$

This is a usual Gaussian integral, and may be worked out, as we have done repeatedly in Chapter 2 and beyond, by complementing the exponent to the full square of momentum plus a constant. The statistical sum $Z$ may be also readily calculated, ${ }^{17}$

$$
\begin{equation*}
Z=\left(2 \pi m k_{B} T\right)^{1 / 2} \tag{7.35}
\end{equation*}
$$

However, for what follows it is more useful to write the result for product $w Z$ (the so-called unnormalized density matrix):

$$
\begin{equation*}
w\left(x, x^{\prime}\right) Z=\left(\frac{m k_{\mathrm{B}} T}{2 \pi \hbar^{2}}\right)^{1 / 2} \exp \left\{-\frac{m k_{\mathrm{B}} T\left(x-x^{\prime}\right)^{2}}{2 \hbar^{2}}\right\} \tag{7.36}
\end{equation*}
$$

This is a very interesting result: the density matrix depends only on the difference of its arguments, dropping to zero fast as the distance between points $x$ and $x$ ' exceeds the following characteristic scale (called the correlation length)

$$
\begin{equation*}
x_{c} \equiv\left\langle\left(x-x^{\prime}\right)^{2}\right\rangle^{1 / 2}=\frac{\hbar}{\left(m k_{\mathrm{B}} T\right)^{1 / 2}} \tag{7.37}
\end{equation*}
$$

This length may be interpreted in the following way. It is straightforward to use Eq. (23) to verify that the average energy $E_{p}=p^{2} / 2 m$ of a particle in the thermal equilibrium, i.e. in the classical mixture (33), equals $k_{\mathrm{B}} T / 2$ - this is just one more manifestation of the equipartition theorem. Hence the average momentum magnitude may be estimated as

$$
\begin{equation*}
p_{c} \equiv\left\langle p^{2}\right\rangle^{1 / 2}=(2 m\langle E\rangle)^{1 / 2}=\left(m k_{B} T\right)^{1 / 2} \tag{7.38}
\end{equation*}
$$

so that $x_{c}$ is of the order of the minimal length allowed by the Heisenberg-like "uncertainty relation":

$$
\begin{equation*}
x_{c}=\frac{\hbar}{p_{c}} . \tag{7.39}
\end{equation*}
$$

[^669]Notice that with the growth of temperature, the correlation length (37) goes to zero, and the density matrix (36) tends to the $\delta$-function:

$$
\begin{equation*}
\left.w\left(x, x^{\prime}\right) Z\right|_{T \rightarrow \infty} \rightarrow \delta\left(x-x^{\prime}\right) \tag{7.40}
\end{equation*}
$$

Since in this limit the average kinetic energy of the particle is larger than its potential energy in any fixed potential profile, Eq. (40) is the general property of the density matrix (33).

Let us discuss the following curious feature of Eq. (36): if we replace $k_{\mathrm{B}} T$ with $\hbar / i\left(t-t_{0}\right)$, and $x$, with $x_{0}$, the un-normalized density matrix $w Z$ for a free particle turns into the particle's propagator - see Eq. (2.49). This is not just an occasional coincidence. Indeed, in Chapter 2 we saw that the propagator of a system with an arbitrary stationary Hamiltonian may be expressed via the stationary eigenfunction as

$$
\begin{equation*}
G\left(x, t ; x_{0}, t_{0}\right)=\sum_{n} \psi_{n}(x) \exp \left\{-i \frac{E_{n}}{\hbar}\left(t-t_{0}\right)\right\} \psi_{n}^{*}\left(x_{0}\right) . \tag{7.41}
\end{equation*}
$$

Comparing this expression with Eq. (33), we see that the replacements

$$
\begin{equation*}
\frac{i\left(t-t_{0}\right)}{\hbar} \rightarrow \frac{1}{k_{\mathrm{B}} T}, \quad x_{0} \rightarrow x^{\prime} \tag{7.42}
\end{equation*}
$$

turn the pure-state propagator $G$ into the un-normalized density matrix $w Z$ of the same system in thermodynamic equilibrium. This important fact, rooted in the formal similarity of the Gibbs distribution (23) with the Schrödinger equation's solution (1.67), enables a theoretical technique of the so-called thermodynamic Green's functions, which is especially productive in condensed matter physics. ${ }^{18}$

For our purposes, we can use Eq. (42) to recycle some of wave mechanics results, in particular the following formula for the harmonic oscillator's propagator

$$
\begin{equation*}
G\left(x, t ; x_{0}, t_{0}\right)=\left(\frac{m \omega_{0}}{2 \pi i \hbar \sin \left[\omega_{0}\left(t-t_{0}\right)\right]}\right)^{1 / 2} \exp \left\{-\frac{m \omega_{0}\left[\left(x^{2}+x_{0}^{2}\right) \cos \left[\omega_{0}\left(t-t_{0}\right)\right]-2 x x_{0}\right]}{2 i \hbar \sin \left[\omega_{0}\left(t-t_{0}\right)\right]}\right\} . \tag{7.43}
\end{equation*}
$$

that may be readily proved to satisfy the Schrödinger equation for Hamiltonian (5.95), with the appropriate initial condition, $G\left(x, t_{0} ; x_{0}, t_{0}\right)=\delta\left(x-x_{0}\right)$. Making substitution (42), we immediately get

Harmonic oscillator in thermal equilibrium

$$
\begin{equation*}
w\left(x, x^{\prime}\right) Z=\left(\frac{m \omega_{0}}{2 \pi \hbar \sinh \left[\hbar \omega_{0} / k_{B} T\right]}\right)^{1 / 2} \exp \left\{-\frac{m \omega_{0}\left[\left(x^{2}+x^{\prime 2}\right) \cosh \left[\hbar \omega_{0} / k_{B} T\right]-2 x x^{\prime}\right]}{2 \hbar \sinh \left[\hbar \omega_{0} / k_{B} T\right]}\right\} . \tag{7.44}
\end{equation*}
$$

As a sanity check, at very low temperatures, $k_{\mathrm{B}} T \ll \hbar \omega_{0}$, both hyperbolic functions, participating in this expression, are very large and nearly equal, and Eq. (44) yields

$$
\begin{equation*}
\left.w\left(x, x^{\prime}\right) Z\right|_{T \rightarrow 0} \rightarrow\left[\left(\frac{m \omega_{0}}{\pi \hbar}\right)^{1 / 4} \exp \left\{-\frac{m \omega_{0} x^{2}}{\hbar}\right\}\right] \times \exp \left\{-\frac{\hbar \omega_{0}}{2 k_{B} T}\right\} \times\left[\left(\frac{m \omega_{0}}{\pi \hbar}\right)^{1 / 4} \exp \left\{-\frac{m \omega_{0} x^{\prime 2}}{\hbar}\right\}\right] . \tag{7.45}
\end{equation*}
$$

[^670]In each of the square brackets we can readily recognize the ground state's wavefunction (2.269), while the middle exponent is just the statistical sum (24) in the low-temperature limit when it is dominated by the ground-level contribution:

$$
\begin{equation*}
\left.Z\right|_{T \rightarrow 0} \rightarrow \exp \left\{-\frac{\hbar \omega_{0}}{2 k_{B} T}\right\} \tag{7.46}
\end{equation*}
$$

As a result, $Z$ in both parts of Eq. (45) may be cancelled, and the density matrix in this limit is described by Eq. (31), with the ground state as the only state of the system. This is natural when temperature is too low for the excitation of any other state.

Returning to arbitrary temperatures, Eq. (44) in coinciding arguments gives the following expression for the probability density: ${ }^{19}$

$$
\begin{equation*}
w(x, x) Z=w(x) Z=\left(\frac{m \omega_{0}}{2 \pi \hbar \sinh \left[\hbar \omega_{0} / k_{B} T\right]}\right)^{1 / 2} \exp \left\{-\frac{m \omega_{0} x^{2}}{\hbar} \tanh \frac{\hbar \omega_{0}}{2 k_{B} T}\right\} \tag{7.47}
\end{equation*}
$$

This is just a Gaussian function of $x$, with the following variance:

$$
\begin{equation*}
\left\langle x^{2}\right\rangle=\frac{\hbar}{2 m \omega_{0}} \operatorname{coth} \frac{\hbar \omega_{0}}{2 k_{B} T} . \tag{7.48}
\end{equation*}
$$

In order to compare this result with our earlier ones, it is useful to recast it as

$$
\begin{equation*}
\langle U\rangle=\frac{m \omega_{0}^{2}}{2}\left\langle x^{2}\right\rangle=\frac{\hbar \omega_{0}}{4} \operatorname{coth} \frac{\hbar \omega_{0}}{2 k_{B} T} . \tag{7.49}
\end{equation*}
$$

Comparing this expression with Eq. (26), we see that the average value of potential energy is exactly one half of the total energy - the other half being the average kinetic energy. This is what we could expect, because according to Eqs. (5.129)-(5.130), such relation holds for each Fock state and hence should also hold for their classical mixture.

Unfortunately, besides the trivial case (30) of coinciding arguments, it is hard to give a straightforward interpretation of the density function in terms of system measurements. This is a fundamental difficulty that has been well explored in terms of the Wigner function (sometimes called the "Wigner-Ville distribution") ${ }^{20}$ defined as

$$
\begin{equation*}
W(X, P) \equiv \frac{1}{2 \pi \hbar} \int w\left(X+\frac{\tilde{X}}{2}, X-\frac{\widetilde{X}}{2}\right) \exp \left\{-\frac{i P \tilde{X}}{\hbar}\right\} d \widetilde{X} \tag{7.50}
\end{equation*}
$$

[^671]From the mathematical standpoint, this is just the Fourier expansion of the density matrix in one of two new coordinates (Fig. 2) defined by relations

$$
\begin{equation*}
x=X+\frac{\tilde{X}}{2}, \quad x^{\prime}=X-\frac{\tilde{X}}{2} . \tag{7.51}
\end{equation*}
$$

Physically, the new argument $X=\left(x+x^{\prime}\right) / 2$ may be understood as the average position of the particle during the time interval $\left(t-t^{\prime}\right)$, while $\tilde{X}=x-x^{\prime}$ as the distance passed by the particle during that time interval, so that $P$ may be interpreted as the characteristic momentum of a particle during that motion. As a result, the Wigner function is a construct intended to characterize the system spread simultaneously in the coordinate and momentum space - for 1D systems, on the phase plane $[X, P]$ that we considered before - see Fig. 5.6. Let us see how fruitful these intentions are.

Fig. 7.2. Coordinates $X$ and $\tilde{X}$ employed in the WeylWigner transform (50). They differ from the coordinates obtained by the rotation of the reference frame by angle $\pi / 2$ only by coefficients $\sqrt{ } 2$, describing scale stretching.

First of all, we may write the Fourier transform reciprocal to Eq. (50):

$$
\begin{equation*}
w\left(X+\frac{\tilde{X}}{2}, X-\frac{\tilde{X}}{2}\right)=\int W(X, P) \exp \left\{+\frac{i P \tilde{X}}{\hbar}\right\} d P \tag{7.52}
\end{equation*}
$$

For the particular case $\tilde{X}=0$, this relation yields

$$
\begin{equation*}
w(X) \equiv w(X, X)=\int W(X, P) d P \tag{7.53}
\end{equation*}
$$

Hence the integral of the Wigner function over momentum $P$ gives the probability density to find the system at point $X$.

Actually, the function has the same property for integration over $X$. To prove that, we should first introduce the momentum representation of the density matrix, in the full analogy with its coordinate representation (27):

$$
\begin{equation*}
w\left(p, p^{\prime}\right) \equiv\langle p| \hat{w}\left|p^{\prime}\right\rangle . \tag{7.54}
\end{equation*}
$$

Inserting, as usual, two identity operators, in the form given by Eq. (5.21), into the right hand part of this equality, we can get the following relation between the momentum and coordinate representations:

$$
\begin{equation*}
w\left(p, p^{\prime}\right) \equiv\langle p| \hat{w}\left|p^{\prime}\right\rangle=\iint d x d x^{\prime}\langle p \mid x\rangle\langle x| \hat{w}\left|x^{\prime}\right\rangle\left\langle x^{\prime} \mid p^{\prime}\right\rangle=\frac{1}{2 \pi \hbar} \iint d x d x^{\prime} \exp \left\{-\frac{i p x}{\hbar}\right\} w\left(x, x^{\prime}\right) \exp \left\{\frac{i p^{\prime} x^{\prime}}{\hbar}\right\} \cdot( \tag{7.55}
\end{equation*}
$$

This is of course nothing else than the unitary transform of an operator from the $x$-basis to $p$-basis, and is similar to the first form of Eq. (5.67). ${ }^{21}$ For coinciding arguments, $p=p$, Eq. (55) is reduced to

$$
\begin{equation*}
w(p) \equiv w(p, p)=\frac{1}{2 \pi \hbar} \iint d x d x^{\prime} w\left(x, x^{\prime}\right) \exp \left\{-\frac{i p\left(x-x^{\prime}\right)}{\hbar}\right\} . \tag{7.56}
\end{equation*}
$$

Using Eq. (29) and then Eq. (5.60), this function may be presented as

$$
\begin{equation*}
w(p)=\frac{1}{2 \pi \hbar} \sum_{j} W_{j} \iint d x d x^{\prime} \psi_{j}(x) \psi_{j}^{*}(x) \exp \left\{-\frac{i p\left(x-x^{\prime}\right)}{\hbar}\right\}=\sum_{j} W_{j} \varphi_{j}(p) \varphi_{j}^{*}(p), \tag{7.57}
\end{equation*}
$$

and hence interpreted as the probability density of the particle's momentum at point $p$. Now, in variables (51), Eq. (56) has the form

$$
\begin{equation*}
w(p)=\frac{1}{2 \pi \hbar} \iint w\left(X+\frac{\widetilde{X}}{2}, X-\frac{\tilde{X}}{2}\right) \exp \left\{-\frac{i p \tilde{X}}{\hbar}\right\} d \widetilde{X} d X \tag{7.58}
\end{equation*}
$$

Comparing this equality with definition (50) of the Wigner function, we see that

$$
\begin{equation*}
w(P)=\int W(X, P) d X . \tag{7.59}
\end{equation*}
$$

Thus, according to Eqs. (53) and (59), the integrals of the Wigner function over either the coordinate or momentum give the probability densities to find them at certain values of these variables. This is of course the main requirement to any candidate joint probability density, $\rho(X, P)$, to find a classical representation point of a stochastic system on the phase plane $[X, P] .{ }^{22}$

Let us look how does the Wigner function look for the simplest systems in the thermodynamic equilibrium. For a free 1D particle, we can use Eq. (34), ignoring for simplicity the normalization issues:

$$
\begin{equation*}
W(X, P) \propto \int_{-\infty}^{+\infty} \exp \left\{-\frac{m k_{B} T \widetilde{X}^{2}}{2 \hbar^{2}}\right\} \exp \left\{-\frac{i P \tilde{X}}{\hbar}\right\} d \widetilde{X} \tag{7.60}
\end{equation*}
$$

The usual Gaussian integration yields:

$$
\begin{equation*}
W(X, P)=\text { const } \times \exp \left\{-\frac{P^{2}}{2 m k_{B} T}\right\} \tag{7.61}
\end{equation*}
$$

We see that the function is independent of $X$ (as it should be for this translational-invariant system), and coincides with the Gibbs distribution (23). We could get the same result directly from classical statistics. This is natural, because as we know from Sec. 2.2, the free motion is essentially not quantized - at least in terms of its energy and momentum.

Now let us consider a substantially quantum system, the harmonic oscillator. Plugging Eq. (44) into Eq. (50), for that system in thermal equilibrium it is easy to show (and hence is left for reader's exercise) that the Wigner function is also Gaussian, but now in both its arguments:

[^672]Thermal equilibrium: harmonic oscillator

$$
\begin{equation*}
W(X, P)=\text { const } \times \exp \left\{-C\left[\frac{m \omega_{0}^{2} X^{2}}{2}+\frac{P^{2}}{2 m}\right]\right\}, \tag{7.62}
\end{equation*}
$$

though coefficient $C$ is now different from $1 / k_{\mathrm{B}} T$, and tends to that limit only at high temperatures, $k_{B} T$ $\gg \hbar \omega_{0}$. Moreover, for the Glauber state it also gives a very plausible result - a Gaussian distribution similar to Eq. (62), but shifted to the central point of the state - see Sec. 5.5.23

Unfortunately, for some other possible states of the harmonic oscillator, e.g., any pure Fock state with $n>0$, the Wigner function takes negative values in some regions of the [ $X, P$ ] plane - Fig. 3. ${ }^{24}$

Fig. 7.3. The Wigner function of several Fock states of a harmonic oscillator: (a) $n=0$, (b) $n=1$; (c) $n=5$. Adapted from http://en.wikipedia.org/wiki/Wigner_function.

The same is true for most other quantum systems. Indeed, this fact could be predicted just by looking at definition (50) applied to a pure quantum state, in which the density function may be factored - see Eq. (31):

[^673]\[

$$
\begin{equation*}
W(X, P)=\frac{1}{2 \pi \hbar} \int \psi\left(X+\frac{\tilde{X}}{2}\right) \psi^{*}\left(X-\frac{\tilde{X}}{2}\right) \exp \left\{-\frac{i P \tilde{X}}{\hbar}\right\} d \widetilde{X} . \tag{7.63}
\end{equation*}
$$

\]

Changing argument $P$ (say, at fixed $X$ ), we are essentially changing the spatial "frequency" (wavenumber) of the wavefunction product's Fourier component we are calculating, and we know that Fourier images typically change sign as the frequency is changed. Hence the wavefunctions should have some high-symmetry properties to avoid this effect. Indeed, the Gaussian functions (describing, for example, the Glauber states, and as the particular case, the ground state of the harmonic oscillator) have such a symmetry, but many other functions do not.

Hence the Wigner function cannot be used in the role of classical probability density $\rho(X, P)$, otherwise we would get a negative probability for measurement in certain intervals $d X d P$ - the notion hard to interpret. However, the Wigner function is still used for a semi-quantitative interpretation of states of open quantum systems.

### 7.3. Open system dynamics: Dephasing

So far we have discussed the density matrix as something given. Now let us discuss the evolution of the matrix in time, starting from the simplest case when the system is in state (15) with time-independent probabilities $W_{j}$. In the Schrödinger picture we can rewrite Eq. (15) as

$$
\begin{equation*}
\hat{w}(t)=\sum_{j}\left|w_{j}(t)\right\rangle W_{j}\left\langle w_{j}(t)\right| . \tag{7.64}
\end{equation*}
$$

Differentiating this equation by parts, and using Eqs. (4.157)-(4.158), with the account of the Hermitian nature of the Hamiltonian operator, we get

$$
\begin{align*}
i \hbar \dot{\hat{w}} & \left.=i \hbar \sum_{j}\left[\dot{w}_{j}(t)\right\rangle W_{j}\left\langle w_{j}(t)\right|+\left|w_{j}(t)\right\rangle W_{j}\left\langle\dot{w}_{j}(t)\right|\right]=\sum_{j}\left[\hat{H}\left|w_{j}(t)\right\rangle W_{j}\left\langle w_{j}(t)\right|-\left|w_{j}(t)\right\rangle W_{j}\left\langle w_{j}(t)\right| \hat{H}\right] \\
& =\hat{H} \sum_{j}\left|w_{j}(t)\right\rangle W_{j}\left\langle w_{j}(t)\right|-\sum_{j}\left|w_{j}(t)\right\rangle W_{j}\left\langle w_{j}(t)\right| \hat{H} . \tag{7.65}
\end{align*}
$$

Now using Eq. (64) again (twice), we get the so-called von Neumann equation ${ }^{25}$

$$
\begin{equation*}
i \hbar \dot{\hat{w}}=[\hat{H}, \hat{w}] . \tag{7.66}
\end{equation*}
$$

This equation is similar in structure to Eq. (4.199) describing the time evolution of the Heisenbergpicture operators:

$$
\begin{equation*}
i \hbar \dot{\hat{A}}=[\hat{A}, \hat{H}] \tag{7.67}
\end{equation*}
$$

besides the operator order in the commutator, i.e., the sign of the right-hand part. This is quite natural, because Eq. (66) belongs to the Schrödinger picture, while Eq. (67) to the Heisenberg picture of the quantum dynamics.

[^674]In the general case when a system, initially out of equilibrium, comes into a contact with the environment, probabilities $W_{j}$ change, and dynamics is described by equations more complex than Eq. (66). However, we still can use this equation to discuss, using a simple model, the second (after the energy relaxation) major effect of the environment, dephasing (also called "decoherence"). ${ }^{26}$ Let us consider the following model of a system interacting (weakly!) with environment: ${ }^{27}$

System's interaction with
environment

$$
\begin{equation*}
\hat{H}=\hat{H}_{s}+\hat{H}_{e}\{\lambda\}+\hat{H}_{\mathrm{int}} \tag{7.68}
\end{equation*}
$$

Let us consider the simplest, two-level system, taking its Hamiltonian in the simplest form,

$$
\begin{equation*}
\hat{H}_{s}=a_{z} \hat{\sigma}_{z}, \tag{7.69}
\end{equation*}
$$

(as we know from Sec. 4.6, such Hamiltonian is sufficient to avoid the energy level degeneracy), and a factorable (bilinear) interaction - cf. Eq. (6.148) and its discussion:

$$
\begin{equation*}
\hat{H}_{\mathrm{int}}=-\hat{f}\{\lambda\} \hat{\sigma}_{z} . \tag{7.70}
\end{equation*}
$$

Here $\hat{f}$ is a Hermitian operator depending only on the set $\{\lambda\}$ of environmental degrees of freedom ("coordinates"). These coordinates belong to the Hilbert space different from that of the two-level system, and hence operators $\hat{f}\{\lambda\}$ and $\hat{H}_{e}\{\lambda\}$ (that describes the environment) commute with $\hat{\sigma}_{z}$ - and any other intrinsic operator of the two-level system. Of course, any realistic $\hat{H}_{e}\{\lambda\}$ is very complex, so that it may be surprising how much we will be able to achieve without specifying it.

Before we proceed to solution, let me remind the reader of the important two-level systems that may be described by this model. The first example is an electron in an external magnetic field of a fixed direction (taken for axis $z$ ), which includes both an average component $\left\langle\mathcal{B}_{z}\right\rangle$ and a random (fluctuating) component $\widetilde{\mathcal{B}}_{z}$. As it follows from the discussion in Chapter 4, it may be described by Hamiltonian (68)(70) with

$$
\begin{equation*}
a_{z}=\mu_{\mathrm{B}}\left\langle\mathcal{B}_{z}\right\rangle, \quad-\hat{f}=\mu_{\mathrm{B}} \hat{\tilde{B}}_{z} . \tag{7.71}
\end{equation*}
$$

The second important example is a particle in a double-quantum-well potential (Fig. 4), with a barrier between them sufficiently high to be impenetrable, and an additional force $F(t)$ exerted by the environment. If the force is sufficiently weak, we can neglect its effects on the shape of quantum wells and hence on the localized wavefunctions $\psi_{L, R}$, so that the force effect is reduced to the variation of the difference $E_{L}-E_{R}=F(t) \Delta x$ between well eigenenergies. As a result, it may described by Eqs. (608)(70) with

$$
\begin{equation*}
a_{z} \approx\langle F\rangle \Delta x / 2 ; \quad-\hat{f} \approx \hat{\tilde{F}} \Delta x / 2 \tag{7.72}
\end{equation*}
$$

[^675]

Fig. 7.4. Dephasing in a double quantum well system.

Returning to the general model (68)-(70), let us start its analysis from writing the usual equation of motion for the Heisenberg operator $\hat{\sigma}_{z}: 28$

$$
\begin{equation*}
i \hbar \dot{\hat{\sigma}}_{z}=\left[\hat{\sigma}_{z}, \hat{H}\right]=\left(a_{z}-\hat{f}\right)\left[\hat{\sigma}_{z}, \hat{\sigma}_{z}\right]=0, \tag{7.73}
\end{equation*}
$$

so that operator $\hat{\sigma}_{z}$ does not evolve in time. What does this mean for the observables? For an arbitrary density matrix of the two-level system,

$$
w=\left(\begin{array}{ll}
w_{11} & w_{12}  \tag{7.74}\\
w_{21} & w_{22}
\end{array}\right)
$$

we can readily calculate the trace of operator $\hat{\sigma}_{z}$ (since operator traces are basis - independent, we can do this in any basis, in particular in the usual $z$-basis):

$$
\operatorname{Tr}\left(\hat{\sigma}_{z} \hat{w}\right)=\operatorname{Tr}\left(\sigma_{z} \mathrm{w}\right)=\operatorname{Tr}\left[\left(\begin{array}{cc}
1 & 0  \tag{7.75}\\
0 & -1
\end{array}\right)\left(\begin{array}{ll}
w_{11} & w_{12} \\
w_{21} & w_{22}
\end{array}\right)\right]=w_{11}-w_{22}=W_{1}-W_{2} .
$$

Hence, according to Eq. (5), $\hat{\sigma}_{z}$ may be considered the operator for observable $W_{1}-W_{2}$, so that in the case (73), the difference $W_{1}-W_{2}$ does not depend on time, and since the sum of the probabilities is also fixed, $W_{1}+W_{2}=1$, both of them are constant. (The physics of this result is especially clear for the model shown in Fig. 4: since the potential barrier separating the quantum wells is so high that tunneling through it is negligible, the interaction with environment cannot move the system from well into another one. It may look like nothing interesting may happen in such situation, but in a minute we will see this is not true.) Hence, we may use the von Neumann equation (66) for the density matrix evolution (in the Schrödinger picture). In the usual $z$-basis:

$$
\begin{align*}
i \hbar \dot{\mathrm{w}} & \equiv i \hbar\left(\begin{array}{cc}
\dot{w}_{11} & \dot{w}_{12} \\
\dot{w}_{21} & \dot{w}_{22}
\end{array}\right)=[\mathrm{H}, \mathrm{w}]=\left(a_{z}-\hat{f}\right)\left[\sigma_{z}, \mathrm{w}\right] \\
& =\left(a_{z}-\hat{f}\right)\left\{\left(\begin{array}{cc}
1 & 0 \\
0 & -1
\end{array}\right)\left(\begin{array}{ll}
w_{11} & w_{12} \\
w_{21} & w_{22}
\end{array}\right)-\left(\begin{array}{ll}
w_{11} & w_{12} \\
w_{21} & w_{22}
\end{array}\right)\left(\begin{array}{cc}
1 & 0 \\
0 & -1
\end{array}\right)\right\}=\left(a_{z}-\hat{f}\right)\left(\begin{array}{cc}
0 & 2 w_{12} \\
-2 w_{21} & 0
\end{array}\right) . \tag{7.76}
\end{align*}
$$

[^676]This means that though the diagonal elements, i.e., the probabilities of the states, do not evolve in time (as we already know), the off-diagonal coefficients do change; for example,

$$
\begin{equation*}
i \hbar \dot{w}_{12}=2\left(a_{z}-\hat{f}\right) w_{12} \tag{7.77}
\end{equation*}
$$

with a similar but complex-conjugate equation for $w_{21}$. The solution of the linear differential equation (77) is straightforward, and yields

$$
\begin{equation*}
w_{12}(t)=w_{12}(0) \exp \left\{-i \frac{2 a_{z}}{\hbar} t\right\} \exp \left\{i \frac{2}{\hbar} \int_{0}^{t} \hat{f}\left(t^{\prime}\right) d t^{\prime}\right\} . \tag{7.78}
\end{equation*}
$$

The first exponent is a deterministic $c$-number factor, while in the second one $\hat{f}(t) \equiv \hat{f}\{\lambda(t)\}$ is still an operator in the Hilbert space of the environment, and, from the point of view of the system of our interest, a random function of time.

Let us start from the limit when the environment behaves classically. ${ }^{29}$ In this case, the operator in Eq. (78) may be considered as a classical random function of time $f(t)$, provided that we average the result over the ensemble of many functions $f(t)$ describing many (macroscopically similar) experiments. For a small time interval $t=d t \rightarrow 0$, we can use the Taylor expansion of the exponent, truncating it after the quadratic term:

$$
\begin{align*}
\left\langle\exp \left\{-i \frac{2}{\hbar} \int_{0}^{d t} f\left(t^{\prime}\right) d t^{\prime}\right\}\right. & =1+\left\langle-i \frac{2}{\hbar} \int_{0}^{d t} f\left(t^{\prime}\right) d t^{\prime}\right\rangle+\left\langle\frac{1}{2}\left(-i \frac{2}{\hbar} \int_{0}^{d t} f\left(t^{\prime}\right) d t^{\prime}\right)\left(-i \frac{2}{\hbar} \int_{0}^{d t} f\left(t^{\prime \prime}\right) d t^{\prime \prime}\right)\right\rangle  \tag{7.79}\\
& =1-i \frac{2}{\hbar} \int_{0}^{d t}\left\langle f\left(t^{\prime}\right)\right\rangle d t^{\prime}-\frac{2}{\hbar^{2}} \int_{0}^{d t} d t^{\prime} \int_{0}^{d t} d t^{\prime \prime}\left\langle f\left(t^{\prime}\right) f\left(t^{\prime \prime}\right)\right\rangle=1-\frac{2}{\hbar^{2}} \int_{0}^{d t} d t^{\prime} \int_{0}^{d t} d t^{\prime \prime} K_{f}\left(t^{\prime}-t^{\prime \prime}\right) .
\end{align*}
$$ classical variable only depend on the time difference $\tau \equiv t^{\prime}-t^{\prime \prime}$ :

$$
\begin{equation*}
\left\langle f\left(t^{\prime}\right) f\left(t^{\prime \prime}\right)\right\rangle \equiv K_{f}\left(t^{\prime}-t^{\prime \prime}\right)=K_{f}(\tau) \tag{7.80}
\end{equation*}
$$

If this difference is much larger than some time scale $\tau_{c}$, called the correlation time of the random force, the values $f\left(t^{\prime}\right)$ and $f\left(t^{\prime \prime}\right)$ are completely independent (uncorrelated), as illustrated in Fig. 5a, so that the correlation function has to tend to zero. On the other hand, at $\tau=0$, i.e. $t^{\prime}=t^{\prime \prime}$, the correlation function is just the variance of $f$ :

$$
\begin{equation*}
K_{f}(0)=\left\langle f^{2}\right\rangle \tag{7.81}
\end{equation*}
$$

and has to be positive. As a result, the function looks (qualitatively) like the sketch in Fig. 5b.

[^677]

Fig. 7.5. (a) Typical random process and (b) its correlation function - schematically.

Hence, if we are only interested in time differences $\tau$ much longer than $\tau_{c}$, we may approximate $K_{f}(\tau)$ with a delta-function. Let us take it in the following convenient form

$$
\begin{equation*}
K_{f}(\tau) \approx \hbar^{2} D_{\varphi} \delta(\tau) \tag{7.82}
\end{equation*}
$$

Phase diffusion coefficient
where $D_{\varphi}$ is a positive constant called the phase diffusion coefficient. The origin of this term stems from the very similar effect of diffusion of atoms or small solid particles in real space - the so-called (the Brownian motion. ${ }^{30}$ Indeed, if a small classical particle moves in a highly viscous medium, its velocity is approximately proportional to the external force. Hence, if the random hits of a 1D particle by the molecules may be described by a force which obeys a law similar to Eq. (82), the velocity (along any Cartesian coordinate) is also delta-correlated:

$$
\begin{equation*}
\langle v(t)\rangle=0, \quad\left\langle v\left(t^{\prime}\right) v\left(t^{\prime \prime}\right)\right\rangle=2 D \delta\left(t^{\prime}-t^{\prime \prime}\right) . \tag{7.83}
\end{equation*}
$$

Now we can integrate the kinematic equation $\dot{x}=v$, to calculate particle's deviation from the initial position,

$$
\begin{equation*}
x(t)-x(0)=\int_{0}^{t} v\left(t^{\prime}\right) d t^{\prime} \tag{7.84}
\end{equation*}
$$

and its the variance:

$$
\begin{equation*}
\left\langle(x(t)-x(0))^{2}\right\rangle=\left\langle\int_{0}^{t} v\left(t^{\prime}\right) d t^{\prime} \int_{0}^{t} v\left(t^{\prime \prime}\right) d t^{\prime \prime}\right\rangle=\int_{0}^{t} d t^{\prime} \int_{0}^{t} d t^{\prime \prime}\left\langle v\left(t^{\prime}\right) v\left(t^{\prime \prime}\right)\right\rangle=\int_{0}^{t} d t^{\prime} \int_{0}^{t} d t^{\prime \prime} 2 D \delta\left(t^{\prime}-t^{\prime \prime}\right)=2 D t \tag{7.85}
\end{equation*}
$$

This is the famous law of diffusion, showing that the r.m.s. deviation of the particle from the initial point grows with time as $(2 D t)^{1 / 2}$, where constant $D$ is called the diffusion coefficient.

Returning to the diffusion of the quantum-mechanical phase, using Eq. (82), the last double integral in Eq. (79) yields $\hbar^{2} D_{\varphi} d t$, so that

$$
\begin{equation*}
\left\langle w_{12}(d t)\right\rangle=w_{12}(0) \exp \left\{-i \frac{2 a_{z}}{\hbar} d t\right\}\left(1-2 D_{\varphi} d t\right) \tag{7.86}
\end{equation*}
$$

Applying this formula to sequential time intervals,

[^678]\[

$$
\begin{equation*}
\left\langle w_{12}(2 d t)\right\rangle=\left\langle w_{12}(d t)\right\rangle \exp \left\{-i \frac{2 a_{z}}{\hbar} d t\right\}\left(1-2 D_{\varphi} d t\right)=w_{12}(0) \exp \left\{-i \frac{2 a_{z}}{\hbar} 2 d t\right\}\left(1-2 D_{\varphi} d t\right)^{2}, \tag{7.87}
\end{equation*}
$$

\]

etc., for a finite time $t=N d t$, in the limit $N \rightarrow \infty$ and $d t \rightarrow 0$ (at fixed $t$ ) we get, ${ }^{31}$

$$
\begin{equation*}
\left\langle w_{12}(t)\right\rangle=\left.w_{12}(0) \exp \left\{-i \frac{2 a_{z}}{\hbar} t\right\} \lim \right|_{N \rightarrow \infty}\left(1-2 D_{\varphi} t \frac{1}{N}\right)^{N} . \tag{7.88a}
\end{equation*}
$$

By the definition of the natural logarithm base $e,{ }^{32}$ this limit is just $\exp \left\{-2 D_{\varphi} t\right\}$, so that, finally:

$$
\begin{equation*}
\left\langle w_{12}(t)\right\rangle=w_{12}(0) \exp \left\{-i \frac{2 a}{\hbar} t\right\} \exp \left\{-2 D_{\phi} t\right\} \equiv w_{12}(0) \exp \left\{-i \frac{2 a}{\hbar} t\right\} \exp \left\{-\frac{t}{T_{2}}\right\} . \tag{7.88b}
\end{equation*}
$$

So, due to coupling to environment, the off-diagonal elements of the density matrix decay with the characteristic dephasing time $T_{2}=1 / 2 D_{\varphi}$, providing a natural evolution from the density matrix (22) of a pure state, to the diagonal matrix,

$$
\mathrm{w}=\left(\begin{array}{cc}
W_{1} & 0  \tag{7.89}\\
0 & W_{2}
\end{array}\right)
$$

with the same probabilities $W_{1,2}$, describing a fully dephased (incoherent) classical mixture.
Our simple model offers a very clear look at the nature of decoherence: "force" $f(t)$, exerted by the environment, "shakes" the energy difference between two eigenstates of the system and hence the instant velocities $2\left(a_{z}-f\right) / \hbar$ of their mutual phase shift $\varphi(t)-\mathrm{cf}$. Eq. (24). Due to randomness of the force, $\varphi(t)$ performs a random walk around the trigonometric circle, so that eventually, averaging of its trigonometric functions $\exp \{ \pm i \varphi\}$ over the possible states of environment yields zero, killing the offdiagonal elements of the density matrix. Our analysis, however, has left open two important issues:
(i) Is it approach valid for a quantum description of a typical environment?
(ii) If yes, what is $D_{\varphi}$ ?

### 7.4. Fluctuation-dissipation theorem

Similar questions may be asked about a more general situation, when the Hamiltonian $\hat{H}_{s}$ of the system of interest ( $s$ ), in the composite Hamiltonian (68), is not specified at all, but the interaction between that system its environment still has the bilinear form similar to Eqs. (70) and (6.130):

$$
\begin{equation*}
\hat{H}_{\mathrm{int}}=-\hat{F}\{\lambda\} \hat{x}, \tag{7.90}
\end{equation*}
$$

[^679]where $x$ is some observable of the subsystem $s$ (say, a generalized coordinate or a generalized momentum). It may look incredible that in this very general situation one may make a very simple and powerful statement about the statistical properties of the generalized external force $F$, under only two (interrelated) conditions - which are satisfied in a huge number of cases of interest:
(i) the coupling of system $s$ of interest to environment $e$ is weak - in the sense of the perturbation theory (see Chapter 6), and
(ii) the environment may be considered as staying in thermodynamic equilibrium, with certain temperature $T$, regardless of the process in the system of interest. ${ }^{33}$

This famous statement is called the fluctuation-dissipation theorem (FDT). ${ }^{34}$ Due to the importance of this fundamental result, let me derive it. ${ }^{35}$

Since by writing Eq. (68) we treat the whole system $(s+e)$ as a Hamiltonian one, ${ }^{36}$ we may use the Heisenberg equation (4.199) to write

$$
\begin{equation*}
i \hbar \dot{\hat{F}}=[\hat{F}, \hat{H}]=\left[\hat{F}, \hat{H}_{e}\right] \tag{7.91}
\end{equation*}
$$

because, as was discussed in the last section, operator $\hat{F}\{\lambda\}$ commutes with operators $\hat{H}_{s}$ and $\hat{x}$. Generally, very little may be done with this equation, because the time evolution of the environment's Hamiltonian depends, in turn, on that of the force. This is where the perturbation theory becomes indispensable. Let us decompose the external force's operator into the following sum:

$$
\begin{equation*}
\hat{F}\{\lambda\}=\langle\hat{F}\rangle+\hat{\tilde{F}}(t), \quad \text { with }\langle\hat{\tilde{F}}(t)\rangle=0 \tag{7.92}
\end{equation*}
$$

where (until further notice) sign $\langle\ldots\rangle$ means the statistical averaging over the environment alone. ${ }^{37}$ From the point of view of system $s$, the first term of the sum (still an operator!) describes the average response

[^680]of the environment to the system dynamics (possibly, including such irreversible effects as friction), and has to be calculated with account of their interaction - as will do later in this section. On the other hand, the second term in Eq. (92) presents fluctuations of the environment, which exist even in the absence of system $s$. Hence, in the first nonvanishing approximation in the interaction strength, the fluctuation part may be calculated ignoring the interaction, i.e. treating the environment as being in the thermodynamic equilibrium: ${ }^{38}$
\[

$$
\begin{equation*}
i \hbar \dot{\tilde{F}}=\left[\hat{\widetilde{F}},\left.\hat{H}_{e}\right|_{\mathrm{eq}}\right] \tag{7.93}
\end{equation*}
$$

\]

Since in this approximation the environment's Hamiltonian does not have an explicit dependence of time, the solution of this equation may be written combining Eqs. (4.175) and (4.190):

$$
\begin{equation*}
\hat{F}(t)=\exp \left\{\left.\frac{i}{\hbar} \hat{H}_{e}\right|_{\mathrm{eq}} t\right\} \hat{F}(0) \exp \left\{-\left.\frac{i}{\hbar} \hat{H}_{e}\right|_{\mathrm{eq}} t\right\} . \tag{7.94}
\end{equation*}
$$

Let us use this relation to calculate the correlation function of fluctuations, defined similarly to Eq. (80), but paying close attention to the order of the time arguments (very soon we will see why):

$$
\begin{equation*}
\left\langle\widetilde{F}(t) \widetilde{F}\left(t^{\prime}\right)\right\rangle=\left\langle\exp \left\{\frac{i}{\hbar} \hat{H}_{e} t\right\} \hat{F}(0) \exp \left\{-\frac{i}{\hbar} \hat{H}_{e} t\right\} \exp \left\{\frac{i}{\hbar} \hat{H}_{e} t^{\prime}\right\} \hat{F}(0) \exp \left\{-\frac{i}{\hbar} \hat{H}_{e^{\prime}} t^{\prime}\right\}\right\rangle, \tag{7.95}
\end{equation*}
$$

where the thermal equilibrium of environment is implied. We are at will to calculate this expectation value in any basis, and the best choice is evident, because in the environment's stationary state basis, its Hamiltonian, the exponents in Eq. (95), and the density operator of the environment are all represented by diagonal matrices. Using Eq. (5), the correlation function becomes

$$
\begin{align*}
\left\langle\widetilde{F}(t) \widetilde{F}\left(t^{\prime}\right)\right\rangle & =\operatorname{Tr}\left[\hat{w} \exp \left\{\frac{i}{\hbar} \hat{H}_{e} t\right\} \hat{F}(0) \exp \left\{-\frac{i}{\hbar} \hat{H}_{e} t\right\} \exp \left\{\frac{i}{\hbar} \hat{H}_{e} t^{\prime}\right\} \hat{F}(0) \exp \left\{-\frac{i}{\hbar} \hat{H}_{e} t^{\prime}\right\}\right] \\
& =\sum_{n}\left[\hat{w} \exp \left\{\frac{i}{\hbar} \hat{H}_{e} t\right\} \hat{F}(0) \exp \left\{-\frac{i}{\hbar} \hat{H}_{e} t\right\} \exp \left\{\frac{i}{\hbar} \hat{H}_{e} t^{\prime}\right\} \hat{F}(0) \exp \left\{-\frac{i}{\hbar} \hat{H}_{e} t^{\prime}\right\}\right]_{n n}  \tag{7.96}\\
& =\sum_{n, n^{\prime}} W_{n} \exp \left\{\frac{i}{\hbar} E_{n} t\right\} \hat{F}_{n n^{\prime}} \exp \left\{-\frac{i}{\hbar} E_{n^{\prime}} t\right\} \exp \left\{\frac{i}{\hbar} E_{n^{\prime}, t^{\prime}}\right\} \hat{F}_{n^{\prime} n} \exp \left\{-\frac{i}{\hbar} E_{n} t^{\prime}\right\} \\
& =\sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \exp \left\{i \frac{\left(E_{n}-E_{n^{\prime}}\right)\left(t-t^{\prime}\right)}{\hbar}\right\}, \quad \text { where } \widetilde{E} \equiv E_{n}-E_{n^{\prime}} .
\end{align*}
$$

Here $W_{n}$ are the Gibbs distribution probabilities, given by Eq. (23) with environment's temperature $T$, and $F_{n n}$, are the Schrödinger-picture matrix elements of the interaction force operator.

We see that correlator (96) is a function of the difference $\tau \equiv t-t^{\prime}$ only (as it should be for fluctuations in a macroscopically stationary system), but may depend on the order of the operands. This is why let us denote this particular correlation function by upper index "+",

$$
\begin{equation*}
K_{F}^{+}(\tau) \equiv\left\langle\widetilde{F}(t) \widetilde{F}\left(t^{\prime}\right)\right\rangle=\sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \exp \left\{i \frac{\widetilde{E} \tau}{\hbar}\right\}, \quad \text { where } \widetilde{E} \equiv E_{n}-E_{n^{\prime}} \tag{7.97}
\end{equation*}
$$

[^681]and its counterpart by upper index "-":
\[

$$
\begin{equation*}
K_{F}^{-}(\tau) \equiv K_{F}^{+}(-\tau)=\left\langle\widetilde{F}\left(t^{\prime}\right) \widetilde{F}(t)\right\rangle=\sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \exp \left\{-i \frac{\widetilde{E} \tau}{\hbar}\right\} . \tag{7.98}
\end{equation*}
$$

\]

So, in contrast with classical processes, in quantum mechanics the correlation function of fluctuations $\widetilde{F}$ is not necessarily time-symmetric:

$$
\begin{equation*}
K_{F}^{+}(\tau)-K_{F}^{-}(\tau) \equiv K_{F}^{+}(\tau)-K_{F}^{+}(-\tau)=\left\langle\widetilde{F}(t) \widetilde{F}\left(t^{\prime}\right)-\widetilde{F}\left(t^{\prime}\right) \widetilde{F}(t)\right\rangle=2 i \sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \sin \frac{\widetilde{E} \tau}{\hbar} \neq 0 \tag{7.99}
\end{equation*}
$$

so that $\hat{F}(t)$ gives a good example of a Heisenberg-picture operator whose "values", taken in different moments of time, generally do not commute - the opportunity already mentioned in Sec. 4.6. ${ }^{39}$

Now let us return to the force decomposition (92), and calculate the first (average) component of the force. In order to do that, let us write the formal solution of Eq. (91) as follows:

$$
\begin{equation*}
\hat{F}(t)=\frac{1}{i \hbar} \int_{-\infty}^{t}\left[\hat{F}\left(t^{\prime}\right), \hat{H}_{e}\left(t^{\prime}\right)\right] d t^{\prime} \tag{7.100}
\end{equation*}
$$

In the right-hand part of this relation, we cannot treat the Hamiltonian of the environment as an unperturbed (equilibrium) one, because the result would have zero statistical average. Hence, we should make one more step in our perturbative treatment, and take into account (in the first nonvanishing approximation) the effect of our system of interest ( $s$ ) on the environment. To do this, let us write the (so far, exact) Heisenberg equation of motion for the environment's Hamiltonian,

$$
\begin{equation*}
i \hbar \dot{\hat{H}}_{e}=\left[\hat{H}_{e}, \hat{H}\right]=-\hat{x}\left[\hat{H}_{e}, \hat{F}\right] \tag{7.101}
\end{equation*}
$$

and its formal solution, similar to Eq. (100), but for an arbitrary time $t^{\prime}$ rather than $t$ :

$$
\begin{equation*}
\hat{H}_{e}\left(t^{\prime}\right)=-\frac{1}{i \hbar} \int_{-\infty}^{t} \hat{x}\left(t^{\prime \prime}\right)\left[\hat{H}_{e}\left(t^{\prime \prime}\right), \hat{F}\left(t^{\prime \prime}\right)\right] d t^{\prime \prime} \tag{7.102}
\end{equation*}
$$

Plugging this equality into the right-hand part of Eq. (100), and averaging the result (again, over the environment only!), we get

$$
\begin{equation*}
\langle\hat{F}(t)\rangle=\frac{1}{\hbar^{2}} \int_{-\infty}^{t} d t^{\prime} \int_{-\infty}^{t^{\prime}} d t^{\prime \prime} \hat{x}\left(t^{\prime \prime}\right)\left\langle\left[\hat{F}\left(t^{\prime}\right),\left[\hat{H}_{e}\left(t^{\prime \prime}\right), \hat{F}\left(t^{\prime \prime}\right)\right]\right\rfloor\right\rangle . \tag{7.103}
\end{equation*}
$$

As we will see imminently, this expression gives a nonvanishing result even if the right-handpart averaging is carried over the unperturbed (thermal-equilibrium) environment, so that unless we are interested in higher-order corrections, there is no need to refine the result any further. This fact enables us to calculate the average in the right-hand part of Eq. (103) absolutely similarly to that in Eq. (96), using Eq. (94):

[^682]\[

$$
\begin{align*}
& \left\langle\left[\hat{F}\left(t^{\prime}\right),\left[\left.\hat{H}_{e}\left(t^{\prime \prime}\right)\right|_{\mathrm{eq}}, \hat{F}\left(t^{\prime \prime}\right)\right]\right]\right\rangle=\operatorname{Tr}\left\{\mathrm{w}\left[\mathrm{~F}\left(t^{\prime}\right),\left[\mathrm{H}_{e} \mathrm{~F}\left(t^{\prime \prime}\right)\right]\right]\right\} \\
& =\operatorname{Tr}\left\{\mathrm{w}\left[\mathrm{~F}\left(t^{\prime}\right) \mathrm{H}_{e} \mathrm{~F}\left(t^{\prime \prime}\right)-\mathrm{F}\left(t^{\prime}\right) \mathrm{F}\left(t^{\prime \prime}\right) \mathrm{H}_{e}-\mathrm{H}_{e} \mathrm{~F}\left(t^{\prime \prime}\right) \mathrm{F}\left(t^{\prime}\right)+\mathrm{F}\left(t^{\prime \prime}\right) \mathrm{H}_{e} \mathrm{~F}\left(t^{\prime}\right)\right]\right\} \\
& =\sum_{n, n^{\prime}} W_{n}\left[F_{n n^{\prime}}\left(t^{\prime}\right) E_{n^{\prime}} F_{n^{\prime} n}\left(t^{\prime \prime}\right)-F_{n n^{\prime}}\left(t^{\prime}\right) F_{n^{\prime} n}\left(t^{\prime \prime}\right) E_{n}-E_{n} F_{n n^{\prime}}\left(t^{\prime \prime}\right) F_{n^{\prime} n}\left(t^{\prime}\right)+F_{n n^{\prime}}\left(t^{\prime \prime}\right) E_{n^{\prime}} F_{n^{\prime} n}\left(t^{\prime \prime}\right)\right] \\
& =-\sum_{n, n^{\prime}} W_{n} \widetilde{E}\left|F_{n n^{\prime}}\right|^{2}\left[\exp \left\{i \frac{\widetilde{E}}{\hbar}\left(t^{\prime}-t^{\prime \prime}\right)\right\}+\text { c.c. }\right] . \tag{7.104}
\end{align*}
$$
\]

Now, if we try to integrate each term of this sum, as Eq. (103) seems to require, we will see that the lower-limit substitution (at $t^{\prime}, t^{\prime \prime} \rightarrow-\infty$ ) is uncertain, because the exponents oscillate without decay. This technical difficulty may be overcome by the following reasoning. As illustrated by the example considered in the previous section, coupling to a disordered environment makes the "memory horizon" of the subsystem of our interest ( $s$ ) finite: its current state does not depend on its history beyond certain time scale - in that example, the dephasing time $T_{2}$. (Actually, this is true for virtually all real physical systems, in contrast to the idealized models such as a dissipation-free pendulum that swings for ever and ever with the same amplitude.) As a result, the functions under integrals of Eq. (103), i.e. the sum (104), should self-average at a certain finite time. One simple technique for expressing this fact mathematically is just dropping the lower-limit substitution; this would give the correct result for Eq. (103). However, a better (mathematically more acceptable) trick is to first multiply the function under each integral by, respectively, $\exp \left\{\varepsilon\left(t-t^{\prime}\right)\right\}$ and $\exp \left\{\varepsilon\left(t-t^{\prime}\right)\right\}$, where $\varepsilon$ is a very small positive constant, then carry out the integration, and after that take the limit $\varepsilon \rightarrow 0$. The physical justification of this procedure may be provided by saying that system's behavior should not be affected if its interaction with the environment was not kept constant but was turned on gradually - say, exponentially with an infinitesimal rate $\varepsilon$. With this modification, Eq. (103) becomes

$$
\begin{equation*}
\langle\hat{F}(t)\rangle=-\frac{1}{\hbar^{2}} \sum_{n, n^{\prime}} W_{n} \widetilde{E}\left|F_{n n^{\prime}}\right|^{2} \lim _{\varepsilon \rightarrow 0} \int_{-\infty}^{t} d t^{\prime} \int_{-\infty}^{t^{\prime}} d t^{\prime \prime} \hat{x}\left(t^{\prime \prime}\right)\left[\exp \left\{i \frac{\widetilde{E}}{\hbar}\left(t^{\prime}-t^{\prime \prime}\right)+\varepsilon\left(t^{\prime \prime}-t\right)\right\}+\text { c.c. }\right] . \tag{7.105}
\end{equation*}
$$

This double integration is over the area shaded in Fig. 6, so that the order of integration may be changed to the opposite one as

$$
\begin{equation*}
\int_{-\infty}^{t} d t^{\prime} \int_{-\infty}^{t^{\prime}} d t^{\prime \prime} \ldots=\int_{-\infty}^{t} d t^{\prime \prime} \int_{t^{\prime \prime}}^{t} d t^{\prime} \ldots=\int_{-\infty}^{t} d t^{\prime \prime} \int_{0}^{\tau} d \tau^{\prime} \ldots \tag{7.106}
\end{equation*}
$$

where $\tau^{\prime} \equiv t-t^{\prime}$, and $\tau \equiv t-t^{\prime \prime}$.

Fig. 7.6. 2D integration area in Eqs. (105) and (106).

As a result, Eq. (105) may be rewritten as a single integral,

$$
\langle\hat{F}(t)\rangle=\int_{-\infty}^{t} G\left(t-t^{\prime \prime}\right) \hat{x}\left(t^{\prime \prime}\right) d t^{\prime \prime}=\int_{0}^{\infty} G(\tau) \hat{x}(t-\tau) d \tau
$$

$$
\begin{align*}
G(\tau>0) & =-\frac{1}{\hbar^{2}} \sum_{n, n^{\prime}} W_{n} \widetilde{E}\left|F_{n n^{\prime}}\right|^{2} \lim _{\varepsilon \rightarrow 0} \int_{0}^{\tau}\left[\exp \left\{i \frac{\widetilde{E}}{\hbar}\left(\tau-\tau^{\prime}\right)-\varepsilon \tau\right\}+\text { c.c. }\right] d \tau^{\prime}  \tag{7.108}\\
& =\lim _{\varepsilon \rightarrow 0} \frac{2}{\hbar} \sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \sin \frac{\widetilde{E} \tau}{\hbar} e^{-\varepsilon \tau}=\frac{2}{\hbar} \sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \sin \frac{\widetilde{E} \tau}{\hbar},
\end{align*}
$$

does not depend on the particular law of evolution of the subsystem ( $s$ ) under study, i.e. provides a general characterization of its coupling to the environment.

In Eq. (107) we may readily recognize the most general form of the linear response of a system (in our case, the environment), taking into account the causality principle, where $G(\tau)$ is the response function (also called the "temporal Green's function") of the environment. ${ }^{40}$ Comparing Eq. (108) with Eq. (99), we get a wonderfully simple universal relation, ${ }^{41}$

$$
\begin{equation*}
\langle[\tilde{\tilde{F}}(\tau), \hat{\tilde{F}}(0)]\rangle=i \hbar G(\tau) . \tag{7.109}
\end{equation*}
$$

that emphasizes once again the quantum nature of the correlation function's time asymmetry. However, the relation between $G(\tau)$ and the force anti-commutator,

$$
\begin{equation*}
\langle\{\hat{\vec{F}}(t+\tau), \hat{\widetilde{F}}(t)\}\rangle \equiv\langle\hat{\tilde{F}}(t+\tau) \hat{\tilde{F}}(t)+\hat{\tilde{F}}(t) \hat{\widetilde{F}}(t+\tau)\rangle=K_{F}^{+}(\tau)+K_{F}^{-}(\tau) \tag{7.110}
\end{equation*}
$$

is much more important because of the following reason. Relations (97)-(98) show that the so-called symmetrized correlation function,

$$
\begin{align*}
K_{F}(\tau) & \equiv \frac{K_{F}^{+}(\tau)+K_{F}^{-}(\tau)}{2}=\frac{1}{2}\langle\langle\hat{\tilde{F}}(\tau), \tilde{\tilde{F}}(0)\}\rangle=\lim _{\varepsilon \rightarrow 0} \sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \cos \frac{\widetilde{E} \tau}{\hbar} e^{-2 \varepsilon|\tau|} \\
& =\sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \cos \frac{\widetilde{E} \tau}{\hbar}, \tag{7.111}
\end{align*}
$$

Fluctuation commutator via Green's function

Symmetrized correlation function

[^683]\[

$$
\begin{equation*}
K_{F}(\tau)=\int_{-\infty}^{+\infty} S_{F}(\omega) e^{-i \omega \tau} d \omega=2 \int_{0}^{+\infty} S_{F}(\omega) \cos \omega \tau d \omega \tag{7.112}
\end{equation*}
$$

\]

with the reciprocal transform

$$
\begin{equation*}
S_{F}(\omega)=\frac{1}{2 \pi} \int_{-\infty}^{+\infty} K_{F}(\tau) e^{i \omega \tau} d \tau=\frac{1}{\pi} \int_{0}^{+\infty} K_{F}(\tau) \cos \omega \tau d \tau \tag{7.113}
\end{equation*}
$$

via the symmetrized spectral density of variable $F$, defined as

$$
\begin{equation*}
S_{F}(\omega) \delta\left(\omega-\omega^{\prime}\right) \equiv \frac{1}{2}\left\langle\hat{F}_{\omega} \hat{F}_{-\omega^{\prime}}+\hat{F}_{-\omega^{\prime}} \hat{F}_{\omega}\right\rangle=\frac{1}{2}\left\langle\left\{\hat{F}_{\omega}, \hat{F}_{-\omega^{\prime}}\right\}\right\rangle, \tag{7.114}
\end{equation*}
$$

where $\hat{F}_{\omega}$ (also an operator rather than a $c$-number!) is defined as

$$
\begin{equation*}
\hat{F}_{\omega} \equiv \frac{1}{2 \pi} \int_{-\infty}^{+\infty} \hat{\tilde{F}}(t) e^{i \omega t} d t, \quad \text { so that } \hat{\tilde{F}}(t)=\int_{-\infty}^{+\infty} \hat{F}_{\omega} e^{-i \omega t} d \omega \tag{7.115}
\end{equation*}
$$

The physical meaning of function $S_{F}(\omega)$ becomes evident if we write Eq. (112) for the particular case $\tau=0$ :

$$
\begin{equation*}
K_{F}(0) \equiv\left\langle\hat{\widetilde{F}}^{2}\right\rangle=\int_{-\infty}^{+\infty} S_{F}(\omega) d \omega=2 \int_{0}^{+\infty} S_{F}(\omega) d \omega \tag{7.116}
\end{equation*}
$$

This formula implies that if we pass function $F(t)$ through a linear filter cutting from its frequency spectrum a narrow band $d \omega$ of real (positive) frequencies, then variance $\left\langle F_{f}^{2}\right\rangle$ of the filtered signal $F_{f}(t)$ would be equal to $2 S_{F}(\omega) d \omega$ - hence the name "spectral density". ${ }^{43}$

Let us use Eqs. (111) and (113) to calculate the spectral density for our model:

$$
\begin{align*}
S_{F}(\omega) & =\sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \frac{1}{2 \pi} \lim _{\varepsilon \rightarrow 0} \int_{-\infty}^{+\infty} \cos \frac{\widetilde{E} \tau}{\hbar} e^{-\varepsilon \mid \tau} e^{i \omega \tau} d \tau \\
& =\frac{1}{2 \pi} \sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \lim _{\varepsilon \rightarrow 0} \int_{0}^{+\infty}\left[\exp \left\{i \frac{\widetilde{E} \tau}{\hbar}\right\}+\text { c.c. }\right] e^{-\varepsilon \tau} e^{i \omega \tau} d \tau  \tag{7.117}\\
& =\frac{1}{2 \pi} \sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \lim _{\varepsilon \rightarrow 0}\left[\frac{1}{i(\widetilde{E} / \hbar+\omega)-\varepsilon}+\frac{1}{i(-\widetilde{E} / \hbar+\omega)-\varepsilon}\right] .
\end{align*}
$$

Now it is a convenient time to recall that each of the two summations here is over the eigenenergy spectrum of the environment whose spectrum is virtually continuous because of its large size, so that we may transform each sum into an integral just as this was done in Sec. 6.6:

$$
\begin{equation*}
\sum_{n} \ldots \rightarrow \int \ldots d n=\int \ldots \rho\left(E_{n}\right) d E_{n} \tag{7.118}
\end{equation*}
$$

${ }^{43}$ An alternative popular measure of spectral density is $S_{F}(v) \equiv\left\langle F_{f}^{2}\right\rangle / d \nu=4 \pi S_{F}(\omega)$, where $v=\omega / 2 \pi$ is the "cyclic" frequency (measured in Hz ).
where $\rho(E)$ is the density of environment's states at a given energy. This transformation yields

$$
\begin{equation*}
S_{F}(\omega)=\frac{1}{2 \pi} \lim _{\varepsilon \rightarrow 0} \int d E_{n} W\left(E_{n}\right) \rho\left(E_{n}\right) \int d E_{n^{\prime}} \rho\left(E_{n^{\prime}}\right)\left|F_{n n^{\prime}}\right|^{2}\left[\frac{1}{i(\widetilde{E} / \hbar-\omega)-\varepsilon}+\frac{1}{i(-\widetilde{E} / \hbar-\omega)-\varepsilon}\right] \tag{7.119}
\end{equation*}
$$

Since the square bracket depends only on a specific linear combination of two energies, $\widetilde{E} \equiv E_{n}-E_{n^{\prime}}$, it is convenient to introduce also another, linearly-independent combination of the energies, for example, the average energy $\bar{E}=\left(E_{n}+E_{n^{\prime}}\right) / 2$, so that the state energies may be presented as

$$
\begin{equation*}
E_{n}=\bar{E}+\frac{\widetilde{E}}{2}, \quad E_{n^{\prime}}=\bar{E}-\frac{\widetilde{E}}{2} . \tag{7.120}
\end{equation*}
$$

With this notation, Eq. (119) becomes

$$
\begin{align*}
S_{F}(\omega)=-\frac{\hbar}{2 \pi} \lim _{\varepsilon \rightarrow 0} \int d \bar{E} & {\left[\int W\left(\bar{E}+\frac{\widetilde{E}}{2}\right)\left|F_{n n^{\prime}}\right|^{2} \rho\left(\bar{E}+\frac{\widetilde{E}}{2}\right) \rho\left(\bar{E}-\frac{\widetilde{E}}{2}\right) \frac{d \widetilde{E}}{i(\widetilde{E}-\hbar \omega)-\hbar \varepsilon}\right.}  \tag{7.121}\\
& \left.+\int W\left(\bar{E}+\frac{\widetilde{E}}{2}\right)\left|F_{n n^{\prime}}\right|^{2} \rho\left(\bar{E}+\frac{\widetilde{E}}{2}\right) \rho\left(\bar{E}-\frac{\widetilde{E}}{2}\right) \frac{d \widetilde{E}}{i(-\widetilde{E}-\hbar \omega)-\hbar \varepsilon}\right]
\end{align*}
$$

Due to the smallness of parameter $\hbar \varepsilon$ (which should be much less than all real energies, including $k_{\mathrm{B}} T$, $\hbar \omega, E_{n}$, and $E_{n}$ '), each of the internal integrals is dominated by an infinitesimal vicinity of one point, $\widetilde{E}_{ \pm}= \pm \hbar \omega$, in which the spectral density, matrix elements, and the Gibbs probabilities do not change considerably, and may be taken out of the integrals, so that they may be worked out explicitly: ${ }^{44}$

$$
\begin{align*}
& S_{F}(\omega)=-\frac{\hbar}{2 \pi} \lim _{\varepsilon \rightarrow 0} \int d \bar{E} \rho_{+} \rho_{-}\left[W_{+}\left|F_{+}\right|^{2} \int_{-\infty}^{+\infty} \frac{d \widetilde{E}}{i(\widetilde{E}-\hbar \omega)-\hbar \varepsilon}+W_{-}\left|F_{-}\right|^{2} \int_{-\infty}^{+\infty} \frac{d \widetilde{E}}{i(-\widetilde{E}-\hbar \omega)-\hbar \varepsilon}\right] \\
& =-\frac{\hbar}{2 \pi} \lim _{\varepsilon \rightarrow 0} \int d \bar{E} \rho_{+} \rho_{-}\left[W_{+}\left|F_{+}\right|^{2} \int_{-\infty}^{+\infty} \frac{-i(\widetilde{E}-\hbar \omega)-\hbar \varepsilon}{(\widetilde{E}-\hbar \omega)^{2}+(\hbar \varepsilon)^{2}} d \widetilde{E}+W_{-}\left|F_{-}\right|^{2} \int_{-\infty}^{+\infty} \frac{i(\widetilde{E}+\hbar \omega)-\hbar \varepsilon}{(\widetilde{E}+\hbar \omega)^{2}+(\hbar \varepsilon)^{2}} d \widetilde{E}\right]  \tag{7.122}\\
& =\frac{\hbar}{2} \int \rho_{+} \rho_{-}\left[W_{+}\left|F_{+}\right|^{2}+W_{-}\left|F_{-}\right|^{2}\right] d \bar{E}
\end{align*}
$$

where indices $\pm$ mark function values at the special points $\widetilde{E}_{ \pm}= \pm \hbar \omega$, i.e. $E_{n}=E_{n}{ }^{\prime} \pm \hbar \omega$. The physics of these points becomes simple if we interpret state $n$, that is the argument of the equilibrium Gibbs distribution function $W_{n}$, as the initial state of the environment, and $n$ ' as its final state. Then the topsign point corresponds to $E_{n}{ }^{\prime}=E_{n}-\hbar \omega$, i.e. to the emission of one energy quantum $\hbar \omega$ of the "observation" frequency $\omega$ by the environment into subsystem $s$ of interest, while the bottom-sign point $E_{n^{\prime}}=E_{n}+\hbar \omega$, corresponds to the absorption of such quantum by the environment. As Eq. (122) shows, both processes give similar positive contributions into force fluctuations.

[^684]The situation is different for the Fourier image of the response function $G(\tau),{ }^{45}$

$$
\begin{equation*}
\chi(\omega) \equiv \int_{0}^{+\infty} G(\tau) e^{i \omega \tau} d \tau \tag{7.123}
\end{equation*}
$$

Generalized susceptibility
that is frequently called either the generalized susceptibility or the response function - in our case, of the environment. Its physical meaning is that the complex function $\chi(\omega)=\chi^{\prime}(\omega)+i \chi$ '" $(\omega)$ relates the Fourier amplitudes of the generalized coordinate and generalized force:46

$$
\begin{equation*}
\left\langle\hat{F}_{\omega}\right\rangle=\chi(\omega) \hat{x}_{\omega} \tag{7.124}
\end{equation*}
$$

The physics of its imaginary part $\chi$ " $(\omega)$ is especially clear. Indeed, if both $F_{\omega}$ and $x_{\omega}$ represent a sinusoidal classical process, say

$$
\begin{equation*}
x(t)=x_{0} \cos \omega t=\frac{x_{0}}{2} e^{-i \omega t}+\frac{x_{0}}{2} e^{+i \omega t}, \text { i.e. } x_{\omega}=x_{-\omega}=\frac{x_{0}}{2} \tag{7.125}
\end{equation*}
$$

Then, in accordance with the correspondence principle, Eq. (124) should hold for the $c$-number complex amplitudes $F_{\omega}$ and $x_{\omega}$, enabling us to calculate the time dependence of force,

$$
\begin{align*}
F(t) & =F_{\omega} e^{-i \omega t}+F_{-\omega} e^{+i \omega t}=\chi(\omega) x_{\omega} e^{-i \omega t}+\chi(-\omega) x_{-\omega} e^{+i \omega t}=\frac{x_{0}}{2}\left[\chi(\omega) e^{-i \omega t}+\chi(-\omega) e^{+i \omega t}\right]  \tag{7.126}\\
& =\frac{x_{0}}{2}\left[\left(\chi^{\prime}+i \chi^{\prime \prime}\right) e^{-i \omega t}+\left(\chi^{\prime}-i \chi^{\prime \prime}\right) e^{+i \omega t}\right]=x_{0}\left[\chi^{\prime}(\omega) \cos \omega t+\chi^{\prime \prime}(\omega) \sin \omega t\right]
\end{align*}
$$

We see that $\chi^{\prime \prime}(\omega)$ scales the part of the force that is $\pi / 2$-shifted from the coordinate oscillations, i.e. is in phase with those of velocity, and hence characterizes the time-average power flow from the system into the environment, i.e. the energy dissipation rate: ${ }^{47}$

$$
\begin{equation*}
\bar{P}=\overline{-F(t) \dot{x}(t)}=\overline{-x_{0}\left[\chi^{\prime}(\omega) \cos \omega t+\chi^{\prime \prime}(\omega) \sin \omega t\right]\left(-\omega x_{0} \sin \omega t\right)}=\frac{x_{0}^{2}}{2} \omega \chi^{\prime \prime}(\omega) \tag{7.127}
\end{equation*}
$$

Let us calculate this function from Eqs. (108) and (123), just as we have done for the spectral density of fluctuations:

$$
\begin{aligned}
\chi^{\prime \prime}(\omega) & =\operatorname{Im} \int_{0}^{+\infty} G(\tau) e^{i \omega \tau} d \tau=\frac{2}{\hbar} \sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \lim _{\varepsilon \rightarrow 0} \operatorname{Im} \int_{0}^{+\infty} \frac{1}{2 i}\left(\exp \left\{i \frac{\widetilde{E} \tau}{\hbar}\right\}-\text { c.c. }\right) e^{i \omega \tau} e^{-\varepsilon \tau} d \tau \\
& =\sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \lim _{\varepsilon \rightarrow 0} \operatorname{Im}\left(\frac{1}{-\widetilde{E}-\hbar \omega-i \hbar \varepsilon}-\frac{1}{\widetilde{E}-\hbar \omega-i \hbar \varepsilon}\right)
\end{aligned}
$$

[^685]\[

$$
\begin{equation*}
=\sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \lim _{\varepsilon \rightarrow 0}\left(\frac{\hbar \varepsilon}{(\widetilde{E}+\hbar \omega)^{2}+(\hbar \varepsilon)^{2}}-\frac{\hbar \varepsilon}{(\widetilde{E}-\hbar \omega)^{2}+(\hbar \varepsilon)^{2}}\right) . \tag{7.128}
\end{equation*}
$$

\]

Making the transfer (118) from the double sum to the double integral, and then the integration variable transfer (120), we get

$$
\begin{align*}
\chi^{\prime \prime}(\omega)=\lim _{\varepsilon \rightarrow 0} \int d \bar{E} & {\left[\int_{-\infty}^{+\infty} W\left(\bar{E}+\frac{\widetilde{E}}{2}\right) \rho\left(\bar{E}+\frac{\widetilde{E}}{2}\right) \rho\left(\bar{E}-\frac{\widetilde{E}}{2}\right)\left|F_{n n^{\prime}}\right|^{2} \frac{\hbar \varepsilon}{(\widetilde{E}+\hbar \omega)^{2}+(\hbar \varepsilon)^{2}} d \widetilde{E}\right.} \\
& \left.-\int_{-\infty}^{+\infty} W\left(\bar{E}+\frac{\widetilde{E}}{2}\right) \rho\left(\bar{E}+\frac{\widetilde{E}}{2}\right) \rho\left(\bar{E}-\frac{\widetilde{E}}{2}\right)\left|F_{n n^{\prime}}\right|^{2} \frac{\hbar \varepsilon}{(\widetilde{E}-\hbar \omega)^{2}+(\hbar \varepsilon)^{2}} d \widetilde{E}\right] . \tag{7.129}
\end{align*}
$$

Now using the same argument about the smallness of parameter $\varepsilon$ as above, we may take the spectral densities, matrix elements of force, and the Gibbs probabilities out of the integrals, and work out the integrals, getting a result very similar to Eq. (122):

$$
\begin{equation*}
\chi^{\prime \prime}(\omega)=\pi \int \rho_{+} \rho_{-}\left[W_{-}\left|F_{-}\right|^{2}-W_{+}\left|F_{+}\right|^{2}\right] d \bar{E} \tag{7.130}
\end{equation*}
$$

In order to relate these results, it is sufficient to notice that according to Eq. (23), the Gibbs probabilities $W_{ \pm}$are related by coefficients dependent on only the temperature $T$ and observation frequency $\omega$ :

$$
\begin{equation*}
W_{ \pm} \equiv W\left(\bar{E}+\frac{\widetilde{E}_{ \pm}}{2}\right) \equiv W\left(\bar{E} \pm \frac{\hbar \omega}{2}\right)=\frac{1}{Z} \exp \left\{-\frac{\bar{E} \pm \hbar \omega / 2}{k_{\mathrm{B}} T}\right\}=W(\bar{E}) \exp \left\{\mp \frac{\hbar \omega}{2 k_{\mathrm{B}} T}\right\} \tag{7.131}
\end{equation*}
$$

so that both the spectral density and the dissipative part of susceptibility may expressed via the same integral over environment energies:

$$
\begin{align*}
& S_{F}(\omega)=\hbar \cosh \left(\frac{\hbar \omega}{2 k_{\mathrm{B}} T}\right) \int \rho_{+} \rho_{-} W(\bar{E})\left[\left|F_{+}\right|^{2}+\left|F_{-}\right|^{2}\right] d \bar{E},  \tag{7.132}\\
& \chi^{\prime \prime}(\omega)=2 \pi \sinh \left(\frac{\hbar \omega}{2 k_{\mathrm{B}} T}\right) \int \rho_{+} \rho_{-} W(\bar{E})\left[\left|F_{+}\right|^{2}+\left|F_{-}\right|^{2}\right] d \bar{E} \tag{7.133}
\end{align*}
$$

and hence are universally related as

$$
\begin{equation*}
S_{F}(\omega)=\frac{\hbar}{2 \pi} \chi^{\prime \prime}(\omega) \operatorname{coth} \frac{\hbar \omega}{2 k_{\mathrm{B}} T} \tag{7.134}
\end{equation*}
$$

This is the Callen-Welton's fluctuation-dissipation theorem (FDT). It reveals the fundamental, intimate relation between dissipation and fluctuations induced by environment ("no dissipation without fluctuations") - hence the name. ${ }^{48}$ In the classical limit, $\hbar \omega \ll k_{\mathrm{B}} T$, the FDT is reduced to

[^686]\[

$$
\begin{equation*}
S_{F}(\omega)=\frac{\hbar}{2 \pi} \chi^{\prime \prime}(\omega) \frac{2 k_{\mathrm{B}} T}{\hbar \omega}=\frac{k_{\mathrm{B}} T}{\pi} \frac{\operatorname{Im} \chi(\omega)}{\omega} . \tag{7.135}
\end{equation*}
$$

\]

In most systems of interest the last fraction tends to a finite (positive) constant in a substantial range of relatively low frequencies. Indeed, expanding Eq. (123) in the Taylor series in small $\omega$, we get

$$
\begin{equation*}
\chi(\omega)=\chi(0)+i \omega \eta+\ldots, \quad \text { with } \quad \chi(0)=\int_{0}^{\infty} G(\tau) d \tau, \quad \text { and } \eta \equiv \int_{0}^{\infty} G(\tau) \tau d \tau \tag{7.136}
\end{equation*}
$$

Since the temporal Green's function is real by definition, the Taylor expansion of $\chi$ " $(\omega) \equiv \operatorname{Im} \chi(\omega)$ starts with the linear term $i \omega \eta$, where $\eta$ is a certain real coefficient, and unless $\eta=0$, is dominated by this term at small $\omega$. (The physical sense of constant $\eta$ becomes clear if we consider an environment that provides viscous friction with the simple law

$$
\begin{equation*}
\langle\hat{F}\rangle=-\eta \dot{\hat{x}}, \quad \eta \geq 0 . \tag{7.137}
\end{equation*}
$$

| Drag |
| :--- |

For the Fourier images of coordinate and force this gives the relation $F_{\omega}=i \omega x_{\omega}$, so that according to Eq. (124),

$$
\begin{equation*}
\chi(\omega)=i \omega \eta \text {, i.e. } \frac{\chi^{\prime \prime}(\omega)}{\omega} \equiv \frac{\operatorname{Im} \chi(\omega)}{\omega}=\eta \geq 0 \tag{7.138}
\end{equation*}
$$

Hence, even in the general case, coefficient $\eta$ describes an effective low-speed drag (kinematic friction) provided by the environment.)

In this case Eq. (134) turns into the Nyquist formula:49
Nyquist
formula

$$
\begin{equation*}
S_{F}(\omega)=\frac{k_{\mathrm{B}} T}{\pi} \eta, \quad \text { i.e. }\left\langle F_{f}^{2}\right\rangle=4 k_{\mathrm{B}} T \eta d v . \tag{7.139}
\end{equation*}
$$

According to Eq. (112), if such a constant spectral density ${ }^{50}$ persisted at all frequencies, it would correspond to a delta-correlated process $F(t)$, with

$$
\begin{equation*}
K_{F}(\tau)=2 \pi S_{F}(0) \delta(\tau)=2 k_{\mathrm{B}} T \eta \delta(\tau), \tag{7.140}
\end{equation*}
$$

similar to already discussed above - see Eq. (82).
oscillator was by no means used in its derivation. As will see in the next section, this fact leads to rather interesting consequences and even conceptual opportunities.
${ }^{49}$ Actually, the 1928 work by H. Nyquist was about electronic noise in resistors, just discovered experimentally by his Bell Labs colleague J. Johnson. For an Ohmic resistor, as a dissipative "environment" of the electric circuit it is connected with, Eq. (137) is just the Ohm's law, and may be recast as either $\langle V\rangle=-R(d Q / d t)=R I$, or $\langle I\rangle=-$ $G(d \Phi / d t)=G V$. Thus for voltage $V$ in an open circuit, $\eta$ corresponds to resistance $R$, while for current $I$ in the short circuit, to conductance $G=1 / R$. In this case, the fluctuations described by Eq. (139) are referred to as the Johnson-Nyquist noise. (Because of this important application, any model leading to Eqs. (136)-(137) is frequently referred to as Ohmic dissipation, even if the physical nature of variables $x$ and $F$ is quite different.) Another note: the Nyquist formula (139) should not be confused with the Nyquist-Shannon theorem describing the minimum sampling rate of an analog signal.
${ }^{50}$ A random process whose properties may be reasonably approximated by constant spectral density is frequently called the white noise, because then it is a random mixture of all possible sinusoidal components with equal weights, reminding natural white light's composition.

Since in the classical limit the right-hand part of Eq. (109) is negligible, and the correlation function may be considered an even function of time, the symmetrized function under the integral in Eq. (113) may be rewritten just as $\langle F(\tau) F(0)\rangle$. In the limit of low observation frequencies (in the sense that $\omega$ is much smaller than not only the quantum frontier $k_{\mathrm{B}} T / \hbar$, but also the frequency scale of function $\left.\chi^{\prime \prime}(\omega) / \omega\right)$, Eq. (138) may be used to recast Eq. (135) in the form ${ }^{51}$

$$
\begin{equation*}
\eta \equiv \lim _{\omega \rightarrow 0} \frac{\chi^{\prime \prime}(\omega)}{\omega}=\frac{1}{k_{\mathrm{B}} T} \int_{0}^{\infty}\langle F(\tau) F(0)\rangle d \tau . \tag{7.141}
\end{equation*}
$$

To conclude this section, let me return for a minute to the questions formulated in our earlier discussion of dephasing in the two-level model. In that problem, the dephasing time scale is $T_{2}=1 / 2 D_{\varphi}$. Hence the classical approach to the environment, used in Sec. 3, is adequate if $\hbar D_{\varphi} \ll k_{\mathrm{B}} T$. Next, we may identify operators $\hat{f}$ and $\hat{\sigma}_{z}$ participating in Eq. (70) with, respectively, operators $\hat{F}$ and $\hat{x}$ of the general Eq. (90). Then the comparison of Eqs. (82), (88) and (140) yields

$$
\begin{equation*}
\frac{1}{T_{2}}=2 D_{\varphi}=\frac{4 k_{\mathrm{B}} T}{\hbar^{2}} \eta, \tag{7.142}
\end{equation*}
$$

so that, for the model described by Eq. (137) with temperature-independent drag coefficient $\eta$, the dephasing rate is proportional to temperature.

### 7.5. The Heisenberg-Langevin approach

The fluctuation-dissipation theorem opens a very simple and efficient way for analysis of the system of interest ( $s$ in Fig. 1). It is to write its Heisenberg equations (4.199) of motion for relevant operators, which would now include the environmental force operator, and explore these equations using the Fourier transform and the Wiener-Khinchin theorem (112)-(113). Such approach to classical equations of motion is commonly associated with the name of Langevin, ${ }^{52}$ so that its extension to dynamics of Heisenberg-picture operators is frequently referred to as the Heisenberg-Langevin (or "quantum Langevin") approach to open system analysis. ${ }^{53}$

Perhaps the best way to describe this method is to demonstrate how it works for the very important case of a 1D harmonic oscillator, so that the generalized coordinate $x$ of Sec. 4 is just the oscillator's coordinate. For the sake of simplicity, let us assume that the environment provides the simple Ohmic dissipation described by Eq. (137) - which is a good approximation in many cases. As we already know from Chapter 5, the Heisenberg equations of motion for operators of coordinate and momentum of the oscillator, in the presence of external force, are
${ }^{51}$ In some fields (especially in physical kinetics and chemical physics), this particular limit of the Nyquist formula, is called the Green-Kubo (or just "Kubo") formula. As was discussed above, these names may be more reasonably associated with Eq. (109).
${ }^{52}$ After P. Langevin, whose 1908 work was the first systematic development of Einstein's ideas (1905) of the Brownian motion theory in the random force language, as an alternative to M. Smoluchowski's approach using the probability density language - see Sec. 6 below.
${ }^{53}$ Perhaps the largest credit for this extension belongs to M. Lax whose work, in the early 1960s, was motivated mostly by quantum electronics applications - see, e.g., his monograph M. Lax, Fluctuation and Coherent Phenomena in Classical and Quantum Physics, Gordon and Breach, 1968, and references therein.

$$
\begin{equation*}
\dot{\hat{x}}=\frac{\hat{p}}{m}, \quad \dot{\hat{p}}=-m \omega_{0}^{2} \hat{x}+\hat{F}, \tag{7.143}
\end{equation*}
$$

so that using Eqs. (92) and (137), we get

$$
\begin{equation*}
\dot{\hat{x}}=\frac{\hat{p}}{m}, \quad \dot{\hat{p}}=-m \omega_{0}^{2} \hat{x}-\eta \dot{\hat{x}}+\hat{\tilde{F}}(t) . \tag{7.144}
\end{equation*}
$$

Combining Eqs. (144), we may write their system as a singe differential equation

$$
\begin{equation*}
m \ddot{\hat{x}}+\eta \dot{\hat{x}}+m \omega_{0}^{2} \hat{x}=\hat{\widetilde{F}}(t) \tag{7.145}
\end{equation*}
$$

that is absolutely similar to the classical equation of motion. ${ }^{54}$ (In the view of Eqs. (5.42) and (5.48), whose corollary the Ehrenfest theorem (5.49) is, this should be by no means surprising.) For the Fourier images of the operators, defined similarly to Eq. (115), Eq. (145) gives the following relation,

$$
\begin{equation*}
\hat{x}_{\omega}=\frac{\hat{F}_{\omega}}{m\left(\omega_{0}^{2}-\omega^{2}\right)-i \eta \omega} \tag{7.146}
\end{equation*}
$$

that should be also well known to the reader from the classical theory of forced oscillations. However, since the Fourier components are still Heisenberg-picture operators, and their "values" for different $\omega$ do not commute, we have to tread carefully. The best way to proceed is to write a copy of Eq. (146) for frequency ( $-\omega^{\prime}$ ), and then combine these equations to form a symmetrical combination similar that used in Eq. (114). The result is

$$
\begin{equation*}
\frac{1}{2}\left\langle\hat{x}_{\omega} \hat{x}_{-\omega^{\prime}}+\hat{x}_{-\omega^{\prime}} \hat{x}_{\omega}\right\rangle=\frac{1}{\left|m\left(\omega_{0}^{2}-\omega^{2}\right)-i \eta \omega\right|^{2}} \frac{1}{2}\left\langle\hat{F}_{\omega} \hat{F}_{-\omega^{\prime}}+\hat{F}_{-\omega^{\prime}} \hat{F}_{\omega}\right\rangle . \tag{7.147}
\end{equation*}
$$

Since the spectral density definition similar to Eq. (114) is valid for any observable, in particular for $x$, Eq. (147) allows us to relate the symmetrized spectral densities of coordinate and force:

$$
\begin{equation*}
S_{x}(\omega)=\frac{S_{F}(\omega)}{\left|m\left(\omega_{0}^{2}-\omega^{2}\right)-i \eta \omega\right|^{2}}=\frac{S_{F}(\omega)}{m^{2}\left(\omega_{0}^{2}-\omega^{2}\right)^{2}+(\eta \omega)^{2}} . \tag{7.148}
\end{equation*}
$$

Now using an analog of Eq. (116) for $x$, we can calculate coordinate's variance:

$$
\begin{equation*}
\left\langle x^{2}\right\rangle=K_{x}(0)=\int_{-\infty}^{+\infty} S_{x}(\omega) d \omega=2 \int_{0}^{+\infty} \frac{S_{F}(\omega) d \omega}{m^{2}\left(\omega_{0}^{2}-\omega^{2}\right)^{2}+(\eta \omega)^{2}}, \tag{7.149}
\end{equation*}
$$

where now, in contrast to the notation used in Sec. 4, sign $\langle\ldots\rangle$ means the averaging over the usual statistical ensemble of many systems of interest - in our current case, of many harmonic oscillators.

If the coupling to environment is so weak that drag coefficient $\eta$ is small (in the sense that the oscillator's dimensionless $Q$-factor ${ }^{48}$ is large, $Q \equiv m \omega_{0} / \eta \gg 1$ ), this integral is dominated by the resonance peak in a narrow vicinity, $\left|\omega-\omega_{0}\right| \equiv|\xi| \ll \omega_{0}$, of its resonance frequency, and we can take the relatively smooth function $S_{F}(\omega)$ out of the integral, thus reducing it to a table integral:55

[^687]\[

$$
\begin{align*}
\left\langle x^{2}\right\rangle & \approx 2 S_{F}\left(\omega_{0}\right) \int_{0}^{+\infty} \frac{d \omega}{m^{2}\left(\omega_{0}^{2}-\omega^{2}\right)^{2}+(\eta \omega)^{2}} \approx 2 S_{F}\left(\omega_{0}\right) \int_{-\infty}^{+\infty} \frac{d \xi}{\left(2 m \omega_{0} \xi\right)^{2}+\left(\eta \omega_{0}\right)^{2}}  \tag{7.150}\\
& =2 S_{F}\left(\omega_{0}\right) \frac{1}{\left(\eta \omega_{0}\right)^{2}} \int_{-\infty}^{+\infty} \frac{d \xi}{(2 m \xi / \eta)^{2}+1}=2 S_{F}\left(\omega_{0}\right) \frac{1}{\left(\eta \omega_{0}\right)^{2}} \frac{\pi \eta}{2 m}=\frac{\pi}{\eta m \omega_{0}^{2}} S_{F}\left(\omega_{0}\right) .
\end{align*}
$$
\]

With the account of the FDT (134) and Eq. (138), this gives

$$
\begin{equation*}
\left\langle x^{2}\right\rangle=\frac{\pi}{\eta m \omega_{0}^{2}} \frac{\hbar}{2 \pi} \eta \omega_{0} \operatorname{coth} \frac{\hbar \omega_{0}}{2 k_{B} T}=\frac{\hbar}{2 m \omega_{0}} \operatorname{coth} \frac{\hbar \omega_{0}}{2 k_{B} T} \tag{7.151}
\end{equation*}
$$

But this is exactly Eq. (48) that was obtained from the Gibbs distribution, without any explicit account of the environment - though keeping it in mind by using the notion of the thermally-equilibrium ensemble. ${ }^{56}$ (Notice that the drag coefficient $\eta$, which characterizes the oscillator-to-environment interaction strength, has cancelled!) Does this mean that we have toiled in vain?

By no means. First of all, the FDT result has an important conceptual value. For example, let us consider the low-temperature limit $k_{\mathrm{B}} T \ll \hbar \omega_{0}$, when Eq. (151) is reduced to

$$
\begin{equation*}
\left\langle x^{2}\right\rangle=\frac{x_{0}^{2}}{2}=\frac{\hbar}{2 m \omega_{0}} . \tag{7.152}
\end{equation*}
$$

Let us ask a naïve question: What exactly is the origin of this coordinate uncertainty? From the point of view of the usual quantum mechanics of closed (Hamiltonian) systems, there is no doubt: this nonvanishing variance of coordinate is the result of the final spatial extension of the ground-state wavefunction, reflecting the Heisenberg's uncertainty relation (that in turn results from the fact that the operators of coordinate and momentum do not commute) - see Eq. (2.271). However, from the point of view of the Heisenberg-Langevin equation (145), variance (152) is an unalienable part of the oscillator's response to the fluctuation force $\widetilde{F}(t)$ exerted by the environment at frequencies $\omega \approx \omega_{0}$. Though it is impossible to refute the former, absolutely legitimate point of view, in many applications it is much easier to subscribe to the latter standpoint, and treat the coordinate uncertainty as the result of the socalled quantum noise of the environment. This notion has received numerous confirmations in experiments that did not include any oscillators with the eigenfrequencies $\omega_{0}$ close to the noise measurement frequency $\omega .{ }^{57}$

The advantage of the Heisenberg-Langevin approach is that for any $\eta>0$ it is possible to calculate the (experimentally measurable!) distribution $S_{x}(\omega)$, i.e. decompose the fluctuations into spectral components. This procedure is not restricted to the limit of small $\eta$ (large $Q$ factors); for any damping we may just plug the FDT (134) into Eq. (149) and integrate. As an example, let us have a look at the so-called quantum diffusion. A free 1D particle may be considered as the particular case of a 1D harmonic oscillator with $\omega_{0}=0$, so that combining Eqs. (134) and (149), we get

[^688]\[

$$
\begin{equation*}
\left\langle x^{2}\right\rangle=2 \int_{0}^{+\infty} \frac{S_{F}(\omega) d \omega}{\left(m \omega^{2}\right)^{2}+(\eta \omega)^{2}}=2 \eta \int_{0}^{+\infty} \frac{1}{\left(m \omega^{2}\right)^{2}+(\eta \omega)^{2}} \frac{\hbar \omega}{2 \pi} \operatorname{coth} \frac{\hbar \omega}{2 k_{B} T} d \omega . \tag{7.153}
\end{equation*}
$$

\]

This integral has two divergences. The first one, of the type $\int d \omega / \omega^{2}$ at the lower limit, is just a classical effect: according to Eq. (85), particle's displacement variance grows with time, so it cannot have a finite time-independent value that Eq. (153) tries to calculate. However, we still can use that result to single out the quantum noise effect on diffusion - say, by comparing it with a similar but purely classical case. These effects are prominent at high frequencies, especially if the quantum noise overcomes the thermal noise before the dynamic cut-off, i.e. if

$$
\begin{equation*}
\frac{k_{\mathrm{B}} T}{\hbar} \ll \frac{\eta}{m} . \tag{7.154}
\end{equation*}
$$

In this case there is a broad range of frequencies where the quantum noise gives a substantial contribution to the integral:

$$
\begin{equation*}
\left\langle x^{2}\right\rangle_{Q} \approx 2 \eta \int_{k_{\mathrm{B}} T / \hbar}^{\eta / m} \frac{1}{(\eta \omega)^{2}} \frac{\hbar \omega}{2 \pi} d \omega=\frac{\hbar}{\pi \eta} \int_{k_{\mathrm{B}} T / \hbar}^{\eta / m} \frac{d \omega}{\omega}=\frac{\hbar}{\pi \eta} \ln \frac{\hbar \eta}{m k_{\mathrm{B}} T} \sim \frac{\hbar}{\eta} \tag{7.155}
\end{equation*}
$$

Formally, this contribution diverges at either $m \rightarrow 0$ or $T \rightarrow 0$, but this logarithmic (i.e. extremely weak) divergence is readily quenched by an almost any change of the environment model at very high frequencies, where the "Ohmic" approximation given by Eq. (136) becomes unrealistic.

The Heisenberg-Langevin approach is extremely simple and powerful, ${ }^{58}$ but is has its limitations. The main one is that if the equations of motion for the Heisenberg operators are not linear, there is no linear relation, such as Eq. (146), between the Fourier images of the generalized force and generalized coordinate, and as the result there is no simple relation, such as Eq. (148), between their spectral densities. In other words, if the Heisenberg equation of motion are nonlinear, there is no regular simple way to use them to calculate statistical properties of the observables. For example, let us return to the dephasing problem described by Eqs. (68)-(70), and assume that the generalized force is characterized by relations similar to (93) and (134). Now writing the Heisenberg equations of motion for the two remaining spin operators, and using the commutation relations between them, we get

$$
\begin{equation*}
\dot{\hat{\sigma}}_{x}=-2 \frac{a-\hat{\tilde{f}}(t)}{\hbar} \hat{\sigma}_{y}, \quad \dot{\hat{\sigma}}_{y}=2 \frac{a-\hat{\tilde{f}}(t)}{\hbar} \hat{\sigma}_{x} \tag{7.156}
\end{equation*}
$$

These equations do not provide a linear relation between the Pauli operators and the fluctuation force, so even if we know spectral properties of the latter from the FDT, this does not help too much - unless we return to the approximate, classical approach described in Sec. 3 above. ${ }^{59}$

[^689]
### 7.6. Density matrix approach

The main alternative approach, that is essentially a generalization of that used in Sec. 2, is to extract the final results from the dynamics of the density matrix of our subsystem $s$ of interest (which, from this point on, will be called $w_{s}$ ). I will discuss this approach in detail, ${ }^{60}$ cutting just a few technical corners, in each case referring the reader to special literature.

We already know that the density matrix allows the calculation of the expectation value of any observable of system $s$ - see Eq. (5). However, our initial recipe (6) for the density matrix calculation, which requires the knowledge of the exact state (2) of the whole Universe, is not too practicable, while the von Neumann equation (66) for the density matrix evolution is limited to cases in which probabilities $W_{j}$ of the system states are fixed - thus excluding such important effects as the energy relaxation. However, such effects may be analyzed using a different assumption - that the system of interest interacts only with some local environment (say, with the lab room) that is in the thermallyequilibrium state described by a diagonal density matrix - see Eqs. (15) and (23).

This calculation is facilitated by the following observation. Let us number the basis states of the full local system (the system of our interest plus its local environment) by index $l$, and apply Eq. (5) to write

$$
\begin{equation*}
\langle A\rangle=\operatorname{Tr}(\hat{A} \hat{w})=\sum_{l, l^{\prime}} A_{l l^{\prime}} w_{l l^{\prime}}=\sum_{l, l^{\prime}}\langle l| \hat{A}\left|l^{\prime}\right\rangle\left\langle l^{\prime}\right| \hat{w}|l\rangle, \tag{7.157}
\end{equation*}
$$

where $\hat{w}$ is the statistical operator of this full composite system. At weak interaction between the system $s$ and local environment $e$, their variables reside in different Hilbert spaces, so that we can write

$$
\begin{equation*}
|l\rangle=\left|s_{j}\right\rangle \otimes\left|e_{k}\right\rangle . \tag{7.158}
\end{equation*}
$$

and if observable $A$ depends only on the coordinates of system $s$, Eq. (157) yields

$$
\begin{align*}
& \langle A\rangle=\sum_{\substack{j, j^{\prime} \\
k, k^{\prime}}}\left\langle e_{k}\right| \otimes\left\langle s_{j}\right| \hat{A}\left|s_{j^{\prime}}\right\rangle \otimes\left|e_{k^{\prime}}\right\rangle\left\langle e_{k^{\prime}}\right| \otimes\left\langle s_{j^{\prime}}\right| \hat{w}\left|s_{j}\right\rangle \otimes\left|e_{k}\right\rangle  \tag{7.159}\\
& =\sum_{\substack{i, j^{\prime} \\
k, k^{\prime}}}\left\langle s_{j}\right| \hat{A}\left|s_{j^{\prime}}\right\rangle \delta_{k k^{\prime}}\left\langle e_{k^{\prime}}\right| \otimes\left\langle s_{j^{\prime}}\right| \hat{w}\left|s_{j}\right\rangle \otimes\left|e_{k}\right\rangle=\sum_{j, j^{\prime}} A_{i j^{\prime}}\left\langle s_{j^{\prime}}\left(\sum_{k} \otimes\left\langle e_{k}\right| \hat{w}\left|e_{k}\right\rangle \otimes\right) \mid s_{j}\right\rangle=\operatorname{Tr}_{j}\left(\hat{A} \hat{w}_{s}\right),
\end{align*}
$$

where $\hat{w}_{s}$ is defined as

$$
\begin{equation*}
\hat{w}_{s} \equiv \sum_{k}\left\langle e_{k}\right| \hat{w}\left|e_{k}\right\rangle=\operatorname{Tr}_{k} \hat{w} . \tag{7.160}
\end{equation*}
$$

Since Eq. (159) is similar to Eq. (5), $\hat{w}_{s}$ may serve as the statistical operator defined in the Hilbert space of the system of our interest. The huge advantage of Eqs. (159)-(160) is that they are valid for an arbitrary state of the local environment, including the case when it is in the thermodynamic equilibrium. By the way, the similarity of Eqs. (5) and (159) may serve as the strong argument, promised in Sec. 1, for the validity of the former relation even if the Universe as a whole is not in a pure state. (The argument is, however, imperfect, because the latter relation has been derived from the former one.)

[^690]Now, since at a sufficiently large size of the local environment $e$, the composite system $(s+e)$ may be considered Hamiltonian, with fixed probabilities of its states, for the description of time evolution of its statistical operator $\hat{w}$ (again, in contrast to that, $\hat{w}_{s}$, of the system of our interest) we may use the von Neumann equation (66). Partitioning its right-hand part in accordance with Eq. (68), we get:

$$
\begin{equation*}
i \hbar \dot{\hat{w}}=\left[\hat{H}_{s}, \hat{w}\right]+\left[\hat{H}_{e}, \hat{w}\right]+\left[\hat{H}_{\mathrm{int}}, \hat{w}\right] . \tag{7.161}
\end{equation*}
$$

The next step is to use the perturbation theory to solve this equation in the lowest order in $\hat{H}_{\text {int }}$ that yields nonvanishing results due to the interaction. For that, Eq. (161) is not very convenient, because its right-hand part contains two other terms, which are much larger than the interaction Hamiltonian. To mitigate this technical difficulty, the interaction picture (which was discussed in the end of Sec. 4.6), is very handy - though not absolutely necessary.

As a reminder, in that picture (whose entities will be marked with index $I$, with the unmarked operators assumed to be in the Schrödinger picture), both the operators and the state vectors (and hence the density matrix) depend on time. However, the time evolution of the operator of any observable $A$ is described by Eq. (67) with the unperturbed part of the Hamiltonian only - see Eq. (4.214). In our current case (68), this means

$$
\begin{equation*}
i \hbar \dot{\hat{A}}_{I}=\left[\hat{A}_{I}, \hat{H}_{0}\right] \tag{7.162}
\end{equation*}
$$

where the unperturbed Hamiltonian consists of two independent parts:

$$
\begin{equation*}
\hat{H}_{0} \equiv \hat{H}_{s}+\hat{H}_{e} \tag{7.163}
\end{equation*}
$$

On the other hand, the state vector evolution is governed by the interaction evolution operator $\hat{u}_{I}$ that obeys Eqs. (4.215). Since this equation, using the interaction-picture Hamiltonian (4.216),

$$
\begin{equation*}
\hat{H}_{I} \equiv \hat{u}_{0}^{\dagger} \hat{H}_{\mathrm{int}} \hat{u}_{0} \tag{7.164}
\end{equation*}
$$

is absolutely similar to the ordinary Schrödinger equation using the full Hamiltonian, we may repeat all arguments given in the beginning of Sec. 3 to conclude that the dynamics of the density matrix in the interaction picture of a Hamiltonian system is governed by the following analog of the von Neumann equation (66):

$$
\begin{equation*}
i \hbar \dot{\hat{w}}_{I}=\left[\hat{H}_{I}, \hat{w}_{I}\right] . \tag{7.165}
\end{equation*}
$$

Since this equation is similar in structure (with the opposite sign) to the Heisenberg equation (66), we may use solution Eq. (4.190) of the latter equation to write its analog: ${ }^{61}$

$$
\begin{equation*}
\hat{w}_{I}(t)=\hat{u}_{I}(t, 0) \hat{w}(0) \hat{u}_{I}^{\dagger}(t .0) . \tag{7.166}
\end{equation*}
$$

It is also straightforward to verify that in this picture, the expectation value of any observable $A$ may be found from the expression similar to the basic Eq. (5):
${ }^{61}$ Notice the opposite order of the unitary operators, which results from the already mentioned sign difference. Note also that we could write a similar expression in the Schrödinger picture: $\hat{w}(t)=\hat{u} \hat{w}(0) \hat{u}^{\dagger}$, where $\hat{u}$ is the full time-evolution operator.

$$
\begin{equation*}
\langle A\rangle=\operatorname{Tr}\left(\hat{A}_{I} \hat{w}_{I}\right), \tag{7.167}
\end{equation*}
$$

so that the interaction and Schrödinger pictures give the same final results.
In the most frequent case of bilinear interaction (90), ${ }^{62}$ Eq. (162) is readily simplified, in different ways, for the both operators participating in the product. In particular, for $\hat{A}=\hat{x}$, it yields

$$
\begin{equation*}
i \hbar \dot{\hat{x}}_{I}=\left[\hat{x}_{I}, \hat{H}_{0}\right]=\left[\hat{x}_{I}, \hat{H}_{s}\right]+\left[\hat{x}_{I}, \hat{H}_{e}\right] . \tag{7.168}
\end{equation*}
$$

Since operator of coordinate is defined in the Hilbert space of system $s$, it commutes with the Hamiltonian of the environment, so that we finally get

$$
\begin{equation*}
i \hbar \dot{\hat{x}}_{I}=\left[\hat{x}_{I}, \hat{H}_{s}\right] \tag{7.169}
\end{equation*}
$$

On the other hand, taking $\hat{A}=\hat{F}$, we should take into account that the last operator is defined in the Hilbert space of the environment, and commutes with the Hamiltonian of the unperturbed system $s$. As a result, we get

$$
\begin{equation*}
i \hbar \dot{\hat{F}}_{I}=\left[\hat{F}_{I}, \hat{H}_{e}\right] \tag{7.170}
\end{equation*}
$$

This means that with our time-independent unperturbed Hamiltonians $\hat{H}_{s}$ and $\hat{H}_{e}$, the time evolution of the interaction-picture operators is rather simple. In particular, the analogy between Eq. (170) and Eq. (93) allows us to immediately write the following analog of Eq. (94):

$$
\begin{equation*}
\hat{F}_{I}(t)=\exp \left\{\frac{i}{\hbar} \hat{H}_{e} t\right\} \hat{F}(0) \exp \left\{-\frac{i}{\hbar} \hat{H}_{e} t\right\}, \tag{7.171}
\end{equation*}
$$

so that in the stationary (eigenstate) basis of the environment,

$$
\begin{equation*}
\left(\hat{F}_{I}\right)_{n n^{\prime}}(t)=\exp \left\{\frac{i}{\hbar} E_{n} t\right\} F_{n n^{\prime}}(0) \exp \left\{-\frac{i}{\hbar} E_{n^{\prime}} t\right\}=F_{n n^{\prime}}(0) \exp \left\{-i \frac{E_{n}-E_{n^{\prime}}}{\hbar} t\right\} \tag{7.172}
\end{equation*}
$$

and similarly (but in the basis of the eigenstates of system $s$ ) for operator $\hat{x}$. As a result, Eq. (164) may be also factored:

$$
\begin{align*}
\hat{H}_{I}(t) & \equiv \hat{u}_{0}^{\dagger}(t, 0) \hat{H}_{\mathrm{int}} \hat{u}_{0}(t, 0)=\exp \left\{\frac{i}{\hbar}\left(\hat{H}_{s}+\hat{H}_{e}\right) t\right\}(-\hat{x} \hat{F}) \exp \left\{-\frac{i}{\hbar}\left(\hat{H}_{s}+\hat{H}_{e}\right) t\right\} \\
& =-\left(\exp \left\{\frac{i}{\hbar} \hat{H}_{s} t\right\} \hat{x} \exp \left\{-\frac{i}{\hbar} \hat{H}_{s} t\right\}\right)\left(\exp \left\{\frac{i}{\hbar} \hat{H}_{e} t\right\} \hat{F}(0) \exp \left\{-\frac{i}{\hbar} \hat{H}_{e} t\right\}\right)=-\hat{x}_{I}(t) \hat{F}_{I}(t) \tag{7.173}
\end{align*}
$$

Now, as in Sec. 4, we may rewrite Eq. (165) in the integral form:

$$
\begin{equation*}
\hat{w}_{I}(t)=\frac{1}{i \hbar} \int_{-\infty}^{t}\left[\hat{H}_{I}\left(t^{\prime}\right), \hat{w}_{I}\left(t^{\prime}\right)\right] d t^{\prime} \tag{7.174}
\end{equation*}
$$

[^691]plugging this result, for time $t^{\prime}$, into the right-hand part of Eq. (174) again, we get
\[

$$
\begin{equation*}
\dot{\hat{w}}_{I}(t)=-\frac{1}{\hbar^{2}} \int_{-\infty}^{t}\left[\hat{H}_{I}(t),\left[\hat{H}_{I}\left(t^{\prime}\right), \hat{w}_{I}\left(t^{\prime}\right)\right]\right] d t^{\prime}=-\frac{1}{\hbar^{2}} \int_{-\infty}^{t}\left[\hat{x}(t) \hat{F}(t),\left[\hat{x}\left(t^{\prime}\right) \hat{F}\left(t^{\prime}\right), \hat{w}_{I}\left(t^{\prime}\right)\right]\right] d t^{\prime} \tag{7.175}
\end{equation*}
$$

\]

where, for the notation brevity, from this point on I will strip operators $\hat{x}$ and $\hat{F}$ of their index $I$. (Their time dependence indicates the interaction picture clearly enough.)

So far, this equation is exact (and cannot be solved analytically), but this is the right time to notice that even if we take the density matrix in its right-hand part equal to its unperturbed value (corresponding to no interaction between system $s$ and its thermally-equilibrium environment $e$ ),

$$
\begin{equation*}
\hat{w}_{I}\left(t^{\prime}\right) \rightarrow \hat{w}_{s}\left(t^{\prime}\right) \hat{w}_{e}, \quad \text { with }\left\langle e_{n}\right| \hat{w}_{e}\left|e_{n^{\prime}}\right\rangle=W_{n} \delta_{n n^{\prime}}, \tag{7.176}
\end{equation*}
$$

where $e_{n}$ are the stationary states of the environment and $W_{n}$ are the Gibbs probabilities (23), Eq. (175) would still provide some nonvanishing time evolution of the density operator. This is exactly the first nonvanishing perturbation we have been looking for. Now using Eq. (160), we find the equation of evolution of the density operator of our system of interest:

$$
\begin{equation*}
\dot{\hat{w}}_{s}(t)=-\frac{1}{\hbar^{2}} \int_{-\infty}^{t} \operatorname{Tr}_{n}\left[\hat{x}(t) \hat{F}(t),\left[\hat{x}\left(t^{\prime}\right) \hat{F}\left(t^{\prime}\right), \hat{w}_{s}\left(t^{\prime}\right) \hat{w}_{e}\right]\right] d t^{\prime} \tag{7.177}
\end{equation*}
$$

where the trace is over the stationary states of the environment. In order to spell out the right-hand part of Eq. (177), note again that the coordinate and force operators commute with each other (but not with themselves at different time moments!) and hence may be swapped, so that we may write

$$
\begin{align*}
\operatorname{Tr}_{n}[\ldots,[\ldots, \ldots]]= & \hat{x}(t) \hat{x}\left(t^{\prime}\right) \hat{w}_{s}\left(t^{\prime}\right) \operatorname{Tr}_{n}\left[\hat{F}(t) \hat{F}\left(t^{\prime}\right) \hat{w}_{e}\right]-\hat{x}(t) \hat{w}_{s}\left(t^{\prime}\right) \hat{x}\left(t^{\prime}\right) \operatorname{Tr}_{n}\left[\hat{F}(t) \hat{w}_{e} \hat{F}\left(t^{\prime}\right)\right] \\
& -\hat{x}\left(t^{\prime}\right) \hat{w}_{s}\left(t^{\prime}\right) \hat{x}(t) \operatorname{Tr}_{n}\left[\hat{F}\left(t^{\prime}\right) \hat{w}_{e} \hat{F}(t)\right]+\hat{w}_{s}\left(t^{\prime}\right) \hat{x}\left(t^{\prime}\right) \hat{x}(t) \operatorname{Tr}_{n}\left[\hat{w}_{e} \hat{F}\left(t^{\prime}\right) \hat{F}(t)\right] \\
= & \hat{x}(t) \hat{x}\left(t^{\prime}\right) \hat{w}_{s}\left(t^{\prime}\right) \sum_{n, n^{\prime}} F_{n n^{\prime}}(t) F_{n^{\prime} n}\left(t^{\prime}\right) W_{n}-\hat{x}(t) \hat{w}_{s}\left(t^{\prime}\right) \hat{x}\left(t^{\prime}\right) \sum_{n, n^{\prime}} F_{n n^{\prime}}(t) W_{n^{\prime}} F_{n^{\prime} n}\left(t^{\prime}\right)  \tag{7.178}\\
& -\hat{x}\left(t^{\prime}\right) \hat{w}_{s} \hat{x}(t) \sum_{n, n^{\prime}} F_{n n^{\prime}}\left(t^{\prime}\right) W_{n^{\prime}} F_{n^{\prime} n}(t)+\hat{w}_{s} \hat{x}\left(t^{\prime}\right) \hat{x}(t) \sum_{n, n^{\prime}} W_{n} F_{n n^{\prime}}\left(t^{\prime}\right) F_{n^{\prime} n}(t) .
\end{align*}
$$

Since the summation on both indices $n$ and $n$ ' in this expression is over the same energy level set (of all eigenstates of the environment), we may swap the indices in any of the sums. Doing that in the terms with factors $W_{n}$, we turn them into $W_{n}$, so that this factor becomes common:

$$
\begin{align*}
\operatorname{Tr}_{n}[\ldots,[\ldots, \ldots]]= & \sum_{n, n^{\prime}} W_{n}\left[\hat{x}(t) \hat{x}\left(t^{\prime}\right) \hat{w}_{s}\left(t^{\prime}\right) F_{n n^{\prime}}(t) F_{n^{\prime} n}\left(t^{\prime}\right)-\hat{x}(t) \hat{w}_{s}\left(t^{\prime}\right) \hat{x}\left(t^{\prime}\right) F_{n^{\prime} n}(t) F_{n n^{\prime}}\left(t^{\prime}\right)\right.  \tag{7.179}\\
& \left.-\hat{x}\left(t^{\prime}\right) \hat{w}_{s} \hat{x}(t) F_{n^{\prime} n}\left(t^{\prime}\right) F_{n n^{\prime}}(t)+\hat{w}_{s} \hat{x}\left(t^{\prime}\right) \hat{x}(t) F_{n n^{\prime}}\left(t^{\prime}\right) F_{n^{\prime} n}(t)\right] .
\end{align*}
$$

Now using Eq. (172), we get

$$
\begin{array}{r}
\begin{array}{r}
\operatorname{Tr}_{n}[\ldots,[\ldots, \ldots]]=\sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2}\left[\hat{x}(t) \hat{x}\left(t^{\prime}\right) \hat{w}_{s}\left(t^{\prime}\right) \exp \left\{i \frac{\widetilde{E}\left(t-t^{\prime}\right)}{\hbar}\right\}-\hat{x}(t) \hat{w}_{s}\left(t^{\prime}\right) \hat{x}\left(t^{\prime}\right) \exp \left\{-i \frac{\widetilde{E}\left(t-t^{\prime}\right)}{\hbar}\right\}\right. \\
\left.-\hat{x}\left(t^{\prime}\right) \hat{w}_{s} \hat{x}(t) \exp \left\{i \frac{\widetilde{E}\left(t-t^{\prime}\right)}{\hbar}\right\}+\hat{w}_{s} \hat{x}\left(t^{\prime}\right) \hat{x}(t) \exp \left\{-i \frac{\widetilde{E}\left(t-t^{\prime}\right)}{\hbar}\right\}\right] \\
=\sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \cos \frac{\widetilde{E}\left(t-t^{\prime}\right)}{\hbar}\left[\hat{x}(t),\left[\hat{x}\left(t^{\prime}\right), \hat{w}_{s}\left(t^{\prime}\right)\right]\right]+i \sum_{n, n^{\prime}} W_{n}\left|F_{n n^{\prime}}\right|^{2} \sin \frac{\widetilde{E}\left(t-t^{\prime}\right)}{\hbar}\left[\hat{x}(t),\left\{\hat{x}\left(t^{\prime}\right), \hat{w}_{s}\left(t^{\prime}\right)\right\}\right],
\end{array}
\end{array}
$$

where $\{\ldots, \ldots\}$ means the anticommutator - see Eq. (4.34). Comparing the two double sums participating in this expression with Eqs. (108) and (111), we see that they are nothing else than, respectively, the symmetrized correlation function and the Green's function (multiplied by $\hbar / 2$ ) of the time-difference argument $\tau=t-t^{\prime} \geq 0$. As the result, Eq. (177) takes a very simple form:

$$
\begin{equation*}
\dot{\hat{w}}_{s}(t)=-\frac{1}{\hbar^{2}} \int_{-\infty}^{t} K_{F}\left(t-t^{\prime}\right)\left[\hat{x}(t),\left[\hat{x}\left(t^{\prime}\right), \hat{w}_{s}\left(t^{\prime}\right)\right]\right] d t^{\prime}-\frac{i}{2 \hbar} \int_{-\infty}^{t} G\left(t-t^{\prime}\right)\left[\hat{x}(t),\left\{\hat{x}\left(t^{\prime}\right), \hat{w}_{s}\left(t^{\prime}\right)\right\}\right] d t^{\prime} \tag{7.181}
\end{equation*}
$$

Let me hope that the reader enjoys this beautiful result as much as I do, and that it is a sufficient intellectual award for his or her effort of following its derivation. It gives a self-sufficient equation for time evolution of the density matrix of the system of our interest ( $s$ ), with the effects of its environment represented only by two real algebraic functions of $\tau$ - one ( $K_{F}$ ) describing environment's fluctuations and another one $(G)$ representing its the average response to system's dynamics. And most spectacularly, these are exactly the same functions as participate in the Heisenberg-Langevin approach to the problem, and hence related to each other by the fluctuation-dissipation theorem (134).

After a short celebration, let us acknowledge that Eq. (181) is still an integro-differential equation that needs to be solved together with Eq. (169). Such equations do not allow explicit analytical solutions except for very simple (and not very interesting) cases. For most applications, further simplifications should be made. One of them is based on the fact (which was already discussed in Sec. 3) that both environmental functions participating in Eq. (181) tend to zero when their argument $\tau$ becomes larger that certain environment correlation time $\tau_{c}$, which is frequently much shorter that the time scales $T_{n n}$ ' of the evolution of the density matrix elements. Moreover, the characteristic time scale of the coordinate operator evolution may be also short on the scale of $T_{n n^{\prime}}$. In this limit, all arguments $t^{\prime}$ of the density operator giving substantial contributions to the right-hand part of Eq. (172) are so close to $t$ that it does not matter whether its argument is $t^{\prime}$ or just $t$. This simplification $\left(t^{\prime} \rightarrow t\right)$ is known as the Markov approximation. ${ }^{63}$ However, this approximation alone is still insufficient for finding the general solution of Eq. (181). Substantial further progress is possible in two important cases.

The most important of them is when the intrinsic Hamiltonian $\hat{H}_{s}$ of our system of interest is time-independent and has a very discrete eigenenergy spectrum $E_{n}{ }^{64}$ with well-separated levels:

[^692]\[

$$
\begin{equation*}
\left|E_{n}-E_{n^{\prime}}\right| \gg \frac{\hbar}{T_{n n^{\prime}}} . \tag{7.182}
\end{equation*}
$$

\]

Let us see what does this condition yield for Eq. (181) rewritten for the matrix elements in the stationary state basis (from this point on, I will drop index $s$ for brevity):

$$
\begin{equation*}
\dot{w}_{n n^{\prime}}=-\frac{1}{\hbar^{2}} \int_{-\infty}^{t} K_{F}\left(t-t^{\prime}\right)\left[\hat{x}(t),\left[\hat{x}\left(t^{\prime}\right), \hat{w}\right]\right]_{n n^{\prime}} d t^{\prime}-\frac{i}{2 \hbar} \int_{-\infty}^{t} G\left(t-t^{\prime}\right)\left[\hat{x}(t),\left\{\hat{x}\left(t^{\prime}\right), \hat{w}\right\}\right]_{n n^{\prime}} d t^{\prime} ; \tag{7.183}
\end{equation*}
$$

after spelling out the commutators, it includes 4 operator products, which differ "only" by the operator order. Let us have a good look at the first product,

$$
\begin{equation*}
\left(\hat{x}(t) \hat{x}\left(t^{\prime}\right) \hat{w}\right)_{n n^{\prime}}=\sum_{m, m^{\prime}} x_{n m}(t) x_{m m^{\prime}}\left(t^{\prime}\right) w_{m^{\prime} n^{\prime}} \tag{7.184}
\end{equation*}
$$

where indices $m$ and $m$ ' run over the same set of eigenenergies of the system $s$ of our interest as indices $n$ and $n^{\prime}$. According to Eq. (169) with a time-independent $H_{s}$, matrix elements $x_{n n}$ ' (in the stationary state basis) oscillate in time as $\exp \left\{i \omega_{n n} \cdot t\right\}$, so that

$$
\begin{equation*}
\left(\hat{x}(t) \hat{x}\left(t^{\prime}\right) \hat{w}\right)_{n n^{\prime}}=\sum_{m, m^{\prime}} x_{n m} x_{m m^{\prime}} \exp \left\{i\left(\omega_{n m} t+\omega_{m m^{\prime}} \cdot t^{\prime}\right)\right\} w_{m^{\prime} n^{\prime}}, \tag{7.185}
\end{equation*}
$$

where the coordinate matrix elements are in the Schrödinger picture now, and I have used the natural notation (6.85) for the quantum transition frequencies:

$$
\begin{equation*}
\hbar \omega_{n n^{\prime}} \equiv E_{n}-E_{n^{\prime}} . \tag{7.186}
\end{equation*}
$$

According to condition (182), frequencies $\omega_{n n^{\prime}}$ with $n \neq n^{\prime}$ are much higher than the speed of evolution of the density matrix elements (in the interaction picture!) - in both the left-hand and right-hand parts of Eq. (183). As we already know from Sec. 6.5, this means that in the right-hand part of Eq. (183) we may keep only the terms that do not oscillate with frequencies $\omega_{n n}$, because they would give negligible contribution to the density matrix dynamics. ${ }^{65}$ For that, in the double sum (185) we may keep only the terms proportional to difference ( $t-t^{\prime}$ ), because they will give (after integration over $t^{\prime}$ ) a slowly changing contribution to the right-hand part. ${ }^{66}$ These terms should have $\omega_{n m}+\omega_{m m^{\prime}}=0$, i.e. $\left(E_{n}-E_{m}\right)+$ $\left(E_{m}-E_{m^{\prime}}\right) \equiv E_{n}-E_{m^{\prime}}=0$. For a non-degenerate energy spectrum, this requirement means $m^{\prime}=n$; as a result, the double sum is reduced to a single one:

$$
\begin{equation*}
\left(\hat{x}(t) \hat{x}\left(t^{\prime}\right) \hat{w}\right)_{n n^{\prime}} \approx \sum_{m} x_{n m} x_{m n} \exp \left\{i \omega_{n m}\left(t-t^{\prime}\right)\right\} w_{n n^{\prime}}=\sum_{m}\left|x_{n m}\right|^{2} \exp \left\{i \omega_{n m}\left(t-t^{\prime}\right)\right\} w_{n n^{\prime}} \tag{7.187}
\end{equation*}
$$

Another product, $\left(\hat{w} \hat{x}\left(t^{\prime}\right) \hat{x}(t)\right)_{n n^{\prime}}$, that appears in the right-hand part of Eq. (183), may be simplified absolutely similarly, giving

$$
\begin{equation*}
\left(\hat{w} \hat{x}\left(t^{\prime}\right) \hat{x}(t)\right)_{n n^{\prime}} \approx \sum_{m}\left|x_{n^{\prime} m}\right|^{2} \exp \left\{i \omega_{n^{\prime} m}\left(t^{\prime}-t\right)\right\} w_{n n^{\prime}} \tag{7.188}
\end{equation*}
$$

[^693]These expressions hold true whether $n$ and $n$ ' are equal or not. The situation is different for two other products in the right-hand part of Eq. (183), with $w$ sandwiched between $x$ and $x$ '. For example,

$$
\begin{equation*}
\left(\hat{x}(t) \hat{w} \hat{x}\left(t^{\prime}\right)\right)_{n n^{\prime}}=\sum_{m, m^{\prime}} x_{n m}(t) w_{m m^{\prime}} x_{m^{\prime} n^{\prime}}\left(t^{\prime}\right)=\sum_{m, m^{\prime}} x_{n m} w_{m m^{\prime}} x_{m^{\prime} n^{\prime}} \exp \left\{i\left(\omega_{n m} t+\omega_{m^{\prime} n^{\prime}}, t^{\prime}\right)\right\} \tag{7.189}
\end{equation*}
$$

For this term, the same requirement of having a fast oscillating function of $\left(t-t^{\prime}\right)$ only yields a different condition: $\omega_{n m}+\omega_{m^{\prime} n^{\prime}}=0$, i.e.

$$
\begin{equation*}
\left(E_{n}-E_{m}\right)+\left(E_{m^{\prime}}-E_{n^{\prime}}\right)=0 . \tag{7.190}
\end{equation*}
$$

Here the double sum reduction is possible only if we make an additional assumption that all interlevel energy distances are unique, i.e. our system of interest has no equidistant levels (such as in the harmonic oscillator). For diagonal elements ( $n=n^{\prime}$ ), the RWA requirement is reduced to $m=m^{\prime}$, giving sums over all diagonal elements of the density matrix:

$$
\begin{equation*}
\left(\hat{x}(t) \hat{w} \hat{x}\left(t^{\prime}\right)\right)_{n n}=\sum_{m}\left|x_{n m}\right|^{2} \exp \left\{i \omega_{n m}\left(t-t^{\prime}\right)\right\} w_{m m} . \tag{7.191}
\end{equation*}
$$

(Another similar term $\left(\hat{x}\left(t^{\prime}\right) \hat{w} \hat{x}(t)\right)_{n n}$, is just a complex conjugate of Eq. (191).) However, for offdiagonal matrix elements $\left(n \neq n^{\prime}\right)$, the situation is different: Eq. (190) may be satisfied only if $m=n$ and also $m^{\prime}=n^{\prime}$, so that the double sum is reduced to just one, non-oscillating term:

$$
\begin{equation*}
\left(\hat{x}(t) \hat{w} \hat{x}\left(t^{\prime}\right)\right)_{n n^{\prime}}=x_{n n} w_{n n^{\prime}} x_{n^{\prime} n^{\prime}}, \quad \text { for } n \neq n^{\prime} . \tag{7.192}
\end{equation*}
$$

The second similar term, $\left(\hat{x}\left(t^{\prime}\right) \hat{w} \hat{x}(t)\right)_{n n}$, is exactly the same, so that in one of the integrals of Eq. (183), these terms add up, while in the second one, they cancel.

This is why the final equations of evolution look differently for diagonal and off-diagonal elements of the density matrix. For the former case ( $n=n^{\prime}$ ), Eq. (183) is reduced to the so-called master equation ${ }^{67}$ relating diagonal elements $w_{n n}$ of the density matrix, i.e. the energy level occupancies $W_{n}$ : ${ }^{68}$

$$
\begin{align*}
\dot{W}_{n}=\sum_{m \neq n}\left|x_{n m}\right|^{2} \int_{0}^{\infty} & {\left[-\frac{1}{\hbar^{2}} K_{F}(\tau)\left(W_{n}-W_{m}\right)\left(\exp \left\{i \omega_{n m} \tau\right\}+\exp \left\{-i \omega_{n m} \tau\right\}\right)\right.}  \tag{7.193}\\
& \left.-\frac{i}{2 \hbar} G(\tau)\left(-W_{n}-W_{m}\right)\left(\exp \left\{i \omega_{n m} \tau\right\}-\exp \left\{-i \omega_{n m} \tau\right\}\right)\right] d \tau
\end{align*}
$$

where $\tau \equiv t-t^{\prime}$. Changing the summation index notation from $m$ to $n$ ', we may rewrite the master equation in its canonical form

$$
\begin{equation*}
\dot{W}_{n}=\sum_{n^{\prime} \neq n}\left(\Gamma_{n^{\prime} \rightarrow n} W_{n^{\prime}}-\Gamma_{n \rightarrow n^{\prime}} W_{n}\right), \tag{7.194}
\end{equation*}
$$

where coefficients

$$
\begin{equation*}
\Gamma_{n^{\prime} \rightarrow n} \equiv\left|x_{n n^{\prime}}\right|^{2} \int_{0}^{\infty}\left[\frac{2}{\hbar^{2}} K_{F}(\tau) \cos \omega_{n n^{\prime}} \tau-\frac{1}{\hbar} G(\tau) \sin \omega_{n n^{\prime}} \tau\right] d t^{\prime} \tag{7.195}
\end{equation*}
$$

[^694]Master equations and interlevel transition rates
are called the interlevel transition rates. ${ }^{69}$ Equation (194) has a very clear physical meaning of the level occupancy dynamics (i.e. the balance of probability flows $\Gamma W$ ) due to the quantum transitions between the energy levels (Fig. 6), in our current case caused by the interaction between the system of our interest and its environment. ${ }^{70}$

Fig. 7.6. Probability flows between the energy levels, described by the master equation (186).

The Fourier transforms (113) and (123) enable us to express two integrals in Eq. (195) via, respectively, the symmetrized spectral density $S_{F}(\omega)$ of environment force fluctuations and the imaginary part $\chi$ " $(\omega)$ of the generalized susceptibility, both at frequency $\omega=\omega_{n n}$. After that we may use the fluctuation-dissipation theorem (134) to exclude the former function, getting finally

Transition
rates via generalized susceptibility

$$
\begin{equation*}
\Gamma_{n^{\prime} \rightarrow n}=\frac{1}{\hbar}\left|x_{n n^{\prime}}\right|^{2} \chi^{\prime \prime}\left(\omega_{n n^{\prime}}\right)\left(\operatorname{coth} \frac{\hbar \omega_{n n^{\prime}}}{2 k_{\mathrm{B}} T}-1\right)=\frac{2}{\hbar}\left|x_{n n^{\prime}}\right|^{2} \frac{\chi^{\prime \prime}\left(\omega_{n n^{\prime}}\right)}{\exp \left\{\left(E_{n}-E_{n^{\prime}}\right) / k_{\mathrm{B}} T\right\}-1} . \tag{7.196}
\end{equation*}
$$

Note that since the imaginary part of the generalized susceptibility is an odd function of frequency, Eq. (196) is in compliance with the Gibbs distribution for arbitrary temperature. Indeed, according to this equation, the ratio of "up" and "down" rates for each pair of levels equals

$$
\begin{equation*}
\frac{\Gamma_{n^{\prime} \rightarrow n}}{\Gamma_{n \rightarrow n^{\prime}}}=\frac{\chi^{\prime \prime}\left(\omega_{n n^{\prime}}\right)}{\exp \left\{\left(E_{n}-E_{n^{\prime}}\right) / k_{\mathrm{B}} T\right\}-1} / \frac{\chi^{\prime \prime}\left(\omega_{n^{\prime}}\right)}{\exp \left\{\left(E_{n^{\prime}}-E_{n}\right) / k_{\mathrm{B}} T\right\}-1}=\exp \left\{-\frac{E_{n}-E_{n^{\prime}}}{k_{\mathrm{B}} T}\right\} . \tag{7.197}
\end{equation*}
$$

On the other hand, according to the Gibbs distribution (23), in thermal equilibrium the level populations should be in the same proportion, satisfying the so-called detailed balance equations,

Detailed balance equations

$$
\begin{equation*}
W_{n} \Gamma_{n \rightarrow n^{\prime}}=W_{n^{\prime}} \Gamma_{n^{\prime} \rightarrow n}, \tag{7.198}
\end{equation*}
$$

for each pair $\left\{n, n^{\prime}\right\}$, so that all right-hand parts of all Eqs. (194) could vanish - as they should. Thus, the stationary solution of the master equations indeed describes the thermal equilibrium.

The closed system of master equations (194), sometimes complemented by additional right-hand-part terms that describe interlevel transitions due to other factors (e.g., by an external ac force with a frequency close to one of $\omega_{n n}$ ), is the key starting point for practical analyses of many quantum

[^695]systems including quantum generators (masers and lasers). It is important to remember that it is strictly valid only in the rotating-wave approximation, i.e. if Eq. (182) is well satisfied for all $n$ and $n$ '.

For a particular but very important case of a two-level system (with, say, $E_{1}>E_{2}$ ), the rate $\Gamma_{1 \rightarrow 2}$ may be interpreted (especially in the low-temperature limit $k_{\mathrm{B}} T \ll \hbar \omega_{12}=E_{1}-E_{2}$, when $\Gamma_{1 \rightarrow 2} \gg \Gamma_{2 \rightarrow 1}$ ) as the reciprocal characteristic time $1 / T_{1} \equiv \Gamma_{1 \rightarrow 2}$ of the energy relaxation process that brings the diagonal elements of the density matrix to their thermally-equilibrium values (24). For the Ohmic dissipation described by Eqs. (137)-(138), Eq. (196) yields

$$
\frac{1}{T_{1}} \equiv \Gamma_{1 \rightarrow 2}=\frac{2}{\hbar^{2}}\left|x_{12}\right|^{2} \eta \times \begin{cases}\hbar \omega_{12}, & \text { for } k_{\mathrm{B}} T \ll \hbar \omega_{12},  \tag{7.199}\\ k_{\mathrm{B}} T, & \text { for } \hbar \omega_{12} \ll k_{\mathrm{B}} T\end{cases}
$$

Of course, time $T_{1}$ should not be confused with the characteristic time $T_{2}$ of relaxation of the offdiagonal elements, i.e. dephasing, which was already discussed in Sec. 3. By the way, let us see what do Eqs. (183) say about the dephasing rate. Taking into account our intermediate results (187)-(192), and merging the non-oscillating components (with $m=n$ and $m=n$ ') of sums Eq. (187) and (188) with the terms (192), that also do not oscillate in time, we get the following equation: ${ }^{71}$

$$
\begin{align*}
\dot{w}_{n n^{\prime}}=-\left\{\int_{0}^{\infty}\right. & {\left[\frac{1}{\hbar^{2}} K_{F}(\tau)\left(\sum_{m \neq n}\left|x_{n m}\right|^{2} \exp \left\{i \omega_{n m} \tau\right\}+\sum_{m \neq n^{\prime}}\left|x_{n^{\prime} m}\right|^{2} \exp \left\{-i \omega_{n^{\prime} m} \tau\right\}+\left(x_{n n}-x_{n^{\prime} n^{\prime}}\right)^{2}\right)\right.} \\
& \left.\left.+\frac{i}{2 \hbar} G(\tau)\left(\sum_{m \neq n}\left|x_{n m}\right|^{2} \exp \left\{i \omega_{n m} \tau\right\}-\sum_{m \neq n^{\prime}}\left|x_{n^{\prime} m}\right|^{2} \exp \left\{-i \omega_{n^{\prime} m} \tau\right\}\right)\right] d \tau\right\} w_{n n^{\prime}}, \text { for } n \neq n^{\prime} . \tag{7.200}
\end{align*}
$$

In contrast with Eq. (194), the right-hand part of this equation includes both a real and an imaginary part, and hence it may be presented as

$$
\begin{equation*}
\dot{w}_{n n^{\prime}}=-\left(1 / T_{n n^{\prime}}+i \Delta_{n n^{\prime}}\right) w_{n n^{\prime}} \tag{7.201}
\end{equation*}
$$

where both factors $1 / T_{n n}$, and $\Delta_{n n^{\prime}}$ are real. ${ }^{72}$ As should be clear from Eq. (201), the second term in the right-hand part of this equation causes slow oscillations of the matrix elements $w_{n n}$, that, after returning to the Schrödinger picture, add just small corrections ${ }^{73}$ to the unperturbed frequencies (186) of their oscillations, and are hence are not important for most applications. More important is the first term,

[^696]\[

$$
\begin{align*}
\frac{1}{T_{n n^{\prime}}}=\int_{0}^{\infty} & \frac{1}{\hbar^{2}} K_{F}(\tau)\left(\sum_{m \neq n}\left|x_{n m}\right|^{2} \cos \omega_{n m} \tau+\sum_{m \neq n^{\prime}}\left|x_{n^{\prime} m}\right|^{2} \cos \omega_{n^{\prime} m} \tau+\left(x_{n n}-x_{n^{\prime} n^{\prime}}\right)^{2}\right)  \tag{7.202}\\
& \left.-\frac{1}{2 \hbar} G(\tau)\left(\sum_{m \neq n}\left|x_{n m}\right|^{2} \sin \omega_{n m} \tau+\sum_{m \neq n^{\prime}}\left|x_{n^{\prime} m}\right|^{2} \sin \omega_{n^{\prime} m} \tau\right)\right] d \tau, \quad \text { for } n \neq n^{\prime},
\end{align*}
$$
\]

because it describes the effect absent without the environment: an exponential decay of the off-diagonal matrix elements, i.e. dephasing. Comparing the first 2 terms of Eq. (202) with Eq. (195), we see that the dephasing rates may be described by a very simple formula: r

$$
\begin{align*}
\frac{1}{T_{n n^{\prime}}} & =\frac{1}{2}\left(\sum_{m \neq n} \Gamma_{n \rightarrow m}+\sum_{m \neq n^{\prime}} \Gamma_{n^{\prime} \rightarrow m}\right)+\frac{\pi}{\hbar^{2}}\left(x_{n n}-x_{n^{\prime} n^{\prime}}\right)^{2} S_{F}(0) \\
& =\frac{1}{2}\left(\sum_{m \neq n} \Gamma_{n \rightarrow m}+\sum_{m \neq n^{\prime}} \Gamma_{n^{\prime} \rightarrow m}\right)+\frac{k_{\mathrm{B}} T}{\hbar^{2}} \eta\left(x_{n n}-x_{n^{\prime} n^{\prime}}\right)^{2}, \quad \text { for } n \neq n^{\prime} \tag{7.203}
\end{align*}
$$

where the low-frequency drag coefficient $\eta$ is again defined as $\lim _{\omega \rightarrow 0} \chi$ " $(\omega) / \omega$ - see Eq. (138).
This result shows that two effects yield independent contributions into dephasing. The first of them may be interpreted as a result of the "virtual" transitions of the system to other energy levels $m$; according to Eq. (187), it is proportional to the strength of coupling to environment at relatively high frequencies $\omega_{n m}$ and $\omega_{n^{\prime} m}$. (If the energy quanta $\hbar \omega$ of these frequencies are much larger than the thermal fluctuation scale $k_{\mathrm{B}} T$, only the lower levels, with $E_{m}<\max \left[E_{n}, E_{n}\right]$ are important.) On the contrary, the second contribution is due to low-frequency, essentially classical fluctuations of the environment, and hence to the low-frequency dissipative susceptibility. If the susceptibility (more exactly, the ratio $\eta=$ $\left.\chi^{\prime \prime}(\omega) / \omega\right)$ is frequency-independent, both contributions are of the same order, but their exact relation depends on the relation between the matrix elements $x_{n n}$ ' of a particular system.

Returning again to the two-level system discussed in Sec. 3, the high-frequency contributions vanish because of the absence of transitions between its energy levels, while the low-frequency contribution yields

$$
\begin{equation*}
\frac{1}{T_{2}} \equiv \frac{1}{T_{12}}=\frac{k_{\mathrm{B}} T}{\hbar^{2}} \eta\left(x_{n n}-x_{n^{\prime} n^{\prime}}\right)^{2} \rightarrow \frac{k_{\mathrm{B}} T}{\hbar^{2}} \eta\left[\left(\sigma_{z}\right)_{11}-\left(\sigma_{z}\right)_{22}\right]^{2}=\frac{4 k_{\mathrm{B}} T}{\hbar^{2}} \eta, \tag{7.204}
\end{equation*}
$$

thus exactly reproducing the result (142) of the Heisenberg-Langevin approach. ${ }^{74}$ Note also that Eq. (204) for $T_{2}$ is very close in structure to Eq. (199) for $T_{1}$. For our simple interaction model (70), the offdiagonal elements of operator $\hat{x}=\hat{\sigma}_{z}$ in the stationary-state $z$-basis vanish, so that $T_{1} \rightarrow \infty$. For the twowell implementation of the model (see Fig. 4 and its discussion), this result corresponds to a very high energy barrier between the wells, that inhibits tunneling, and hence any change of well occupancies $W_{L}$
electromagnetic environment is ignored.) The explanation of the shift, by H. Bethe in the same 1947, has launched the whole field of quantum electrodynamics - to be briefly discussed in Chapter 9.
${ }^{74}$ The first form of Eq. (203), as well as the analysis of Sec. 3, imply that low-frequency fluctuations of any other origin, not taken into account in own current calculations (say, unintentional noise from experimental equipment), may also cause dephasing; such "technical fluctuations" are indeed a serious challenge at the experimental implementation of coherent qubit systems - see Sec. 8.5 below.
and $W_{R}$. However, $T_{1}$ may become finite, and comparable with $T_{2}$, if tunneling between the wells is substantial. ${ }^{75}$

Now let us briefly discuss dissipative systems with continuous spectrum. Unfortunately, for them the only (relatively :-) simple results that may be obtained from Eq. (181) are essentially classical in nature. As an illustration, let us consider the simplest example of a 1D particle that interacts with a thermally-equilibrium environment, but otherwise is free to move (unconfined). As we know from Chapters 2 and 5, in this case the most convenient basis is that of momentum eigenstates $p$. In the momentum representation, the density matrix is just the $c$-number function $w\left(p, p^{\prime}\right)$, defined by Eq. (54), that has already been discussed in brief in Sec. 2. On the other hand, the coordinate operator, that also participates in the right-hand part of Eq. (181), has the form given by the first of Eqs. (5.64),

$$
\begin{equation*}
\hat{x}=i \hbar \frac{\partial}{\partial p} \tag{7.205}
\end{equation*}
$$

dual to the coordinate representation formula (5.29). As we already know, such operators are local - see, e.g., Eq. (5.28b). Due to this locality, the whole right-hand part of Eq. (181) is local as well, and hence (within the framework of our perturbative treatment) the interaction with environment affects essentially only the diagonal values $w(p, p)$ of the density matrix, i.e. the momentum probability density $w(p)$. Let us find the equation governing the evolution of this function in time.

Generally, in the interaction picture, matrix elements of operators $\hat{x}$ and $\hat{w}$ acquire some time dependence, but in the limit $p^{\prime} \rightarrow p$, this dynamics lacks the high frequencies (186) that have been so helpful for the derivation of master equations. As a result, the only serious simplification of Eq. (181) is possible in the Markov approximation, when the time scale of the density matrix evolution is much longer than the correlation time $\tau_{c}$ of the environment, i.e. the time scale of functions $K_{F}(\tau)$ and $G(\tau)$. In this approximation, we may take the matrix elements out of the first integral of Eq. (181),

$$
\begin{align*}
& -\frac{1}{\hbar^{2}} \int_{-\infty}^{t} K_{F}\left(t-t^{\prime}\right) d t^{\prime}\left[\hat{x}(t),\left[\hat{x}\left(t^{\prime}\right), \hat{w}\left(t^{\prime}\right)\right]\right] \approx-\frac{1}{\hbar^{2}} \int_{0}^{\infty} K_{F}(\tau) d \tau[\hat{x},[\hat{x}, \hat{w}]]  \tag{7.206}\\
& =-\frac{\pi}{\hbar^{2}} S_{F}(0)[\hat{x},[\hat{x}, \hat{w}]]=-\frac{k_{\mathrm{B}} T}{\hbar^{2}} \eta[\hat{x},[\hat{x}, \hat{w}]]
\end{align*}
$$

and calculate the double commutator in the Schrödinger picture. This may be done either using an explicit expression for the matrix elements of the coordinate operator, dual to Eq. (5.28b), or in a simpler way, using the same trick as at the derivation of the Ehrenfest theorem in Sec. 5.2. Namely, expanding an arbitrary function $f(p)$ into the Taylor series in one of its arguments (say, $p$ ),

$$
\begin{equation*}
f(p)=\sum_{k=0}^{\infty} \frac{1}{k!} \frac{\partial^{k} f}{\partial p^{k}} p^{k} \tag{7.207}
\end{equation*}
$$

and applying Eq. (205) to each term, we can prove the following simple commutation relation:

[^697]\[

$$
\begin{equation*}
[\hat{x}, f]=\sum_{k=0}^{\infty} \frac{1}{k!} \frac{\partial^{k} f}{\partial p^{k}}\left[\hat{x}, p^{k}\right]=\sum_{k=0}^{\infty} \frac{1}{k!} \frac{\partial^{k} f}{\partial p^{k}}\left(i \hbar k p^{k-1}\right)=i \hbar \sum_{k=1}^{\infty} \frac{1}{(k-1)!} \frac{\partial^{k-1}}{\partial p^{k-1}}\left(\frac{\partial f}{\partial p}\right) p^{k-1}=i \hbar \frac{\partial f}{\partial p} . \tag{7.208}
\end{equation*}
$$

\]

Now applying this result sequentially, first to $w\left(p, p^{\prime}\right)$ and then to the resulting commutator, we get

$$
\begin{equation*}
[\hat{x},[\hat{x}, w]]=\left[\hat{x}, i \hbar \frac{\partial w}{\partial p}\right]=i \hbar \frac{\partial}{\partial p}\left(i \hbar \frac{\partial w}{\partial p}\right)=-\hbar^{2} \frac{\partial^{2} w}{\partial p^{2}} . \tag{7.209}
\end{equation*}
$$

It may look like the second integral in Eq. (181) might be simplified similarly. However, it vanishes at $p^{\prime} \rightarrow p$, and $t^{\prime} \rightarrow t$, so that in order to calculate the first nonvanishing contribution from that integral for $p=p$, we have to take into account the small difference $\tau \equiv t-t^{\prime} \sim \tau_{c}$ between the arguments of the coordinate operators under that integral. This may be done using Eq. (169) with the free-particle Hamiltonian consisting of the kinetic-energy contribution alone:

$$
\begin{equation*}
\hat{x}\left(t^{\prime}\right)-\hat{x}(t) \approx-\tau \dot{\hat{x}}=-\tau \frac{1}{i \hbar}\left[\hat{x}, \hat{H}_{s}\right]=-\tau \frac{1}{i \hbar}\left[\hat{x}, \frac{\hat{p}^{2}}{2 m}\right]=-\tau \frac{\hat{p}}{m}, \tag{7.210}
\end{equation*}
$$

where the exact argument of the operator in the right-hand part is already unimportant, and may be taken for $t$. As a result, we may use the last of Eqs. (136) to reduce the second term in the right-hand part of Eq. (181) to

$$
\begin{equation*}
-\frac{i}{2 \hbar} \int_{-\infty}^{t} G\left(t-t^{\prime}\right)\left[\hat{x}(t),\left\{\hat{x}\left(t^{\prime}\right), \hat{w}\left(t^{\prime}\right)\right\}\right] d t^{\prime} \approx \frac{i}{2 \hbar} \int_{0}^{\infty} G(\tau) \tau d \tau\left[\hat{x},\left\{\frac{\hat{p}}{m}, \hat{w}\right\}\right]=\frac{\eta}{2 i \hbar}\left[\hat{x},\left\{\frac{\hat{p}}{m}, \hat{w}\right\}\right] . \tag{7.211}
\end{equation*}
$$

In the momentum representation, the momentum operator and the density matrix $w$ are just $c$-numbers and commute, so that, applying Eq. (208) to product $p w$, we get

$$
\begin{equation*}
\left[\hat{x},\left\{\frac{\hat{p}}{m}, \hat{w}\right\}\right]=\left[\hat{x}, 2 \frac{p}{m} w\right]=2 i \hbar \frac{\partial}{\partial p}\left(\frac{p}{m} w\right), \tag{7.212}
\end{equation*}
$$

and may finally reduce the integro-differential equation Eq. (181) to a partial differential equation: Equation: free 1D particle

$$
\begin{equation*}
\frac{\partial w}{\partial t}=\frac{\partial}{\partial p}\left(\eta \frac{p}{m} w\right)+k_{\mathrm{B}} T \eta \frac{\partial^{2} w}{\partial p^{2}} \tag{7.213}
\end{equation*}
$$

This is the 1D form of the famous Fokker-Planck equation describing the classical statistics of motion of a free 1D particle in a medium with a linear drag characterized by the coefficient $\eta$. The first, drift term in the right-hand part of Eq. (213) describes particle's deceleration due to the average viscous force (137), $\langle F\rangle=-\eta v=-\eta p / m$, provided by the environment, while the second, diffusion term describes the effect of fluctuations: particle's random walk that obeys Eq. (85) with the diffusion coefficient

Einstein relation

$$
\begin{equation*}
D=\eta k_{\mathrm{B}} T \tag{7.214}
\end{equation*}
$$

This fundamental Einstein relation, ${ }^{76}$ shows again the intimate connection between the dissipation (friction) and fluctuations, in this classical limit represented by their thermal energy scale $k_{\mathrm{B}} T .{ }^{.77}$

[^698]Just for reader's reference, let me note that the Fokker-Planck equation (213) may be readily generalized to the 3D motion of a particle under the effect of an additional external force $F_{\text {ext }}(\mathbf{r}, t):{ }^{78}$

$$
\begin{equation*}
\frac{\partial w}{\partial t}=-\nabla\left(\frac{\mathbf{p}}{m} w\right)-\nabla_{p} \cdot(\mathbf{F} w)+D \nabla_{p}^{2} w, \quad \text { with } \mathbf{F}=\mathbf{F}_{\mathrm{ext}}-\eta \frac{\mathbf{p}}{m} \tag{7.215}
\end{equation*}
$$

where $w=w(\mathbf{r}, \mathbf{p}, t)$ is the time-dependent probability density in the 6 D phase space, and $\nabla_{p}$ is the nabla/del operator of differentiation over the momentum components, defined similarly to its coordinate counterpart $\nabla$. The Fokker-Planck equation in this form is the basis for many important applications; however, due to its classical character, its discussion is left for the SM part of my lecture notes. ${ }^{79}$

To summarize our discussion of the two alternative approaches to the analysis of quantum systems interacting with a thermally-equilibrium environment, described in the last three sections, let me emphasize that they give descriptions of the same phenomena, and are characterized by the same two functions $G(\tau)$ and $K_{F}(\tau)$, but from two different points of view. Namely, in the Heisenberg-Langevin approach we describe the system by operators that change (fluctuate) in time, even in thermal equilibrium, while in the density-matrix approach the system is described by non-fluctuating probability functions, such as $W_{n}(t)$ or $w(p)$, that are stationary in equilibrium. In the (relatively rare) cases when a problem may be solved by either method, they give identical results for all observables.

### 7.7. Quantum measurements

Now we have got a sufficient quantum mechanics background for a brief discussion of quantum measurements. ${ }^{80}$ Let me start with reminding the reader the only postulate of quantum mechanics that relates this theory with experiment. In Chapter 4 it was formulated for a pure state described with ketvector

$$
\begin{equation*}
|\alpha\rangle=\sum_{j} \alpha_{j}\left|a_{j}\right\rangle, \tag{7.216}
\end{equation*}
$$

${ }^{77}$ This classical relation may be derived using several other ways - including those much simpler than used above. For example, since the Brownian particle's motion may be described by a linear Langevin equation, Eq. (214) may be readily obtained from the Nyquist formula (139) - see, e.g., SM Sec. 5.5.
${ }^{78}$ Moreover, Eq. (213) may be generalized to the motion in an additional periodic potential $U(\mathbf{r})$. In this case, an analog of Eq. (215) for the probability density of quasi-momentum $\hbar \mathbf{q}$ (rather than the genuine momentum $\mathbf{p}$ ) includes an additional energy band index (say, $n$ ), an additional force $\mathbf{F}_{n}=-\nabla E_{n}$ (where $E_{n}(\mathbf{q})$ is the energy band structure that was discussed in Secs. 2.7 and 3.4), and an additional term similar to the right-hand part of Eq. (194), describing interband transitions with quasi-momentum-dependent rates $\Gamma_{n \rightarrow n}(\mathbf{q})$. These rates are still expressed by Eq. (196), but with the matrix elements $x_{n n}$, replaced by those of the vector operator $\hat{\boldsymbol{\Omega}} \equiv \hat{\mathbf{r}}-i \nabla_{q}$ of interband transitions, which was discussed in Chapter 5. For details and a particular example of a sinusoidal potential see, e.g., K. Likharev and A. Zorin, J. Low Temp. Phys. 59, 347 (1985).
${ }^{79}$ For a more detailed analysis and several examples of quantum effects in dissipative systems with continuous spectra see, e. g., U. Weiss, Quantum Dissipative Systems, $2^{\text {nd }}$ ed., World Scientific, 1999, or H.-P. Breuer and F. Petruccione, The Theory of Open Quantum Systems, Oxford U. Press, 2007.
80 "Quantum measurements" is a very unfortunate term; it would be more sensible to speak about "measurements of quantum mechanical observables". However, the former term is so common and compact that I will use it.
where $a_{j}$ and $A_{j}$ are, respectively, the eigenstates of the operator of observable $A$, defined by Eq. (4.68). According to the postulate, the outcome of each particular measurement of observable $A$ may be uncertain, ${ }^{81}$ but is restricted to the set of eigenstates $A_{j}$, with the probability of outcome $A_{j}$ equal to

$$
\begin{equation*}
W_{j}=\left|\alpha_{j}\right|^{2} \tag{7.217}
\end{equation*}
$$

Since we know now that the state of the system (or rather of the statistical ensemble of similar systems we are using for measurements) is generally not pure, this postulate should be re-worded as follows: even if the system is in the least uncertain state (216), the measurement outcomes are still probabilistic, and obey Eq. (133). ${ }^{82}$

Quantum measurement may be understood as a procedure of transferring the "microscopic" information contained in coefficients $\alpha_{j}$ into "macroscopically" available information about the outcomes of particular experiments, that may be recorded and reliably stored - say, on paper, or in a computer, or in our minds. If we believe that such transfer may be always done well enough, and do not worry too much how exactly, we are subscribing to the mathematical notion of measurement, that was (rather reluctantly) used in these notes - up to this point. However, every physicist should understand that measurements are performed by physical devices that also should obey the laws of quantum mechanics, and it is important to understand the basic laws of their operation.

The founding fathers of quantum mechanics have not paid much attention to these issues, probably because of the following two reasons. First, at that time it looked like the experimental instruments (at least the best of them :-) were doing exactly what postulate (217) was telling. For example, had not the $z$-oriented Stern-Gerlach experiment turned two complex coefficients $\alpha \uparrow$ and $\alpha \downarrow$, describing the incoming electron beam, into particle counter clicks with rates proportional to, respectively, $|\alpha \uparrow|^{2}$ and $|\alpha \downarrow|^{2}$ ? Also, the crude internal nature of these instruments made more detailed questions unnatural. For example, the electron rate counting with a Geiger counter involves an effective disappearance of each incoming electron inside a zillion-particle electric discharge avalanche. Thinking about such devices, it was hard to even imagine measurements that would not disturb the quantum state of the particle being measured.

However, since that time the experimental techniques, notably including high vacuum, low temperatures, and low-noise electronics, have much improved, and eventually more inquisitive questions started to look not so hopeless. In my scheme of things, these questions may be grouped as follows:
(i) What are the main laws of a quantum measurement as a physical process? In particular, should it always involve time irreversibility? a human/intelligent observer? (The last question is not as laughable as it may look - see below.)
(ii) What is the state of the measured system just after a single-shot measurement - meaning the measurement process limited to a time interval much shorter that the time scale of measured system's evolution? This question is naturally related to the issues of repeated measurements and continuous monitoring of system's state.

[^699](iii) If a measurement of observable $A$ produced a certain outcome $A_{j}$, can we believe that the system had been in the corresponding state $\alpha_{j}$ just before the measurement?

The last question is most closely related to various interpretations of quantum mechanics, and will be discussed in the concluding Chapter 10, and now let me provide some input on the first two groups of issues.

First of all, I am happy to report that these is a virtual consensus of physicists on the two first questions of series (i). According to this consensus, any quantum measurement needs to result in a certain, distinguishable state of a macroscopic output component of the measurement instrument - see Fig. 7. (Traditionally, its component is called a pointer, though its role may be played by a printer or a plotter, an electronic circuit sending out the result as a number, etc.).

This requirement implies that the measurement process should have the following features:

- be time-irreversible,
- provide large "signal gain", i.e. mapping the quantum process with its $\hbar$-scale of action (i.e. of the energy-by-time product) onto a macroscopic motion of the pointer with a much larger action scale, and
- if we want high measurement fidelity, the process should introduce as little additional uncertainty as permitted by the law of physics.

Fig.7.7. General scheme of quantum measurement.

All these requirements are fulfilled in a good Stern-Gerlach experiment. However, since the internal physics of the particle detector at this measurement is rather complex, let me give an example of a different, more simple single-shot scheme ${ }^{83}$ capable of measuring the instant state of a typical twolevel system, for example, a particle in a double quantum well potential (Fig. 8). ${ }^{84}$ Let the system be, at $t$ $=0$, in a pure quantum state described by ket-vector

$$
\begin{equation*}
|\alpha\rangle=\alpha_{\rightarrow}|\rightarrow\rangle+\alpha_{\leftarrow}|\leftarrow\rangle, \tag{7.218}
\end{equation*}
$$

[^700]where the component states $\rightarrow$ and $\leftarrow$ may be described by wavefunctions localized near the potential well bottoms at $x_{s} \sim \pm x_{0}$ - see the blue lines in Fig. 8b. Let us rapidly change the potential profile of the system at $t=0$, so that at $t>0$, and near the origin, it may be well approximated by an inverted parabola (see the red line in Fig. 8b):
\[

$$
\begin{equation*}
U\left(x_{s}\right) \approx-\frac{m \lambda^{2}}{2} x_{s}^{2}, \quad \text { at } t>0,\left|x_{s}\right| \ll x_{f} . \tag{7.219}
\end{equation*}
$$

\]

Fig. 7.8. Potential inversion on (a) "macroscopic" and (b) "microscopic" scales of coordinate $x$.

It is straightforward to verify that the Heisenberg equations of motion in such inverted potential describe an exponential growth of operator $\hat{x}_{s}$ in time (proportional to $\exp \{\lambda t\}$ and hence a similar growth of the expectation value $\left\langle x_{s}\right\rangle$ and its r.m.s. uncertainty $\delta x_{s} .{ }^{85}$ At this "inflation" stage, the coherence between the two component states $\rightarrow$ and $\leftarrow$ is still preserved, i.e. the time evolution is reversible.

Now let the system be weakly coupled to a dissipative (e.g., Ohmic) environment. As we already know, the environment performs two functions. First, it provides motion with the drag coefficient $\eta$ (141), so that the system would eventually come to rest at one of the relatively distant minima, $\pm x_{f}$, of the inverted potential (Fig. 8a). Second, the dissipative environment ensures state's dephasing on some time scale $T_{2}$. If we select the measurement system parameters in such a way that

$$
\begin{equation*}
x_{0} \ll x_{0} \exp \left\{\lambda T_{2}\right\} \ll x_{f}, \tag{7.220}
\end{equation*}
$$

then the process, after the potential inversion, consists of the following stages, well separated in time:

- the "inflation" stage, preserving the component state coherence but providing an exponential increase of its energy,

[^701]- the dephasing stage, at which the coherence is suppressed, and the density matrix of the system is reduced to a diagonal form describing the classical mixture of the probability packets propagating to the left and to the right, and
- the stage of settling to a new stationary state - a classical mixture of two states located near points $x_{s}= \pm x_{f}$, with probabilities (217) equal to, respectively, $W_{\rightarrow}=\left|\alpha_{\rightarrow}\right|^{2}$ and $W_{\leftarrow}=\left|\alpha_{\leftarrow}\right|^{2}=1-\left|\alpha_{\rightarrow}\right|^{2}$.

If the final states are macroscopically distinguishable (i.e. may play the role of a bistable pointer), as they are in the balanced-comparator implementation, there is absolutely no need, at any of these stages, to involve any mysterious "another mechanism of wavefunction change" (different from the regular, Schrödinger evolution) for the measurement process description.

This may be the only appropriate time to mention, very briefly, the famous - or rather infamous Schrödinger cat paradox so much overplayed in popular press. (The only good aspect of this popularity is that the formulation of this paradox is certainly so well known to the reader, that I do not need to repeat it.) In this thought experiment, there is no need to discuss the (rather complex :-) physics of the cat. As soon as the charged particle, produced at the radioactive decay, reaches the Geiger counter, the process rapidly becomes irreversible, so that the coherent state of the system is reduced to a classical mixture of two possible states: "decay" - "no decay", leading, correspondingly, to the "cat alive" - "cat dead" states. So, despite attempts by numerous authors, typically without proper physics background, to present this situation as a mystery whose discussion needs the involvement of professional philosophers, hopefully by this point the reader knows enough about dephasing to pay any attention. Let me, however, note the two non-trivial features of this gedanken experiment, that are met in most real experiments as well, including that with the potential inversion (Fig. 8).

First, the role of the measured coordinate of the system under observation ( $s$ ) may be played not by a coordinate of a single fundamental particle, but a certain combination of coordinates of many microscopic components of a macroscopic body. In particular, in Josephson junction systems such as the balanced comparator we essentially measure the persistent electric current ("supercurrent") - a certain linear combination of Cartesian components of the momenta of the electrons that constitute the BoseEinstein condensate of Cooper pairs. At that, the role of the local environment (that contributes significantly to dissipative phenomena) is played by the same electrons, with other linear combinations of electron momenta playing the role of environmental degrees of freedom - which were called $\{\lambda\}$ in the last few sections. This makes the coupling to environment somewhat less apparent (at least for the people who do not know what a linear combination is :-).

Second, one may argue that even after the balanced comparator (in our first example) or the cat (in the second example) has reached its final macroscopic state, human observer's realization that in this particular experiment the bistable pointer is in a certain state instantly decreases the probability (for the same observer!) of its being in the opposite state to zero. However, as was already discussed in Sec. 2.5, this is a very classical problem of the statistical ensemble redefinition that may be (or may be not) performed at observer's will. Such redefinition, if performed, is the only possible role of a human (or otherwise intelligent :-) observer in the measurement process; if we are only interested in an objective recording of results of a pre-fixed sequence of experiments, there is no need to include such observer into any discussion.

The ensemble redefinition at measurement leads to several other paradoxes, of which the socalled quantum Zeno paradox is perhaps most spectacular. ${ }^{86}$ Let us return to a two-level system with the unperturbed Hamiltonian given by Eq. (4.166), with $2 \pi / \Omega$ much longer than the single-shot measurement time, in which the system initially (at $t=0$ ) is in a certain quantum well. Then, as we know from Secs. 2.6 and 4.6, before the first measurement, the probability to find state in the initial state at time $t$ is

$$
\begin{equation*}
W(t)=\cos ^{2} \frac{\Omega t}{2} . \tag{7.221}
\end{equation*}
$$

If the time is small enough $(t=d t \ll 1 / \Omega)$, we may use the Taylor expansion to write

$$
\begin{equation*}
W(d t) \approx 1-\frac{\Omega^{2} d t^{2}}{4} . \tag{7.222}
\end{equation*}
$$

Now, let us return the two-level system, after its measurement, into the same quantum well, and let it evolve with the same Hamiltonian. Since the occupation of the opposite state is very small, the evolution of $W$ will closely follow the same law as in Eq. (221), but with the initial value given by Eq. (222) Thus, when the system is measured again at time $2 d t$,

$$
\begin{equation*}
W(2 d t) \approx W(d t)\left(1-\frac{\Omega^{2} d t^{2}}{4}\right)=\left(1-\frac{\Omega^{2} d t^{2}}{4}\right)^{2} \tag{7.223}
\end{equation*}
$$

After repeating this cycle $N$ times (with the total time $t=N d t$ still much less than $N^{1 / 2} / \Omega$ ), the probability that the system is still in the initial state is

$$
\begin{equation*}
W(N d t) \equiv W(t) \approx\left(1-\frac{\Omega^{2} d t^{2}}{4}\right)^{N}=\left(1-\frac{\Omega^{2} t^{2}}{4 N^{2}}\right)^{N} \approx 1-\frac{\Omega^{2} t^{2}}{4 N} \tag{7.224}
\end{equation*}
$$

Comparing this result with Eq. (222), we see that the process of system transfer to the opposite quantum well has been slowed down rather dramatically, and in the limit $N \rightarrow \infty$ (at fixed $t$ ), its evolution is completely stopped by the measurement process. There is of course nothing mysterious here; the evolution slowdown is due to statistical ensemble's redefinition.

Now let me proceed to question group (ii), in particular to the general issue of the back action of the instrument upon the system under measurement (symbolized with the back arrow in Fig. 7). In instruments like the Geiger counter or the balanced comparator, such back action is very large, because the instrument essentially destroys ("demolishes") the initial state of the system under measurement.

[^702]However, in the 1970s it was realized that this is not really necessary. In Sec. 3, we have already discussed an example of a two-level system coupled with environment (in our current context, with measurement instrument) and described by Hamiltonian

$$
\begin{equation*}
\hat{H}=\hat{H}_{s}+\hat{H}_{\mathrm{int}}+\hat{H}_{e}\{\lambda\}, \quad \text { with } \hat{H}_{s}=a \hat{\sigma}_{z}, \quad \hat{H}_{\mathrm{int}}=-f\{\lambda\} \hat{\sigma}_{z}, \tag{7.225}
\end{equation*}
$$

so that

$$
\begin{equation*}
\left[\hat{H}_{s}, \hat{H}_{\mathrm{int}}\right]=0 \tag{7.226}
\end{equation*}
$$

Comparing this equality with Eq. (67) we see that in the Heisenberg picture, the Hamiltonian operator (and hence the energy) of the system of our interest does not change with time. On the other hand, the interaction can change the state of the instrument, so it may be used to measure its energy - or another observable whose operator commutes with the interaction Hamiltonian. Such trick is called either the quantum non-demolition (QND) or back-action-evading (BAE) measurements. ${ }^{87}$ Let me present a fine example of a real measurement of this kind - see Fig. $9 .{ }^{88}$

(b)

Fig. 7.9. QND measurement of single electron's energy by Peil and Gabrielse: (a) the core of experimental setup, and (b) a record of the thermal excitation and spontaneous relaxation of Fock states. © 1999 APS.

In this experiment, a single electron is captured in a Penning trap - a combination of a (virtually) uniform magnetic field $\mathbf{B}$ and a quadrupole electric field. ${ }^{89}$ Such electric field stabilizes cyclotron orbits but does not have any noticeable effect on electron motion in the plane perpendicular to the magnetic field, and hence on its Landau level energies (see Sec. 3.2):

[^703]\[

$$
\begin{equation*}
E_{n}=\hbar \omega_{c}\left(n+\frac{1}{2}\right), \quad \text { with } \omega_{c}=\frac{e B}{m_{e}} \tag{7.227}
\end{equation*}
$$

\]

(In the cited work, at $B \approx 5.3 \mathrm{~T}$, the cyclic frequency $\omega_{c} / 2 \pi$ was about 147 GHz , so that the level splitting $\hbar \omega_{c}$ was close to $10^{-22} \mathrm{~J}$, i.e. corresponded to temperature $\sim 10 \mathrm{~K}$, while the physical temperature of the system might be reduced well below that, down to $\sim 80 \mathrm{mK}$ ). Now note that the analogy between a particle on a Landau levels and a harmonic oscillator goes beyond the energy spectrum. Indeed, since the Hamiltonian of a 2D particle in a perpendicular magnetic field may be reduced to that of a 1D oscillator, we may repeat all procedures of Sec. 5.4 and rewrite it in the terms of creation-annihilation operators:

$$
\begin{equation*}
\hat{H}_{s}=\hbar \omega_{c}\left(\hat{a}^{\dagger} \hat{a}+\frac{1}{2}\right) \tag{7.228}
\end{equation*}
$$

In the Peil and Gabrielse experiment, the electron had one more degree of freedom - along the magnetic field. The electric field of the Penning trap creates a soft confining potential along this direction (vertical in Fig. 9a; let us take it for axis $z$ ), so that small electron oscillations along that axis could be well described as a 1D harmonic oscillator of much lower eigenfrequency, in that particular experiment with $\omega_{z} / 2 \pi \approx 64 \mathrm{MHz}$. This frequency could be measured very accurately (with error $\sim 1 \mathrm{~Hz}$ ) by sensitive electronics whose electric field affects $z$-motion of the electron, but not its motion in the perpendicular plane. In an exactly uniform magnetic field, the two modes of electron motion would be completely uncoupled. However, the experimental setup included two special superconducting rings made of niobium (Fig. 9a), which slightly distorted the magnetic field and created an interaction between the modes, which might be well approximated by Hamiltonian ${ }^{90}$

$$
\begin{equation*}
\hat{H}_{\mathrm{int}}=\operatorname{const} \times\left(\hat{a}^{\dagger} \hat{a}+\frac{1}{2}\right) \hat{z}^{2} \tag{7.228}
\end{equation*}
$$

so that the main condition (226) of a QND measurement was well satisfied. At the same time, coupling (228) ensured that a change of the Fock state number $n$ by 1 changed the $z$-oscillation eigenfrequency by $\sim 12.4 \mathrm{~Hz}$. Since this shift was substantially larger than electronics noise, spontaneous changes of $n$ (due to an uncontrolled coupling of the electron to environment) could be readily observed - moreover, continuously monitored - see Fig. 9b. (These data imply that there is virtually no effect of the measuring instrument on the statistics on $n-$ at least on the scale of minutes, i.e. as many as $\sim 10^{13}$ cyclotron orbit periods.) Of course, any measurement - QND or not - cannot avoid the Heisenberg uncertainty relations; in this particular case, a permanent monitoring of the Fock state number $n$ keeps its quantum phase fully uncertain.

It is natural to wonder whether the QND measurement concept may be extended from quadratic forms like the energy to "usual" observables such as coordinates and momenta whose uncertainties are bound by the fundamental Heisenberg's relation. The answer is yes, but the required methods are a bit more tricky. For example, let us place an electrically charged particle into a uniform electric field $\boldsymbol{\varepsilon}=$ $\mathbf{n}_{x} \mathcal{E}(t)$ of the instrument, so that their interaction Hamiltonian is

[^704]\[

$$
\begin{equation*}
\hat{H}_{\mathrm{int}}=-q \hat{\varepsilon}(t) \hat{x} \tag{7.229}
\end{equation*}
$$

\]

Such interaction certainly passes the information on the time evolution of coordinate $x$ to the instrument. However, since Eq. (226) is not satisfied - at least for the kinetic-energy part of system's Hamiltonian; as a result the interaction simultaneously distorts the time evolution of particle's momentum. Indeed, writing the Heisenberg equation of motion (4.199) for the $x$-component of momentum, we get

$$
\begin{equation*}
\dot{\hat{p}}-\left.\dot{\hat{p}}\right|_{\varepsilon=0}=q \hat{\varepsilon}(t) \tag{7.230}
\end{equation*}
$$

Integrating Eq. (5.139) for the coordinate operator evolution, ${ }^{91}$ we get expression,

$$
\begin{equation*}
\hat{x}(t)=\hat{x}(0)+\frac{1}{m} \int_{0}^{t} \hat{p}\left(t^{\prime}\right) d t^{\prime} \tag{7.231}
\end{equation*}
$$

that shows that the perturbations (230) of the momentum would eventually find their way to the coordinate evolution.

However, for such an important particular system as a harmonic oscillator, the following trick is possible. For this system, Eqs. (5.170) and (230) may be readily combined to give a second-order differential equation for the coordinate operator, that is absolutely similar to the classical equation of motion, and has a similar solution: ${ }^{92}$

$$
\begin{equation*}
\hat{x}(t)=\hat{x}(0)+\frac{q}{m \omega_{0}} \int_{0}^{t} \hat{\varepsilon}\left(t^{\prime}\right) \sin \omega_{0}\left(t-t^{\prime}\right) d t^{\prime} \tag{7.232}
\end{equation*}
$$

This formula confirms that generally the external field $\mathscr{A} t$ ) (in our case, the sensing field of the measurement instrument) affects the time evolution law. Note, however, that if the field is applied only at moments $t_{n}^{\prime}$ separated by intervals $T / 2$, where $T=2 \pi / \omega_{0}$ is the oscillation period, its effect on coordinate vanishes at similarly spaced observation instants $t_{n}=t_{n}{ }^{\prime}+(m+1 / 2) T$. This the idea of stroboscopic QND measurements. Of course, according to Eq. (230), even such measurement strongly perturbs the oscillator momentum, so that even if values $x_{n}$ are measured with high accuracy, the Heisenberg's uncertainty relation is not violated.

Experimental implementation of such measurements is not simple (and to the best of my knowledge they have never been successfully demonstrated), but this initial idea has opened a way to more practicable solutions. For example, it straightforward to use the Heisenberg equations of motion to show that if coupling of two harmonic oscillators, with coordinates $x$ and $X$, and unperturbed eigenfrequencies $\omega$ and $\Omega$, is modulated in time as

$$
\begin{equation*}
\hat{H}_{\mathrm{int}} \propto \hat{x} \hat{X} \cos \omega t \cos \Omega t \tag{7.233}
\end{equation*}
$$

[^705]then the process in one of oscillators (say, that with frequency $\Omega$ ) does not affect dynamics of one of the quadrature components of another oscillator, defined by relations ${ }^{93}$
\[

$$
\begin{equation*}
\hat{x}_{1} \equiv \hat{x} \cos \omega t-\frac{\hat{p}}{m \omega} \sin \omega t, \quad \hat{x}_{2} \equiv \hat{x} \sin \omega t+\frac{\hat{p}}{m \omega} \cos \omega t, \tag{7.234}
\end{equation*}
$$

\]

while this component's motion does affect the dynamics of one of quadrature components of the counterpart oscillator. (For the counterpart couple of quadrature components, the information transfer goes in the opposite direction.) This scheme has been successfully used for QND measurements in the optical range, with coupling (233) provided by the optical Kerr effect. ${ }^{94}$

Please note that the last two QND measurement examples are based on the idea of modulation of a certain parameter in time - either in a short-pulse or sinusoidal form. So, the reader should not be surprised that if the only role of a QND measurement is a sensitive measurement of a weak classical force acting on a quantum probe system, ${ }^{95}$ i.e. a 1 D oscillator of eigenfrequency $\omega_{0}$, it may be implemented much simpler - just by modulating the oscillator parameter with frequency $\omega \approx 2 \omega_{0}$. From classical dynamics, we know that if the depth of such modulation exceeds a certain threshold value, it results in excitation of the so-called parametric oscillations with frequency $\omega / 2$, and one of two opposite phases. ${ }^{96}$ In the language of Eq. (234), parametric excitation means an exponential growth of one of the quadrature components, with the sign depending on initial conditions, while the counterpart component is suppressed. Close to, but below the excitation threshold, the parameter modulation boosts all perturbations of the almost-excited component (including its quantum-mechanical uncertainty), and suppresses (squeezes) those of the counterpart component. The result is a squeezed state, already discussed in Sec. 5.5 above (see in particular Fig. 5.6), that allows one to notice the effect of external force on the oscillator on the backdrop of a quantum uncertainty smaller that the standard quantum limit (5.138) - see the first of Eqs. (5.174).

In electrical engineering, this fact may be conveniently formulated in terms of noise parameter $\Theta_{N}$ of a linear amplifier - the instrument for continuous monitoring of an input "signal" - e.g., a microwave or optical waveform. ${ }^{97}$ Namely, $\Theta_{N}$ of "usual" (say, transistor or maser) amplifiers which are equally sensitive to both quadrature components of the signal, $\Theta_{N}$ has a minimum value $\hbar \omega / 2$, due to the quantum uncertainty pertinent to the quantum state of the amplifier itself (which therefore plays the role

[^706]of its "quantum noise"). ${ }^{98}$ On the other hand, a degenerate parametric amplifier, sensitive to just one quadrature component, may have $\Theta_{N}$ well below $\hbar \omega / 2$, due to the squeezing of its ground state. ${ }^{99}$

Finally, let me note that the parameter-modulation schemes of the QND measurements are not limited to harmonic oscillators, and may be applied to other important quantum systems, notably including two-level (i.e. spin-1/2-like) systems. ${ }^{100}$

### 7.8. Exercise problems

7.1. Calculate the density matrix of a two-level system described by Hamiltonian with matrix

$$
\mathrm{H}=\mathbf{a} \cdot \boldsymbol{\sigma}=a_{x} \sigma_{x}+a_{y} \sigma_{y}+a_{z} \sigma_{z},
$$

where $\sigma_{k}$ are the Pauli matrices, and $a_{k}$ are $c$-numbers, in thermodynamic equilibrium.
7.2. Find the Wigner function of a harmonic oscillator in:
(i) at the thermodynamic equilibrium at temperature $T$,
(ii) in the ground state, and
(ii) in the Glauber state with dimensionless complex amplitude $\alpha$.

Discuss the relation between the first of the results and the Gibbs distribution.
7.3. Calculate the Wigner function of a harmonic oscillator, with mass $m$ and frequency $\omega_{0}$, in its first excited stationary state $(n=1)$.
7.4. Show that the quantum-mechanical Golden Rule (6.111) and the master equation (196) give the same results for the rate of spontaneous quantum transitions $n^{\prime} \rightarrow n$ in a system with discrete energy spectrum, weakly coupled to a low-temperature the heat bath $\left(k_{\mathrm{B}} T \ll \hbar \omega_{n n}\right)$.

Hint: Try to establish a relation between function $\operatorname{Im} \chi\left(\omega_{n n}\right)$ that participates in Eq. (196), and the density of states $\rho_{n}$ that participates in the Golden Rule formulas, by considering a particular case of sinusoidal oscillations in the system of interest.
7.5.* A harmonic oscillator is weakly coupled to an Ohmic environment.
(i) Use the rotating-wave approximation to write equations of motion for the Heisenberg operators of the complex amplitude of oscillations.
(ii) Calculate the expectation values of the correlators of the fluctuation force operators, participating in these equations, and express them via the average number $\langle n\rangle$ of thermally-induced excitations in equilibrium, given by the second of Eqs. (26b).
7.6. For a harmonic oscillator with weak Ohmic dissipation:
(i) Spell out the system of differential equations for the energy level occupancies $W_{n}$.

[^707](ii) Use this system to find the time evolution of the expectation value $\langle E\rangle$ of oscillator's energy. (iii) Compare the last result with that following from the Heisenberg-Langevin approach.
7.7. Derive Eq. (209) in an alternative way, using an expression dual to Eq. (5.28b).
7.8. ${ }^{*}$ A particle in a system of two coupled quantum wells (see, e.g., Fig. 4) is weakly coupled to an Ohmic environment.
(i) Derive the equations of time evolution of the density matrix elements.
(ii) Solve these equations in the low-temperature limit, when the energy level splitting is much larger than $k_{\mathrm{B}} T$, to calculate the time evolution of the probability $W_{L}(t)$ of finding the particle one of the wells, after it had been placed there at $t=0$.
7.9. ${ }^{*}$ A spin- $-1 / 2$ particle is placed into magnetic field $\mathcal{B}(t)=\mathcal{B}_{0}+\widetilde{\mathcal{B}}(t)$ with an arbitrary but small time-dependent component $\left(|\widetilde{\mathcal{B}}| \ll\left|\mathcal{B}_{0}\right|\right)$, and is also weakly coupled to dissipative environment. Derive the differential equations describing the time evolution of the expectation values ( $\left\langle S_{x}\right\rangle$, etc.) of spin's Cartesian components.

## Chapter 8. Multiparticle Systems

This chapter is a brief introduction to quantum mechanics of systems of similar particles, with a special attention to the case when they are indistinguishable. For such systems, the theory predicts (and experiment confirms) very specific effects even in the case of negligible explicit ("direct") interaction between the particles. The effects notably include the Bose-Einstein condensation of bosons, and the Pauli exclusion principle and exchange interaction for fermions.

### 8.1. Distinguishable and indistinguishable particles

The importance of quantum systems of many similar particles is probably self-evident; just the very fact of that most atoms include several/many electrons is sufficient to attract our attention. There are also important systems where the number of electrons is much higher than in one atom; for example, a cubic centimeter of a typical metal features $\sim 10^{23}$ conduction electrons that cannot be attributed to particular atoms, and have to considered as common (and interacting!) pats of the system as the whole. Though quantum mechanics offers virtually no exact analytical solutions for systems of strongly interacting particles, ${ }^{1}$ it reveals very important new effects even in the simplest case when particles do not interact, and least explicitly (directly).

If non-interacting particles are either different from each other by their nature (say, an electron and a proton), or physically similar but still distinguishable because of other reasons (say, because of their reliable spatial separation) everything is simple - at least, conceptually. Then, as was already discussed in Sec. 6.7, a system of two particles, 1 and 2, each in a pure quantum state, may be described by a ket vector

$$
\begin{equation*}
|\alpha\rangle=|\beta\rangle_{1} \otimes\left|\beta^{\prime}\right\rangle_{2} \tag{8.1a}
\end{equation*}
$$

where the single-particle states $\beta$ and $\beta^{\prime}$ are defined in different Hilbert spaces. (Below, I will frequently use the following convenient shorthand,

$$
\begin{equation*}
|\alpha\rangle=\left|\beta \beta^{\prime}\right\rangle, \tag{8.1b}
\end{equation*}
$$

in which the state position within a vector codes the particle number.) Hence the permuted state

$$
\begin{equation*}
\hat{\mathcal{P}}\left|\beta \beta^{\prime}\right\rangle \equiv\left|\beta^{\prime} \beta\right\rangle=\left|\beta^{\prime}\right\rangle_{1} \otimes|\beta\rangle_{2}, \tag{8.2}
\end{equation*}
$$

where $\hat{P}$ is the permutation operator, is clearly different from the initial one.

[^708]Again, such description is valid even for identical particles if they are still distinguishable by their spatial separation. (The separation does not preclude particles from interacting with each other, e.g., electrostatically.) Such systems of similar but clearly distinguishable particles (or subsystems) are broadly discussed nowadays, for example in the context of quantum computing and encryption - see Sec. 8.5 below. This is why it is unfortunate that term "identical particles" is frequently used in the sense of indistinguishable particles. I will try to avoid this confusion by using the latter term, despite it being rather unpleasant grammatically.

Now comes the most important experimental fact: identical elementary particles, ${ }^{2}$ if they are not reliably separated, are genuinely indistinguishable, i.e. their Hilbert spaces are not separable. Hence, instead of Eq. (1), for a set of two particles, we need to use a linear combination of products like $\left|\beta \beta^{\prime}\right\rangle$ and $\left|\beta^{\prime} \beta\right\rangle$ for the construction of genuine quantum states. ${ }^{3}$ In order to comprehend what exactly linear combinations should be used, it is convenient to discuss properties of the permutation operator defined by the first of Eqs. (2).

Let us consider an observable $A$, and a system of eigenstates of its operator:

$$
\begin{equation*}
\hat{A}\left|a_{j}\right\rangle=A_{j}\left|a_{j}\right\rangle . \tag{8.3}
\end{equation*}
$$

If the particles are indistinguishable indeed, the observable expectation value should not be affected by their permutation. Hence operators $\hat{A}$ and $\hat{P}$ have to commute, and share their eigenstates. This is why eigenstates of operator $\hat{\mathcal{P}}$ are so important: in particular, they are also eigenstates of the Hamiltonian, i.e. the stationary states of the system of particles.

Now let us have a look at the operation described by the square of the permutation operator, on an elementary ket-vector product:

$$
\begin{equation*}
\hat{\mathcal{P}}^{2}\left|\beta \beta^{\prime}\right\rangle=\hat{\mathcal{P}}\left(\hat{\mathcal{P}}\left|\beta \beta^{\prime}\right\rangle\right)=\hat{\mathcal{P}}\left|\beta^{\prime} \beta\right\rangle=\left|\beta \beta^{\prime}\right\rangle, \tag{8.4}
\end{equation*}
$$

[^709]i.e. $\hat{P}^{2}$ brings the state back to its original form. Since any pure state of a two-particle system may be represented as a linear combination of such products, this result does not depend on the state, and may be represented as an operator relation:
\[

$$
\begin{equation*}
\hat{\mathcal{P}}^{2}=\hat{I} . \tag{8.5}
\end{equation*}
$$

\]

Now let us find the possible eigenvalues $\mathcal{P}_{j}$ of the permutation operator. Acting by both sides of Eq. (5) on any of eigenstates $\left|\alpha_{j}\right\rangle$ of the permutation operator, we get a very simple equation for its eigenvalues:

$$
\begin{equation*}
P_{j}^{2}=1, \tag{8.6}
\end{equation*}
$$

with two possible solutions:

$$
\begin{equation*}
P_{j}= \pm 1 . \tag{8.7}
\end{equation*}
$$

Let us find the eigenstates of the permutation operator in the simplest case when each of the component particles can be only in two single-particle states - say, $\beta$ and $\beta$ '. Evidently, none of the simple products $\left|\beta \beta^{\prime}\right\rangle$ and $\left|\beta^{\prime} \beta\right\rangle$, taken alone, does qualify for the eigenstate - unless states $\beta$ and $\beta^{\prime}$ are identical. Let us try their linear combination

$$
\begin{equation*}
\left|\alpha_{j}\right\rangle=a\left|\beta \beta^{\prime}\right\rangle+b\left|\beta^{\prime} \beta\right\rangle, \tag{8.8}
\end{equation*}
$$

so that

$$
\begin{equation*}
\hat{\mathcal{P}}\left|\alpha_{j}\right\rangle=\mathcal{P}_{j}\left|\alpha_{j}\right\rangle=a\left|\beta^{\prime} \beta\right\rangle+b\left|\beta \beta^{\prime}\right\rangle . \tag{8.9}
\end{equation*}
$$

For the case $P_{j}=+1$ we have to require states (8) and (9) to be the same, so that $a=b$. Assuming also that the single-particle states $\beta$ and $\beta$ ' are normalized, and requiring the same for the composite state $\alpha$, we get the so-called symmetric eigenstate ${ }^{4}$

$$
\begin{equation*}
\left|\alpha_{+}\right\rangle=\frac{1}{\sqrt{2}}\left(\left|\beta \beta^{\prime}\right\rangle+\left|\beta^{\prime} \beta\right\rangle\right) \tag{8.10}
\end{equation*}
$$

Symmetric and antisymmetric entangled eigenstates

Similarly, for $\mathcal{P}_{j}=-1$ we get $a=-b$, and the antisymmetric eigenstate

$$
\begin{equation*}
\left|\alpha_{-}\right\rangle=\frac{1}{\sqrt{2}}\left(\left|\beta \beta^{\prime}\right\rangle-\left|\beta^{\prime} \beta\right\rangle\right) \tag{8.11}
\end{equation*}
$$

where the front coefficients guarantee the orthonormality of the two-particle states, provided that the single-particle states are orthonormal. These are typical examples of entangled states, defined as multiparticle states whose state vectors cannot be factored into a product of single-particle vectors.

So far, our math does not preclude either sign of $\mathcal{P}_{j}$, in particular the possibility that the sign depends on the state (i.e. index $j$ ). Here, however, comes in another crucial experimental fact: all elementary particles fall into two groups: ${ }^{5}$

[^710](i) bosons, particles with integer spin $s$, for which $\mathcal{P}_{j}=+1$ for any $j$, and
(ii) fermions, particles with half-integer spin, with $\mathcal{P}_{j}=-1$, also for any $j$.

In the non-relativistic theory we are discussing now, this key fact should be considered as experimental one. (The relativistic quantum theory, to be discussed in Chapter 9, offers a proof that half-integer-spin particles cannot be bosons and integer-spin ones cannot be fermions, but not more than that.) However, our discussion of spin in Sec. 5.7 allows the following interpretation of the fermionboson difference. In free space, the permutation of particles 1 and 2 may be viewed as a result of rotation of this pair by angle $\pm \pi$ about a certain axis. As we have seen in Sec. 5.7, at a rotation by such an angle, the state vector $|\beta\rangle$ of a particle with quantum number $m_{s}$ (that ranges from $-s$ to $+s$, and hence may take only integer values for integer $s$, and only half-integer values for half-integer $s$ ) changes by factor $\exp \left\{ \pm i \pi m_{s}\right\}$, so that the state product $\left|\beta \beta^{\prime}\right\rangle$ changes by $\exp \left\{ \pm i 2 \pi m_{s}\right\}$, i.e. by factor +1 for integer $s$, and by factor (-1) for half-integer $s$.

Since eigenvalues $P_{j}$ do not depend on the particular state of the system, we can write explicit expressions for the permutation operator:

$$
\hat{\mathcal{P}}=\hat{I} \times\left\{\begin{array}{lr}
+1, & \text { for bosons },  \tag{8.12}\\
-1, & \text { for fermions } .
\end{array}\right.
$$

The most impressive corollaries of Eqs. (10) and (11) are for the case when the partial states of the two particles are the same: $\beta=\beta^{\prime}$. The corresponding Bose state $\alpha_{+}$is possible; in particular, at sufficiently low temperatures, a set of non-interacting Bose particles condenses on the ground state of each of them - the so-called Bose-Einstein condensate ("BEC"). ${ }^{6}$ Its examples include superfluid fluids like helium, the Cooper-pair condensate in superconductors, and the BEC of weakly interacting atoms. Perhaps the most fascinating feature of a multiparticle Bose-Einstein condensate is that dynamics of its observables is governed by laws of quantum mechanics, while (for nearly all purposes) may be treated as $c$-numbers - see, e.g., Eqs. (2.54)-(2.55). ${ }^{7}$

On the other hand, if we take $\beta=\beta^{\prime}$ in Eq. (11), we see that state $\alpha$ - vanishes, i.e. cannot exist at all. This is the mathematical expression of the Pauli exclusion principle: two indistinguishable fermions cannot be in the same quantum state. ${ }^{8}$ (As will be discussed below, this is true for systems with more than two fermions as well.) Probably, the key importance of this principle is self-evident: if it was not valid for electrons (that are fermions), all electrons of each atom would condense on its ground ( $1 s$ ) level, and all the usual chemistry (and biochemistry, and biology, including dear us!) would not exist. The Pauli principle effectively makes fermions interacting even if they do not interact directly, in the usual sense of this word.

[^711]
### 8.2. Singlets, triplets, and the exchange interaction

Now let us discuss possible approaches to analysis of identical particles on a simple but very important example of a pair of spin- $1 / 2$ particles (say, electrons) whose interaction with either each other or the external world does not involve spin. Then the ket-vector of a total state is factorable as

$$
\begin{equation*}
\left|\alpha_{-}\right\rangle=\left|o_{12}\right\rangle \otimes\left|s_{12}\right\rangle, \tag{8.13}
\end{equation*}
$$

with the orbital function $\left|o_{12}\right\rangle$ and the spin function $\left|s_{12}\right\rangle$ (that depends on the state of both spins of the pair) belonging to different Hilbert spaces. It is frequently convenient to use the coordinate representation of such state, sometimes called the spinor:

2-particle spinor

$$
\begin{equation*}
\left\langle\mathbf{r}_{1}, \mathbf{r}_{2} \mid \alpha_{-}\right\rangle=\left\langle\mathbf{r}_{1}, \mathbf{r}_{2} \mid o_{12}\right\rangle \otimes\left|s_{12}\right\rangle \equiv \psi\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right)\left|s_{12}\right\rangle . \tag{8.14}
\end{equation*}
$$

Since spin- $1 / 2$ particles are fermions, the particle permutation,

$$
\begin{equation*}
\hat{\mathcal{P}} \psi\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right)\left|s_{12}\right\rangle=\psi\left(\mathbf{r}_{2}, \mathbf{r}_{1}\right)\left|s_{21}\right\rangle=-\psi\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right)\left|s_{12}\right\rangle, \tag{8.15}
\end{equation*}
$$

has to change the sign of either the spin part or the orbital factor of the spinor. In the case of a symmetric orbital factor,

$$
\begin{equation*}
\psi\left(\mathbf{r}_{2}, \mathbf{r}_{1}\right)=\psi\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right), \tag{8.16}
\end{equation*}
$$

the spin factor has to obey relation

$$
\begin{equation*}
\left|s_{21}\right\rangle=-\left|s_{12}\right\rangle . \tag{8.17}
\end{equation*}
$$

Let us use the ordinary $z$-basis (where $z$, in the absence of external magnetic field, is an arbitrary spatial axis) for each of the spins. In this basis, any ket-vector $\left|m_{s}\right\rangle$ of spin orientation of two particles may be represented as a linear combination of four single-spin basis vectors:

$$
\begin{equation*}
|\uparrow \uparrow\rangle, \quad|\downarrow \downarrow\rangle, \quad|\uparrow \downarrow\rangle, \quad \text { and } \quad|\downarrow \uparrow\rangle . \tag{8.18}
\end{equation*}
$$

The first two kets evidently do not satisfy Eq. (17), and cannot participate in the state. Applying to the remaining kets the same argumentation as has resulted in Eq. (11), we get

Singlet state

$$
\begin{equation*}
\left|s_{12}\right\rangle=\frac{1}{\sqrt{2}}(|\uparrow \downarrow\rangle-|\downarrow \uparrow\rangle) . \tag{8.19}
\end{equation*}
$$

Such orbital-symmetric and spin-asymmetric state is called the singlet. The origin of this name becomes clear from the analysis of the opposite (orbital-asymmetric and spin-symmetric) case:

$$
\begin{equation*}
\psi\left(\mathbf{r}_{2}, \mathbf{r}_{1}\right)=-\psi\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right), \quad\left|s_{12}\right\rangle=\left|s_{21}\right\rangle . \tag{8.20}
\end{equation*}
$$

For the composition of such symmetric spin state, the first two kets of Eq. (18) are completely acceptable (with arbitrary weights), and so is a specific symmetric combination of two last kets, similar to Eq. (10):

Triplet states

$$
\begin{equation*}
\left|s_{12}\right\rangle=c_{+}|\uparrow \uparrow\rangle+c_{-}|\downarrow \downarrow\rangle+c_{0} \frac{1}{\sqrt{2}}(|\uparrow \downarrow\rangle+|\downarrow \uparrow\rangle) . \tag{8.21}
\end{equation*}
$$

We may use this composite state with any values of coefficients $c$ (satisfying the normalization condition), because they correspond to the same orbital wavefunction and hence the same energy. However, each of these three states has a specific value of the $z$-component of the net spin (respectively, $+\hbar,-\hbar$, and 0$).{ }^{9}$ Because of this, an even small external magnetic field lifts their degeneracy, splitting the energy level in three, and giving it the natural name of triplet.

In the particular case when the particles do not interact at all, for example ${ }^{10}$

$$
\begin{equation*}
\hat{H}=\hat{h}_{1}+\hat{h}_{2}, \quad \hat{h}_{k}=\frac{\hat{p}_{k}^{2}}{2 m}+\hat{U}\left(\mathbf{r}_{k}\right), \quad k=1,2 \tag{8.22}
\end{equation*}
$$

the 2-particle Schrödinger equation for the symmetrical orbital wavefunction (16) is obviously satisfied by the simple product,

$$
\begin{equation*}
\psi\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right)=\psi_{n}\left(\mathbf{r}_{1}\right) \psi_{n^{\prime}}\left(\mathbf{r}_{2}\right), \tag{8.23}
\end{equation*}
$$

of single-particle eigenfunctions, with arbitrary sets $n$, $n$ ' of quantum numbers. For the particular (but very important!) case $n=n^{\prime}$, this means that the eigenenergy of the singlet state,

$$
\begin{equation*}
\frac{1}{\sqrt{2}} \psi_{n}\left(\mathbf{r}_{1}\right) \psi_{n}\left(\mathbf{r}_{2}\right)(|\uparrow \downarrow\rangle-|\downarrow \uparrow\rangle) \tag{8.24}
\end{equation*}
$$

is just $2 \varepsilon_{n}$, where $\varepsilon_{n}$ is the single-particle energy level. It may be proved that the lowest energy of the triplet state is always higher than that. Hence, for the limited (but extremely important!) goal of finding ground-state energies of multi-electron systems, we may ignore the actual singlet structure of spinor (24), and reduce the Pauli exclusion principle to the semi-qualitative picture of single-particle levels, each "occupied" with 2 independent particles.

As a very simple example, let us find the ground energy of a deep, cubic-shaped, 3D quantum well with side $a$, filled with 5 fermions, ignoring their direct interaction. From the solution of the singleparticle Schrödinger equation in Sec. 1.5, we know the single-particle energy spectrum of the system:

$$
\begin{equation*}
\varepsilon_{n_{x}, n_{y}, n_{z}}=\varepsilon_{0}\left(n_{x}^{2}+n_{y}^{2}+n_{z}^{2}\right), \quad \text { with } \quad \varepsilon_{0} \equiv \frac{\pi^{2} \hbar^{2}}{2 m a^{2}}, \quad \text { and } n_{x}, n_{y}, n_{z}=1,2, \ldots \tag{8.25}
\end{equation*}
$$

so that the lowest-energy orbital states are:

- one ground state with $\left\{n_{x}, n_{y}, n_{z}\right\}=\{1,1,1\}$, and energy $\varepsilon_{111}=\left(1^{2}+1^{2}+1^{2}\right) \varepsilon_{0}=3 \varepsilon_{0}$, and
- three excited states, with $\left\{n_{x}, n_{y}, n_{z}\right\}$ equal to $\{2,1,1\},\{1,2,1\}$, and $\{1,1,2\}$, with equal energies $\varepsilon_{211}=\varepsilon_{121}=\varepsilon_{112}=\left(2^{2}+1^{2}+1^{2}\right) \varepsilon_{0}=6 \varepsilon_{0}$.

According to the Pauli principle, each of these energy levels states can accommodate up to 2 electrons. Hence the lowest-energy (ground) state of the 5 -electron system is achieved by placing 2 of

[^712]them on the ground level $\varepsilon_{111}=3 \varepsilon_{0}$, and the remaining 3 particles, in any of the degenerate "excited" states of energy $6 \varepsilon_{0}$. Hence the ground energy of the system is
\[

$$
\begin{equation*}
E_{g}=2 \times 3 \varepsilon_{0}+3 \times 6 \varepsilon_{0}=24 \varepsilon_{0}=\frac{12 \pi^{2} \hbar^{2}}{m a^{2}} \tag{8.26}
\end{equation*}
$$

\]

In many cases of relatively weak interaction between particles, it does not blow up such a simple quantum state classification scheme, and the Pauli principle allows tracing the order of single-particle state filling with Fermi particles. This is exactly the approach that has been used at our discussion of atoms in Sec. 3.7.

Now let us describe the results of particle interaction more quantitatively, on the simplest example ${ }^{11}$ of the lowest energy states of a neutral atom ${ }^{12}$ of helium - more exactly, helium-4, usually denoted ${ }^{4} \mathrm{He}$, consisting of a nucleus with two protons and two neutrons, of the total electric charge $q=$ $+2 e$, and two electrons "rotating" about it. Neglecting the small relativistic effects that was discussed in Sec. 6.3, the Hamiltonian describing the electron motion may be represented as

$$
\begin{equation*}
\hat{H}=\hat{h}_{1}+\hat{h}_{2}+\hat{u}_{\text {int }}, \quad \hat{h}_{k}=\frac{\hat{p}_{k}^{2}}{2 m}-\frac{2 e^{2}}{4 \pi \varepsilon_{0} r_{k}}, \quad \hat{u}_{\text {int }}=\frac{e^{2}}{4 \pi \varepsilon_{0}\left|\mathbf{r}_{1}-\mathbf{r}_{2}\right|} . \tag{8.27}
\end{equation*}
$$

As most problems of multiparticle quantum mechanics, the eigenvalue/eigenstate problem for this Hamiltonian does not have an exact analytical solution, so let us start an approximate analysis considering the electron-electron interaction as a perturbation. As was discussed in Chapter 6, we have to start with the " $0^{\text {th }}$-order" approximation in which the perturbation is ignored, so that the Hamiltonian is reduced to sum (22). In this approximation, the ground state $g$ of the atom is the singlet (24), with the orbital factor

$$
\begin{equation*}
\psi_{g}\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right)=\psi_{100}\left(\mathbf{r}_{1}\right) \psi_{100}\left(\mathbf{r}_{2}\right), \tag{8.28}
\end{equation*}
$$

and energy $2 \varepsilon_{\mathrm{g}}$. Here each operand $\psi_{100}(\mathbf{r})$ is the single-particle wavefunction of the ground ( $1 s$ ) state of the hydrogen-like atom with $Z=2$, with quantum numbers $n=1, l=0, m=0$. According to Eqs. (3.174) and (3.198),

$$
\begin{equation*}
\psi_{100}(\mathbf{r})=Y_{0}^{0}(\theta, \varphi) R_{1,0}(r)=\frac{1}{\sqrt{4 \pi}} \frac{2}{r_{0}^{3 / 2}} e^{-r / r_{0}}, \quad \text { with } r_{0}=\frac{r_{\mathrm{B}}}{Z}=\frac{r_{\mathrm{B}}}{2}, \tag{8.29}
\end{equation*}
$$

so that according to Eq. (3.191), in this approximation the total ground state energy is

$$
\begin{equation*}
E_{g}^{(0)}=2 \varepsilon_{g}^{(0)}=2\left(-\frac{\varepsilon_{0}}{2 n^{2}}\right)_{n=1, Z=2}=2\left(-\frac{Z^{2} E_{\mathrm{H}}}{2}\right)_{Z=2}=-4 E_{\mathrm{H}} \approx-109 \mathrm{eV} . \tag{8.30}
\end{equation*}
$$

This is still somewhat far (though not terribly far!) from the experimental value $E_{g} \approx-78.8 \mathrm{eV}$ - see the bottom level in Fig. 1a.

[^713]Making a small detour from our main topic, electron indistinguishability effects, let us note that we can get a much better agreement with experiment by calculating the electron interaction energy in the $1^{\text {st }}$ order of the perturbation theory. Indeed, in application to our system, Eq. (6.13) reads

$$
\begin{equation*}
E_{g}^{(1)}=\langle g| \hat{u}_{\mathrm{int}}|g\rangle=\int d^{3} r_{1} \int d^{3} r_{2} \psi_{g}^{*}\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right) u_{\mathrm{int}}\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right) \psi_{g}\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right) . \tag{8.31}
\end{equation*}
$$

Plugging in Eqs. (27)-(29), we get

$$
\begin{equation*}
E_{g}^{(1)}=\left(\frac{1}{4 \pi} \frac{4}{r_{0}^{3}}\right)^{2} \int d^{3} r_{1} \int d^{3} r_{2} \frac{e^{2}}{4 \pi \varepsilon_{0}\left|\mathbf{r}_{1}-\mathbf{r}_{2}\right|} \exp \left\{-\frac{2\left(r_{1}+r_{2}\right)}{r_{0}}\right\} . \tag{8.32}
\end{equation*}
$$

As may be readily evaluated analytically (this exercise is left for the reader), this expression equals $(5 / 4) E_{\mathrm{H}}$, so that the corrected ground state energy,

$$
\begin{equation*}
E_{g} \approx E_{g}^{(0)}+E_{g}^{(1)}=\left(-4+\frac{5}{4}\right) E_{\mathrm{H}}=-74.8 \mathrm{eV} \tag{8.33}
\end{equation*}
$$

is much closer to experiment.

Fig. 8.1. The lowest energy levels of a helium atom: (a) experimental data and (b) a schematic structure of an excited state with fixed $n$ and $l$ in the first order of the perturbation theory. On panel (a), all energies are referred to that $\left(-2 E_{\mathrm{H}} \approx-55.4 \mathrm{eV}\right)$ of the ground state of ion $\mathrm{He}^{+1}$, so that their magnitudes are the (readily measurable) energies of atom's ionization starting from the corresponding bound state.

There is still a room for improvement - that may be made, for example, using the variational method, ${ }^{13}$ based on the following, very general observation. Let $n$ be the exact, full and orthonormal set of stationary states of a quantum system, and use it as the basis for expansion of a normalized but otherwise arbitrary trial state $\alpha$ (defined in the same Hilbert space):

$$
\begin{equation*}
|\alpha\rangle=\sum_{n} \alpha_{n}|n\rangle \tag{8.34}
\end{equation*}
$$

[^714]with the energy that may be calculated using the general (4.125):
\[

$$
\begin{equation*}
E_{\alpha}=\langle\alpha| \hat{H}|\alpha\rangle=\sum_{n} W_{n} E_{n}, \text { where } W_{n}=\left|\alpha_{n}\right|^{2} \geq 0 \tag{8.35}
\end{equation*}
$$

\]

Since, by definition, the exact ground state energy $E_{g}$ is the lowest one of the set $E_{n}$, we can use Eq. (35) to compose the following inequality:

Variational
method's justification

$$
\begin{equation*}
E_{\alpha} \geq \sum_{n} W_{n} E_{g}=E_{g} \sum_{n} W_{n}=E_{g} \tag{8.36}
\end{equation*}
$$

Thus, the ground state energy is always lower then (or equal to) the energy of any trial state $\alpha$. Hence, if we make several attempts with reasonably selected trial states, we may expect the lowest of the results to approximate the genuine ground state energy reasonably well.

For our particular case of a ${ }^{4} \mathrm{He}$ atom, we may try to use, as the trial state, the wavefunction given by Eqs. (28)-(29), but with the atomic number $Z$ considered as an adjustable parameter $Z_{\text {ef }}<Z=2$ rather than a fixed number. The physics behind this idea is that each the electric charge density $\rho(\mathbf{r})=-$ $e|\psi(\mathbf{r})|^{2}$ of each electron forms a negatively charged "cloud" that reduces the effective charge of the nuclei, as seen by another electron, to $Z_{\mathrm{ef}} e^{2}$, with some $Z_{\mathrm{ef}}<2$. As a result, the single-particle wavefunction spreads further in space ( $r_{0}=r_{\mathrm{B}} / Z_{\mathrm{ef}}>r_{\mathrm{B}} / Z$ ), while keeping its functional form (29) nearly intact. Since the kinetic energies $T$ in system's Hamiltonian are proportional to $r_{0}{ }^{-2}$, while the potential energies scale as $r_{0}{ }^{-1}$, we can write

$$
\begin{equation*}
E_{g}\left(Z_{\mathrm{ef}}\right)=\left(\frac{Z_{\mathrm{ef}}}{2}\right)^{2}\left\langle T_{g}\right\rangle_{Z=2}+\frac{Z_{\mathrm{ef}}}{2}\left\langle U_{g}\right\rangle_{Z=2} \tag{8.37}
\end{equation*}
$$

Now we can use the fact that according to Eq. (3.202), for any stationary state of a hydrogen-like atom (just as for the classical circular motion in the Coulomb potential), $\langle U\rangle=2 E$, and hence $\langle T\rangle=E-\langle U\rangle=-$ $E$. Using Eq. (8.30), and adding the correction $U_{g}^{(1)}=-(5 / 4) E_{\mathrm{H}}$ calculated above, to the potential energy, we get

$$
\begin{equation*}
E_{g}\left(Z_{\mathrm{ef}}\right)=\left[4\left(\frac{Z_{\mathrm{ef}}}{2}\right)^{2}+\left(-8+\frac{5}{4}\right) \frac{Z_{\mathrm{ef}}}{2}\right] E_{\mathrm{H}} \tag{8.38}
\end{equation*}
$$

The minimum of function $E_{g}\left(Z_{\mathrm{ef}}\right)$ and the corresponding "optimal" value of $Z_{\mathrm{ef}}$ are as follows:

$$
\begin{equation*}
\left(Z_{\mathrm{eff}}\right)_{\mathrm{opt}}=2\left(1-\frac{5}{32}\right)=1.6875, \quad\left(E_{g}\right)_{\min } \approx-2.85 E_{\mathrm{H}} \approx-77.5 \mathrm{eV} \tag{8.39}
\end{equation*}
$$

Given the trial function crudeness, this number is in a surprisingly good agreement with experimental value cited above, with a difference of the order of $1 \% .{ }^{14}$

Now let us return of our basic topic - the effects of electron indistinguishability. As we have just seen, the ground level energy of the helium atom is not affected directly by this fact, but the situation is

[^715]different for its excited states - even the lowest ones. The reasonably good convergence of the perturbation theory, that we have seen for the ground state, tells us that we can base our analysis of wavefunctions $\left(\psi_{e}\right)$ of the lowest excited state orbitals, on products like $\psi_{100}\left(\mathbf{r}_{k}\right) \psi_{n l m}\left(\mathbf{r}_{k}\right)$, with $n>1$. However, in order to satisfy the fermion permutation rule, $\mathcal{P}_{j}=-1$, we have to take the orbital part of the state in an either symmetric or asymmetric form:
\[

$$
\begin{equation*}
\psi_{e}\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right)=\frac{1}{\sqrt{2}}\left[\psi_{100}\left(\mathbf{r}_{1}\right) \psi_{n m l}\left(\mathbf{r}_{2}\right) \pm \psi_{n m l}\left(\mathbf{r}_{1}\right) \psi_{100}\left(\mathbf{r}_{2}\right)\right] \tag{8.40}
\end{equation*}
$$

\]

with the proper total permutation asymmetry provided by the corresponding spin part given by, respectively, Eq. (19) or Eq. (21), so that the upper/lower signs in Eq. (40) correspond to the singlet/triplet spin state. Let us calculate the expectation values of the total energy of the system in the first order of the perturbation theory. Plugging Eq. (40) into the $0^{\text {th }}$ order expression

$$
\begin{equation*}
\left\langle E_{e}\right\rangle^{(0)}=\int d^{3} r_{1} \int d^{3} r_{2} \psi_{e}^{*}\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right)\left(\hat{h}_{1}+\hat{h}_{2}\right) \psi_{e}\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right), \tag{8.41}
\end{equation*}
$$

we get two groups of similar terms that differ only by the particle index. We can merge the terms of each pair by changing the notation as $\left(\mathbf{r}_{1} \rightarrow \mathbf{r}, \mathbf{r}_{2} \rightarrow \mathbf{r}^{\prime}\right)$ in one of them, and $\left(\mathbf{r}_{1} \rightarrow \mathbf{r}^{\prime}, \mathbf{r}_{2} \rightarrow \mathbf{r}\right)$ in the other term. Using Eq. (27), and the mutual orthogonality of wavefunctions $\psi_{100}(\mathbf{r})$ and $\psi_{n l m}(\mathbf{r})$, we get the following result,

$$
\begin{align*}
\left\langle E_{e}\right\rangle^{(0)} & =\int \psi_{100}^{*}(\mathbf{r})\left(-\frac{\hbar^{2} \hat{\nabla}_{\mathbf{r}}^{2}}{2 m}-\frac{2 e^{2}}{4 \pi \varepsilon_{0} r}\right) \psi_{100}(\mathbf{r}) d^{3} r+\int \psi_{n l m}^{*}\left(\mathbf{r}^{\prime}\right)\left(-\frac{\hbar^{2} \hat{\nabla}_{\mathbf{r}^{\prime}}^{2}}{2 m}-\frac{2 e^{2}}{4 \pi \varepsilon_{0} r^{\prime}}\right) \psi_{n m l}\left(\mathbf{r}^{\prime}\right) d^{3} r^{\prime}  \tag{8.42}\\
& =\varepsilon_{100}+\varepsilon_{n m l}
\end{align*}
$$

which may be interpreted as the sum of eigenenergies of two separate single particles, one in the ground state 100 , and another in the excited state $n l m$ - despite that actually the electron states are entangled. Thus, in the $0^{\text {th }}$ order of the perturbation theory, the electron entanglement does not affect their energy.

However, the potential energy of the system also includes the interaction term $u_{\text {int }}$ (27) that does not allow such separation. As a result, in the first approximation of the perturbation theory, the total energy of the system may be represented as

$$
\begin{gather*}
E_{e}=\varepsilon_{100}+\varepsilon_{n l m}+E_{\text {int }}^{(1)}  \tag{8.43a}\\
E_{\text {int }}^{(1)}=\left\langle U_{\text {int }}\right\rangle=\int d^{3} r_{1} \int d^{3} r_{2} \psi_{e}^{*}\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right) U_{\text {int }}\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right) \psi_{e}\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right) \tag{8.43b}
\end{gather*}
$$

Plugging Eq. (40) into this result, using the symmetry of $u_{\text {int }}$ with respect to the particle number permutation, and the same particle coordinate re-numbering as above, we get

$$
\begin{equation*}
E_{\mathrm{int}}^{(1)}=E_{\mathrm{dir}} \pm E_{\mathrm{ex}} \tag{8.44}
\end{equation*}
$$

with deceivingly similar expressions for the operands:

$$
\begin{align*}
& E_{\mathrm{dir}} \equiv \int d^{3} r \int d^{3} r^{\prime} \psi_{100}^{*}(\mathbf{r}) \psi_{n l m}^{*}\left(\mathbf{r}^{\prime}\right) u_{\mathrm{int}}\left(\mathbf{r}, \mathbf{r}^{\prime}\right) \psi_{100}(\mathbf{r}) \psi_{n l m}\left(\mathbf{r}^{\prime}\right),  \tag{8.45a}\\
& E_{\mathrm{ex}} \equiv \int d^{3} r \int d^{3} r^{\prime} \psi_{100}^{*}(\mathbf{r}) \psi_{n l m}^{*}\left(\mathbf{r}^{\prime}\right) u_{\mathrm{int}}\left(\mathbf{r}, \mathbf{r}^{\prime}\right) \psi_{n l m}(\mathbf{r}) \psi_{100}\left(\mathbf{r}^{\prime}\right) \tag{8.45b}
\end{align*}
$$

Since the single-particle orbitals can be always made real, both components are positive (or at least non-negative). However, their physics is completely different. Integral (45a), called the direct electron-electron interaction, allows a simple semi-classical interpretation as the Coulomb energy of interacting electrons, each distributed in space with the electric charge density $\rho_{n m l}(\mathbf{r})=$ $e \psi_{n m l} *(\mathbf{r}) \psi_{n m l}(\mathbf{r}):{ }^{15}$

$$
\begin{equation*}
E_{\mathrm{dir}}=\int d^{3} r \int d^{3} r^{\prime} \frac{\rho_{100}(\mathbf{r}) \rho_{n l m}\left(\mathbf{r}^{\prime}\right)}{4 \pi \varepsilon_{0}\left|\mathbf{r}-\mathbf{r}^{\prime}\right|}=\int \rho_{100}(\mathbf{r}) \phi(\mathbf{r}) d^{3} r \tag{8.46}
\end{equation*}
$$

where $\phi(\mathbf{r})$ is the electrostatic potential created, at point $\mathbf{r}$, by the counterpart electron's "electric charge cloud": ${ }^{16}$

$$
\begin{equation*}
\phi(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} \int d^{3} r^{\prime} \frac{\rho_{n l m}\left(\mathbf{r}^{\prime}\right)}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|} \tag{8.47}
\end{equation*}
$$

However, integral (45b), called the exchange interaction, evades a classical interpretation, and (as it is clear from its derivation) is the direct corollary of the electron indistinguishability. The magnitude of $E_{\text {ex }}$ is also very much different from $E_{\text {dir }}$, because the function under integral (45b) disappears in those regions where single-particle wavefunctions do not overlap. This is in a full agreement with the discussion in Sec. 1: if two particles are identical but well separated, i.e. their wavefunctions do not overlap, the exchange interaction disappears, because all effects of particle indistinguishability vanish.

Historically, the fact of having two different hydrogen-like spectra (48) and (49) was taken as an evidence for two different species of ${ }^{4} \mathrm{He}$, called, respectively, the parahelium and orthohelium. Figure 1 b shows the structure of an excited energy level, with certain quantum numbers $n>1, l$, and $m$, given by Eqs. (44)-(45). The upper level, with energy

$$
\begin{equation*}
E_{\text {para }}=\left(\varepsilon_{100}+\varepsilon_{n l m}\right)+E_{\mathrm{dir}}+E_{\mathrm{ex}}>\varepsilon_{100}+\varepsilon_{n l m}, \tag{8.48}
\end{equation*}
$$

corresponds to the "parahelium", i.e. the symmetric orbital state and hence to the singlet spin state (19), with zero net spin, $s=0$. The lower level, with

$$
\begin{equation*}
E_{\text {ortho }}=\left(\varepsilon_{100}+\varepsilon_{n l m}\right)+E_{\text {dir }}-E_{\text {ex }}<E_{\text {para }}, \tag{8.49}
\end{equation*}
$$

corresponds to "orthohelium", i.e. the antisymmetric orbital, and hence to the triplet spin state(s) with $s$ = 1 - see Eq. (21). Its degeneracy may be lifted by magnetic field, so that the splitting is identical to that of an elementary particle with spin $s=1$. Calculations of the direct and exchange interaction integrals (45) for various values of $n$ and $l$ show that the perturbation theory explains the experimental spectrum of the orthohelium and parahelium (Fig. 1) pretty well.

Encouraged by this success, and motivation by the very important task of description of atoms, molecules, and metals, we may try to apply the same approach to systems with $N>2$ electrons. In this case the mathematical expression of the Pauli principle for fermions is

[^716]\[

$$
\begin{equation*}
\hat{P}_{k k^{\prime}}=-1, \quad \text { for all } k, k^{\prime}=1,2, \ldots, N ., \tag{8.50}
\end{equation*}
$$

\]

where operator $\hat{\mathcal{P}}_{k k^{\prime}}$ permutes particle with numbers $k$ and $k^{\prime}$. In order to understand how common eigenstates of all such operators may be formed, let us return for a minute to two non-interacting electrons, and rewrite Eq. (11) in the following compact form:

$$
\left|\alpha_{-}\right\rangle=\frac{1}{\sqrt{2}}\left(|\beta\rangle \otimes\left|\beta^{\prime}\right\rangle-\left|\beta^{\prime}\right\rangle \otimes|\beta\rangle\right)=\frac{1}{\sqrt{2}} \begin{array}{cc}
\text { state } 1 & \text { state 2 }  \tag{8.51}\\
\downarrow & \downarrow \\
\| \beta\rangle \otimes & \left|\beta^{\prime}\right\rangle \\
|\beta\rangle \otimes & \left.\left|\beta^{\prime}\right\rangle\right\rangle \leftarrow \text { particle number 1, } \\
\left|\beta^{\prime}\right\rangle & \text { particle number 2. }
\end{array}
$$

In this way, the Pauli principle is mapped on the well-known property of matrix determinants: if any of two columns of a matrix coincide, its determinant vanishes. This Slater determinant approach may be readily generalized to $N$ fermions in $N$ (not necessarily lowest) single-particle states $\beta$, $\beta$, etc:

Even though the Slater determinant form is extremely nice and compact (in comparison with direct writing of a sum of $N$ ! products, each of $N$ ket factors), there are two major problems with using it for practical calculations:
(i) For the calculation of any bra-ket product (say, within the perturbation theory) we need to spell out each bra- and ket-vector as a sum of component terms. Even for a limited number of electrons (say $N \sim 10^{2}$ in a typical atom), the number $N!\sim 10^{160}$ of terms in such a sum is impracticably large for any analytical calculation.
(ii) In the case of interacting fermions, Slater determinants do not describe the eigenvectors of the system; rather the stationary state is a superposition of such determinants - each for a specific selection of $N$ states from the general set of single-particle states - that is generally different from $N$.

These challenges make the development of a more general theory that would not use particle numbers (which are superficial for indistinguishable particles to start with) a must for getting any final results for multiparticle systems.

### 8.3. Second quantization

The most useful formalism for this purpose, that avoids particle numbering at all, is called the second quantization. ${ }^{17}$ Actually, we have already discussed a particular version of this formalism, for

[^717]the a case of 1D harmonic oscillator's excitations, in Sec. 5.4. As a reminder, we have used Eqs. (5.98) to define the "creation" and "annihilation" operators via the usual operators of coordinate and momentum, and then proved their key property (5.122),
\[

$$
\begin{equation*}
\hat{a}^{\dagger}|n\rangle=(n+1)^{1 / 2}|n+1\rangle, \quad \hat{a}|n\rangle=n^{1 / 2}|n-1\rangle, \tag{8.53}
\end{equation*}
$$

\]

where $n$ are the stationary (Fock) states of the oscillator. This property allows an interpretation of operators' actions as the creation/annihilation of a single excitations of energy $\hbar \omega_{0}$ - thus justifying the operator names. In the next chapter, we will show that such an excitation of an electromagnetic field mode may be considered as a massless boson with $s=1$, called the photon.

In order to generalize this approach to arbitrary bosons, not appealing to a specific system such as the harmonic oscillator, we may use relations similar to Eq. (53) to define the creation and annihilation operators. The definition looks simple in the language of the so-called Dirac states, with ket-vectors

Dirac state

$$
\begin{equation*}
\left|N_{1}, N_{2}, \ldots N_{j}, \ldots\right\rangle \tag{8.54}
\end{equation*}
$$

where $N_{j}$ are the state occupancies, i.e. the numbers of bosons in each single-particle state $j$. Let me emphasize that here indices $1,2, \ldots j, \ldots$, are the positions of each number in the Dirac ket vector, i.e. are the numbers of single-particle states (including their spin parts) rather than particles. Thus the very notion of individual particle numbers is completely (and for indistinguishable particles, very relevantly) absent from this formalism. Generally, the set of single-particle states participating in the Dirac state may be selected in an arbitrary way (provided that it is full and orthonormal),

$$
\begin{equation*}
\left\langle N_{1}^{\prime}, N_{2}^{\prime} \ldots, N_{j^{\prime}}^{\prime}, \ldots \mid N_{1}, N_{2} \ldots, N_{j}, \ldots\right\rangle=\delta_{N_{1} N_{1}^{\prime}} \delta_{N_{2} N_{2}^{\prime}} \ldots \delta_{N_{j} N_{j}^{\prime}} \ldots \tag{8.55}
\end{equation*}
$$

though for system of non- (or weakly) interacting bosons, using the stationary states of individual particles in the system under analysis are almost always the best choice.

Now we can define the particle annihilation operator as follows:

Boson
annihilation operator

$$
\begin{equation*}
\hat{a}_{j}\left|N_{1}, N_{2}, \ldots N_{j}, \ldots\right\rangle \equiv N_{j}^{1 / 2}\left|N_{1}, N_{2}, \ldots N_{j}-1, \ldots\right\rangle . \tag{8.56}
\end{equation*}
$$

Note that the pre-ket coefficient, similar to that in Eq. (53), guarantees that an attempt to annihilate a particle in an unpopulated state gives the non-existing (null) state:

$$
\begin{equation*}
\hat{a}_{j}\left|N_{1}, N_{2}, \ldots 0_{j}, \ldots\right\rangle=0 \tag{8.57}
\end{equation*}
$$

where symbol $0_{j}$ means zero occupancy of $j$-th state. An alternative way to write Eq. (56) is

$$
\begin{equation*}
\left\langle N_{1}^{\prime}, N_{2}^{\prime}, \ldots, N_{j}^{\prime}, \ldots\right| \hat{a}_{j}\left|\cdot N_{1}, N_{2}, \ldots, N_{j}, \ldots\right\rangle=N_{j}^{1 / 2} \delta_{N_{1} N_{1}^{\prime}} \delta_{N_{2} N_{2}^{\prime}} \ldots \delta_{N_{j}^{\prime}, N_{j}-1} \ldots \tag{8.58}
\end{equation*}
$$

According to Eq. (4.65), the matrix element of the Hermitian conjugate operator $\hat{a}_{j}^{\dagger}$ is

$$
\begin{align*}
& \left\langle N_{1}^{\prime}, N_{2}^{\prime}, \ldots, N_{j}^{\prime}, \ldots\right| \hat{a}_{j}^{\dagger}\left|N_{1}, N_{2}, \ldots N_{j}, \ldots\right\rangle=\left\langle N_{1}, N_{2}, \ldots, N_{j}, \ldots\right| \hat{a}_{j}\left|N_{1}^{\prime}, N_{2}^{\prime}, \ldots, N_{j}^{\prime}, \ldots\right\rangle^{*} \\
& =\left\langle N_{1}, N_{2}, \ldots, N_{j}, \ldots\right|\left(N_{j}^{\prime}\right)^{1 / 2}\left|N_{1}^{\prime}, N_{2}^{\prime}, \ldots, N_{j}^{\prime}-1, \ldots\right\rangle=\left(N_{j}^{\prime}\right)^{1 / 2} \delta_{N_{1} N_{1}^{\prime}} \delta_{N_{2} N_{2}^{\prime}} \ldots \delta_{N_{j}, N_{j}^{\prime}-1} \ldots  \tag{8.59}\\
& =\left(N_{j}+1\right)^{1 / 2} \delta_{N_{1} N_{1}^{\prime}} \delta_{N_{2} N_{2}^{\prime}} \ldots \delta_{N_{j}+1, N_{j}^{\prime}} \ldots,
\end{align*}
$$

meaning that

$$
\begin{equation*}
\hat{a}_{j}^{\dagger}\left|N_{1}, N_{2}, \ldots, N_{j}, \ldots\right\rangle=\left(N_{j}+1\right)^{1 / 2}\left|N_{1}, N_{2}, \ldots, N_{j}+1, \ldots\right\rangle, \tag{8.60}
\end{equation*}
$$

Boson creation operator
in the total compliance with the first of Eqs. (53). In particular, this particle creation operator $\hat{a}_{j}^{\dagger}$ allows the description of the generation of a single particle from the vacuum (not null!) state $|0,0, \ldots\rangle$ :

$$
\begin{equation*}
\hat{a}_{j}^{\dagger}\left|0,0, \ldots, 0_{j}, \ldots, 0\right\rangle=\left|0,0, \ldots, 1_{j}, \ldots 0\right\rangle \tag{8.61}
\end{equation*}
$$

and hence a product of such operators may create, from the vacuum, a multiparticle state with an arbitrary set of occupancies: ${ }^{18}$

Next, combining Eqs. (56) and (60), we get

$$
\begin{equation*}
\hat{a}_{j}^{\dagger} \hat{a}_{j}\left|N_{1}, N_{2}, \ldots N_{j}, \ldots\right\rangle=N_{j}\left|N_{1}, N_{2}, \ldots, N_{j}, \ldots\right\rangle \tag{8.63}
\end{equation*}
$$

so that, just as for the particular case of harmonic oscillator excitations, operator

$$
\begin{equation*}
\hat{N}_{j} \equiv \hat{a}_{j}^{\dagger} \hat{a}_{j} \tag{8.64}
\end{equation*}
$$

Numbercounting operator
conserves the numbers of particles in all single-particle states, and simultaneously "counts" their number in the $j$-th state. Acting by the creation-annihilation operators in the reverse order, we get

$$
\begin{equation*}
\hat{a}_{j} \hat{a}_{j}^{\dagger}\left|N_{1}, N_{2}, \ldots, N_{j}, \ldots\right\rangle=\left(N_{j}+1\right)\left|N_{1}, N_{2}, \ldots, N_{j}, \ldots\right\rangle . \tag{8.65}
\end{equation*}
$$

This result shows that for any state of a multiparticle system (which always may be represented as a linear superposition of Dirac states with different sets of $N_{j}$ ), we can write

$$
\begin{equation*}
\hat{a}_{j} \hat{a}_{j}^{\dagger}-\hat{a}_{j}^{\dagger} \hat{a}_{j} \equiv\left[\hat{a}_{j}, \hat{a}_{j}^{\dagger}\right]=\hat{I}, \tag{8.66}
\end{equation*}
$$

again in agreement with what we had for the 1D oscillator - cf. Eq. (5.101). According to Eq. (55), the creation and annihilation operators corresponding to different single-particle states do commute, so that Eq. (66) may be generalized as

[^718]Commutation relations for bosonic operators

$$
\begin{equation*}
\left[\hat{a}_{j}, \hat{a}_{j^{\prime}}^{\dagger}\right]=\hat{I} \delta_{j j^{\prime}}, \tag{8.67}
\end{equation*}
$$

and that similar bosonic creation and annihilation operators commute, regardless of which states do they act upon:

$$
\begin{equation*}
\left[\hat{a}_{j}^{\dagger}, \hat{a}_{j^{\prime}}^{\dagger}\right]=\left[\hat{a}_{j}, \hat{a}_{j^{\prime}}\right]=0 \tag{8.68}
\end{equation*}
$$

Relations (66)-(68) are the mathematical expression of the independence of occupancies of different boson states.

As was mentioned earlier, a major challenge in the Dirac approach is to rewrite the Hamiltonian of a multiparticle system, that naturally carries particle numbers $k$ (see, e.g., Eq. (22) for $k=1,2$ ), in the second quantization language, in which there are no these numbers. Let us start with single-particle components of such Hamiltonians, i.e. operators of the type

$$
\begin{equation*}
\hat{F}=\sum_{k=1}^{N} \hat{f}_{k} \tag{8.69}
\end{equation*}
$$

where all $N$ operators $\hat{f}_{k}$ are similar, besides that each of them acts on one specific ( $k$-th) particle, and $N$ is the total number of particles in the system, that is naturally equal to the sum of single-particle state occupancies:

$$
\begin{equation*}
N=\sum_{j} N_{j} . \tag{8.70}
\end{equation*}
$$

The most important examples of such operators are the kinetic energy of $N$ similar single particles, and their potential energy in an external field:

$$
\begin{equation*}
\hat{T}=\sum_{k=1}^{N} \frac{\hat{p}_{k}^{2}}{2 m}, \quad \hat{U}=\sum_{k=1}^{N} \hat{u}\left(\mathbf{r}_{k}\right) . \tag{8.71}
\end{equation*}
$$

In order to express a particle-separable operator of the type (69) in terms of the Dirac formalism, we need to return for a minute to the particle-number representations used in the beginning of this chapter. Instead of the Slater determinant (52), for bosons we have to write a similar expression, but without the sign changes (sometimes called the permanent):

$$
\begin{equation*}
\left|N_{1}, \ldots N_{j}, \ldots\right\rangle=\left(\frac{N_{1}!\ldots N_{j}!\ldots}{N!}\right)^{1 / 2} \sum_{P}|\underbrace{\ldots \beta \beta^{\prime} \beta^{\prime \prime} \ldots}_{N_{\text {operands }}}\rangle . \tag{8.72}
\end{equation*}
$$

Note again that the left-hand part of this relation is written in the Dirac notation (that does not use particle numbering), while in its right-hand part, just in relations of Secs. 1-2, particle numbers are coded with the positions of the single-particle states inside the ket-vectors, and the sum is over all different permutations of the states in the ket - cf. Eq. (10). (According to the elementary combinatorics, ${ }^{19}$ there are $N!/\left(N_{1}!\ldots N_{j}!\ldots\right)$ such permutations, so that the coefficient before the sum ensures the proper normalization of the single-particle states.) Let us use Eq. (72) to spell out the following bra-ket of a system with $(N-1)$ particles:

[^719]\[

$$
\begin{align*}
& \left\langle\ldots N_{j}, \ldots N_{j^{\prime}}-1, \ldots\right| \hat{F}\left|\ldots N_{j}-1, \ldots N_{j^{\prime}}, \ldots\right\rangle \\
& =\frac{N_{1}!\ldots . .\left(N_{j}-1\right)!\ldots\left(N_{j^{\prime}}-1\right)!\ldots}{(N-1)!}\left(N_{j^{\prime}} N_{j^{\prime}}\right)^{1 / 2} \sum_{P\langle N-1|} \sum_{P|N-1\rangle}\left\langle\left.\ldots \beta \beta^{\prime} \beta^{\prime \prime} \ldots\right|_{k=1} ^{N-1} \hat{f}_{k} \mid \ldots \beta \beta^{\prime} \beta^{\prime \prime} \ldots\right\rangle, \tag{8.73}
\end{align*}
$$
\]

where all non-specified occupation numbers in the corresponding positions of the bra- and ket-vectors are equal to each other. Each single-particle operator $\hat{f}_{k}$, participating in the operator sum, acts on the bra- and ket-vectors of states $j$ and $j^{\prime}$, respectively, in a certain (say, $k^{\text {th }}$ ) position, giving the result that does not depend on the position number:

$$
\begin{equation*}
\left\langle\left.\beta_{j}\right|_{\text {in } k^{\text {th }} \text { position }} \hat{f}_{k} \mid \beta_{j^{\prime}}\right\rangle_{\text {in } k^{\text {th }} \text { position }}=\left\langle\beta_{j}\right| \hat{f}\left|\beta_{j^{\prime}}\right\rangle \equiv f_{i j^{\prime}} . \tag{8.74}
\end{equation*}
$$

Since in both permutation sets participating in Eq. (73), with ( $N-1$ ) vectors each, all positions are equivalent, we can fix the position (say, take the first one) and replace the sum over $k$ by the multiplication by factor $(N-1)$. The fraction of permutations with the necessary bra-vector (with number $j$ ) in that position is $N_{j} /(N-1)$, while that with the necessary ket-vector (with number $j^{\prime}$ ) in the same position in $N_{j} / /(N-1)$. As the result, the permutation sum in Eq. (73) reduces to

$$
\begin{equation*}
(N-1) \frac{N_{j}}{N-1} \frac{N_{j^{\prime}}}{N-1} f_{i j^{\prime}} \sum_{P\langle N-2| P|N-2\rangle} \sum\left\langle\ldots \beta \beta^{\prime} \beta^{\prime \prime} \ldots \mid \ldots \beta \beta^{\prime} \beta^{\prime \prime} \ldots\right\rangle, \tag{8.75}
\end{equation*}
$$

where our specific position $k$ is now excluded from both the bra- and ket-vector permutations. Each of these permutations now includes only $\left(N_{j}-1\right)$ states $j$ and $\left(N_{j^{\prime}}-1\right)$ states $j^{\prime}$, so that, using the state orthonormality, we finally arrive at a very simple result:

$$
\begin{align*}
& \left\langle\ldots N_{j}, \ldots N_{j^{\prime}}-1, \ldots\right| \hat{F}\left|\ldots N_{j}-1, \ldots N_{j^{\prime}}, \ldots\right\rangle \\
& =\frac{N_{1}!\ldots\left(N_{j}-1\right)!\ldots\left(N_{j^{\prime}}-1\right)!\ldots}{(N-1)!}\left(N_{j^{\prime}} N_{j^{\prime}}\right)^{1 / 2}(N-1) \frac{N_{j}}{N-1} \frac{N_{j^{\prime}}}{N-1} f_{i j^{\prime}} \frac{(N-2)!}{N_{1}!\ldots\left(N_{j}-1\right)!\ldots\left(N_{j^{\prime}}-1\right)!\ldots}  \tag{8.76}\\
& =\left(N_{j^{\prime}} N_{j^{\prime}}\right)^{1 / 2} f_{j j^{\prime}} .
\end{align*}
$$

Now let us calculate matrix elements of the following operator:

$$
\begin{equation*}
\sum_{j, j^{\prime}} f_{i j^{\prime}} \hat{a}_{j}^{\dagger} \hat{a}_{j^{\prime}} \tag{8.77}
\end{equation*}
$$

A direct application of Eqs. (56) and (60) shows that the only nonvanishing of them are

$$
\begin{equation*}
\left\langle\ldots N_{j}, \ldots N_{j^{\prime}}-1, \ldots\right| f_{j j^{\prime}} \hat{a}_{j}^{\dagger} \hat{a}_{j^{\prime}}\left|\ldots N_{j}-1, \ldots, N_{j^{\prime}}, \ldots\right\rangle=\left(N_{j} N_{j^{\prime}}\right)^{1 / 2} f_{i j^{\prime}} . \tag{8.78}
\end{equation*}
$$

But this is exactly the last form of Eq. (76), so that in the basis of Dirac states, operator (69) may be represented as

$$
\begin{equation*}
\hat{F}=\sum_{j, j^{\prime}} f_{i j^{\prime}} \hat{a}_{j}^{\dagger} \hat{a}_{j^{\prime}} \tag{8.79}
\end{equation*}
$$

This beautifully simple equation is the most important formula of the second quantization theory, and is essentially the Dirac-language analog of Eq. (4.59) of the single-particle quantum mechanics. Each term of the sum may be described by a very simple mnemonic rule: if an operator "connects" two
single-particle states $j$ and $j$ ', move the particle from state $j$ ' into state $j$, and weigh the result with the corresponding single-particle matrix element. (One of the corollaries of Eq. (79) is that the expectation value of an operator whose eigenstates coincide with the Dirac states, is

$$
\begin{equation*}
\langle F\rangle \equiv\left\langle\ldots N_{j}, \ldots\right| \hat{F}\left|\ldots N_{j}, \ldots\right\rangle=\sum_{j} f_{i j} N_{j} \tag{8.80}
\end{equation*}
$$

with an evident physical interpretation as the sum of single-particle expectation values over all states, weighed by state occupancies.)

Proceeding to fermions, which have to obey the Pauli principle, we immediately notice that any occupation number $N_{j}$ may only take two values, 0 or 1 . In order to account for that, and also make the key equation (76) valid for fermions as well, the creation-annihilation operators are now defined by relations

Fermion creationannihilation operators

$$
\begin{align*}
& \hat{a}_{j}\left|N_{1}, N_{2}, \ldots, 0_{j}, \ldots\right\rangle=0, \quad \hat{a}_{j}\left|N_{1}, N_{2}, \ldots, 1_{j}, \ldots\right\rangle=(-1)^{\Sigma(1, j-1)}\left|N_{1}, N_{2}, \ldots, 0_{j}, \ldots\right\rangle,  \tag{8.81}\\
& \hat{a}_{j}^{\dagger}\left|N_{1}, N_{2}, \ldots, 0_{j}, \ldots\right\rangle=(-1)^{\Sigma(1, j-1)}\left|N_{1}, N_{2}, \ldots, 1_{j}, \ldots\right\rangle, \quad \hat{a}_{j}^{\dagger}\left|N_{1}, N_{2}, \ldots, 1_{j}, \ldots\right\rangle=0 . \tag{8.82}
\end{align*}
$$

In these relations, symbol $\Sigma\left(J, J^{\prime}\right)$ means the sum of all occupancy numbers in state positions from $J$ to $J^{\prime}$, including the border points:

$$
\begin{equation*}
\Sigma\left(J, J^{\prime}\right) \equiv \sum_{j=J}^{J^{\prime}} N_{j} \tag{8.83}
\end{equation*}
$$

so that the sum participating in Eqs. (81) and (82) is the total occupancy of all states with the numbers below $j$. (The states have to be numbered in a fixed albeit arbitrary order.) As a result, Eqs. (81)-(82) may be readily summarized in the verbal form: if an operator replaces the $j^{\text {th }}$ state occupancy with the opposite one ( 1 with 0 , or vice versa), it also changes sign before the result if (and only if) the total number of particles in states with $j^{\prime}<j$ is odd.

One of corollaries of this (somewhat counter-intuitive) rule of sign alternation is that the sign of the ket-vector of a completely filled two-state system depends on how exactly it has been formed from the vacuum state. Indeed, if we start from creating the fermion in state 1 , we get

$$
\begin{equation*}
\hat{a}_{1}^{\dagger}|0,0\rangle=(-1)^{0}|1,0\rangle=|1,0\rangle, \quad \hat{a}_{2}^{\dagger} \hat{a}_{1}^{\dagger}|0,0\rangle=\hat{a}_{2}^{\dagger}|1,0\rangle=(-1)^{1}|1,1\rangle=-|1,1\rangle, \tag{8.84}
\end{equation*}
$$

while if the operator order is different, the result's sign is opposite:

$$
\begin{equation*}
\hat{a}_{2}^{\dagger}|0,0\rangle=(-1)^{0}|0,1\rangle=|0,1\rangle, \quad \hat{a}_{1}^{\dagger} \hat{a}_{2}^{\dagger}|0,0\rangle=\hat{a}_{1}^{\dagger}|0,1\rangle=(-1)^{0}|1,1\rangle=+|1,1\rangle . \tag{8.85}
\end{equation*}
$$

Since the action of any of these operator products on any initial state rather than vacuum gives the null ket, we can write the following operator equality:

$$
\begin{equation*}
\hat{a}_{1}^{\dagger} \hat{a}_{2}^{\dagger}+\hat{a}_{2}^{\dagger} \hat{a}_{1}^{\dagger} \equiv\left\{\hat{a}_{1}^{\dagger}, \hat{a}_{2}^{\dagger}\right\}=0 \tag{8.86}
\end{equation*}
$$

It is straightforward to check that this result is valid for the Dirac vector of an arbitrary length, and does not depend on the occupancy of other states, so that we can always write

$$
\begin{equation*}
\left\{\hat{a}_{j}^{\dagger}, \hat{a}_{j^{\prime}}^{\dagger}\right\}=\left\{\hat{a}_{j}, \hat{a}_{j^{\prime}}\right\}=0 \tag{8.87}
\end{equation*}
$$

these equalities hold for $j=j$ ' as well. On the other hand, the absolutely similar calculation shows that the mixed creation-annihilation operator products do depend on whether the states are different or not: ${ }^{20}$

$$
\begin{equation*}
\left\{\hat{a}_{j}, \hat{a}_{j^{\prime}}^{\dagger}\right\}=\hat{I} \delta_{i j^{\prime}} \tag{8.88}
\end{equation*}
$$

Commutation relations for fermionic operators

These equations look very much like Eqs. (67)-(68) for bosons, "only" with the replacement of commutators with anticommutators. Since the core laws of quantum mechanics, including the operator compatibility (Sec. 4.5) and the Heisenberg equation (4.199) of operator evolution in time, involve commutators rather than anticommutators, so that one might think that all the behavior of bosonic and fermionic multiparticle systems should be dramatically different. However, the difference is not as huge as one could expect, for one, a straightforward check shows that the sign factors in Eqs. (81)-(82) compensate those in the Slater determinant, and make the key relation (79) valid for the fermions as well. (Indeed, this is the very goal of the introduction of these factors.)

As the simplest example, let us examine what does the second quantization formalism say about dynamics of non-interacting particles in the system whose single-particle properties we know well, namely two nearly-similar, coupled quantum wells - see Fig. 2.23. If the coupling (tunneling) between the wells is so small that the states localized in the wells are only weakly perturbed, in the basis of these states, the single-particle Hamiltonian of the system may be represented by $2 \times 2$ matrix (6.27). Selecting the origin of energy at the middle between energies of unperturbed states, so that coefficient $a_{0}$ in Eq. (6.27) vanishes, we can reduce the matrix to

$$
\mathrm{h}=\mathbf{a} \cdot \boldsymbol{\sigma}=\left(\begin{array}{cc}
a_{z} & a_{-}  \tag{8.89}\\
a_{+} & -a_{z}
\end{array}\right), \quad a_{ \pm} \equiv a_{x} \pm i a_{y}
$$

with eigenvalues

$$
\begin{equation*}
\varepsilon_{ \pm}= \pm a, \quad a=|\mathbf{a}|=\left(a_{x}^{2}+a_{y}^{2}+a_{z}^{2}\right)^{1 / 2} \tag{8.90}
\end{equation*}
$$

Now following recipe (79), we can represent the Hamiltonian of the whole system of particles in terms of the creation-annihilation operators:

$$
\begin{equation*}
\hat{H}=a_{z} \hat{a}_{1}^{\dagger} \hat{a}_{1}+a_{-} \hat{a}_{1}^{\dagger} \hat{a}_{2}+a_{+} \hat{a}_{2}^{\dagger} \hat{a}_{1}-a_{z} \hat{a}_{2}^{\dagger} \hat{a}_{2}, \tag{8.91}
\end{equation*}
$$

where $\hat{a}_{1,2}^{\dagger}$ and $\hat{a}_{1,2}$ are the operators of creation and annihilation of a particle localized in the corresponding quantum well. According to Eq. (64), the first and the last terms of the right-hand part of Eq. (91) describe particle energies in uncoupled wells,

$$
\begin{equation*}
a_{z} \hat{a}_{1}^{\dagger} \hat{a}_{1}=\varepsilon_{1} \hat{N}_{1}, \quad-a_{z} \hat{a}_{2}^{\dagger} \hat{a}_{2}=\varepsilon_{2} \hat{N}_{2} \tag{8.92}
\end{equation*}
$$

[^720]while the sum of middle two terms is the second-quantization description of tunneling between the wells.

Now we can use the general Eq. (4.199) of the Heisenberg picture to find the equations of motion for the creation-annihilation operators. For example,

$$
\begin{equation*}
i \hbar \dot{\hat{a}}_{1}=\left[\hat{a}_{1}, \hat{H}\right]=a_{z}\left[\hat{a}_{1}, \hat{a}_{1}^{\dagger} \hat{a}_{1}\right]+a_{-}\left[\hat{a}_{1}, \hat{a}_{1}^{\dagger} \hat{a}_{2}\right]+a_{+}\left[\hat{a}_{1}, \hat{a}_{2}^{\dagger} \hat{a}_{1}\right]-a_{z}\left[\hat{a}_{1}, \hat{a}_{2}^{\dagger} \hat{a}_{2}\right] . \tag{8.93}
\end{equation*}
$$

Since the Bose and Fermi operators satisfy different commutation relations, one could expect the right hand part of this equation would be different for bosons and fermions. However, it is not so. Indeed, all commutators in the right-hand part of Eq. (93) have the following form:

$$
\begin{equation*}
\left[\hat{a}_{j}, \hat{a}_{j^{\prime}}^{\dagger}, \hat{a}_{j^{\prime \prime}}\right] \equiv \hat{a}_{j} \hat{a}_{j^{\prime}}^{\dagger} \hat{a}_{j^{\prime \prime}}-\hat{a}_{j^{\prime}}^{\dagger} \hat{a}_{j^{\prime \prime}} \hat{a}_{j} . \tag{8.94}
\end{equation*}
$$

According to Eqs. (67) and (88), the first pair product of the operators may be recast as

$$
\begin{equation*}
\hat{a}_{j} \hat{a}_{j^{\prime}}^{\dagger}=\hat{I} \delta_{i j^{\prime}} \pm \hat{a}_{j^{\prime}}^{\dagger} \hat{a}_{j}, \tag{8.95}
\end{equation*}
$$

where the upper sign pertains to bosons and the lower to fermions, while according to Eqs. (68) and (87), the very last pair product is

$$
\begin{equation*}
\hat{a}_{j^{\prime \prime}} \hat{a}_{j}= \pm \hat{a}_{j} \hat{a}_{j^{\prime \prime}}, \tag{8.96}
\end{equation*}
$$

with the same sign convention. Plugging these expressions into Eq. (94), we see that regardless of the particle statistics, two last terms cancel, and we arrive at a universal (and generally very useful) commutation rule

$$
\begin{equation*}
\left[\hat{a}_{j}, \hat{a}_{j^{\prime}}^{\dagger} \hat{a}_{j^{\prime \prime}}\right]=\hat{a}_{j^{\prime \prime}} \delta_{j j^{\prime}}, \tag{8.97}
\end{equation*}
$$

valid for particles of both kinds. As a result, the Heisenberg equation of motion for operator $\hat{a}_{1}$, and the equation for $\hat{a}_{2}$ (that may be obtained absolutely similarly), are also statistics-independent: ${ }^{21}$

$$
\begin{align*}
& i \hbar \dot{\hat{a}}_{1}=a_{z} \hat{a}_{1}+a_{-} \hat{a}_{2},  \tag{8.98}\\
& i \hbar \dot{\hat{a}}_{2}=a_{+} \hat{a}_{1}-a_{z} \hat{a}_{2} .
\end{align*}
$$

Thus we have got a system of coupled, linear differential equations that are identical to equations for the $c$-number probability amplitudes of single-particle wavefunctions of a two-level system - see Eq. (2.201) and Problem 4.10. Their general solution is a linear superposition of exponents:

$$
\begin{equation*}
\hat{a}_{1,2}(t)=\sum_{ \pm} \hat{c}_{1,2}^{( \pm)} \exp \left\{\lambda_{ \pm} t\right\} . \tag{8.99}
\end{equation*}
$$

[^721]As usual, in order to find exponents $\lambda_{ \pm}$, it is sufficient to plug in a particular solution $\hat{a}_{1,2}(t)=\hat{c}_{1,2} \exp \{\lambda t\}$ into Eq. (98) and require that the determinant of the resulting homogeneous, linear system for "coefficients" (actually, time-independent operators) $\hat{c}_{1,2}$ equals zero. This gives us the following characteristic equation

$$
\left|\begin{array}{cc}
a_{z}-i \hbar \lambda & a_{-}  \tag{8.100}\\
a_{+} & -a_{z}-i \hbar \lambda
\end{array}\right|=0,
$$

with two roots $\lambda_{ \pm}= \pm i \Omega / 2$, where $\Omega \equiv 2 a / \hbar$. Now plugging each of the roots, one by one, into the system of equations for $\hat{c}_{1,2}$, we can find these operators, and hence the general solution of system (98) for arbitrary initial conditions.

Let us consider the simple case $a_{y}=a_{z}=0$ (meaning in particular that the well eigenenergies are exactly aligned), so that $\hbar \Omega / 2 \equiv a=a_{x}$; then the solution of Eq. (98) is

$$
\begin{equation*}
\hat{a}_{1}(t)=\hat{a}_{1}(0) \cos \frac{\Omega t}{2}-i \hat{a}_{2}(0) \sin \frac{\Omega t}{2}, \quad \hat{a}_{2}(t)=-i \hat{a}_{1}(0) \sin \frac{\Omega t}{2}+\hat{a}_{2}(0) \cos \frac{\Omega t}{2} . \tag{8.101}
\end{equation*}
$$

Multiplying the first of Eqs. (101) by its Hermitian conjugate, and ensemble-averaging the result, we get

$$
\begin{align*}
\left\langle N_{1}\right\rangle= & \left\langle\hat{a}_{1}^{\dagger}(t) \hat{a}_{1}(t)\right\rangle=\left\langle\hat{a}_{1}^{\dagger}(0) \hat{a}_{1}(0)\right\rangle \cos ^{2} \frac{\Omega t}{2}+\left\langle\hat{a}_{2}^{\dagger}(0) \hat{a}_{2}(0)\right\rangle \sin ^{2} \frac{\Omega t}{2}  \tag{8.102}\\
& -i\left\langle\hat{a}_{1}^{\dagger}(0) \hat{a}_{2}(0)+\hat{a}_{2}^{\dagger}(0) \hat{a}_{1}(0)\right\rangle \sin \frac{\Omega t}{2} \cos \frac{\Omega t}{2} .
\end{align*}
$$

Let us consider the particular case when the initial state of the system is a Dirac state, i.e. has a definite number of particles in each well; in this case only two first terms in the right hand part are different from zero: ${ }^{22}$

$$
\begin{equation*}
\left\langle N_{1}\right\rangle=N_{1}(0) \cos ^{2} \frac{\Omega t}{2}+N_{2}(0) \sin ^{2} \frac{\Omega t}{2} . \tag{8.103}
\end{equation*}
$$

For one particle, initially placed in either well, this gives us our old result (2.185) describing quantum oscillations of the particle between two wells with frequency $\Omega$. However, Eq. (103) is valid for any set of initial occupancies; let us use it. For example, starting from two particles, with initially one particle in each well, we get $\left\langle N_{1}\right\rangle=1$, regardless of time. So, the occupancies do not oscillate, and no experiment may detect the quantum oscillations, though their frequency $\Omega$ is still formally present in the time evolution equations. This fact may be interpreted as the simultaneous quantum oscillations of two particles exactly in anti-phase. For bosons, we can go to even larger occupancies by preparing the system, for example, in the state with $N_{1}(0)=N, N_{2}(0)=0$. Equation (103) says that in this case we see that the quantum oscillation amplitude increases $N$-fold; this is a particular manifestation of the general fact that bosons can be (and evolve in time) in the same quantum state. On the other hand, for fermions we cannot increase initial occupancies beyond 1 , so that the largest oscillation amplitude we can get is if we initially fill just one well.

[^722]The Dirac approach may be readily generalized to more complex systems. For example, an arbitrary system of quantum wells with weak tunneling coupling between the adjacent wells may be described by Hamiltonian

$$
\begin{equation*}
\hat{H}=\sum_{j} \varepsilon_{j} a_{j}^{\dagger} \hat{a}_{j}+\sum_{\left\langle j, j^{\prime}\right\rangle} \delta_{i j^{\prime}} a_{j}^{\dagger} \hat{a}_{j^{\prime}}+\text { h.c. } \tag{8.104}
\end{equation*}
$$

where symbol $\langle j, j\rangle\rangle$ means that the second sum is restricted to pairs of next-neighbor wells - see, e.g., Eq. (2.203) and its discussion. Note that this Hamiltonian is still a quadratic form of the creationannihilation operators, so the Heisenberg-picture equations of motion of these operators are linear, and its exact solutions, though possibly cumbersome, may be studied in detail. Due to this fact, Hamiltonian (104) is widely used for the study of some phenomena, for example the very interesting Anderson localization effect, in which a random distribution of eigenenergies $\varepsilon_{j}$ prevents particles within certain energy range from spreading to unlimited distances. ${ }^{23,24}$

### 8.4. Perturbative approaches

The situation becomes much more difficult if the problem requires an account of direct interactions between the particles. Let us assume that the interaction may be reduced to that between pairs - as it is the case at their Coulomb interaction ${ }^{25}$ and most other interactions, so that it may be described with the following "pair-interaction" Hamiltonian

$$
\begin{equation*}
\hat{U}_{\mathrm{int}}=\frac{1}{2} \sum_{\substack{k, k k^{\prime}=1 \\ k \neq k^{\prime}}}^{N} \hat{\mathrm{int}}\left(\mathbf{r}_{k}, \mathbf{r}_{k^{\prime}}\right) \tag{8.105}
\end{equation*}
$$

interaction Hamiltonian in two alternative forms
with the front factor of $1 / 2$ compensating the double-counting of each particle pair. The translation of this operator to the second-quantization form may be done absolutely similarly to the derivation of Eq. (77), and gives a similar (though naturally more bulky) result ${ }^{26}$

$$
\begin{equation*}
\hat{U}_{\mathrm{int}}=\frac{1}{2} \sum_{j, j^{\prime}, l, l^{\prime}} u_{i j^{\prime} l l^{\prime}} \hat{a}_{j}^{\dagger} \hat{a}_{j^{\prime}}^{\dagger}, \hat{a}_{l^{\prime}} \hat{a}_{l} \tag{8.106}
\end{equation*}
$$

where the two-particle matrix elements are defined similarly to Eq. (74):

$$
\begin{equation*}
u_{i j I^{\prime}} \equiv\left\langle\beta_{j} \beta_{j^{\prime}}\right| \hat{u}_{\mathrm{int}}\left|\beta_{l} \beta_{l^{\prime}}\right\rangle . \tag{8.107}
\end{equation*}
$$

Even in this case, the resulting Heisenberg equations of motion are nonlinear, so that solving them and calculating observables from the results is usually impossible, at least analytically. The only

[^723]case when some general results may be obtained is the weak interaction limit. In this case the unperturbed Hamiltonian contains only single-particle terms such as in Eqs. (71), so we can always (at least conceptually :-) find such a basis of orthonormal single-particle states $\beta_{j}$ in which that Hamiltonian is diagonal in the Dirac representation:
\[

$$
\begin{equation*}
\hat{H}^{(0)}=\sum_{j} \varepsilon_{j}^{(0)} \hat{a}_{j}^{\dagger} \hat{a}_{j} . \tag{8.108}
\end{equation*}
$$

\]

Now we can use Eq. (6.13) in this basis to calculate the interaction energy as a first-order perturbation:

$$
\begin{align*}
E_{\text {int }}^{(1)} & =\left\langle N_{1}, N_{2}, \ldots\right| \hat{U}_{\mathrm{int}}\left|N_{1}, N_{2}, \ldots\right\rangle=\frac{1}{2}\left\langle N_{1}, N_{2}, \ldots\right| \sum_{j, j^{\prime} l, l l^{\prime}} u_{j j^{\prime \prime l}} \hat{a}_{j}^{\dagger} \hat{a}_{j^{\prime}}^{\dagger} \hat{a}_{l^{\prime}} \hat{a}_{l}\left|N_{1}, N_{2}, \ldots\right\rangle  \tag{8.109}\\
& =\frac{1}{2} \sum_{j, j^{\prime}, l, l^{\prime}} u_{\text {jjlll}}\left\langle N_{1}, N_{2}, \ldots\right| \hat{a}_{j}^{\dagger} \hat{a}_{j^{\prime}}^{\dagger} \hat{a}_{l^{\prime}} \hat{a}_{l}\left|N_{1}, N_{2}, \ldots\right\rangle .
\end{align*}
$$

Since, according to Eqs. (81)-(82), the Dirac states with different occupancies are orthogonal, the last average yields nonvanishing results only for three particular subsets of the indices:
(i) $j \neq j^{\prime}, l=j$, and $l^{\prime}=j^{\prime}$. In this case the 4-operator product in Eq. (109) equals $\hat{a}_{j}^{\dagger} \hat{a}_{j^{\prime}}^{\dagger} \hat{a}_{j^{\prime}} \hat{a}_{j}$, and applying the commutation rules twice, we can bring it to the so-called normal ordering, with each creation operator standing to the right of the corresponding annihilation operator, thus forming the particle number operator (64):

$$
\begin{equation*}
\hat{a}_{j}^{\dagger} \hat{a}_{j^{\prime}}^{\dagger} \hat{a}_{j^{\prime}} \hat{a}_{j}= \pm \hat{a}_{j}^{\dagger} \hat{a}_{j^{\prime}}^{\dagger} \hat{a}_{j} \hat{a}_{j^{\prime}}= \pm \hat{a}_{j}^{\dagger}\left( \pm \hat{a}_{j} \hat{a}_{j^{\prime}}^{\dagger}\right) \hat{a}_{j^{\prime}}=\hat{a}_{j}^{\dagger} \hat{a}_{j} \hat{a}_{j^{\prime}}^{\dagger} \hat{a}_{j^{\prime}}=\hat{N}_{j} \hat{N}_{j^{\prime}} \tag{8.110}
\end{equation*}
$$

with the similar sign of the final result for bosons and fermions.
(ii) $j \neq j^{\prime}, l=j^{\prime}$, and $l^{\prime}=j$. In this case the 4-operator product equals $\hat{a}_{j}^{\dagger} \hat{a}_{j^{\prime}}^{\dagger} \hat{a}_{j} \hat{a}_{j^{\prime}}$, and bringing it to the form $\hat{N}_{j} \hat{N}_{j^{\prime}}$ requires only one commutation:

$$
\begin{equation*}
\hat{a}_{j}^{\dagger} \hat{a}_{j^{\prime}}^{\dagger} \hat{a}_{j} \hat{a}_{j^{\prime}}=\hat{a}_{j}^{\dagger}\left( \pm \hat{a}_{j} \hat{a}_{j^{\prime}}^{\dagger}\right) \hat{a}_{j^{\prime}}= \pm \hat{a}_{j}^{\dagger} \hat{a}_{j} \hat{a}_{j^{\prime}}^{\dagger} \hat{a}_{j^{\prime}}= \pm \hat{N}_{j} \hat{N}_{j^{\prime}} \tag{8.111}
\end{equation*}
$$

with the upper sign for bosons and lower sign for fermions.
(iii) All indices equal to each other, giving $\hat{a}_{j}^{\dagger} \hat{a}_{j^{\prime}}^{\dagger} \hat{a}_{l} \hat{a}_{l}=\hat{a}_{j}^{\dagger} \hat{a}_{j}^{\dagger} \hat{a}_{j} \hat{a}_{j}$. For fermions, such operator (that "tries" to create or kill two particles in a row, in the same state) immediately gives the null vector. In the case of bosons, we may use Eq. (66) to commute the internal pair of operators, getting

$$
\begin{equation*}
\hat{a}_{j}^{\dagger} \hat{a}_{j}^{\dagger} \hat{a}_{j} \hat{a}_{j}=\hat{a}_{j}^{\dagger}\left(\hat{a}_{j} \hat{a}_{j}^{\dagger}-\hat{I}\right) \hat{a}_{j}=\hat{N}_{j}\left(\hat{N}_{j}-\hat{I}\right) \tag{8.112}
\end{equation*}
$$

Note, however, that this formula formally covers the fermion case as well (always giving zero). As a result, Eq. (109) may be rewritten in the following universal form:

$$
\begin{equation*}
E_{\mathrm{int}}^{(1)}=\frac{1}{2} \sum_{\substack{j, j^{\prime} \\ j \neq j^{\prime}}} N_{j} N_{j^{\prime}}\left(u_{j j j j^{\prime}} \pm u_{j j j^{\prime} j}\right)+\frac{1}{2} \sum_{j} N_{j}\left(N_{j}-1\right) u_{j j j j} \tag{8.113}
\end{equation*}
$$

Particle interaction: $1^{\text {st }}$-order energy perturbation

The consequences of this result are very different for bosons and fermions. In the former case, the last term usually dominates, because the matrix elements (107) are typically the largest when all basis functions coincide. Note that this term allows a very simple interpretation: the number of the diagonal matrix elements it sums up for each state $(j)$ is just the number of interacting particle pairs residing in that state.

In contrast, for fermions the last term is zero, and the interaction energy is the difference of two terms inside the first parentheses. In order to spell them out, let us consider the case when there is no direct spin-orbit interaction. Then vectors $|\beta\rangle_{j}$ of the single-particle state basis may be represented as products $|o\rangle_{j} \otimes|m\rangle_{j}$ of their orbital and spin orientation parts. (Here, for brevity, I am using $m$ instead of $m_{s}$.) For spin- $1 / 2$ particles (say, electrons), these orientations $m$ may equal only $+1 / 2$ and $-1 / 2$; in this case the spin part of the matrix element $u_{j j}{ }^{\prime j j}$, equals

$$
\begin{equation*}
\langle m| \otimes\left\langle m^{\prime} \| m\right\rangle \otimes\left|m^{\prime}\right\rangle \tag{8.114}
\end{equation*}
$$

where, as in the general Eq. (107), the position of a particular vector in a product codes the particle number. Now since spins of different electrons are defined in different Hilbert spaces, we may move their vectors around to get

$$
\begin{equation*}
\langle m| \otimes\left\langle m^{\prime} \| m\right\rangle \otimes\left|m^{\prime}\right\rangle=(\langle m \mid m\rangle)_{1} \times\left(\left\langle m^{\prime} \mid m^{\prime}\right\rangle\right)_{2}=1 \tag{8.115}
\end{equation*}
$$

for any pair of $j$ and $j^{\prime}$. On the other hand, $u_{j j^{\prime} j^{\prime} j}$ is proportional to

$$
\begin{equation*}
\langle m| \otimes\left\langle m^{\prime} \| m^{\prime}\right\rangle \otimes|m\rangle=\left(\left\langle m \mid m^{\prime}\right\rangle\right)_{1} \times\left(\left\langle m^{\prime} \mid m\right\rangle\right)_{2}=\delta_{m m^{\prime}} \tag{8.116}
\end{equation*}
$$

In this case, it is convenient to rewrite Eq. (113) in the coordinate representation, using singleparticle wavefunctions called spin-orbitals

functions

$$
\begin{equation*}
\psi_{j}(\mathbf{r}) \equiv\left\langle\mathbf{r} \mid \beta_{j}\right\rangle=\left\langle\mathbf{r} \mid o_{j}\right\rangle \otimes|m\rangle_{j} . \tag{8.117}
\end{equation*}
$$

They differ from the "usual" orbital wavefunctions of the type (5.19) only by that their index $j$ should be understood as the set of the orbital state index and the spin orientation index $m .{ }^{27}$ Also, due to the Pauliprinciple restriction of numbers $N_{j}$ to either 0 or 1, Eq. (113) may be also rewritten without the occupancy numbers, with the understanding that the summation is extended only over the pairs of occupied states. As a result, Eq. (113) becomes

[^724]\[
E_{\mathrm{int}}^{(1)}=\frac{1}{2} \sum_{\substack{j, j^{\prime}  \tag{8.118}<br>

j \neq j^{\prime}}} \int d^{3} r \int d^{3} r^{\prime}\left[$$
\begin{array}{l}
\psi_{j}^{*}(\mathbf{r}) \psi_{j^{\prime}}^{*}\left(\mathbf{r}^{\prime}\right) u_{\mathrm{int}}\left(\mathbf{r}, \mathbf{r}^{\prime}\right) \psi_{j}(\mathbf{r}) \psi_{j^{\prime}}\left(\mathbf{r}^{\prime}\right) \\
-\psi_{j}^{*}(\mathbf{r}) \psi_{j^{\prime}}^{*}\left(\mathbf{r}^{\prime}\right) u_{\mathrm{int}}\left(\mathbf{r}, \mathbf{r}^{\prime}\right) \psi_{j^{\prime}}(\mathbf{r}) \psi_{j}\left(\mathbf{r}^{\prime}\right)
\end{array}
$$\right]
\]

If, for a system of 2 electrons, we limit the summation to 2 states $\left(j, j^{\prime}=1,2\right)$, we get the result absolutely similar to Eqs. (44)-(45), with the minus sign in Eq. (44). Hence, Eq. (118) may be considered as the generalization of the direct and exchange interaction balance picture to an arbitrary number of orbitals and an arbitrary total number $N$ of electrons. Note, however, that this equation cannot

[^725]correctly describe the energy of the excited singlet state, corresponding to the plus sign in Eq. (44). ${ }^{28}$ The reason is that the description of entangled spin states, given by Eq. (19) and the last term of Eq. (21), require linear superpositions of different Dirac states, and hence not covered by our assumption (108).

Now comes a very important fact: the approximate result (118), added to the sum of unperturbed energies $\varepsilon_{j}^{(0)}$, equals the sum of exact eigenenergies of the so-called Hartree-Fock equation: ${ }^{29}$

$$
\begin{align*}
& \left(-\frac{\hbar^{2}}{2 m} \nabla^{2}+u(\mathbf{r})\right) \psi_{j}(\mathbf{r})  \tag{8.119}\\
& +\sum_{j^{\prime} \neq j} \int\left[\psi_{j^{\prime}}^{*}\left(\mathbf{r}^{\prime}\right) u_{\mathrm{int}}\left(\mathbf{r}, \mathbf{r}^{\prime}\right) \psi_{j}(\mathbf{r}) \psi_{j^{\prime}}\left(\mathbf{r}^{\prime}\right)-\psi_{j^{\prime}}^{*}\left(\mathbf{r}^{\prime}\right) u_{\mathrm{int}}\left(\mathbf{r}, \mathbf{r}^{\prime}\right) \psi_{j^{\prime}}(\mathbf{r}) \psi_{j}(\mathbf{r})\right] d^{3} r^{\prime}=\varepsilon_{j} \psi_{j}(\mathbf{r}),
\end{align*}
$$

where $u(\mathbf{r})$ is the external-field potential acting on each particle separately - see Eq. (71). An advantage of this equation in comparison with Eq. (118) is that it allows the (approximate) calculation of not only the energy of the system, but also the corresponding spin-orbitals, taking into account the electronelectron interaction.

In the limit when the single-particle wavefunction overlaps are small and hence the exchange interaction is negligible, the last term in square brackets may be ignored, term $\psi_{j}(\mathbf{r})$ may be taken out of the integral, and becomes similar to the single-particle Schrödinger equation with the following effective potential

$$
\begin{equation*}
\left.u_{\mathrm{ef}}(\mathbf{r})=u(\mathbf{r})+u_{\mathrm{dir}}(\mathbf{r}), \quad u_{\mathrm{dir}}(\mathbf{r})=\sum_{j^{\prime} \neq j} \int_{j^{\prime}}^{*} \psi_{\mathbf{r}^{\prime}}^{*}\right) u_{\mathrm{int}}\left(\mathbf{r}, \mathbf{r}^{\prime}\right) \psi_{j^{\prime}}\left(\mathbf{r}^{\prime}\right) d^{3} r^{\prime} \tag{8.120}
\end{equation*}
$$

This is the so-called Hartree approximation - that gives reasonable results for some systems. ${ }^{30}$ However, in dense electrons systems (such as typical atoms, molecules, and condensed matter) the exchange interaction, described by the second term in the square brackets of Eq. (119), is typically of the order of $30 \%$ of the direct interaction, and frequently this effect cannot be ignored. In this case, Eq. (119) is an integro-differential rather than just differential equation.

There are efficient methods of numerical solution of such equations, typically based on iterative methods, though they require large memory and CPU-cycle resources even for systems of $\sim 10^{2}$ electrons. ${ }^{31}$ This is why the Hartree-Fock approximation is the de-facto baseline of all so-called ab-initio
${ }^{28}$ Note that due to condition $j^{\prime} \neq j$, and Eq. (116), the exchange interaction is limited to electron state pairs with the same spin direction - again in a good correspondence with the triplet states (like $\uparrow \uparrow$ or $\downarrow \downarrow$ ) of a two-electron system, in which the contribution of $E_{\text {ex }}(8.45 \mathrm{~b})$ to the total energy is also negative.
${ }^{29}$ This equation was suggested in 1929 by D. Hartree for the direct interaction, and extended to the exchange interaction by V. Fock in 1930. In order to verify its equivalence to Eq. (118), it is sufficient to multiply all terms of Eq. (119) by $\psi^{*}(\mathbf{r})$, integrate them over all $\mathbf{r}$ space (so that the right-hand part would give $\varepsilon_{j}$ ), and then sum these single-particle energies over all occupied states $j$.
${ }^{30}$ An extreme expression of the Hartree approximation is the very simple Thomas-Fermi model of heavy atoms (with the atomic number $Z \gg 1$ ), in which the gradient of the electrostatic potential is also neglected, i.e. the atomic electrons are treated essentially as an ideal Fermi gas - see SM Chapter 3.
${ }^{31}$ Surprisingly, this is sufficient to describe, with reasonable accuracy, many properties of condensed matter, by breaking it to similar elementary spatial cells (say, Bravais cells of crystals), with cyclic boundary conditions and a limited number of electrons in each cell.
("first-principle") calculations in condensed matter physics and quantum chemistry. ${ }^{32}$ In departures from this baseline, there are two opposite trends. For larger accuracy (and typically smaller systems), several "post-Hartree-Fock methods", notably including the configuration interaction method, ${ }^{33}$ that are more complex but may provide higher accuracy, have been developed.

There is also a strong opposite trend of extending ab-initio methods to larger systems, while sacrificing the result accuracy and reliability. This trend is currently dominated by the Density Functional Theory, ${ }^{34}$ universally known by its acronym DFT. In this approach, the equation solved for each eigenfunction $\psi_{j}(\mathbf{r})$ is a differential, Schrödinger-like Kohn-Sham equation

Kohn-
Sham
equation and its components
where

$$
\begin{equation*}
u_{\mathrm{dir}}^{\mathrm{KS}}(\mathbf{r})=-e \phi(\mathbf{r}), \quad \phi(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}} \int d^{3} r^{\prime} \frac{\rho\left(\mathbf{r}^{\prime}\right)}{\left|\mathbf{r}-\mathbf{r}^{\prime}\right|}, \quad \rho(\mathbf{r})=-e n(\mathbf{r}), \tag{8.122}
\end{equation*}
$$

and $n(\mathbf{r})$ is the total electron density in a particular point, calculated as

$$
\begin{equation*}
n(\mathbf{r}) \equiv \sum_{j} \psi_{j}^{*}(\mathbf{r}) \psi_{j}(\mathbf{r}) \tag{8.123}
\end{equation*}
$$

The effective exchange-correlation potential $u_{\mathrm{XC}}(\mathbf{r})$ (that differs from the genuine exchange potential, participating in Eq. (121), by the inclusion of the term with $j=j^{\prime}$ ) is calculated in various approximations, most valid only asymptotically in the limit when the electron number is high. The simplest of them is the Local Density Approximation (LDA) in which the effective exchange potential at each point is a function only of the electron density (123) at the same point, taken from the theory of a uniform gas of free electrons. ${ }^{35}$ Another simplification, that dramatically cuts the computing resources necessary for systems of relatively heavy atoms, is the exclusion of the filled internal electron shells (see Sec. 3.7) from the explicit calculations, because the shell states are virtually unperturbed by the valence electron effects involved in typical atomic phenomena and chemical reactions. In this approach, the Coulomb field of the shells, described by fixed, pre-calculated and tabulated pseudo-potentials, added to that of the nuclei. Unfortunately, because of lack of time, for details I have to refer the reader to specialized literature. ${ }^{36}$

[^726]Let me, however, emphasize that despite the wide use of the DFT, ${ }^{37}$ and its undisputable successes in describing some experimental data, it has problems. For me personally, its largest conceptual deficiency is the incorporation of the absolutely unphysical Coulomb interaction of an electron with itself (by dropping condition $j^{\prime} \neq j$ ). As a result, existing DFT packages require substantial artificial tinkering to use them for description of such processes as single-electron transfer. ${ }^{38} \mathrm{~A}$ little bit light-heartedly (but still correctly), one may say that an advanced DFT software package, run on a huge supercomputer, cannot be used to calculate the correct energy spectrum of a hydrogen atom - a century after this had been done by Niels Bohr on a slip of paper!

### 8.5. Quantum computation and cryptography

Now I have to review the emerging fields of quantum computation and encryption. ${ }^{39}$ These fields are currently the subject of a very intensive research effort, which has brought (besides much hype :-) a few results of genuine importance for quantum mechanics. My coverage, by necessity short, will emphasize these fundamental results, referring the reader interested in details to special literature. ${ }^{40}$ Because of the active stage of the fields, I will also provide quite a few references to recent publications, making the style of this section closer to a brief research review than to a part of a textbook.

Presently, the work on quantum computation and encryption is focused on systems of spatiallyseparated (and hence distinguishable) two-level systems - in this context, commonly called qubits. ${ }^{41}$ Due to this distinguishability, the issues that were the focus of the past few sections (including the benefits of the second quantization) are irrelevant here. On the other hand, systems of distinguishable qubits have some interesting properties that had not been yet discussed in this course.

First of all, a system of $N \gg 1$ qubits may contain much more information than the $N$ classical bits - which is the maximum information capacity of $N$ classical bistable systems. Indeed, according to the discussions in Chapter 4, an arbitrary pure state of a single qubit may be represented by its ket vector (4.37) - see also Eq. (5.1):

$$
\begin{equation*}
|\alpha\rangle_{N=1}=\alpha_{1}\left|u_{1}\right\rangle+\alpha_{2}\left|u_{2}\right\rangle, \tag{8.124}
\end{equation*}
$$

where $\{u\}$ is any orthonormal two-state basis. In the quantum information theory, it is natural and common to employ, as $u_{j}$, the eigenstates $a_{j}$ of the observable $A$ that is eventually measured in the particular physical implementation of the qubit - say, a certain spatial component of spin- $1 / 2$ particle, etc. It is also common to write the kets of these base states as $|0\rangle$ and $|1\rangle$, so that Eq. (124) takes the form ${ }^{42}$

[^727]Single qubit
state's representation

$$
\begin{equation*}
|\alpha\rangle_{N=1}=a_{0}|0\rangle+a_{1}|1\rangle=\sum_{j=0,1} a_{j}|j\rangle, \tag{8.125}
\end{equation*}
$$

where in the rest of this chapter, letter $j$ will be used to denote an integer equal to either 0 or 1 . Hence any pure state $\alpha$ of a qubit is completely defined by two complex $c$-numbers $a_{j}$, i.e. by 4 real numbers. Moreover, due to the normalization condition $\left|a_{1}\right|^{2}+\left|a_{2}\right|^{2}=1$, we need just 3 independent real numbers say, the Bloch sphere coordinates $\theta$ and $\varphi$ (see Fig. 5.1), plus the common phase $\gamma$, which becomes important when we consider coherent states of several qubits - see Eq. (5.3).

Now, if we have a system of 2 qubits, its arbitrary pure state (4.37) may be represented as a sum of $2^{2}=4$ terms, ${ }^{43}$

$$
\begin{equation*}
|\alpha\rangle_{N=2}=a_{00}|00\rangle+a_{01}|01\rangle+a_{10}|10\rangle+a_{11}|11\rangle \equiv \sum_{j_{1}, j_{2}=0,1} a_{j_{1} j_{2}}\left|j_{1} j_{2}\right\rangle, \tag{8.126}
\end{equation*}
$$

with 4 complex coefficients, i.e. $4 \times 2=8$ real numbers, subject to just one normalization condition ${ }^{44}$

$$
\begin{equation*}
\sum_{j_{1,2}=0,1}\left|a_{j_{1} j_{2}}\right|^{2}=1 \tag{8.127}
\end{equation*}
$$

An evident generalization of Eqs. (125)-(126) to an arbitrary pure state of an $N$-qubit system is given by a sum of $2^{N}$ terms:

$$
\begin{equation*}
|\alpha\rangle_{N}=\sum_{j_{1}, j_{2}, \ldots j_{N}=0,1} a_{j_{1} j_{2} \ldots j_{N}}\left|j_{1} j_{2} \ldots j_{N}\right\rangle, \tag{8.128}
\end{equation*}
$$

including all possible combinations of 0 s and 1 s inside the ket, so that the state is fully described by $2^{N}$ complex numbers, i.e. $2 \cdot 2^{N}=2^{N+1}$ real numbers, with only one constraint, similar to Eq. (127), imposed by the normalization condition. Let me emphasize that this exponential growth of the information contents would not be possible without the qubit state entanglement. Indeed, in the particular case when qubit states are unentangled (separable),

$$
\begin{equation*}
\left.|\alpha\rangle_{N}=\left|\alpha_{1}\right\rangle\left|\alpha_{2}\right\rangle \ldots \alpha_{N}\right\rangle \tag{8.129}
\end{equation*}
$$

where each $\left|\alpha_{n}\right\rangle$ is described by an equality similar to Eq. (125) with its individual expansion coefficients, the system state description requires only $3 N$ real numbers - e.g., $N$ sets $\{\theta, \varphi, \gamma\}$.

However, it is wrong (as it is sometimes done in popular reviews) to project this exponential growth of information contents directly on the capabilities of quantum computation, because this process has to include the output information readout, i.e. qubit state measurements. Due to the fundamental intrinsic uncertainty of quantum systems, the measurement of a single qubit even in a pure state (125) generally gives uncertain results, with probabilities $W_{0}=\left|a_{0}\right|^{2}$ and $W_{1}=\left|a_{1}\right|^{2}$. In order to comply with the general notion of digital computation, a quantum computer has to provide certain (or

[^728]virtually certain) results, and hence probabilities $W_{j}$ have to be very close to either 0 or 1 , so that before the measurement, each qubit has to be in a basis state - either 0 or 1 . This means that the computational system of $N$ qubits, just before the final readout, has to be one of the basis states
\[

$$
\begin{equation*}
\left.|\alpha\rangle_{N}=\left|j_{1}\right\rangle\left|j_{2}\right\rangle \ldots j_{N}\right\rangle \equiv\left|j_{1} j_{2} \ldots j_{N}\right\rangle, \tag{8.130}
\end{equation*}
$$

\]

which is a very small subset even of the set (129) of all unentangled states, and whose maximum information contents in just $N$ classical bits.

Now the reader may start thinking that this constraint strips quantum computations of any advantages over their classical counterparts, but this view is also superficial. In order to show that, let us consider the scheme of the most frequently explored type of quantum computation, shown in Fig. 2.45

Fig. 8.2. The baseline scheme of quantum computation.

Here each horizontal line (sometimes called a "wire"46) corresponds to a single qubit, tracing its time evolution in the same direction as at the usual time function plots: from left to right. This means that the left column $|\alpha\rangle_{\text {in }}$ of ket-vectors describes the initial state of qubits, ${ }^{47}$ while the right column $|\alpha\rangle_{\text {out }}$ describes their final (pre-detector) state. The box labeled $U$ represents the qubit evolution in time due to

[^729]their specially arranged interactions between each other and/or external drive "forces". Besides these forces, during this evolution the system is supposed to be isolated from the dephasing and energydissipating environment, so that it may be described by a unitary operator defined in the $2^{N}$-dimensional Hilbert space of $N$ qubits:
\[

$$
\begin{equation*}
|\alpha\rangle_{\text {out }}=\hat{U}|\alpha\rangle_{\text {in }} \tag{8.131}
\end{equation*}
$$

\]

With the condition that the input and output states have the simple form (130), this equality reads

$$
\begin{equation*}
\left|\left(j_{1}\right)_{\text {out }}\left(j_{2}\right)_{\text {out }} \ldots\left(j_{N}\right)_{\text {out }}\right\rangle=\hat{U}\left|\left(j_{1}\right)_{\text {in }}\left(j_{2}\right)_{\text {in }} \ldots\left(j_{N}\right)_{\text {in }}\right\rangle \tag{8.132}
\end{equation*}
$$

The art of quantum computer design is selecting such unitary operators $\hat{U}$ that would:

- satisfy Eq. (132),
- be physically implementable,
- enable substantial performance advantages of the quantum computation over its classical counterpart of similar functionality, at least for some digital functions (algorithms).

I will have time to demonstrate the possibility of such advantages on just one, perhaps the simplest example - the so-called Deutsch problem. ${ }^{48}$ Let us consider the family of single-bit classical Boolean functions $j_{\text {out }}=f\left(j_{\text {in }}\right)$. Since both $j$ are Boolean variables, i.e. may take only values 0 and 1 , there are evidently only 4 such functions:

| $f$ | $f(0)$ | $f(1)$ | class | $F$ | $f(1)-f(0)$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| $f_{1}$ | 0 | 0 | constant | 0 | 0 |
| $f_{2}$ | 0 | 1 | balanced | 1 | 1 |
| $f_{3}$ | 1 | 0 | balanced | 1 | -1 |
| $f_{4}$ | 1 | 1 | constant | 0 | 0 |

Of them, functions $f_{1}$ and $f_{4}$, whose values are independent of their arguments, are called constants, while functions $f_{2}$ (called "YES" or "IDENTITY") and $f_{3}$ ("NOT" or "INVERSION") are called balanced. The Deutsch problem is to determine the class of a single-bit function, implemented as a "black box", as being either constant or balanced, using just one experiment.

Classically, this is clearly impossible, and the simplest way to perform the function classification involves two similar black boxes $f$ - see Fig. 3a.

Fig. 8.3. The simplest (a) classical and (b) quantum ways to classify a single-bit Boolean function $f$.

[^730]This solution uses the so-called exclusive-OR (for short, XOR) gate whose output is described by the following function $F$ of its two Boolean arguments $j_{1}$ and $j_{2}$ :

$$
F\left(j_{1}, j_{2}\right) \equiv j_{1} \oplus j_{2} \equiv\left\{\begin{array}{lll}
0, & \text { if } j_{1}=j_{2}  \tag{8.134}\\
1, & \text { if } & j_{1} \neq j_{2}
\end{array}\right.
$$

In the circuit shown in Fig. 3a, the gate produces output

$$
\begin{equation*}
F=f(0) \oplus f(1), \tag{8.135}
\end{equation*}
$$

equal to 1 if $f(0) \neq f(1)$, i.e. if function $f$ is balanced, and 0 in the opposite case - see the $4^{\text {th }}$ column in Eq. (133). ${ }^{49}$

On the other hand, let us assume that all four functions $f$ may be implemented quantummechanically, for example as a unitary transform acting on two qubits (Fig. 4a), and acting as follows each of basis components $\left.\left|j_{j_{2}}\right\rangle \equiv\left|j_{1}\right\rangle j_{2}\right\rangle$ of the general input state (126):

$$
\begin{equation*}
\hat{f}\left|j_{1}\right\rangle\left|j_{2}\right\rangle=\left|j_{1}\right\rangle\left|j_{2} \oplus f\left(j_{1}\right)\right\rangle, \tag{8.136}
\end{equation*}
$$

where $f$ is any of the classical Boolean functions defined by Eq. (133).
(a)

Fig. 8.4. Two-qubit quantum gates: (a) two-qubit function $f$ and (b) its particular case $C$ (CNOT), and their actions on the basis states.

In the particular case when $f$ is the YES function: $f(j)=f_{2}(j)=j$, gate $f$ is reduced to the socalled CNOT gate - a key ingredient of other quantum computation schemes, performing transform

$$
\begin{equation*}
\hat{C}\left|j_{1} j_{2}\right\rangle=\left|j_{1}\right\rangle\left|j_{2} \oplus j_{1}\right\rangle \tag{8.137a}
\end{equation*}
$$

Let us spell out this rule for all four possible input qubit combinations:

$$
\begin{equation*}
\hat{C}|00\rangle=|00\rangle, \quad \hat{C}|01\rangle=|01\rangle, \quad \hat{C}|10\rangle=|11\rangle, \quad \hat{C}|11\rangle=|10\rangle . \tag{8.137b}
\end{equation*}
$$

In plain English, this means that acting on basis states $\left\langle j_{j} j_{2}\right\rangle$, the CNOT gate leaves the state of first, source qubit (shown by the upper lines in Fig. 4) intact, but flips the state of the second, target qubit if the first one is in the basis state $|1\rangle$. In even simpler words, the state $j_{1}$ of the source qubit controls the NOT function acting on the target qubit - hence the gate's name CNOT (the semi-acronym of "Controlled NOT").

[^731]For the quantum function (136), the Deutsch problem may be solved within the general scheme shown in Fig. 2, with the particular structure of the unitary-transform box $U$ spelled out in Fig. 3b, which involves just one implementation of the function. Here the singe-qubit quantum gate it symbolizes the so-called Hadamard (or "Walsh-Hadamard") transform" ${ }^{50}$ whose linear operator is defined by the following actions on qubit's basis states:

Hadamard transform

$$
\begin{equation*}
\hat{\forall}|0\rangle=\frac{1}{\sqrt{2}}(|0\rangle+|1\rangle), \quad \hat{\lambda}|1\rangle=\frac{1}{\sqrt{2}}(|0\rangle-|1\rangle), \tag{8.138}
\end{equation*}
$$

- see also the 4 left state labels in Fig. $3 b .{ }^{51}$ On the Bloch sphere (Fig. 5.1), and in the usual spin- $1 / 2$ notation, Eqs. (138) correspond to the transfer of the representing point from the North Pole's state $\uparrow$, i.e. one of the eigenstates of matrix $\sigma_{z}$, to one of equatorial states, $\rightarrow$, i.e. one of the eigenstates of matrix $\sigma_{x}$, and from the South Pole state $\downarrow$ to the another equatorial state, $\leftarrow$, see Eq. (4.122). However, a $\pi / 2$-rotation in the $[x, z]$ plane would be a poor interpretation of this function. Indeed, since its operator has to be linear (to be physically realistic), it needs to perform action (138) on the basis states even when they are parts of an arbitrary linear superposition - as they are, e.g., for the two right Hadamard gates in Fig. 3b. For example, as immediately follows from Eq. (137) and operator's linearity,

$$
\begin{equation*}
\hat{\mathcal{H}}(\hat{\nexists H}|0\rangle)=\hat{\mathcal{H}^{\prime}}\left(\frac{1}{\sqrt{2}}(|0\rangle+|1\rangle)\right)=\frac{1}{\sqrt{2}} \hat{\mathcal{H}}\left(|0\rangle+\hat{\mathcal{H}^{\prime}}|1\rangle\right)=\frac{1}{\sqrt{2}}\left(\frac{1}{\sqrt{2}}(|0\rangle+|1\rangle)+\frac{1}{\sqrt{2}}(|0\rangle-|1\rangle)\right)=|0\rangle, \tag{8.139a}
\end{equation*}
$$

Absolutely similarly, we may get ${ }^{52}$

$$
\begin{equation*}
\hat{\mathcal{H}}(\hat{\forall X}|1\rangle)=|1\rangle . \tag{8.139b}
\end{equation*}
$$

Due to this reason, a better interpretation of the Hadamard transform is a $\pi$-rotation about the axis that bisects the angle between axes $x$ and $z$.

Now let us carry out an analysis of the "circuit" shown in Fig. 3b, minding all the time the operator linearity, and the fact that the transformation rules (136)-(138) are only applicable to basis kets of the initial ("input") state vector. In particular, taking into account that according to Fig. 3b, the input states of gate $f$ in this particular circuit are described by Eqs. (138), its output state's ket is

$$
\begin{equation*}
\hat{f}(\hat{z}|0\rangle \hat{\vec{f}}|1\rangle)=\hat{f}\left(\frac{1}{\sqrt{2}}(|0\rangle+|1\rangle) \frac{1}{\sqrt{2}}(|0\rangle-|1\rangle)\right)=\frac{1}{2}(\hat{f}|00\rangle-\hat{f}|01\rangle+\hat{f}|10\rangle-\hat{f}|11\rangle) . \tag{8.140}
\end{equation*}
$$

Now we may apply Eq. (136) to each of the basis kets to get:

$$
\begin{align*}
\hat{f}|00\rangle-\hat{f}|01\rangle+\hat{f}|10\rangle-\hat{f}|11\rangle & \equiv \hat{f}|0\rangle|0\rangle-\hat{f}|0\rangle|1\rangle+\hat{f}|1\rangle|0\rangle-\hat{f}|1\rangle|1\rangle \\
& =|0\rangle|0 \oplus f(0)\rangle-|0\rangle|1 \oplus f(0)\rangle+|1\rangle|0 \oplus f(1)\rangle-|1\rangle|1 \oplus f(1)\rangle  \tag{8.141}\\
& =|0\rangle(|0 \oplus f(0)\rangle-|1 \oplus f(0)\rangle)+|1\rangle(|0 \oplus f(1)\rangle-|1 \oplus f(1)\rangle) .
\end{align*}
$$

[^732]Note that the expression in the first parentheses, characterizing the state of the target qubit, is equal to $(|0\rangle-|1\rangle) \equiv(-1)^{0}(|0\rangle-|1\rangle)$ if $f(0)=0($ and hence $0 \oplus f(0)=0$ and $1 \oplus f(0)=1)$, and to $(|1\rangle-|0\rangle) \equiv(-1)^{1}(|0\rangle-$ $|1\rangle$ ) in the opposite case $f(0)=1$, so that both cases may be described in one shot by rewriting the parentheses as $(-1)^{f(0)}(|0\rangle-|1\rangle)$. The second parentheses is absolutely similarly controlled by the value of $f(1)$, so that the state of the system at the output of gate $f$ is unentangled again:

$$
\begin{equation*}
\hat{f}\left(\hat{y}|0\rangle \hat{X_{X}}|1\rangle\right)=\frac{1}{2}\left((-1)^{f(0)}|0\rangle+(-1)^{f(1)}|1\rangle\right)(|0\rangle-|1\rangle)= \pm \frac{1}{\sqrt{2}}\left(|0\rangle+(-1)^{F}|1\rangle\right) \frac{1}{\sqrt{2}}(|0\rangle-|1\rangle), \tag{8.142}
\end{equation*}
$$

where the last transition has used the fact that the Boolean function $F$, defined by Eq. (135), equals to $\pm[f(1)-f(0)]$ - compare the last two columns in Eq. (133). Since the common sign (i.e. the common phase shift by $\pi$ ) is inconsequential, it may be prescribed to any of the component ket-vectors - for example to that of the target qubit, as shown by the third pair of state labels in Fig. 3b.

This intermediate result is already rather remarkable. Indeed, it shows that, despite the impression one could get from Fig. 4, gates $f$ and even $C$, being "controlled" by the source qubit, may change that qubit's state as well! This fact (partly reflected by the vertical direction of the control lines in Figs. 3, 4, symbolizing the same stage of system's evolution in time) shows how careful one should be interpreting quantum-computational "circuits".

At the second stage of the circuit shown in Fig. 3b, the qubit components of state (142) are fed into one more pair of Hadamard gates, whose outputs therefore are

Now using Eqs. (138) again, we see that the output state ket-vectors of the source and target qubits are, respectively,

$$
\begin{equation*}
\frac{1+(-1)^{F}}{2}|0\rangle+\frac{1-(-1)^{F}}{2}|1\rangle, \quad \text { and } \pm|1\rangle \tag{8.144}
\end{equation*}
$$

Since, according to Eq. (135), the Boolean function $F$ may take only values 0 or 1, the final state of the source qubit is always one of its basis states $j$, namely the one with $j=F$. Its measurement (see Fig. 2) immediately tells us whether function $f$, participating in Eq. (136), is constant or balanced. ${ }^{53}$

Thus, the quantum circuit shown in Fig. 3b indeed solves the Deutsch problem in one shot. Reviewing our analysis, we may see that this is possible because the unitary transform performed by gate $f$ is applied to quantum superpositions (138) rather than to the basis states. Due to this trick, the quantum state components depending on $f(0)$ and $f(1)$ are processed simultaneously, in parallel. This quantum parallelism may be extended to circuits with many ( $N \gg 1$ ) qubits and, for some tasks, provide a dramatic performance increase - for example, reducing the necessary circuit component number from $O(\exp \{N\})$ to $O\left(N^{p}\right)$, where $p$ is a finite (and not very big) number.

[^733]However, this efficiency comes at a high price. Indeed, let us discuss the physical implementation of quantum gates, starting from the Hadamard gate, which performs a single-qubit transform - see Eq. (138). With the linearity requirement, its action on the arbitrary state (125) should be

$$
\begin{equation*}
\hat{\mathcal{H}}|\alpha\rangle=a_{0} \hat{\forall}|0\rangle+a_{1} \hat{\mathcal{H}}|1\rangle=a_{0} \frac{1}{\sqrt{2}}(|0\rangle+|1\rangle)+a_{1} \frac{1}{\sqrt{2}}(|0\rangle-|1\rangle)=\frac{1}{\sqrt{2}}\left(a_{0}+a_{1}\right)|0\rangle+\frac{1}{\sqrt{2}}\left(a_{0}-a_{1}\right)|1\rangle, \tag{8.145}
\end{equation*}
$$

meaning that the state expansion coefficients in the end $(t=T)$ and beginning $(t=0)$ of the qubit evolution in time have to be related as

$$
\begin{equation*}
a_{0}(T)=\frac{a_{0}(0)+a_{1}(0)}{\sqrt{2}}, \quad a_{1}(T)=\frac{a_{0}(0)-a_{1}(0)}{\sqrt{2}} \tag{8.146}
\end{equation*}
$$

This task may be again performed using the Rabi oscillations, which were discussed in Sec. 6.5, i.e. by applying to the qubit (a two-level system), for a limited time period $T$, a weak sinusoidal external signal of frequency $\omega$ equal to the intrinsic quantum oscillation frequency $\omega_{n n}$, defined by Eq. (6.85). A perturbative analysis of the Rabi oscillations was carried out in Sec. 6.5, even for nonvanishing (though small) detuning $\Delta=\omega-\omega_{n n}$, but only for the particular initial conditions when at $t=0$ the system was in one on the basis states (there labeled as $n$ '), i.e. another state (there labeled $n$ ) was empty. For our current purposes we need to find coefficients $a_{0,1}(t)$ of expansion (125) for arbitrary initial conditions $a_{0,1}(0)$, subject only to the time-independent normalization condition $\left|a_{0}\right|^{2}+\left|a_{1}\right|^{2}=1$. For the case of exact tuning, $\Delta=0$, the solution of Eqs. (6.94) is elementary, and gives, instead of Eq. (6.102), ${ }^{54}$ the following solutions:

$$
\begin{align*}
& a_{0}(t)=a_{0}(0) \cos \Omega t-i a_{1}(0) e^{i \varphi} \sin \Omega t \\
& a_{1}(t)=a_{1}(0) \cos \Omega t-i a_{0}(0) e^{-i \varphi} \sin \Omega t \tag{8.147}
\end{align*}
$$

where $\Omega$ is the Rabi oscillation frequency (6.101), in the exact-tuning case proportional to amplitude $|A|$ of the external rf drive $A=|A| \exp \{i \varphi\}$, while $\varphi$ is the phase of the driving signal - see Eqs. (6.86)(6.87). Comparing these expressions with Eqs. (146), we see that for $t=T=\pi / 4 \Omega$ and $\varphi=\pi / 2$ they "almost" coincide, besides the opposite sign of $a_{1}(T)$.

Conceptually the simplest way to correct this deficiency is to follow the rf " $\pi / 4$-pulse", just discussed, by a short dc " $\pi$-pulse" of duration $T$ " $=\pi / \delta$, which temporary creates an small additional energy difference $\delta$ between basis states 0 and 1. According to the basic Eq. (1.61), such difference creates an additional phase difference $T$ ' $\delta / \hbar$ between the states, equal to $\pi$ for the " $\pi$-pulse".

Another way (that may be also useful for two-qubit operations) is to use another, auxiliary energy level $E_{2}$ whose distances from the basic levels $E_{1}$ and $E_{0}$ are significantly different from the difference $\left(E_{1}-E_{0}\right)$ - see Fig. 5a. In this case, the weak external rf field tuned to any of 3 potential quantum transition frequencies $\omega_{n n^{\prime}} \equiv\left(E_{n^{-}} E_{n^{\prime}}\right) / \hbar$ initiates such transitions between the corresponding states only, with a negligible perturbation of the state not involved in this transition. Such transitions may be again described by Eqs. (147), with the appropriate index changes. For the Hadamard transform implementation, it is sufficient to apply (after the already discussed $\pi / 4$-pulse of frequency $\omega_{10}$, and with

[^734]the initially empty level $E_{2}$ ), an additional $\pi$-pulse of frequency $\omega_{20}$, with any phase $\varphi$. Indeed, according to the first of Eqs. (147), with the due replacement $a_{1}(0) \rightarrow a_{2}(0)=0$, such pulse flips the sign of coefficient $a_{0}(t)$, while coefficient $a_{1}(t)$, not involved in this additional transition, remains unchanged.

(a)
(b)

(c)

Fig. 8.5. Energy-level schemes used for unitary transformations of (a) single qubits and (b, c) two-qubit systems.

Now let me describe the conceptually simplest (though, for some qubit types, not practically most convenient) scheme for the implementation of the CNOT gate, whose action is described by a linear unitary operator satisfying Eq. (137). For that, evidently, qubits have to let interact for some time $T$. As was repeatedly discussed in two past chapters, in most cases such interaction of two subsystems is bilinear - see, e.g., Eq. (6.148). For qubits, i.e. two-level systems, each of the component operators may be represented by a $2 \times 2$ matrix in the basis of states 0 and 1 . According to Eq. (4.105), such matrix may be expressed as a linear combination $\left(c_{0} I+\mathbf{c} \cdot \sigma\right)$, where $c_{0}$ and three Cartesian components of vector $\mathbf{c}$ are $c$-numbers. Let us take such bilinear interaction Hamiltonian in the simplest form

$$
\hat{H}_{\mathrm{int}}(t)=\left\{\begin{array}{cc}
\kappa \hat{\sigma}_{z}^{(1)} \hat{\sigma}_{z}^{(2)}, & \text { for } 0<t<T  \tag{8.148}\\
0, & \text { otherwise }
\end{array}\right.
$$

where the upper index is the qubit number, and $\kappa$ is a $c$-number constant. ${ }^{55}$ According to Eq. (4.175), by the end of the interaction period, this Hamiltonian produces the following unitary transform:

$$
\begin{equation*}
\hat{U}_{\mathrm{int}}=\hat{I} \exp \left\{-\frac{i}{\hbar} \hat{H}_{\mathrm{int}} T\right\}=\hat{I} \exp \left\{-\frac{i}{\hbar} \kappa \hat{\sigma}_{z}^{(1)} \hat{\sigma}_{z}^{(2)} T\right\} \tag{8.149}
\end{equation*}
$$

Since in the basis of unperturbed two-bit states $\left|j_{1} j_{2}\right\rangle$ the product operator $\hat{\sigma}_{z}^{(1)} \hat{\sigma}_{z}^{(2)}$ is diagonal, so is the unitary operator (149), with the following action on the basis states:

$$
\begin{equation*}
\hat{U}_{\mathrm{int}}\left|j_{1} j_{2}\right\rangle=\exp \left\{i \theta \sigma_{z}^{(1)} \sigma_{z}^{(2)}\right\}\left|j_{1} j_{2}\right\rangle, \tag{8.150}
\end{equation*}
$$

[^735]where $\theta \equiv-\kappa T / \hbar$, and $\sigma_{z}$ are the eigenvalues of the Pauli matrix $\sigma_{z}$ for the basis states of the corresponding qubit: $\sigma_{z}=+1$ for $|j\rangle=|0\rangle$, and $\sigma_{z}=-1$ for $|j\rangle=|1\rangle$. Let me, for clarity, spell out Eq. (150) for the particular case $\theta=-\pi / 4$ (corresponding to the qubit coupling time $T=\pi \hbar / 4 \kappa$ ):
\[

$$
\begin{equation*}
\hat{U}_{\mathrm{int}}|00\rangle=e^{-i \pi / 4}|00\rangle, \quad \hat{U}_{\mathrm{int}}|01\rangle=e^{i \pi / 4}|01\rangle, \quad \hat{U}_{\mathrm{int}}|10\rangle=e^{i \pi / 4}|10\rangle, \quad \hat{U}_{\mathrm{int}}|11\rangle=e^{-i \pi / 4}|11\rangle . \tag{8.151}
\end{equation*}
$$

\]

In order to compensate the undesirable parts of this joint phase shift of the basis states, let us apply (either before or after it) similar individual "rotations" of each qubit by angle $\theta$ ' $=+\pi / 4$, using the following product of two independent operators, plus (just for the result clarity) a common, and hence inconsequential, phase shift $\theta^{\prime \prime}=-\pi / 4:^{56}$

$$
\begin{equation*}
\hat{U}_{\mathrm{com}}=\hat{I} \exp \left\{i \theta^{\prime}\left(\hat{\sigma}_{z}^{(1)}+\hat{\sigma}_{z}^{(2)}\right)+i \theta^{\prime \prime}\right\}=\hat{I} \exp \left\{i \frac{\pi}{4} \hat{\sigma}_{z}^{(1)}\right\} \exp \left\{i \frac{\pi}{4} \hat{\sigma}_{z}^{(2)}\right\} \exp \left\{-i \frac{\pi}{4}\right\} \tag{8.152}
\end{equation*}
$$

Since this operator is also diagonal in the $\left\langle j_{1} j_{2}\right\rangle$ basis, it is equally easy to calculate the change of the basis states by the total unitary operator $\hat{U}_{t} \equiv \hat{U}_{\text {com }} \hat{U}_{\text {int }}$ :

$$
\begin{equation*}
\hat{U}_{t}|00\rangle=|00\rangle, \quad \hat{U}_{t}|01\rangle=|01\rangle, \quad \hat{U}_{t}|10\rangle=|10\rangle, \quad \hat{U}_{t}|11\rangle=-|11\rangle . \tag{8.153}
\end{equation*}
$$

This result already shows the main "miracle action" of two-qubit gates, such as shown in Fig. 4: the source qubit is left intact (only if it is in a basis state!), while the state of the target qubit is altered. True, this is still different from the CNOT operator's action (137), but may be readily reduced to it by its sandwiching of transform $U_{t}$ between two Hadamard transforms applied to the target qubit:

$$
\begin{equation*}
\hat{C}=\frac{1}{2} \hat{\mathcal{H}}^{(2)} \hat{U}_{t} \hat{\mathcal{H}}^{(2)} . \tag{8.154}
\end{equation*}
$$

We have spend quite a bit of time on the discussion of the CNOT gate, ${ }^{57}$ and now I can reward the reader for his/her effort with a bit of good news: it has been proved that an arbitrary unitary transform that satisfies Eq. (132), i.e. may be used within the general scheme outlined in Fig. 2, may be decomposed into a set of CNOT gates mixed with simpler single-qubit gates - for example, the Hadamard gate plus the $\pi / 2$ rotation discussed above. ${ }^{58}$ Unfortunately, I have no time for a detailed discussion of more complex circuits. ${ }^{59}$ Perhaps the most famous of them is the scheme for integer

[^736]number factoring, suggested in 1994 by P. Shor. ${ }^{60}$ Due to its potential practical importance for breaking broadly used communication encryption schemes such as the RSA code, ${ }^{61}$ this opportunity has incited a huge wave of enthusiasm, and triggered experimental efforts to implement quantum gates and circuits using a broad variety of two-level quantum systems. Presently, the following options are most eagerly pursued: ${ }^{62}$
(i) Trapped ions. The first experimental demonstrations of quantum state manipulation (including the already mentioned first CNOT gate) have been carried out using deeply cooled atoms in optical traps, similar to those used in frequency and time standards. Their electron spins are natural qubits, whose states may be manipulated using the Rabi transfers excited by suitably tuned lasers. The spin interactions with environment may be very weak, resulting in large dephasing times ( $T_{2}$, see Sec. 7.3), up to a few seconds. Since the distances between atoms in the traps are relatively large (of the order of a micron), their direct spin-spin interaction is even weaker, but atoms may be made effectively interacting either via their mechanical oscillations about the potential minima of the trapping field, or via photons in electromagnetic resonators ("cavities"). ${ }^{63}$ Perhaps the main challenge of using this approach for quantum computation is poor "scalability", i.e. the enormous challenge of creating large, ordered systems of individually addressable qubits.
(ii) Nuclear spins are also typically very weakly connected to environment, with $T_{2}$ exceeding 10 seconds in some cases. Their eigenenergies $E_{0}$ and $E_{1}$ may be split by external dc magnetic fields (typically, of the order of 10 T ), while the interstate Rabi transfers may be readily achieved by application of external rf fields with frequencies $\omega=\left(E_{1}-E_{0}\right) / \hbar$ of a few hundred $\mathrm{MHz} .{ }^{64}$ The challenges of this option include the weakness of spin-spin interactions (typically mediated through molecular electrons), resulting in a very slow spin evolution, whose time scale $\hbar / \kappa$ may become comparable with $T_{2}$, and small level separations $E_{1}-E_{0}$, corresponding to a few K, ${ }^{65}$ i.e. much smaller than the room temperature, creating a problem with qubit state preparation. ${ }^{66}$

Despite these challenges, the nuclear spin option was used for the first implementation of the Shor algorithm for factoring of a small number $(15=5 \times 3)$ as early as in $2001 .{ }^{67}$ However, the extension of this success to larger systems, beyond the set of spins inside one molecule, is problematic.
(iii) Josephson-junction devices. Much better scalability may be achieved with solid state devices, especially in superconductor integrated circuits including weak contacts - Josephson junctions. As was already discussed in Sec. 2.8, if the coupling of a Josephson junction to its dissipative environment is sufficiently weak (in particular if its effective parallel resistance is much higher than the

[^737]quantum resistance unit $R_{Q} \sim 10^{4} \Omega$ ), the Josephson phase variable $\varphi$ behaves as a coordinate of a 1D quantum particle with effective mass (2.252), moving in a $2 \pi$-periodic potential - see Eq. (2.250). This fact creates several opportunities for qubit implementation using quantum behavior of this macroscopic degree of freedom.

In an insulated junction, ${ }^{68}$ the phase motion in the periodic potential $U(\varphi)=-E_{j} \cos \varphi$ creates the energy band structure $E(q)$ that was discussed in detain in Sec. 2.7. In particular, in the weak potential limit (which, for the Josephson junction case, is valid at $E_{J} \ll e^{2} / 2 C-$ see the discussion in Sec. 2.8), the lowest bandgaps are very narrow, and function $E(q)$ in their vicinity is well described by the usual level anticrossing - see Figs. 2.28 and 2.29 and their discussion. The translation of this fact to the Josephson junction language (see, in particular, Eq. (2.256) and its discussion) shows that the values of the effective electric charge $Q$ of the junction, on two anticrossing energy branches, differ by charge $2 e$ of one Cooper pair. Since, according to Eq. (2.222) and its discussion, the system dynamics in this case is reduced to the interaction of these two states with different $Q$, in application to quantum computation this system is called the charge qubit. Unfortunately, the states of such qubit are rather sensitive to random charged impurities in junction's vicinity, causing strong fluctuations, and hindering its control, so this option is not actively pursued nowadays.

Other options are based on the modification of potential $U(\varphi)$ at Josephson junction incorporation into superconducting loops, i.e. in SQUIDs. ${ }^{69}$ In the simplest case of a single loop of inductance $L$ closed by one junction with critical current $I_{C}$, the total potential energy of the system in an external magnetic field is ${ }^{70}$

$$
\begin{equation*}
U(\varphi)=E_{J}\left[\frac{\left(\varphi-\varphi_{\mathrm{ext}}\right)^{2}}{2 \beta_{L}}-\cos \varphi\right], \quad \text { with } E_{J}=\frac{\hbar I_{C}}{2 e}, \beta_{L} \equiv \frac{4 e I_{C} L}{\hbar}, \tag{8.155}
\end{equation*}
$$

where $\varphi_{\text {ext }}$ is proportional to the external magnetic flux $\Phi_{\text {ext }}$ through the loop. According to this relation, at $E_{J} \gg e^{2} / 2 C$ (corresponding to the tight-binding limit of the energy band theory), one convenient way to implement a two-level system is to take the dimensionless inductance parameter $\beta_{L}$ above but very close to $1\left(0<\beta_{L}-1 \ll 1\right)$, the "symmetrizing" magnetic field ( $\varphi_{\mathrm{ext}} \approx \pi$ ), and $E_{J} \approx\left(e^{2} / C\right) /\left(\beta_{L}-1\right)^{3}$. In this case, the potential profile has the shape of a nearly symmetrical double well, with ground states in each well coupled by tunneling through a relatively low tunnel barrier, creating a pair of eigenstates with relatively low eigenenergy splitting $\Delta=E_{1}-E_{0} \ll E_{J}$ (Fig. 6a).
(a)

(b)

Fig. 8.6. Typical potential profiles and energy levels of SQUID-based qubits: (a) "flux qubit" and (b) "phase qubit". Red dashed lines show eigenenergies of the used states 0 and 1 .

[^738]Such flux qubits have a relatively large magnitude $\left|\Phi_{10}\right|=\left|\Phi_{01}\right|$ of the matrix elements of the operator of magnetic flux $\Phi=(\hbar / 2 e) \varphi$ piercing the SQUID loop. This certainly makes the arrangement of necessary coupling between flux qubits (see, e.g., Eq. (149) and its discussion) very easy, despite the macroscopic $(\sim 10 \mu \mathrm{~m})$ sizes of SQUIDs and hence of the distances between them, decreasing the time $T$ $\sim \hbar / \kappa$ necessary for the most critical two-bit (e.g., CNOT) operations, to a just few nanoseconds. However, the large flux matrix elements also increase the undesirable coupling of such qubits to dephasing environment, and hence decrease dephasing time $T_{2}$ - typically, to just a few tens or hundreds nanoseconds, uncomfortably close to $T$.

This coupling may be decreased, leading to a substantial increase of $T_{2}$ (up to a few microseconds) by moving the bias phase $\varphi_{\text {ext }}$ away from the symmetrizing value $\pi$, i.e. using the asymmetric potential profile sketched in Fig. 6b. The working states 0 and 1 of such phase qubit, localized in a higher potential well (shown left in Fig. 6b), are actually metastable, but with a very long lifetime because of the relatively high barrier separating the wells. An additional benefit of this arrangement is that a fast lowering of the tunnel barrier causes the system in state 1 to tunnel into the lower well, with the sequential energy relaxation (see the arrows in Fig. 6b); this process be used for qubit state readout. A major problem of phase qubits is that the part of potential $U(\varphi)$, in which qubit states are localized, is almost quadratic, so that the energy levels are nearly equidistant - cf. Eqs. (2.114), (6.15), and (6.22). ${ }^{71}$ As a result, the external rf drive of frequency $\omega=\left(E_{1}-E_{0}\right) / \hbar$, used to arrange the state transforms described by Eq. (146), may induce simultaneous undesirable transitions to (and between) higher energy levels. This effect may be mitigated by the rf drive amplitude reduction (see Problem 6.6), but at a price of the proportional increase of transfer time $T$, that may again become comparable to $T_{2}$. Despite this problem, phase qubits have been used for a successful experimental demonstration of the core single-operand and two-operand gates, and recently, for the reproduction of number 15 factoring " $48 \%$ of the time"..$^{72}$
(iv) Optical systems pose a special challenge for quantum computation: due to the virtual linearity of most electromagnetic media at reasonable light power, the implementation of interaction Hamiltonians, such as (149), is problematic. However, in 2001 a very smart way around this hurdle was invented. ${ }^{73}$ In this KLM scheme, nonlinear elements are not needed, and quantum gates may be composed just of linear devices (such as optical waveguides, mirrors and beam splitters), plus singlephoton sources and detectors. Unfortunately, a quantitative discussion of this scheme would require using the basics of quantum electrodynamics that will be discussed only in the next chapter. The work in this direction has already led to an experimental demonstration of factoring number $21=3 \times 7$ (which in some aspects is easier than that of 15)..$^{74}$

Let me, however, note that due to the statistical nature of Shore's algorithm, and the so-far imperfect fidelity of qubit manipulations, all number factoring experiments carried out so far may be more fairly described merely as demonstrations of their result consistency with the (evident) mathematical facts. So, despite a very substantial research effort, the progress is rather slow, with the

[^739]main culprit being the unintentional coupling of qubits to environment, leading most importantly to their state dephasing, and eventually to errors. (Another major problem of this research field is the lack of algorithms (besides Shor's number factoring) that would give quantum computation a substantial advantage over classical counterparts, and hence a potential customer base broader that the communication encryption community, that could provide the necessary significant support.)

Of course, some error probability exists in classical digital logic gates and memory cells as well. However, in this case, there is no conceptual problem with the device state measurement, so that the error may be detected and corrected in many ways; perhaps the simplest one is the so-called majority voting. For that, the input bit is reproduced in several (say, three) copies and sent to three similar devices whose outputs are measured and compared. If the output bits differ, at least one of the devices has made at error. The error may be not only detected, but also corrected by taking the two coinciding output bits for the correct one. If the probability of a single device error is $W \ll 1$, the probability of error of any device pair is close to $W^{2}$, and that of two pairs (and hence of the whole majority voting scheme) is close to $W^{3}$. Since for the currently dominating CMOS integrated circuits, $W$ is very small, such error correction circuit creates a dramatic fidelity improvement - at the cost of higher circuit complexity (which may be traded for larger time delay) and consumed power.

For quantum computation, the general idea of using several devices (say, qubits) for coding the same information remains the same; however, there are two major complications, both due to the analog nature of qubit states. First, as we know from Chapter 7, the dephasing effect of environment may be described as a slow random drift of coefficients $a_{j}$ in expansion (128), leading to the deviation of the output state $\alpha_{\text {fin }}$ from the basis form (132), and hence to a nonvanishing probability of wrong qubit state readout (Fig. 2). Hence the quantum error correction has to protect the result not only against possible random state flips $0 \leftrightarrow 1$ as in the classical digital computer, but also against these "creeping" analog errors.

Second, the qubit state is impossible to copy exactly (clone) without disturbing it, as follows from the following simple calculation. ${ }^{75}$ Cloning state $\alpha$ of one qubit to another qubit, initially in an independent state (say the basis state 0 ), means the following transformation of the two-qubit ket: $|\alpha 0\rangle$ $\rightarrow|\alpha \alpha\rangle$. If we want such transform to be performed by a real quantum system whose evolution is described by a unitary operator $\hat{u}$, and to be correct for an arbitrary state $\alpha$, it has to work not only for both basis states of the qubit:

$$
\begin{equation*}
\hat{u}|00\rangle=|00\rangle, \quad \hat{u}|10\rangle=|11\rangle, \tag{8.156}
\end{equation*}
$$

and also for their arbitrary linear combination (125). Since operator $\hat{u}$ has to be linear, we may use Eq. (156) to calculate

$$
\begin{equation*}
\hat{u}|\alpha 0\rangle=\hat{u}\left(a_{0}|0\rangle+a_{1}|1\rangle\right)|0\rangle=a_{0} \hat{u}|00\rangle+a_{1} \hat{u}|10\rangle=a_{0}|00\rangle+a_{1}|11\rangle . \tag{8.157}
\end{equation*}
$$

On the other hand, the desired result of cloning is

$$
\begin{equation*}
|\alpha \alpha\rangle=\left(a_{0}|0\rangle+a_{1}|1\rangle\right)\left(a_{0}|0\rangle+a_{1}|1\rangle\right)=a_{0}^{2}|00\rangle+a_{0} a_{1}(|10\rangle+|01\rangle)+a_{1}^{2}|11\rangle, \tag{8.158}
\end{equation*}
$$

i.e. evidently different, so that, for an arbitrary $\alpha$,

[^740]\[

$$
\begin{equation*}
\hat{u}|\alpha 0\rangle \neq|\alpha \alpha\rangle \tag{8.159}
\end{equation*}
$$

\]

showing that the qubit state cloning is indeed impossible. ${ }^{76}$
This problem may be circumvented in the way shown in Fig. 7a. Here the CNOT gate, whose action is described by Eq. (137), entangles an arbitrary input state (125) of the source qubit with a basis initial state of an ancillary qubit - frequently called ancilla. Using Eq. (137), we may readily calculate the output two-qubit state's vector:

$$
\begin{equation*}
|\alpha\rangle_{N=2}=\hat{C}\left(a_{0}|0\rangle+a_{1}|1\rangle\right)|0\rangle=a_{0} \hat{C}|00\rangle+a_{1} \hat{C}|10\rangle=a_{0}|00\rangle+a_{1}|11\rangle \tag{8.160}
\end{equation*}
$$

We see that this circuit does perform operation (157), i.e. re-prescribes the initial source qubit's expansion coefficients $a_{0}$ and $a_{1}$ equally to two qubits, i.e. duplicates the input information, though in contrast with the "genuine" cloning, it changes the state of the source qubit. Such "quasi-cloning" is the key to virtually all quantum error correction techniques.

(b)

Quasicloning

Fig. 8.7. (a) Quasi-cloning, and (b) detection and correction of dephasing errors in a single qubit.

Consider, for example, the three-qubit circuit shown in Fig. 7b. At its input, the double application of the quasi-cloning produces an intermediate state $A$ with the ket-vector

$$
\begin{equation*}
|A\rangle=a_{0}|000\rangle+a_{1}|111\rangle, \tag{8.161}
\end{equation*}
$$

which is an evident generalization of Eq. (160). ${ }^{77}$ Subjecting the source qubit to the Hadamard transform (138), we get three-qubit state $B$ represented by vector

$$
\begin{equation*}
|B\rangle=a_{0} \frac{1}{\sqrt{2}}(|0\rangle+|1\rangle)|00\rangle+a_{1} \frac{1}{\sqrt{2}}(|0\rangle-|1\rangle)|1\rangle . \tag{8.162}
\end{equation*}
$$

Now let us assume that at this stage, the source qubit comes into a contact with a dephasing environment (in Fig. 7, symbolized by single-qubit "gate" $\varphi$ ). As we know from Sec. 7.3, its effect

[^741](besides some inconsequential shift of common phase) may be described by a random mutual phase shift of the basis states: ${ }^{78}$
\[

$$
\begin{equation*}
|0\rangle \rightarrow e^{i \varphi}|0\rangle, \quad|1\rangle \rightarrow e^{-i \varphi}|1\rangle \tag{8.163}
\end{equation*}
$$

\]

As a result, for the intermediate state $C$ (see Fig. 7b) we may write

$$
\begin{equation*}
|C\rangle=a_{0} \frac{1}{\sqrt{2}}\left(e^{i \varphi}|0\rangle+e^{-i \varphi}|1\rangle\right)|00\rangle+a_{1} \frac{1}{\sqrt{2}}\left(e^{i \varphi}|0\rangle-e^{-i \varphi}|1\rangle\right)|11\rangle . \tag{8.164}
\end{equation*}
$$

At this stage, in this simple theoretical model, the coupling with environment is completely quenched (ahh, if this could be possible in reality! we would have quantum computers by now :-), and the source qubit is fed into one more Hadamard gate. Using Eqs. (138) again, for state $D$ after this gate we get

$$
\begin{equation*}
|D\rangle=a_{0}(\cos \varphi|0\rangle+i \sin \varphi|1\rangle)|00\rangle+a_{1}(i \sin \varphi|0\rangle+\cos \varphi|1\rangle)|11\rangle . \tag{8.165}
\end{equation*}
$$

Now the qubits are passed through the second, similar pair of CNOT gates - see Fig. 7b. Using Eq. (137), for the ket-vector of the resulting state $E$ we readily get expression

$$
\begin{equation*}
|E\rangle=a_{0} \cos \varphi|000\rangle+a_{0} i \sin \varphi|111\rangle+a_{1} i \sin \varphi|011\rangle+a_{1} \cos \varphi|100\rangle \tag{8.166a}
\end{equation*}
$$

which evidently may be grouped as

$$
\begin{equation*}
|E\rangle=\left(a_{0}|0\rangle+a_{1}|1\rangle\right) \cos \varphi|00\rangle+\left(a_{1}|0\rangle+a_{0}|1\rangle\right) i \sin \varphi|11\rangle . \tag{8.166b}
\end{equation*}
$$

This is already a rather remarkable result. It shows that if we measure the ancilla qubits at stage $E$, and both results corresponded to states 0 , we may be $100 \%$ sure that the source qubit (which is not affected by the measurement!) is in its initial state even after the interaction with environment. The only result of an increase of this interaction (as quantified by the magnitude of phase $\varphi$ ) is the growth of the probability,

$$
\begin{equation*}
W=\sin ^{2} \varphi \tag{8.167}
\end{equation*}
$$

of getting the opposite result, which signals a dephasing-induced error in the source qubit. This implicit measurement, without disturbing the source qubit, is called quantum error detection.

Even more impressive result may be achieved by adding to the circuit one more component, the so-called Toffoli (or "CCNOT") gate, denoted by the rightmost symbol in Fig. 7b. This 3-qubit gate is conceptually similar to the CNOT gate discussed above, besides that it flips the basis state of its target qubit only if both basis states of its two source qubits are 1. (In the circuit shown in Fig. 7b, the former role is played by our source qubit, while the latter role, by two ancilla qubits.) According to its

[^742]definition, the Toffoli gate has no effect on the first parentheses in Eq. (166b), but flips the source qubit's state in the second parentheses. The result may be factorized as follows,
\[

$$
\begin{equation*}
|F\rangle=\left(a_{0}|0\rangle+a_{1}|1\rangle\right)(\cos \varphi|00\rangle+i \sin \varphi|11\rangle) \tag{8.168}
\end{equation*}
$$

\]

showing that now the source qubit is again fully unentangled from the ancilla qubits. Moreover, calculating the norm squared of the second operand, we get

$$
\begin{equation*}
(\cos \varphi\langle 00|-i \sin \varphi\langle 11|)(\cos \varphi|00\rangle+i \sin \varphi|11\rangle)=\cos ^{2} \varphi+\sin ^{2} \varphi=1 \tag{8.169}
\end{equation*}
$$

Quantum
so that the final state of the source qubit always, exactly coincides with its initial state. This is the famous miracle of quantum state correction, taking place "automatically" - without any qubit measurements, and for any random phase shift $\varphi$.

The circuit shown in Fig. 7b may be improved by adding the Hadamard gate pairs, similar to that used for the source qubit, to the ancilla qubits as well. If dephasing is small in the sense that the $W$ given by Eq. (167) is much less than 1, this modified circuit may provide substantial error probability reduction (to $\sim W^{2}$ ) even if the ancilla qubits are also subjected to a similar dephasing and the source qubits, at the same stage - i.e. between two Hadamard gates. The perfect automatic correction of any error (not only inner dephasing of a qubit and its relaxation/excitation, but also the mutual dephasing between qubits) of any used qubit needs even more parallelism. The first circuit of that kind, based on 9 parallel qubits, which is a natural generalization of the circuit discussed above, had been invented in 1995 by the same P. Shor. Later, 5-qubit circuits enabling similar error correction were suggested. (The further parallelism reduction has been proved impossible.)

However, all these results assume that the error correction circuits as such are perfect, i.e. completely isolated from the environment. In the real world this cannot be done. Now the key question is what maximum level $W_{\max }$ of error probability in each gate (including those in the used error correction scheme) can be automatically corrected, thus opening a way toward large quantum computers producing some useful results - first of all, the factoring of large numbers - with at least $10^{3}$ bits to be of interest for practice. To the best of my knowledge, this critical level has not yet been strictly calculated, partly because the error correction greatly inflates the number of the total gates in the system - by a factor crudely proportional to the number $N$ of used qubits. Various authors give broadly different estimates: from $W_{\max } \sim 10^{-6}$ to $W_{\max } \sim 10^{-2}$. Whatever the critical level is, it has not been reached yet.

This situation has motivated the search for the quantum computation schemes different from that shown in Fig. 2; the most prominent alternative is called adiabatic quantum computation. ${ }^{79}$ In its most actively pursued option (for which "quantum system modeling" would be a more appropriate name), the interaction between a system of qubits is organized so that the system's Hamiltonian is similar to that of some quantum system of interest. Then the qubit system, first prepared in a certain initial state with relatively high energy, e.g., in an unentangled state described by Eq. (130), is let to evolve on its own. Due to the unavoidable dissipation due to interaction with environment, the system eventually relaxes to a final unentangled state of its qubits, which is then measured. From numerous runs of such experiment, outcome statistics may be revealed for various temperatures of the environment. Thus, at this approach (which is very close to the numerical modeling technique called quantum annealing), the interaction

[^743]with environment is allowed to play a certain role in the system evolution, though every effort is made to reduce it, to allow qubit "quantumness" to make a substantial difference at least at the beginning of the relaxation process.

Generally speaking, adiabatic quantum computation may be used for performing any quantum algorithm, including number factoring. ${ }^{80}$ Unfortunately, due to technical difficulties of the organization and precise control of long-range interaction in multi-qubit systems, ${ }^{81}$ the list of modeled systems is presently limited to a few simple 1D or 2D arrays described by the so-called extended quantum Ising ("spin-glass") model ${ }^{82}$

$$
\begin{equation*}
\hat{H}=-J \sum_{\left\{j, j^{\prime}\right\}} \hat{\sigma}_{z}^{(j)} \hat{\sigma}_{z}^{\left(j^{\prime}\right)}-\sum_{j} h_{j} \hat{\sigma}_{z}^{(j)} \tag{8.170}
\end{equation*}
$$

where the curly bracket denotes the summation over pairs of close (though not necessarily closest) neighbors. Though Hamiltonian (170) is the traditional playground of phase transitions theory (see, e.g., SM Chapter 4), to the best of my knowledge there are not many practically valuable tasks that could be achieved by studying the statistics of its solutions. Moreover, even for this limited task, the speed of the best experimental adiabatic quantum "computer" with $N=108$ qubits is still lower than that of a classical, off-the-shelf semiconductor processor (with a dollar cost lower by some 6 orders of magnitude), and no dramatic change of this comparison is predicted for realistic larger values of $N .{ }^{83}$

There may be better prospects for another application of entangled qubit systems, namely for telecommunication cryptography. ${ }^{84}$ The goal here is to replace the currently dominating classical encryption, based on the public-key RSA code mentioned above, that may be broken by factoring of very large numbers, by a quantum encryption that would be fundamentally unbreakable. The basis of this opportunity are the measurement postulate and the no-cloning theorem: if a message is carried out by a qubit such as a single photon, it is impossible for an eavesdropper (in cryptography, traditionally called Eve) to either measure or copy its faithfully, without also disturbing its state. However, as we have seen from the discussion of Fig. 7a, state quasi-cloning using entangled qubits is possible, so that the issue is far from being simple, especially if we want to use a publicly distributed quantum key, in some sense similar to the classical public key used at the RSA encryption.

Unfortunately, I do not have time/space to discuss various options for quantum encryption, but cannot help demonstrating how counter-intuitive they may be, on the famous example of the so-called quantum teleportation (Fig. 8). ${ }^{85}$ Suppose that party A (in cryptography, traditionally called Alice) wants to send party $\mathrm{B}(B o b)$ the full information about the quantum state $\alpha$ of a qubit, unknown to either party. Instead of sending her qubit directly to Bob, Alice asks him to send her one qubit ( $\beta$ ) of the pair of other qubits, prepared in a certain entangled state, for example in the singlet state (11):

[^744]\[

$$
\begin{equation*}
\left|\beta \beta^{\prime}\right\rangle=\frac{1}{\sqrt{2}}(|01\rangle-|10\rangle) \tag{8.171}
\end{equation*}
$$

\]

Using Eq. (125), the initial state of the whole 3-qubit system may be represented by the ket-vector

$$
\begin{equation*}
\left|\alpha \beta \beta^{\prime}\right\rangle=\left(a_{0}|0\rangle+a_{1}|1\rangle\right)\left|\beta \beta^{\prime}\right\rangle=\frac{a_{0}}{\sqrt{2}}|001\rangle-\frac{a_{0}}{\sqrt{2}}|010\rangle+\frac{a_{1}}{\sqrt{2}}|010\rangle-\frac{a_{1}}{\sqrt{2}}|111\rangle, \tag{8.172a}
\end{equation*}
$$

which may be rewritten as a linear superposition,

$$
\begin{align*}
\left|\alpha \beta \beta^{\prime}\right\rangle & =\frac{1}{2}|\alpha \beta\rangle_{s}^{+}\left(-a_{1}|0\rangle+a_{0}|1\rangle\right)+\frac{1}{2}|\alpha \beta\rangle_{s}^{-}\left(a_{1}|0\rangle+a_{0}|1\rangle\right)  \tag{8.172b}\\
& +\frac{1}{2}|\alpha \beta\rangle_{e}^{+}\left(-a_{0}|0\rangle+a_{1}|1\rangle\right)+\frac{1}{2}|\alpha \beta\rangle_{e}^{-}\left(-a_{0}|0\rangle-a_{1}|1\rangle\right),
\end{align*}
$$

of the following 4 states of qubit pair $\alpha \beta$ :

$$
\begin{equation*}
|\alpha \beta\rangle_{s}^{ \pm} \equiv \frac{1}{\sqrt{2}}(|00\rangle \pm|11\rangle), \quad|\alpha \beta\rangle_{e}^{ \pm} \equiv \frac{1}{\sqrt{2}}(|01\rangle \pm|10\rangle) . \tag{8.173}
\end{equation*}
$$

Fig. 8.8. Sequential stages of a quantum teleportation procedure: (a) the initial state with entangled qubits $\beta$ and $\beta^{\prime}$, (b) back transfer of qubit $\beta$, (c) measurement of pair $\alpha \beta$, (d) forward transfer of 2 classical bits with the measurement result, and (e) the final state, with the state of qubit $\beta^{\prime}$ mirroring the initial state of qubit $\alpha$.

After having received qubit $\beta$ from Bob, Alice measures which of these 4 states does pair $\alpha \beta$ have. This may be achieved, for example, by measurement of one observable represented by operator $\hat{\sigma}_{z}^{(\alpha)} \hat{\sigma}_{z}^{(\beta)}$ and another one corresponding to $\hat{\sigma}_{x}^{(\alpha)} \hat{\sigma}_{x}^{(\beta)}$ - cf. Eq. (148). ${ }^{86}$ The measured eigenvalue of the former operator enables distinguishing the couples of states (173) with different values of the lower index, while the latter measurement distinguishes the states with different upper indices.

Then Alice reports the result (that may be coded by just 2 classical bits) to Bob over a classical channel. Since the measurement places pair $\alpha \beta$ definitely in the corresponding state, the remaining Bob's bit $\beta^{\prime}$ is now definitely in the unentangled single-qubit state that is represented by the corresponding parentheses in Eq. (172b). Note that each of these parentheses contains both coefficients $a_{0,1}$, i.e. the whole information about the initial state of qubit $\alpha$ had initially. If Bob likes, he may now use appropriate single-qubit operations, similar to those discussed above, to move qubit $\beta$ into the state exactly similar to the initial state of qubit $\alpha$. (This fact does not violate the no-cloning theorem (159), because the measurement has already changed the state of $\alpha$.) This is of course a "teleportation" only in

[^745]a very special sense of this rather ambiguous term, but a good example of the importance of qubit entanglement's preservation at their spatial transfer. For us, this is also a good primer for the forthcoming discussion of the EPR paradox and Bell's inequalities in Sec. 10.1.

Returning for a minute to practical quantum cryptography, since its two most common quantum key distribution protocols ${ }^{87}$ require just a few simple quantum gates, whose experimental implementation is not a large obstacle, the main focus of the current effort is on decreasing singlephoton dephasing in long optical fiber waveguides, ${ }^{88}$ and hence increasing the maximum distance of quantum channels with sufficiently high qubit transfer fidelity. The recent progress was impressive, with demonstrated two lines (using either protocol) longer than $100 \mathrm{~km},{ }^{89}$ and active plans for 560 km and 700 km landlines and several satellite-based systems. Let me hope that if not the author, then the reader of these notes will see this technology accepted for practical secure telecommunications.

### 8.6. Exercise problems

8.1. $N$ electrons are placed in a 3D, spherically-symmetric quadratic potential $U(\mathbf{r})=m \omega_{0}^{2} r^{2} / 2$. Neglecting the direct interaction of the electrons, find the ground-state energy of the system.
8.2. $N \gg 1$ indistinguishable, non-interacting quantum particles are placed in a hard-wall, rectangular box with sides $a_{x}, a_{y}$, and $a_{z}$. Calculate the ground-state energy of the system, and the average forces it exerts on each face of the box. Can we characterize the forces by certain pressure?

Hint: Consider separately the cases of bosons and fermions.
8.3. Prove that the singlet state, and each triplet state of a system of two indistinguishable spin-1/2 particles, are eigenstates of the operator of the scalar product $\mathbf{S}_{1} \cdot \mathbf{S}_{2}$ of the spin vectors, and calculate the corresponding eigenvalues. Compare the results with the scalar product of two classical vectors of magnitude $\hbar / 2$ each, being either parallel or antiparallel.
8.4. The interaction of two, indistinguishable spin- $1 / 2$ particles (that are otherwise free) has the form

$$
\hat{H}_{\mathrm{int}}=U(\mathbf{r})+f(\mathbf{r}) \hat{\mathbf{S}}_{1} \cdot \hat{\mathbf{S}}_{2},
$$

where $\mathbf{r} \equiv \mathbf{r}_{1}-\mathbf{r}_{2}$ is the distance between the particles. Reduce the problem to two independent wave mechanical problems.
8.5. Two similar spin- $1 / 2$ particles, with the gyromagnetic ratio $\gamma$, localized at two points separated by distance $a$, interact via the field of their magnetic dipole moments. Calculate the eigenstates and eigenvalues of the system.

[^746]8.6. In the simple case of just two similar spin-interacting particles, distinguishable by their spatial location, the famous Heisenberg model of ferromagnetism ${ }^{90}$ is reduced to the following Hamiltonian:
$$
\hat{H}=-J \hat{\mathbf{S}}_{1} \cdot \hat{\mathbf{S}}_{2}-\gamma \boldsymbol{B} \cdot\left(\hat{\mathbf{S}}_{1}+\hat{\mathbf{S}}_{2}\right)
$$
where $J$ is the spin interaction constant, $\gamma$ is the gyromagnetic ratio of each particle, and $B$ is the external magnetic field. Find the stationary states and eigenenergies of this system for spin- $1 / 2$ particles.
8.7. Two distinguishable particles, both with spin $1 / 2$, but different gyromagnetic ratios $\gamma_{1}$ and $\gamma_{2}$, are placed into external magnetic field $\mathcal{B}$. In addition, their spins interact as
$$
\hat{H}_{\mathrm{int}}=-J \hat{\mathbf{S}}_{1} \cdot \hat{\mathbf{S}}_{2} .
$$

Find the eigenstates and eigenenergies of the system. ${ }^{91}$
8.8. A system of 3 similar but distinguishable spin- $1 / 2$ particles is described by the following Hamiltonian:

$$
\hat{H}=-J\left(\hat{\mathbf{S}}_{1} \cdot \hat{\mathbf{S}}_{2}+\hat{\mathbf{S}}_{2} \cdot \hat{\mathbf{S}}_{3}+\hat{\mathbf{S}}_{3} \cdot \hat{\mathbf{S}}_{1}\right)
$$

where $J$ is the spin interaction constant. Find the stationary states and eigenenergies of this system.
8.9. For a system of three distinguishable spins- $1 / 2$, find the joint eigenstates (and the corresponding eigenvalues) of operators $S_{z}$ and $S^{2}$, where

$$
\hat{\mathbf{S}} \equiv \hat{\mathbf{S}}_{1}+\hat{\mathbf{S}}_{2}+\hat{\mathbf{S}}_{3}
$$

is the vector operator of the total spin of the system. Do the corresponding quantum numbers $s$ and $m_{s}$ obey Eqs. (5.197)?
8.10. Prove that Eq. (8.32) of the lecture notes indeed yields $E_{g}{ }^{(1)}=(5 / 4) E_{\mathrm{H}}$.
8.11. For a diluted gas on helium atom in their ground state, with $n$ atoms per unit volume, on density $n$, calculate its:
(i) electric susceptibility $\chi_{e}$, and
(ii) magnetic susceptibility $\chi_{m}$,
and compare the results.
8.12. Represent the operators of the total kinetic energy and the total orbital angular momentum of a system of two particles, with masses $m_{1}$ and $m_{2}$, as combinations of terms describing their center-ofmass motion and relative motion.
8.13. Two particles, with masses $m_{1}$ and $m_{2}$, interact as described by 3D potential

[^747]$$
U\left(\mathbf{r}_{1}, \mathbf{r}_{2}\right)=\frac{\kappa}{2}\left(\mathbf{r}_{1}-\mathbf{r}_{2}\right)^{2},
$$
but otherwise are free to move. Calculate the energy spectrum and the degeneracy of each energy level of the system for the cases when the particles are:
(i) distinguishable, and
(ii) indistinguishable spin- $1 / 2$ fermions (such as electrons).
8.14. Two particles with similar masses $m$ and charges $q$ are free to move along a round, plane ring of radius $R$. In the limit of their strong Coulomb interaction, find the lowest eigenenergies of the system, and sketch the system of its energy levels.
8.15. Two similar 1D, spin- $1 / 2$ particles are attracting each other at contact:
$$
U\left(x_{1}, x_{2}\right)=-w \delta\left(x_{1}-x_{2}\right), \quad \text { with } w>0
$$
but are otherwise free to move. Find the energy and the wavefunction of the ground state of the system.
Hint: Mind the possibility of various spin states of the particles.
8.16. Two indistinguishable, 1 D , spin- $1 / 2$ particles in a triplet spin state are attracting each other at limited distance:
\[

U\left(x_{1}, x_{2}\right)=\left\{$$
\begin{array}{rc}
-U_{0}, & \text { for }\left|x_{1}-x_{2}\right|<a / 2, \\
0, & \text { otherwise },
\end{array}
$$ \quad with U_{0}>0\right.
\]

but are otherwise free to move. How large should be $a$ for the system to have at least one localized eigenstate? Relate the result to the solution of the previous problem.
8.17. ${ }^{*}$ Two indistinguishable spin- $1 / 2$ particles are confined to move around a circle of radius $R$, and interact only at a very short distance $l=R \varphi=R\left(\varphi_{1}-\varphi_{2}\right)$ between them, so that the interaction potential $U$ may be well approximated with a delta-function of $\varphi$. Calculate their lowest ground states and their energy for the following two cases:
(i) "orbital" (spin-independent) interaction: $\hat{U}=w \delta(\varphi)$,
(ii) spin-spin interaction: $\hat{U}=-w \hat{\mathbf{S}}_{1} \cdot \hat{\mathbf{S}}_{2} \delta(\varphi)$,
both with constant $w>0$. Analyze the trends of your results in the limits $w \rightarrow 0$ and $w \rightarrow \infty$.
8.18. Low-energy spectrum of many diatomic molecules may be well described modeling the molecule as a system of two spinless particles connected with a light and elastic, but very stiff spring. Calculate the spectrum in this approximation.
8.19. Two particles of mass $M$, separated by two much lighter particles, of mass $m \ll M$, are placed on a ring of radius $R$ - see Fig. on the right. The particles strongly repulse at contact, but otherwise each of them is fee to move along the ring. Calculate the lower part of the energy spectrum of the system.

8.20.* Use the perturbation theory to calculate the contribution to the hyperfine splitting of the ground energy of the hydrogen atom, due to the interaction between spins of the nuclei (proton) and of the electron.

Hint: The proton's magnetic moment operator is described by Eq. (4.116), with a positive gyromagnetic factor $\gamma_{p}=g_{p} e / 2 m_{p} \approx 2.675 \times 10^{8} \mathrm{~s}^{-1} \mathrm{~T}^{-1}$, whose magnitude is much smaller than that of the electron $\left(\left|\gamma_{e}\right| \approx 1.761 \times 10^{11} \mathrm{~s}^{-1} \mathrm{~T}^{-1}\right)$, due to a different $g$-factor, $g_{p} \approx 5.586,{ }^{92}$ and of course a much higher mass, $m_{p} \approx 1.673 \times 10^{-27} \mathrm{~kg}$.
8.21. Discuss the factors $\pm 1 / \sqrt{ } 2$ that participate in Eqs. (19) and (21), in terms of the ClebshGordan coefficients discussed in Sec. 5.7.
8.22. Compose the simplest model Hamiltonians of the following systems, in terms of the second quantization formalism:
(i) a system of two weakly coupled quantum wells, taking into account pair on-site interactions (additional energy $J$ per each pair of particles in the same quantum well), and
(ii) same for the motion in a periodic 1D potential, in the tight-binding limit.
8.23. For each of the Hamiltonians composed in the previous problem, derive the Heisenberg equations of motion for particle creation operators, for (i) bosons, and (ii) fermions.
8.24. Express the ket-vectors all possible Dirac states for the system of 3 indistinguishable
(i) bosons, and
(ii) fermions, via those of their single-particle states.
8.25. Explain why the Hartree-Fock approximation (118), applied to the ${ }^{4} \mathrm{He}$ atom, gives "correct" ${ }^{93}$ expression (31) for the ground singlet state, and correct Eqs. (44)-(45) (with the minus sign in the former relation) for the excited triplet state, but cannot describe result (44), with the plus sign, for the excited singlet state.
8.26. Find a time-independent Hamiltonian that may cause the qubit evolution described by Eq. (147). Discuss the result and its relation to the time-dependent Hamiltonian (6.86).

[^748]
## Chapter 9. Introduction to Relativistic Quantum Mechanics

This chapter gives a brief introduction to relativistic quantum mechanics. It starts with a discussion of the basic elements of the quantum theory of electromagnetic field (quantum electrodynamics, $Q E D$ ), including the quantization scheme, photon statistics, radiative atomic transitions, the spontaneous and stimulated radiation, and the so-called cavity $Q E D$. Then I will briefly review the relativistic quantum theory of particles with nonvanishing rest mass, notably Dirac' theory of spin- $1 / 2$ particles, and mark the point of entry into the most complete relativistic quantum theory - the quantum field theory, QFT which is beyond the scope of these notes. ${ }^{1}$

### 9.1. Electromagnetic field quantization

Classical mechanics tells us ${ }^{2}$ that the relativistic relation between momentum $\mathbf{p}$ and energy $E$ of a free particle with rest mass $m$ may be simplified in two limits, non-relativistic and ultra-relativistic: relativistic energy

$$
E=\left[(p c)^{2}+\left(m c^{2}\right)^{2}\right]^{1 / 2} \rightarrow \begin{cases}m c^{2}+p^{2} / 2 m, & \text { for } p \ll m c  \tag{9.1}\\ p c, & \text { for } p \gg m c\end{cases}
$$

In both limits, the transfer from classical to quantum mechanics is easier than in the arbitrary case. Since all the previous part of this course was committed to the first, non-relativistic limit, I will now jump to a brief discussion of the ultra-relativistic limit $p \gg m c$, for a particular but very important system - the electromagnetic field. Since the excitations of this field, called photons, are currently believed to have zero rest mass $m,{ }^{3}$ the ultra-relativistic limit is valid for any photon energy $E$, and the quantization scheme is rather straightforward.

As usual, the quantization has to be based on the classical theory of the system, in this case the Maxwell equations. As the simplest case, let us consider electromagnetic field in a free-space volume limited by ideal walls that reflect incident waves perfectly. ${ }^{4}$ Inside the volume, the Maxwell equations may be reduced to a simple wave equation ${ }^{5}$ for electric field

$$
\begin{equation*}
\nabla^{2} \varepsilon-\frac{1}{c^{2}} \frac{\partial^{2} \varepsilon}{\partial t^{2}}=0 \tag{9.2}
\end{equation*}
$$

and an absolutely similar equation for magnetic field $\mathcal{B}$. We may look for the general solution of Eq. (2) in the variable-separating form

[^749]\[

$$
\begin{equation*}
\varepsilon(\mathbf{r}, t)=\sum_{j} p_{j}(t) \mathbf{e}_{j}(\mathbf{r}) . \tag{9.3}
\end{equation*}
$$

\]

Physically, each term of this sum is a standing wave whose spatial distribution and polarization ("mode") is described by vector function $\mathbf{e}_{j}(\mathbf{r})$, and the temporal dynamics, by function $p_{j}(t)$. Plugging an arbitrary term of this sum into Eq. (2), and separating variables exactly as we did, e.g., for the Schrödinger equation in Sec. 1.4, we get

$$
\begin{equation*}
\frac{\nabla^{2} \mathbf{e}_{j}}{\mathbf{e}_{j}}=\frac{1}{c^{2}} \frac{\ddot{p}_{j}}{p_{j}}=\text { const } \equiv-k_{j}^{2}, \tag{9.4}
\end{equation*}
$$

so that the spatial distribution of the mode satisfies the $3 D$ Helmholtz equation:

$$
\begin{equation*}
\nabla^{2} \mathbf{e}_{j}+k_{j}^{2} \mathbf{e}_{j}=0 \tag{9.5}
\end{equation*}
$$

Equation
for spatial distribution

The set of solutions of this equation, with appropriate boundary conditions, determines the set of functions $\mathbf{e}_{j}$ and simultaneously the spectrum of wave number moduli $k_{j}$. The latter values determine mode eigenfrequencies, following from Eq. (4):

$$
\begin{equation*}
\ddot{p}_{j}+\omega_{j}^{2} p_{j}=0, \quad \text { with } \omega_{j} \equiv k_{j} c . \tag{9.6}
\end{equation*}
$$

There is a big philosophical difference between the approaches to equations (5) and (6), despite their single origin (4). The first (Helmholtz) equation may be rather difficult to solve in realistic geometries, ${ }^{6}$ but it remains intact in quantum theory, with the scalar components of vector functions $\mathbf{e}_{j}(\mathbf{r})$ still treated (at each point $\mathbf{r}$ ) as $c$-numbers. In contrast, Eq. (6) is readily solvable (giving sinusoidal oscillations with frequency $\omega_{j}$ ), but this is exactly where we can make a transfer to quantum mechanics, because we already know how to quantize a mechanical 1D harmonic oscillator that obeys, in classics, the same equation.

As usual, we need to start with the appropriate Hamiltonian corresponding to the classical Hamiltonian function $H$ of the proper set of generalized coordinates and momenta. The electromagnetic field's Hamiltonian function (that in this case coincides with field's energy) is ${ }^{7}$

$$
\begin{equation*}
H=\int d^{3} r\left(\frac{\varepsilon_{0} \varepsilon^{2}}{2}+\frac{\mathcal{B}^{2}}{2 \mu_{0}}\right) \tag{9.7}
\end{equation*}
$$

Let us represent the magnetic field in a form similar to Eq. (3),

$$
\begin{equation*}
\mathcal{B}(\mathbf{r}, t)=-\sum_{j} \omega_{j} q_{j}(t) \mathbf{b}_{j}(\mathbf{r}) . \tag{9.8}
\end{equation*}
$$

Since, according to the Maxwell equations, in our case the magnetic field satisfies the equation similar to Eq. (2), the time-dependent amplitude $q_{j}$ of each of its modes obey the equation similar to Eq. (6), i.e. also changes in time sinusoidally, with the same frequency $\omega_{j}$. Plugging Eqs. (3) and (8) into Eq. (7), we may recast it as

[^750]\[

$$
\begin{equation*}
H=\sum_{j} \frac{p_{j}^{2}}{2} \int \varepsilon_{0} e_{j}^{2}(\mathbf{r}) d^{3} r+\frac{\omega_{j}^{2} q_{j}^{2}}{2} \int \frac{1}{\mu_{0}} b_{j}^{2}(\mathbf{r}) d^{3} r \tag{9.9}
\end{equation*}
$$

\]

Since the distribution of constant factors between two multiplication operands in each term of Eq. (3) is arbitrary, we may fix it by requiring the first integral in Eq. (9) to equal 1. It is straightforward to check that according to the Maxwell equations, which give a specific relation between vectors $\varepsilon$ and $\mathcal{B}, 8$ this normalization makes the second integral in Eq. (9) equal 1 as well, and Eq. (9) becomes

$$
\begin{equation*}
H=\sum_{j} H_{j}, \quad H_{j}=\frac{p_{j}^{2}}{2}+\frac{\omega_{j}^{2} q_{j}^{2}}{2} \tag{9.10}
\end{equation*}
$$

Now we can carry out the standard quantization procedure, namely declare $H_{j}, p_{j}$, and $q_{j}$ the quantum-mechanical operators related exactly as in Eq. (10),

Electromagnetic mode's Hamiltonian

$$
\begin{equation*}
\hat{H}_{j}=\frac{\hat{p}_{j}^{2}}{2}+\frac{\omega_{j}^{2} \hat{q}_{j}^{2}}{2} \tag{9.11}
\end{equation*}
$$

we see that this Hamiltonian coincides with that of a 1 D harmonic oscillator with the mass $m_{j}$ formally equal to $1,{ }^{9}$ and the eigenfrequency equal to $\omega_{j}$. Now, in order to plug Eq. (11) into Eq. (4.199) for the time evolution of Heisenberg-picture operators $\hat{p}_{j}$ and $\hat{q}_{j}$, we need to know the commutation relation between these operators. For that, returning to the classical case, let us calculate the Poisson bracket (4.204) for "functions" $A=q_{j}$, and $B=p_{j}$ ":

$$
\begin{equation*}
\left\{q_{j^{\prime}}, p_{j^{\prime \prime}}\right\} \equiv \sum_{j}\left(\frac{\partial q_{j^{\prime}}}{\partial p_{j}} \frac{\partial p_{j^{\prime \prime}}}{\partial q_{j}}-\frac{\partial q_{j^{\prime}}}{\partial q_{j}} \frac{\partial p_{j^{\prime \prime}}}{\partial p_{j}}\right) . \tag{9.12a}
\end{equation*}
$$

Since in the classical Hamiltonian mechanics, all generalized coordinates $q_{j}$ and momenta $p_{j}$ have to be considered independent arguments of $H$, only one term (with $j=j^{\prime}=j^{\prime \prime}$ ) in only one sum (12) (with $j^{\prime}=$ $j$ '), gives a nonvanishing value ( -1 ), so that

$$
\begin{equation*}
\left\{q_{j^{\prime}}, p_{j^{\prime \prime}}\right\}=-\delta_{j j^{\prime \prime}} \tag{9.12b}
\end{equation*}
$$

Hence, according to the general quantization rule (4.205), the commutation relation of the operators corresponding to $q_{j^{\prime}}$ and $p_{j^{\prime \prime}}$ is

$$
\begin{equation*}
\left[\hat{q}_{j^{\prime}}, \hat{p}_{j^{\prime \prime}}\right]=i \hbar \delta_{j j^{\prime \prime}} \tag{9.13}
\end{equation*}
$$

i.e. is exactly the same as for the usual Cartesian components of the radius-vector and momentum of a mechanical particle.

As the reader already knows, Eqs. (11) and (13) open for us several alternative ways to proceed:

[^751](i) Use the Schrödinger-picture wave mechanics based on wavefunctions $\Psi_{j}\left(q_{j}, t\right)$. As we know from Sec. 2.10, this way is inconvenient for most tasks, because eigenfunctions of the harmonic oscillator are rather clumsy.
(ii) A substantially better way is to write the equations of time evolution of the Heisenbergpicture operators $\hat{q}_{j}(t)$ and $\hat{p}_{j}(t)$.
(iii) An even more convenient approach is to use equations similar to Eqs. (5.99) to decompose operators $\hat{q}_{j}(t)$ and $\hat{p}_{j}(t)$ into the creation-annihilation operators $\hat{a}_{j}^{\dagger}$ and $\hat{a}_{j}$, and work with these operators using either the Schrödinger or the Heisenberg picture, depending on the problem.

I will mostly use the last route. Replacing $m$ with $m_{j} \equiv 1$, and $\omega_{0}$ with $\omega_{j}$, the last forms of Eqs. (5.98) become

$$
\begin{equation*}
\hat{a}_{j}=\left(\frac{\omega_{j}}{2 \hbar}\right)^{1 / 2}\left(\hat{q}_{j}+i \frac{\hat{p}_{j}}{\omega_{j}}\right), \quad \hat{a}_{j}^{\dagger}=\left(\frac{\omega_{j}}{2 \hbar}\right)^{1 / 2}\left(\hat{q}_{j}-i \frac{\hat{p}_{j}}{\omega_{j}}\right) \tag{9.14}
\end{equation*}
$$

and due to Eq. (13), the creation-annihilation operators obey the commutation similar to Eq.(5.101),

$$
\begin{equation*}
\left[\hat{a}_{j}, \hat{a}_{j^{\prime}}^{\dagger}\right]=\hat{I} \delta_{j j^{\prime}} \tag{9.15}
\end{equation*}
$$

so that, according to Eqs. (3) and (8), the quantum-mechanical operators corresponding to the electric and magnetic fields are

$$
\begin{align*}
& \hat{\boldsymbol{\varepsilon}}(\mathbf{r}, t)=i \sum_{j}\left(\frac{\hbar \omega_{j}}{2}\right)^{1 / 2} \mathbf{e}_{j}(\mathbf{r})\left(\hat{a}_{j}^{\dagger}-\hat{a}_{j}\right),  \tag{9.16a}\\
& \hat{\mathcal{B}}(\mathbf{r}, t)=\sum_{j}\left(\frac{\hbar \omega_{j}}{2}\right)^{1 / 2} \mathbf{b}_{j}(\mathbf{r})\left(\hat{a}_{j}^{\dagger}+\hat{a}_{j}\right), \tag{9.16b}
\end{align*}
$$

and Eq. (11) for $j^{\text {th }}$ mode's Hamiltonian becomes

$$
\begin{equation*}
\hat{H}_{j}=\hbar \omega_{j}\left(\hat{a}_{j}^{\dagger} \hat{a}_{j}+\frac{1}{2} \hat{I}\right)=\hbar \omega_{j}\left(\hat{n}_{j}+\frac{1}{2} \hat{I}\right), \quad \text { with } \hat{n}_{j} \equiv \hat{a}_{j}^{\dagger} \hat{a}_{j}, \tag{9.17}
\end{equation*}
$$

absolutely similar to Eq. (5.505) for a mechanical oscillator.
Now comes a very important conceptual step. From Sec. 5.4 we know that eigenstates (Fock states $n_{j}$ ) of Hamiltonian (17) have energies

$$
\begin{equation*}
E_{j}=\hbar \omega_{j}\left(n_{j}+\frac{1}{2}\right), \quad n_{j}=0,1,2, \ldots \tag{9.18}
\end{equation*}
$$

Electromagnetic mode's energies
and, according to Eq. (5.115), operators $\hat{a}_{j}^{\dagger}$ and $\hat{a}_{j}$ act on the eigenkets of these states as

$$
\begin{equation*}
\hat{a}_{j}\left|n_{j}\right\rangle=\left(n_{j}\right)^{1 / 2}\left|n_{j}-1\right\rangle, \quad \hat{a}_{j}^{\dagger}\left|n_{j}\right\rangle=\left(n_{j}+1\right)^{1 / 2}\left|n_{j}+1\right\rangle, \tag{9.19}
\end{equation*}
$$

regardless of the quantum states of other modes (frequently called field oscillators). These rules coincide with definitions (8.56) and (8.60) of bosonic creation-annihilation operators, and hence their action may be considered as the creation/annihilation of certain bosons. Such a "particle" (actually, an excitation of an electromagnetic field oscillator) is exactly what is, strictly speaking, called a photon. Note immediately that according to Eq. (16), such an excitation does not change the spatial distribution of the $j^{\text {th }}$ mode of the field. So, such a "global" photon is an excitation created simultaneously at all points of the field confinement region.

If this picture is too contrary to the intuitive image of a particle, please recall that we had a similar situation in Chapter 2 with eigenstates of the non-relativistic Schrödinger equation: the represented a standing de Broglie wave existing simultaneously in all points of the particle confinement region. The (partial :-) reconciliation with the classical picture of a moving particle might be obtained by using the linear superposition principle to assemble a quasi-localized wave packet of sinusoidal waves, with close wave numbers. Very similarly, we may form a quasi-localized wave packet using a linear superposition of the "global" photons with close values of $k_{j}\left(\right.$ and hence $\left.\omega_{j}\right)$. An additional simplification here is that since the dispersion relation for electromagnetic waves is linear:

$$
\begin{equation*}
\frac{\partial \omega_{j}}{\partial k_{j}}=c=\text { const, i.e. } \frac{\partial^{2} \omega_{j}}{\partial k_{j}^{2}}=0 \tag{9.20}
\end{equation*}
$$

so that, according to Eq. (2.39a), the electromagnetic wave packets (localized photons) do not spread out during their propagation.

The next important conceptual issue is that of the ground-state energy. Equation (18) implies that the total ground-state (i.e., the lowest) energy of the field is

Ground-
state energy of the field

$$
\begin{equation*}
E_{g}=\sum_{j}\left(E_{g}\right)_{j}=\sum_{j} \frac{\hbar \omega_{j}}{2} \tag{9.21}
\end{equation*}
$$

This sum diverges at high frequencies for any realistic any realistic model of the field-confining volume - either infinite or not. Any attempt to dismiss this paradox by declaring the zero-point energy unobservable and hence non-existing fails due to several experimental facts.

First of all, the ground-state "fluctuations" (sometimes called "quantum noise") can be directly observed - see Sec. 7.5 and in particular the literature cited therein. Second, there is the Casimir effect. ${ }^{10}$ The simplest manifestation of the effect involves two parallel plates separated by a vacuum gap of thickness $d \ll A^{1 / 2}$, where $A$ is the plate area (Fig. 1). Rather counter-intuitively, the plates attract each other with a force proportional to area $A$, and rapidly increasing at the decrease of gap $d$.

Fig. 9.1. Generic geometry of the Casimir effect manifestation.

[^752]The effect's explanation is that the energy of each the electromagnetic field mode, including the ground-state energy, is intimately related with the average pressure,

$$
\begin{equation*}
\left\langle P_{j}\right\rangle=-\frac{\partial E_{j}}{\partial V} \tag{9.22}
\end{equation*}
$$

exerted by the field on the walls constraining it to volume $V$. While its pressure on the external surfaces on the plates is due to sum (21) over all free-space modes, with arbitrary values of $k_{z}$ (the $z$-component of the wave vector $\mathbf{k}_{j}$ ), between the plates the spectrum of $k_{z}$ is limited to multiples of $\pi / d$, so that the pressure on the internal surfaces is lower. The net pressure may be found as the sum of contributions (22) from all "missing" low-frequency modes in the gap. The calculations are rather simple if the plates are made of an ideal conductor (which provides boundary conditions $E_{n}=0$ and $B_{\tau}=0$ on the plate surfaces), and the result is ${ }^{11}$

$$
\begin{equation*}
\langle P\rangle=\sum_{j}\left\langle P_{j}\right\rangle=-\frac{\pi^{2} \hbar c}{240 d^{4}} . \tag{9.23}
\end{equation*}
$$

[^753]Note that for this summation, the high-frequency divergence of Eq. (21) at high frequencies is not important, because it participates in the forces exerted on all surfaces of each plate, and hence cancels out from the net pressure. In this way, the Casimir effect not only gives a confirmation of Eq. (21), but also teaches us an important lesson how to deal with the divergence of this sum at $\omega_{j} \rightarrow \infty$ : just get accustomed to the idea that the divergence exists and ignore the fact while you can. However, for more complex tasks of quantum electrodynamics (and quantum theory of any other field) this approach becomes impossible, and then more complex, renormalization techniques become necessary. For their study, I have to refer the reader to a quantum field theory course - see the literature cited in the end of this chapter.

### 9.2. Photon statistics

As a matter of principle, the Casimir effect may be used to measure not only the free-space electromagnetic field, but also that arriving from local sources - lasers, etc. However, usually this is done by simpler detectors in which the absorption of a photon by a single atom leads to its ionization. This ionization, i.e. emission of a free electron, triggers a chain reaction (i.e., an electric discharge in a Geiger-type counter) that may readily be registered by appropriate electronic circuitry. In order to discuss the statistics of such photon counts, it is sufficient to consider the field interaction with just one,

[^754]"trigger" atom. The atom's size $a$ is typically much smaller that the radiation wave length $\lambda_{j}=2 \pi / k_{j}$, so that their interaction is adequately described in the electric dipole approximation,
\[

$$
\begin{equation*}
\hat{H}_{\mathrm{int}}=-\hat{\boldsymbol{\varepsilon}} \cdot \hat{\mathbf{d}}, \tag{9.24}
\end{equation*}
$$

\]

where $\hat{\mathbf{d}}$ is the dipole moment's operator. ${ }^{12}$ In Sec. 6.5 we have already developed an approach suitable for the analysis of this problem, based on the Golden Rule - see Fig. 6.14 and Eq. (6.152). ${ }^{13}$ In our current case, we may associate system $b$ with the "trigger atom" (whose ionized states form a continuum spectrum), and hence operator $\hat{\mathbf{d}}$ in Eq. (24) with operand $\hat{B}$ in Eq. (6.148), while the electromagnetic field is represented by system $a$, and its electric field operator $\hat{\varepsilon}$ is associated with operand $\hat{A}$ in that relation. Let us assume, for simplicity, that our field consists of only one mode $\mathbf{e}_{j}(\mathbf{r}) .{ }^{14}$ Then we can keep only one term in Eq. (16a), and drop index $j$, so that Eq. (6.152), for the transition from certain initial state ini to a final state fin may be rewritten as

$$
\begin{align*}
\Gamma & \left.=\frac{2 \pi}{\hbar}|\langle f i n| \hat{\varepsilon}(\mathbf{r}, t)| i n i\right\rangle\left.\right|^{2} \mid\left.\langle\text { fin }| \hat{\mathbf{d}} \cdot \mathbf{n}_{e}|i n i\rangle\right|^{2} \rho_{f} \\
& \left.=\frac{2 \pi}{\hbar} \frac{\hbar \omega}{2}\left|\langle f i n|\left(\hat{a}^{\dagger}-\hat{a}\right) e(\mathbf{r})\right| i n i\right\rangle\left.\right|^{2} \mid\left.\langle\text { fin }| \mathbf{r} \cdot \mathbf{n}_{e}|i n i\rangle\right|^{2} \rho_{f}, \tag{9.25}
\end{align*}
$$

where $e(\mathbf{r})$ is the local magnitude of vector $\mathbf{e}(\mathbf{r})$, and $\mathbf{n}_{\mathrm{e}} \equiv \mathbf{e}(\mathbf{r}) / e(\mathbf{r})$ is its local direction. ${ }^{15}$ As a reminder, in the Heisenberg picture of quantum mechanics, the initial and final states are time-independent, while the creation-annihilation operators are functions of time. In this Golden Rule formula, as in any perturbation result, this time dependence has to be calculated ignoring the perturbation - in this case the field-atom interaction. For the field's creation-annihilation operators, this dependence coincides with that of the usual 1D oscillator - see Eq. (5.171), in which $\omega_{0}$ should be now replaced with $\omega$ :

$$
\begin{equation*}
\hat{a}(t)=\hat{a}(0) e^{-i \omega t}, \quad \hat{a}^{\dagger}(t)=\hat{a}^{\dagger}(0) e^{+i \omega t} \tag{9.26}
\end{equation*}
$$

Hence Eq. (9.25) becomes

$$
\begin{equation*}
\left.\left.\Gamma=\pi \omega\left|\langle f i n|\left(\hat{a}^{\dagger}(0) e^{i \omega t}-\hat{a}(0) e^{-i \omega t}\right) e(\mathbf{r})\right| i n i\right\rangle\left.\right|^{2}\left|\langle f i n| \hat{\mathbf{d}}(t) \cdot \mathbf{n}_{e}\right| i n i\right\rangle\left.\right|^{2} \rho_{f i n} . \tag{9.27a}
\end{equation*}
$$

Now let us multiply the first bra-ket by $\exp \{i \omega t\}$, and the second one by $\exp \{-i \omega t\}$ :

[^755]\[

$$
\begin{equation*}
\left.\Gamma=\pi \omega\left|\left\langle f i n\left(\hat{a}^{\dagger}(0) e^{2 i \omega t}-\hat{a}(0)\right) e(\mathbf{r}) \mid i n i\right\rangle\right|^{2}\left|\langle f i n| \hat{\mathbf{d}}(t) \cdot \mathbf{n}_{e} e^{-i \omega t}\right| i n i\right\rangle\left.\right|^{2} \rho_{f i n} . \tag{9.27b}
\end{equation*}
$$

\]

The physical sense of this, mathematically trivial, operation is that at resonant photon absorption, only the annihilation operator gives a significant time-averaged contribution to the first bra-ket matrix element. (Similarly, according to Eq. (4.199), the Heisenberg operator of the dipole moment, corresponding to the increase of atom's energy, has only the Fourier components that differ from $\omega$ only by $\sim \Gamma \ll \omega$, so that its time dependence compensates the additional factor in the second bra-ket of Eq. (27b), so that this bra-ket is also frequency-independent and has a substantial time average.) Hence, we can neglect the fast-evolving term in the first bra-ket whose average over time interval $\sim 1 / \Gamma$ is very close to zero. ${ }^{16}$

Now let us assume that we use the same detector, characterized by the same second bra-ket and the same state density $\rho_{\text {fin }}$, for measurement of various electromagnetic fields - or just the same field at different points $\mathbf{r}$. Then we are only interested in the behavior of the first, field-related factor, and may write

$$
\begin{equation*}
\left.\Gamma \propto|\langle f i n| \hat{a} e(\mathbf{r})| i n i\rangle\left.\right|^{2}=\langle f i n| \hat{a} e(\mathbf{r})|i n i\rangle\langle f i n| \hat{a} e(\mathbf{r})|i n i\rangle^{*}=\langle i n i| \hat{a}^{\dagger} e^{*}(\mathbf{r}) \mid \text { fin }\right\rangle\langle\text { fin }| \hat{a} e(\mathbf{r})|i n i\rangle, \tag{9.28}
\end{equation*}
$$

where the creation-annihilation operators are assumed to be taken in the initial moment (i.e., in the Schrödinger picture), and the initial and final states are those of the field alone. As we know, any 1D harmonic oscillator (and hence the electromagnetic field oscillator) has many equidistant levels, so even if it initially was in a certain state, it may undergo be several coherent transitions to different final Fock states. If we want to calculate the total rate, we may sum the transition rates into all final states. Then, since these states form a full and orthonormal set, we may use the closure condition (4.44) to get

$$
\begin{equation*}
\left.\left.\Gamma \propto \sum_{f i n}\langle i n i| \hat{a}^{\dagger} e^{*}(\mathbf{r})|f i n\rangle\langle\text { fin }| \hat{a} e(\mathbf{r}) \mid \text { ini }\right\rangle=\langle\text { ini }| \hat{a}^{\dagger} \hat{a} \mid \text { ini }\right\rangle e^{*}(\mathbf{r}) e(\mathbf{r})=\langle n\rangle_{\text {ini }}|e(\mathbf{r})|^{2} \tag{9.29}
\end{equation*}
$$

Let us apply this formula to several possible quantum states of the field mode.
(i) First, as a sanity check, the ground initial state $(n=0)$ gives no photon counts at all. The interpretation is easy: the ground state cannot emit a photon that would trigger an atom in the counter. Again, this does not mean that the ground-state motion is not observable (if you still think so, please review the Casimir effect discussion in the last section), just that it cannot ionize an atom in the detector - because it does not have any spare energy for doing that.
(ii) All other coherent states (Fock, Glauber, squeezed, etc.) of the field oscillator give the same counting rate, provided that their $\langle n\rangle$ is the same. This result may be less evident if we apply Eq. (29) to an interference of two light beams from the same source (say, in the double-slit or the Bragg-scattering configurations). In this case we may present the spatial distribution of the field as a sum

$$
\begin{equation*}
e(\mathbf{r})=e_{1}(\mathbf{r})+e_{2}(\mathbf{r}) . \tag{9.30}
\end{equation*}
$$

Here each term describes one possible wave path, so that the field product in Eq. (29) may be a rapidly changing function of the detector position. For this configuration, our result (29) means that the

[^756]interference pattern (and its contrast) are independent of the particular state of the electromagnetic field's mode.
(iii) Surprisingly, the last statement is also valid for a classical mixture of the different eigenstates of the same field mode, for example for its thermal-equilibrium state. Indeed, in this case we need to average Eq. (29) over the corresponding classical ensemble, but it would only result in a different meaning of averaging $n$ in that equation; the field part describing the interference pattern is not affected.

The last result may look a bit counter-intuitive, because common sense tells us that the stochasticity associated with thermal equilibrium has to suppress the interference pattern contrast. These expectations are (partly :-) justified, because a typical thermal source of radiation produces many field modes $j$, rather than one mode we have analyzed. These modes may have different wave numbers $k_{j}$ and hence different field distribution functions $\mathbf{e}_{j}(\mathbf{r})$, resulting in shifted interference patterns. Their summation would indeed smear the interference, suppressing its contrast.

So the use of a single photon detector is not a suitable way to distinguish different quantum states of an electromagnetic field modes. This task, however, may be achieved using the photon counting correlation technique shown in Fig. 2. ${ }^{17}$

Fig. 9.2. Photon count correlation measurement.

In this experiment, the counter rate correlation may be characterized by the so-called secondorder correlation function ${ }^{18}$ of the counting rates,
 function: definition

$$
\begin{equation*}
g^{(2)}(\tau) \equiv \frac{\left\langle\Gamma_{1}(t) \Gamma_{2}(t-\tau)\right\rangle}{\left\langle\Gamma_{1}(t)\right\rangle\left\langle\Gamma_{2}(t)\right\rangle} \tag{9.31}
\end{equation*}
$$

[^757]where the averaging may be carried out either over many similar experiments, or over time $t$, due to the ergodicity of the experiment (with a stationary light source). Using the normalized correlation function (31) is very convenient, because characteristics of the detectors and beam splitter drop our from this fraction.

Very unexpectedly for the mid-1950s, Hanbury Brown and Twiss discovered that the correlation function depends on time delay $\tau$ in the way shown schematically by the solid line in Fig. 3. It is evident from Eq. (31) that if the counting events are completely independent, $g^{(2)}(\tau)$ should be equal 1 - which is always the case in the limit $\tau \rightarrow \infty$. Hence, the observed behavior at $\tau \rightarrow 0$ corresponds to the positive correlation of detector counts at small time delays, i.e. to a higher probability of the nearly-simultaneous arrival of photons to both counters. This effect is called the photon bunching.

Fig. 9.3. Photon bunching (solid line) and antibunching for various $n$ (dashed lines). The lines approach level $g^{(2)}=1$ at $\tau \rightarrow \infty$ (on the time scale depending on the light source).

Let us use our simple single-mode model to analyze this experiment. Now the elementary quantum process, characterized by the numerator of Eq. (31), is the correlated triggering of two counters, at two spatial-temporal points $\left\{\mathbf{r}_{1}, t\right\}$ and $\left(\mathbf{r}_{2}, t-\tau\right\}$, by the same field mode, so that we need to make the following replacement, in the first of Eqs. (25):

$$
\begin{equation*}
\hat{\mathcal{E}}(\mathbf{r}, t) \rightarrow \text { const } \times \hat{\mathcal{E}}\left(\mathbf{r}_{1}, t\right) \hat{\mathcal{E}}\left(\mathbf{r}_{2}, t-\tau\right) . \tag{9.32}
\end{equation*}
$$

Repeating all the manipulations done in the single-counter case, we get

$$
\begin{equation*}
\left\langle\Gamma_{1}(t) \Gamma_{2}(t-\tau)\right\rangle \propto\langle i n i| \hat{a}(t)^{\dagger} \hat{a}(t-\tau)^{\dagger} \hat{a}(t-\tau) \hat{a}(t)|i n i\rangle e^{*}\left(\mathbf{r}_{1}\right) e^{*}\left(\mathbf{r}_{2}\right) e\left(\mathbf{r}_{1}\right) e\left(\mathbf{r}_{2}\right) . \tag{9.33}
\end{equation*}
$$

Plugging this expression, as well as Eq. (29) for single-counter rates, into Eq. (31), we see that the field distribution factors (as well as the detector-specific bra-kets and the density of states $\rho_{\text {fin }}$ ) cancel, giving a very simple final expression

$$
\begin{equation*}
g^{(2)}(\tau)=\frac{\left\langle\hat{a}^{\dagger}(t) \hat{a}^{\dagger}(t-\tau) \hat{a}(t-\tau) \hat{a}(t)\right\rangle}{\left\langle\hat{a}^{\dagger}(t) \hat{a}(t)\right\rangle^{2}} \tag{9.34}
\end{equation*}
$$

where the averaging should be carried out, as before, over the initial state of the field. Still, the calculation of this expression for arbitrary $\tau$ may be quite complex, because the relaxation of the correlation function to the asymptotic value $\mathrm{g}^{(2)}(\infty)$ in many cases is due to the interaction of the light source with environment, and hence requires the open-system techniques which were discussed in Chapter 7. However, the zero-delay value $g^{(2)}(0)$ may be calculated in a straightforward way, because the time arguments of all operators are equal, so that we may write

$$
\begin{equation*}
g^{(2)}(0)=\frac{\left\langle\hat{a}^{\dagger} \hat{a}^{\dagger} \hat{a} \hat{a}\right\rangle}{\left\langle\hat{a}^{\dagger} \hat{a}\right\rangle^{2}} \tag{9.35}
\end{equation*}
$$

Let us evaluate this ratio for the simplest states of the field. (Remember, we are working in the Schrödinger picture now.)
(i) $n^{\text {th }}$ Fock state. In this case, it is convenient to act by the annihilation operators upon the ketvectors, and by the creation operators, upon the bra-vectors, using Eq. (19):

Photon
anti-
bunching

$$
\begin{equation*}
g^{(2)}(0)=\frac{\langle n| \hat{a}^{\dagger} \hat{a}^{\dagger} \hat{a} \hat{a}|n\rangle}{\langle n| \hat{a}^{\dagger} \hat{a}|n\rangle^{2}}=\frac{\langle n-2|[n(n-1)]^{1 / 2}[n(n-1)]^{1 / 2}|n-2\rangle}{\langle n-1| n^{1 / 2} n^{1 / 2}|n-1\rangle^{2}}=\frac{n(n-1)}{n^{2}}=1-\frac{1}{n} . \tag{9.36}
\end{equation*}
$$

We see that the correlation function at small delays is suppressed rather than enhanced - see the dashed line in Fig. 3. This photon antibunching effect has a very simple explanation: a single photon emitted by the wave source may be absorbed by just one of the detectors. For the initial state $n=1$, this is the only option, and it is very natural that Eq. (36) predicts no simultaneous counts at $\tau=0$. Despite this theoretical simplicity, reliable observations of the antibunching have not been carried out until 1977, ${ }^{19}$ due to the experimental difficulty of creating Fock states of electromagnetic field oscillators - see Sec. 4 below.
(ii) The Glauber state $\alpha$. A similar procedure, but now using Eq. (5.155) and its Hermitian conjugate, $\langle\alpha| \hat{a}^{\dagger}=\langle\alpha| \alpha^{*}$, yields

Glauber
field statistics

$$
\begin{equation*}
g^{(2)}(0)=\frac{\langle\alpha| \hat{a}^{\dagger} \hat{a}^{\dagger} \hat{a} \hat{a}|\alpha\rangle}{\langle\alpha| \hat{a}^{\dagger} \hat{a}|\alpha\rangle^{2}}=\frac{\alpha^{*} \alpha^{*} \alpha \alpha}{\left(\alpha^{*} \alpha\right)^{2}}=1, \tag{9.37}
\end{equation*}
$$

for any parameter $\alpha$. We see that the result is very different result from the Fock states, unless in the latter case $n \rightarrow \infty$. (We know that the Fock and Glauber properties should also coincide for the ground state, but at that state the correlation function's value is uncertain, because there are no photon counts at all.)
(iii) Classical mixture. From Chapter 7, we know that such ensembles cannot be described by single state vectors, and require the density matrix $w$ for their description. In particular, we can use the key Eq. (7.5) to write

$$
\begin{equation*}
g^{(2)}(0)=\frac{\operatorname{Tr}\left(\hat{w} \hat{a}^{\dagger} \hat{a}^{\dagger} \hat{a} \hat{a}\right)}{\left[\operatorname{Tr}\left(\hat{w} \hat{a}^{\dagger} \hat{a}\right)\right]^{2}} . \tag{9.38}
\end{equation*}
$$

The calculation is easy for an ensemble in thermodynamic equilibrium, because here the density matrix is diagonal in the basis of Fock states $n$-see Eqs. (7.23)-(7.25):

[^758]\[

$$
\begin{equation*}
w_{n n^{\prime}}=W_{n} \delta_{n n^{\prime}}, \quad W_{n}=\frac{1}{Z} \exp \left\{-\frac{E_{n}}{k_{\mathrm{B}} T}\right\}=\frac{\lambda^{n}}{\sum_{n=0}^{\infty} \lambda^{n}}, \quad \text { where } \lambda \equiv \exp \left\{-\frac{\hbar \omega}{k_{\mathrm{B}} T}\right\} . \tag{9.39}
\end{equation*}
$$

\]

So, for the operators in the numerator and denominator of Eq. (38) we also need just the diagonal terms of the operator products that have already been calculated - see Eq. (36). As a result, we get

$$
\begin{equation*}
g^{(2)}(0)=\frac{\sum_{n=0}^{\infty} W_{n} n(n-1)}{\left(\sum_{n=0}^{\infty} W_{n} n\right)^{2}}=\frac{\sum_{n=0}^{\infty} \lambda^{n} n(n-1) \times \sum_{n=0}^{\infty} \lambda^{n}}{\left(\sum_{n=0}^{\infty} \lambda^{n} n\right)^{2}} . \tag{9.40}
\end{equation*}
$$

One of these sums is just the geometric progression,

$$
\begin{equation*}
\sum_{n=0}^{\infty} \lambda^{n}=\frac{1}{1-\lambda}, \tag{9.41}
\end{equation*}
$$

and the remaining two sums may be readily calculated by its differentiation over parameter $\lambda$ :

$$
\begin{align*}
& \sum_{n=0}^{\infty} \lambda^{n} n=\lambda \sum_{n=0}^{\infty} \lambda^{n-1} n=\lambda \frac{d}{d \lambda} \sum_{n=0}^{\infty} \lambda^{n}=\lambda \frac{d}{d \lambda} \frac{1}{1-\lambda}=\frac{\lambda}{(1-\lambda)^{2}}, \\
& \sum_{n=0}^{\infty} \lambda^{n} n(n-1)=\lambda^{2} \sum_{n=0}^{\infty} \lambda^{n-2} n(n-1)=\lambda^{2} \frac{d^{2}}{d^{2} \lambda}\left(\sum_{n=0}^{\infty} \lambda^{n}\right)=\lambda^{2} \frac{d^{2}}{d \lambda^{2}} \frac{1}{1-\lambda}=\frac{2 \lambda^{2}}{(1-\lambda)^{3}}, \tag{9.42}
\end{align*}
$$

and for the correlation function we get an extremely simple result independent of parameter $\lambda$ and hence of temperature:

$$
\begin{equation*}
g^{(2)}(0)=\frac{\left[2 \lambda^{2} /(1-\lambda)^{3}\right][1 /(1-\lambda)]}{\left[\lambda /(1-\lambda)^{2}\right]^{2}}=2 \tag{9.43}
\end{equation*}
$$

Photon bunching

This is the exactly the photon bunching effect first observed by Hanbury Brown and Twiss (Fig. 3). We see that in contrast to antibunching, this is an essentially classical (statistical) effect. Indeed, Eq. (43) allows a purely classical proof. In the classical theory, the counting rate is proportional to the wave intensity $I$, so that Eq. (31) is reduced to

$$
\begin{equation*}
g^{(2)}(0)=\frac{\left\langle I^{2}\right\rangle}{\langle I\rangle^{2}}, \quad \text { with } I \propto \overline{E^{2}(t)} \propto E_{\omega} E_{\omega}^{*} \tag{9.44}
\end{equation*}
$$

For a sinusoidal field, the intensity is constant, and $g^{(2)}(0)=1$. (This is also evident from Eq. (37), because the classical state may be considered as the Glauber state with $\alpha \rightarrow \infty$.) On the other hand, if intensity fluctuates (either in time, or from one experiment to another), the averages should be calculated as

$$
\begin{equation*}
\left\langle I^{N}\right\rangle=\int_{0}^{\infty} w(I) I^{N} d I, \quad \text { with } \int_{0}^{\infty} w(I) d I=1 \tag{9.45}
\end{equation*}
$$

where $w(I)$ is the probability density. For the classical (Boltzmann) statistics, the probability is an exponential function of the electromagnetic field energy, and hence its intensity:

$$
\begin{equation*}
w(I)=C e^{-\beta I}, \quad \text { where } \beta \propto 1 / k_{\mathrm{B}} T \tag{9.46}
\end{equation*}
$$

so that Eqs. (48) yield:

$$
\begin{align*}
& \int_{0}^{\infty} C \exp \{-\beta I\} d I=1, \quad \text { so that } C=\beta  \tag{9.47}\\
& \left\langle I^{N}\right\rangle=\int_{0}^{\infty} w(I) I^{N} d I=C \int_{0}^{\infty} \exp \{-\beta I\} I^{N} d I=\frac{1}{\beta^{N}} \int_{0}^{\infty} \exp \{-\xi\} \xi^{N} d \xi= \begin{cases}1 / \beta, & \text { for } N=1, \\
2 / \beta^{2}, & \text { for } N=2 .\end{cases}
\end{align*}
$$

Plugging these results into Eq. (44), we get $g^{(2)}(0)=2$, in a complete agreement with Eq. (43). ${ }^{20}$

### 9.3. Spontaneous and stimulated emission

In our simple model for photon counting, considered in the last section, trigger atoms of the photon counter absorbed light. Now let us have a look at the opposite process of spontaneous emission of photons by an atom in an excited state, still using the same electric-dipole approximation for the atom-to-field interaction. We may still use the Golden Rule for the model depicted in Fig. 6.14, but now the roles have changed: we have to associate operator $\hat{A}$ with the electric dipole moment of the atom, while operator $\hat{B}$ with the electric field, and the continuous spectrum of system $b$ represents the plurality of the electromagnetic field modes into which the spontaneous radiation may happen. Since now the transition increases the energy of the electromagnetic field, after the multiplication of the field bra-ket by $\exp \{i \omega t\}$, we may keep only the photon creation operator whose time evolution compensates this fast "rotation". As a result, the Golden Rule takes the following form:

Spontaneous photon
pmission emission
rate

$$
\begin{equation*}
\Gamma_{s}=\pi \omega \mid\left.\langle\text { fin }| \hat{a}^{\dagger}|0\rangle\right|^{2} \mid\left.\langle\text { fin }| \hat{\mathbf{d}} \cdot \mathbf{e}(\mathbf{r})|i n i\rangle\right|^{2} \rho_{f i n} \tag{9.48}
\end{equation*}
$$

where all operators and states are time-independent, and $\rho_{\text {fin }}$ is now the density of final states of the electromagnetic field - which in this problem plays the role of atom's environment. Here the electromagnetic field has been assumed to be initially in the ground state - the assumption that will be altered later in this section.

Relation (48), together with Eq. (19), shows that in order for field's matrix element be different from zero, the final state of the field has to be the first excited Fock state, $n=1$. (By the way, this is exactly the most practicable way of generating an excited Fock state of a field oscillator field - whose existence was taken for granted in our discussion in Sec. 2.) With that, Eq. (48) yields

$$
\begin{equation*}
\left.\left.\Gamma_{s}=\pi \omega|\langle f i n| \hat{\mathbf{d}} \cdot \mathbf{e}(\mathbf{r})| i n i\right\rangle\left.\right|^{2} \rho_{\mathrm{fin}}=\pi \omega\left|\langle f i n| \hat{d} e_{d}(\mathbf{r})\right| i n i\right\rangle\left.\right|^{2} \rho_{f i n}, \tag{9.49}
\end{equation*}
$$

[^759]where the density $\rho_{\text {fin }}$ of excited electromagnetic field states should be calculated at energy $\hbar \omega$, and $e_{d}$ is the component of the vector $\mathbf{e}(\mathbf{r})$ along the electric dipole direction. ${ }^{21}$ For plane waves, the calculation of this density was our first step in this course - see Eq. (1.1). ${ }^{22}$ From it, we get
\[

$$
\begin{equation*}
\rho_{\mathrm{fin}} \equiv \frac{d N}{d E}=V \frac{8 \pi v^{2}}{c^{3}} \frac{d v}{d E}=V \frac{\omega^{2}}{\pi^{2} \hbar c^{3}} \tag{9.50}
\end{equation*}
$$

\]

where the bounding volume $V$ should be large enough to ensure spectrum's virtual continuity. Because of that, in the normalization condition used to simplify Eq. (9), we may consider $e^{2}(\mathbf{r})$ constant. Let us present the square of this vector as a sum of squares of its three perpendicular components (one of those, $e_{d}$, aligned with the dipole direction), due to space isotropy we may write

$$
\begin{equation*}
e^{2} \equiv e_{d}^{2}+e_{\perp 1}^{2}+e_{\perp 2}^{2}=3 e_{d}^{2} \tag{9.51}
\end{equation*}
$$

As a result, the normalization condition yields

$$
\begin{equation*}
e_{d}^{2}=\frac{1}{3 \varepsilon_{0} V} . \tag{9.52}
\end{equation*}
$$

and Eq. (49) gives the famous (and very important) formula ${ }^{23}$

$$
\begin{equation*}
\left.\Gamma_{s}=\frac{1}{4 \pi \varepsilon_{0}} \frac{4 \omega^{3}}{3 \hbar c^{3}}|\langle f i n| \hat{\mathbf{d}}| i n i\right\rangle\left.\right|^{2}=\frac{1}{4 \pi \varepsilon_{0}} \frac{4 \omega^{3}}{3 \hbar c^{3}}\langle\text { fin }| \hat{\mathbf{d}}|i n i\rangle \cdot\langle i n i| \hat{\mathbf{d}}|f i n\rangle^{*} . \tag{9.53}
\end{equation*}
$$

Leaving a comparison of this formula with the classical theory of radiation, ${ }^{24}$ and the exact evaluation of $\Gamma_{\mathrm{s}}$ for a particular transition in the hydrogen atom, for reader's exercises, let me just estimate its order of magnitude. Assuming that $d \sim e r_{\mathrm{B}} \equiv e \hbar^{2} / m_{e}\left(e^{2} / 4 \pi \varepsilon_{0}\right)$ and $\hbar \omega \sim E_{\mathrm{H}} \equiv m_{e}\left(e^{2} / 4 \pi \varepsilon_{0}\right)^{2} / \hbar^{2}$, and taking into account the definition (6.62) of the fine structure constant $\alpha \approx 1 / 137$, we get

$$
\begin{equation*}
\frac{\Gamma}{\omega} \sim\left(\frac{e^{2}}{4 \pi \varepsilon_{0} \hbar c}\right)^{3} \equiv \alpha^{3} \sim 3 \times 10^{-7} \tag{9.54}
\end{equation*}
$$

This estimate says that the emission lines at atomic transitions are typically very sharp. With the present-day availability of high-speed electronics, it also makes sense to evaluate the time scale $\tau=1 / \Gamma$ of the typical quantum transition: for a typical optical frequency $\omega \sim 3 \times 10^{15} \mathrm{~s}^{-1}$, it is close to 1 ns . This is

[^760]exactly the time constant that determines the photon counting statistics of the emitted radiation - see Fig. 3. Colloquially, this is the temporal scale of the photon spontaneously emitted by an atom. ${ }^{25}$

Note, however, that the above estimate of $\tau$ is only valid for a transition with a non-vanishing dipole matrix element. If it equals zero - say, due to the initial and final state symmetry - the dipole transitions are "forbidden". (Another commonly used term is the transition selection rules. ${ }^{26}$ ) The "forbidden" transition may still take place due to a different, smaller interaction (say, via a magnetic dipole field of the atom, or its quadrupole electric field ${ }^{27}$ ), but would take much longer. In some cases the increase of $\tau$ is rather dramatic - sometimes to hours! Such long-lasting radiation is called luminescence - or fluorescence if the initial atom's excitation was due to an external radiation of higher frequency, followed first by non-radiative transitions down the energy level ladder.

Now let us consider a more general case when the electromagnetic field is initially in an arbitrary Fock state $n$, and from it may either get energy from the atomic system (photon emission) or, vice versa, give it back to the atom (photon absorption). For the photon emission rate, an evident generalization of Eq. (48) gives

$$
\begin{equation*}
\frac{\Gamma_{e}}{\Gamma_{s}} \equiv \frac{\Gamma_{n \rightarrow \text { fin }}}{\Gamma_{0 \rightarrow 1}}=\frac{\mid\left.\langle\text { fin }| \hat{a}^{\dagger}|n\rangle\right|^{2}}{\left.\left|\langle 1| \hat{a}^{\dagger}\right| 0\right\rangle\left.\right|^{2}}, \tag{9.55}
\end{equation*}
$$

where both bra-kets may be taken in the Schrödinger picture, and $\Gamma_{\mathrm{s}}$ is the spontaneous emission rate (53) of the same atomic system. This relation, with the account of Eq. (19), shows that at photon

$$
\begin{equation*}
\Gamma_{e}=(n+1) \Gamma_{s} . \tag{9.56}
\end{equation*}
$$

Thus the initial field increases the photon emission rate; this effect is called the stimulated emission of radiation. Note that the spontaneous emission may be considered as a particular case of stimulated emission for $n=0$, and interpreted as the emission stimulated by zero-point fluctuations of the electromagnetic field.

On the other hand, in accordance with the arguments of Sec. 2, for the description of radiation absorption the photon creation operator has to be replaced with the annihilation one, to get

$$
\begin{equation*}
\frac{\Gamma_{a}}{\Gamma_{s}}=\frac{|\langle f i n| \hat{a}| n\rangle\left.\right|^{2}}{\left.\left|\langle 1| \hat{a}^{\dagger}\right| 0\right\rangle\left.\right|^{2}} . \tag{9.57}
\end{equation*}
$$

[^761]According to this equation, the final state of the field at absorption is the Fock state with $n$ ' $=n-1$, and Eq. (57) yields ${ }^{28}$

$$
\begin{equation*}
\Gamma_{a}=n \Gamma_{s} . \tag{9.58}
\end{equation*}
$$

Photon absorption rate

Results (56) and (58) are usually be formulated in terms of between the Einstein coefficients $A$ and $B$ defined in the way shown in Fig. 4, where the two energy levels are those of the atom, $\Gamma_{a}$ is the rate of energy absorption from the electromagnetic field, and $\Gamma_{e}$ is that of the energy emission into the field. In this notation, Eqs. (56) and (58) say

$$
\begin{equation*}
A_{21}=B_{21}=B_{12} \tag{9.59}
\end{equation*}
$$

Einstein coefficients' relation
because each of these coefficients equals the spontaneous emission rate $\Gamma_{\mathrm{s}}$.

Fig. 9.4. The Einstein coefficients on the atomic energy spectrum diagram.

It is curious that from this point, there is just one step to an alternative derivation of the BoseEinstein statistics for photons. Indeed, in the thermodynamic equilibrium, the average probability flows between levels 1 and 2 should be equal:

$$
\begin{equation*}
W_{2}\left\langle\Gamma_{e}\right\rangle=W_{1}\left\langle\Gamma_{a}\right\rangle, \tag{9.60}
\end{equation*}
$$

where $W_{1}$ and $W_{2}$ are the probabilities for the atomic system to be on the corresponding levels, so that Eqs. (56) and (58) yield

$$
\begin{equation*}
W_{2} \Gamma_{s}\langle 1+n\rangle=W_{1} \Gamma_{s}\langle n\rangle, \quad \text { i.e. } \quad \frac{W_{2}}{W_{1}}=\frac{\langle n\rangle}{\langle n\rangle+1} . \tag{9.61}
\end{equation*}
$$

But, on the other hand, for the atomic subsystem, only weakly coupled to its electromagnetic environment, we ought to have the Gibbs distribution of probabilities:

$$
\begin{equation*}
\frac{W_{2}}{W_{1}}=\frac{\exp \left\{-E_{2} / k_{\mathrm{B}} T\right\}}{\exp \left\{-E_{1} / k_{\mathrm{B}} T\right\}}=\exp \left\{-\frac{\Delta E}{k_{\mathrm{B}} T}\right\}=\exp \left\{-\frac{\hbar \omega}{k_{\mathrm{B}} T}\right\} . \tag{9.62}
\end{equation*}
$$

Requiring Eqs. (61) and (62) to give the same result for the probability ratio, we get the Bose-Einstein distribution for the electromagnetic field in equilibrium:

$$
\begin{equation*}
\langle n\rangle=\frac{1}{\exp \left\{\hbar \omega / k_{\mathrm{B}} T\right\}-1}, \tag{9.63}
\end{equation*}
$$

the same as obtained in Sec. 7.1 by other means - see Eqs. (7.26).

[^762]Another, very important implication of Eqs. (56) and (58) is the possibility to achieve the stimulated emission coherence by level occupancy (or "population") inversion. Indeed, if $W_{2}>W_{1}$, then the net power flow from the atomic system into the electromagnetic field,

$$
\begin{equation*}
\text { power }=\hbar \omega \times \Gamma_{s}\left[W_{2}(\langle n\rangle+1)-W_{1}\langle n\rangle\right], \tag{9.64}
\end{equation*}
$$

may be positive. The necessary inversion may be produced using several ways, notably by a intensive quantum transitions to level 2 from an even higher level (which, in turn, is populated, e.g., by absorption of an external radiation, called pumping, at a higher frequency.)

A less obvious feature of the stimulated emission is spelled out by Eq. (55): again, it shows that the final state of the field after the absorption of energy $\hbar \omega$ from the atom is a pure (coherent) Fock state $(n+1)$. Colloquially, one may say that the new, $(n+1)^{\text {st }}$ photon emitted from the atom is automatically in phase with the $n$ photons that had been in the field mode initially. ${ }^{29}$ The idea of stimulated emission of coherent radiation using population inversion ${ }^{30}$ was implemented in the early 1950s in the microwave range (masers) and in 1960 in the optical range (lasers). Nowadays, lasers are ubiquitous and constitute one of cornerstones of our technological civilization.

A quantitative discussion of laser operation is beyond the framework of this course, and I have to refer the reader to special literature, ${ }^{31}$ and would only like to mention only two key points:
(i) In a typical laser, each generated electromagnetic field mode is in the Glauber (rather than the Fock) state, so that Eqs. (56) and (58) are applicable only for $n$ is averaged over the Fock-state decomposition of the Glauber state - see Eq. (5.165).
(ii) Since in a typical laser $\langle n\rangle \gg 1$, its operation may be well described using quasi-classical theories that use Eq. (64) to describe the electromagnetic energy balance (with the addition of a term describing the energy loss due to field absorption in external components of the laser, including the useful load), plus the equation describing the balance of occupancies $W_{1,2}$ due to all inter-level transitions - similar to Eq. (60), but including also the contribution(s) from the particular population inversion mechanism used in the laser. At this approach, the role of quantum mechanics is essentially reduced to the calculation of parameter $\Gamma_{\mathrm{s}}$.

The role becomes more prominent if one needs to describe fluctuations of the laser field. Here two approaches are possible, following the two options discussed in Chapter 7. If the fluctuations are relatively small, one can linearize the Heisenberg equations of motion of the field oscillator operators near their stationary-lasing "values", with the Langevin "forces" (also time-dependent operators) to describe the fluctuation sources, and use these Heisenberg-Langevin equations to the radiation fluctuations, just as was described in Sec. 7.5. On the other hand, near the lasing threshold the field fluctuations are relatively strong, smearing the phase transition between the no-lasing and lasing states. Here the linearization is not an option, but one can use the density-matrix approach described in Sec. 7.6 , for the fluctuation analysis. ${ }^{32}$

[^763]
### 9.4. Cavity QED

Now I have to mention, at least in passing, the cavity quantum electrodynamics (usually called cavity $Q E D$ for short) - an art and science of creating and using entanglement between quantum states of a single atomic system (either an atom, or an ion, or a molecule, etc.) and the electromagnetic field in a macroscopic volume called the resonant cavity (or just "resonator", or just "cavity"). This field is very popular nowadays, especially in the context of the quantum computation and communication research discussed in Sec. 8.5. ${ }^{33}$

Let me start its discussion by noting that the narrative of two last sections was based on an implicit assumption that the energy spectrum of the electromagnetic field interacting with an atomic system is essentially continuous. This assumption has justified the use of Golden Rule, implying that the emitted radiation is spread among many field modes, effectively loosing their coherence with the initial quantum state of the atom. However, this assumption becomes invalid if the electromagnetic field is contained inside a relatively small volume, with a linear size comparable with the radiation wavelength. Classical electrodynamics shows ${ }^{34}$ that if the walls of such a cavity mostly reflect, rather than absorb, radiation, so that in the crude approximation the power dissipation may be disregarded, then particular solutions $\mathbf{e}_{j}(\mathbf{r})$ of the Helmholtz equation (5) correspond to discrete, well separated mode wavenumbers $k_{j}$ and hence well separated eigenfrequencies $\omega_{j}$. Due to the energy conservation, an atomic transition corresponding to energy $\Delta E=\left|E_{\text {ini }}-E_{\text {fin }}\right|$ may be effective only if the corresponding quantum oscillation frequency $\Omega \equiv \Delta E / \hbar$ is close to one of $\omega_{j}$ and hence relatively far from other eigenfrequencies. ${ }^{35}$ As a result, the quantum states of a single atomic system and the resonant electromagnetic mode may become entangled.

A very popular approximation for the qualitative description of this effect is the so-called Rabi model, ${ }^{36}$ in which the atom is treated as a two-level system ${ }^{37}$ interacting with a single electromagnetic field mode of the resonant cavity. As the reader knows well from Chapters 4-6, any two-level ("spin-1/2") system may be described by Hamiltonian $\mathbf{c} \cdot \hat{\boldsymbol{\sigma}}$, and we may always select the state basis in that the Hamiltonian is diagonal:

$$
\begin{equation*}
\hat{H}_{\mathrm{atom}}=c \hat{\sigma}_{z} \equiv \frac{\hbar \Omega}{2} \hat{\sigma}_{z}, \tag{9.65}
\end{equation*}
$$

where $\hbar \Omega \equiv 2 c$ is the energy difference between the eigenenergies in the absence of interaction with the field. Next, according to Eq. (17), ignoring the constant ground-state energy $\hbar \omega / 2$ (that may be added to
while the laser radiation fluctuations may look like a peripheral issue, pioneering research in that field has led to the development of the general theory of open quantum systems (which was discussed in Chapter 7), that has much broader applications.
${ }^{33}$ This popularity was demonstrated, for example, by the 2012 Nobel Prize in Physics award to cavity QED experimentalists S. Haroche and D. Wineland.
${ }^{34}$ See, e.g., EM Sec. 7.9.
${ }^{35}$ On the contrary, if $\Omega$ is far from any $\omega_{j}$, the interaction is much suppressed; in particular, the spontaneous emission rate may be much lower than that given by Eq. (53) - so that this result is not as fundamental as it may look.
${ }^{36}$ After the pioneering work by I. Rabi in 1936-37.
${ }^{37}$ As was shown in Sec. 6.5, this model is justified, e.g., if transitions between all other energy level pairs have considerably different frequencies.
the final energy in the very end - if necessary), the contribution of a single mode of eigenfrequency $\omega$ to the Hamiltonian is

$$
\begin{equation*}
\hat{H}_{\text {cavity }}=\hbar \omega \hat{a}^{\dagger} \hat{a} \tag{9.66}
\end{equation*}
$$

Finally, according to Eq. (16a), in quantum electrodynamics the electric field of the mode may be presented as

$$
\begin{equation*}
\hat{\mathcal{E}}(\mathbf{r}, t)=\frac{1}{i}\left(\frac{\hbar \omega}{2}\right)^{1 / 2} \mathbf{e}(\mathbf{r})\left(\hat{a}-\hat{a}^{\dagger}\right), \tag{9.67}
\end{equation*}
$$

so that in the electric-dipole approximation (24), the cavity-atom interaction may be presented as a product of the field by one of Cartesian components (say, $\sigma_{y}$ ) of the "spin" operator:38

$$
\begin{equation*}
\hat{H}_{\mathrm{int}}=\mathrm{const} \times \hat{\sigma}_{y} \times \varepsilon=\mathrm{const} \times \hat{\sigma}_{y} \times\left(\frac{\hbar \omega}{2}\right)^{1 / 2} \frac{1}{i}\left(\hat{a}-\hat{a}^{\dagger}\right)=i \hbar \kappa \hat{\sigma}_{y}\left(\hat{a}-\hat{a}^{\dagger}\right) \tag{9.68}
\end{equation*}
$$

where $\kappa$ is a coupling constant (with the dimension of frequency). The sum of these terms is called the Rabi Hamiltonian,

$$
\begin{equation*}
\hat{H} \equiv \hat{H}_{\mathrm{atom}}+\hat{H}_{\mathrm{cavity}}+\hat{H}_{\mathrm{int}}=\frac{\hbar \Omega}{2} \hat{\sigma}_{z}+\hbar \omega \hat{a}^{\dagger} \hat{a}+i \hbar \kappa \hat{\sigma}_{y}\left(\hat{a}-\hat{a}^{\dagger}\right) \tag{9.69}
\end{equation*}
$$

Despite its apparent simplicity, using this Hamiltonian for calculations is not that simple. For example, an exact quasi-analytical expression for its eigenenergies (as zeros of a Taylor series in parameter $\kappa$, with coefficients determined by a recurrence relation) was found only recently. ${ }^{39}$ Only in the case when the electromagnetic field is very intensive and hence may be treated as the classical one, the results following from Eq. (69) are reduced to the Rabi oscillations discussed in Sec. 6.3.

In the opposite case when the field oscillator is in an essentially quantum state, $\left\langle\hat{a}^{\dagger} \hat{a}\right\rangle \sim 1$, Eq. (69) may be simplified in a different way, assuming that frequencies $\Omega$ and $\omega$ are very close, and the atom-to-cavity interaction is relatively weak, so that magnitudes of the coupling constant $\kappa$ and the detuning parameter (similar to parameter $\Delta$ used in Sec. 6.5),

$$
\begin{equation*}
\xi \equiv \Omega-\omega, \tag{9.70}
\end{equation*}
$$

are both much smaller than $\Omega \approx \omega$. To discuss this limit, it is convenient to use the spin ladder operators defined absolutely similarly for those of the orbital angular momentum - see Eqs. (5.182):

$$
\begin{equation*}
\hat{\sigma}_{ \pm} \equiv \hat{\sigma}_{x} \pm i \hat{\sigma}_{y}, \text { so that } \hat{\sigma}_{y}=\frac{\hat{\sigma}_{+}-\hat{\sigma}_{-}}{2 i} . \tag{9.71}
\end{equation*}
$$

From Eq. (4.105), it is easy to find matrices of these operators (in the standard $z$-basis),

$$
\sigma_{+}=\left(\begin{array}{ll}
0 & 2  \tag{9.72}\\
0 & 0
\end{array}\right), \quad \sigma_{-}=\left(\begin{array}{ll}
0 & 0 \\
2 & 0
\end{array}\right)
$$

[^764]and their commutation rules - that are naturally similar to Eqs. (5.183):
\[

$$
\begin{equation*}
\left[\hat{\sigma}_{+}, \hat{\sigma}_{-}\right]=4 \hat{\sigma}_{z}, \quad\left[\hat{\sigma}_{z}, \hat{\sigma}_{ \pm}\right]= \pm 2 \hat{\sigma}_{ \pm} \tag{9.73}
\end{equation*}
$$

\]

In this notation, the Rabi Hamiltonian looks like

$$
\begin{equation*}
\hat{H}=\frac{\hbar \Omega}{2} \hat{\sigma}_{z}+\hbar \omega \hat{a}^{\dagger} \hat{a}+\frac{\hbar \kappa}{2}\left(\hat{\sigma}_{+}-\hat{\sigma}_{-}\right)\left(\hat{a}-\hat{a}^{\dagger}\right) \tag{9.74}
\end{equation*}
$$

and it is straightforward to use Eq. (4.199) and (73) to derive the Heisenberg-picture equations of motion for the involved operators. (Doing this, we have to remember that operators of the "spin" subsystem, on one hand, and of the field mode, on the other hand, are defined in different Hilbert spaces and hence commute - at least at coinciding time moments.) The result (so far, exact!) is

$$
\begin{gather*}
\dot{\hat{a}}=-i \omega \hat{a}+\frac{i \kappa}{2}\left(\hat{\sigma}_{+}-\hat{\sigma}_{-}\right), \quad \dot{\hat{a}}^{\dagger}=i \omega \hat{a}^{\dagger}-\frac{i \kappa}{2}\left(\hat{\sigma}_{+}-\hat{\sigma}_{-}\right), \\
\dot{\hat{\sigma}}_{ \pm}= \pm i \Omega \hat{\sigma}_{ \pm}+i 2 \kappa\left(\hat{a}-\hat{a}^{\dagger}\right) \hat{\sigma}_{z}, \quad \dot{\hat{\sigma}}_{z}=i \kappa\left(\hat{a}^{\dagger}-\hat{a}\right)\left(\hat{\sigma}_{+}+\hat{\sigma}_{-}\right) . \tag{9.75}
\end{gather*}
$$

Now note that at negligible coupling, $\kappa \rightarrow 0$, equations (75) have very simple solutions,

$$
\begin{equation*}
\hat{a}(t) \propto e^{-i \omega t}, \quad \hat{a}^{\dagger}(t) \propto e^{i \omega t}, \quad \hat{\sigma}_{ \pm}(t) \propto e^{ \pm i \Omega t}, \quad \hat{\sigma}_{z}(t) \approx \mathrm{const} \tag{9.76}
\end{equation*}
$$

and small terms proportional to $\kappa$ in the right-hand parts of Eqs. (75) cannot affect these time evolution laws dramatically even if $\kappa$ is not exactly zero (but small). Of those terms, ones with frequencies close to the "basic" frequency of each variable would act in resonance and hence may have a substantial impact on system dynamics, while non-resonant terms may be ignored. In this rotating-wave approximation (RWA), used several times before in this course, Eqs. (75) are reduced to a much simpler system of equations:

$$
\begin{gather*}
\dot{\hat{a}}=-i \omega \hat{a}-\frac{i \kappa}{2} \hat{\sigma}_{-}, \quad \dot{\hat{a}}^{\dagger}=i \omega \hat{a}^{\dagger}+\frac{i \kappa}{2} \hat{\sigma}_{+},  \tag{9.77}\\
\dot{\hat{\sigma}}_{+}=i \Omega \hat{\sigma}_{+}+i 2 \kappa \hat{a}^{\dagger} \hat{\sigma}_{z}, \quad \dot{\hat{\sigma}}_{-}=-i \Omega \hat{\sigma}_{-}-i 2 \kappa \hat{a} \hat{\sigma}_{z}, \quad \dot{\hat{\sigma}}_{z}=i \kappa\left(\hat{a}^{\dagger} \hat{\sigma}_{-}-\hat{a} \hat{\sigma}_{+}\right) .
\end{gather*}
$$

Alternatively, these equations of motion may be obtained from the Rabi Hamiltonian after it has been cleared of the terms proportional to $\hat{\sigma}_{+} \hat{a}^{\dagger}$ and $\hat{\sigma}_{-} \hat{a}$, that oscillate fast and hence self-average to virtually zero:

$$
\begin{equation*}
\hat{H}=\frac{\hbar \Omega}{2} \hat{\sigma}_{z}+\hbar \omega \hat{a}^{\dagger} \hat{a}+\frac{\hbar \kappa}{2}\left(\hat{\sigma}_{+} \hat{a}+\hat{\sigma}_{-} \hat{a}^{\dagger}\right), \quad \text { at } \kappa,|\xi| \ll \omega, \Omega . \tag{9.78}
\end{equation*}
$$

Janes-
Cummings
Hamiltonian

This is the famous Janes-Cummings Hamiltonian, ${ }^{40}$ which is central to the cavity QED and its applications. ${ }^{41}$ In order to find its eigenstates and eigenenergies, let us note that at negligible interaction

[^765]( $\kappa \rightarrow 0$ ), the spectrum of the total energy $E$ of the system, that in this limit is the sum of two independent contributions from the atomic ("spin") and resonant-cavity subsystems,
\[

$$
\begin{equation*}
\left.E\right|_{\kappa=0}= \pm \frac{\hbar \Omega}{2}+\hbar \omega n \equiv E_{n} \pm \frac{\hbar \xi}{2} \tag{9.79}
\end{equation*}
$$

\]

consists ${ }^{42}$ of close level pairs (Fig. 5) centered to values

$$
\begin{equation*}
E_{n} \equiv \hbar \omega\left(n-\frac{1}{2}\right), \quad \text { with } n=1,2, \ldots \tag{9.80}
\end{equation*}
$$

(At the exact resonance $\omega=\Omega$, i.e. at $\xi=0$, each pair merges into one double-degenerate level $E_{n}$.)

Since at $\kappa \rightarrow 0$ the two subsystems do not interact, the eigenstates corresponding to the sublevels of $n$-th pair may be represented by products of their independent ket-vectors:

As we know from Chapter 6, weak interaction leads to strong hybridization of quantum states with close energies (in this case, two states (81) with each pair with the same $n$ ) and their negligible mixing with other states. Hence, at $0<\kappa \ll \omega \approx \Omega$, a good approximation of an eigenstate with $E \approx E_{n}$ is given by a linear superposition of states (81):

$$
\begin{equation*}
|\alpha\rangle=c_{+}|\uparrow\rangle \otimes|n-1\rangle+c_{-}|\downarrow\rangle \otimes|n\rangle \tag{9.82}
\end{equation*}
$$

with certain $c$-number coefficients $c_{ \pm}$. This relation describes the entanglement of atomic eigenstates $\uparrow$ and $\downarrow$ with Fock states $n$ and $n-1$ of the field mode.

Let me leave the (straightforward) calculation of coefficients $c_{ \pm}$and eigenenergies of the two entangled state pairs for reader's exercise. This calculation shows, in particular, that at the exact resonance $(\omega=\Omega),\left|c_{+}\right|=\left|c_{-}\right|=1 / \sqrt{ } 2$ for both states of each pair. This fact may be interpreted as a (coherent!) equal sharing of an energy quantum $\hbar \omega=\hbar \Omega$ by the atom and the cavity.

A by-product of the calculation of $c_{ \pm}$, is the fact that the dynamics of state $\alpha$ described by Eq. (82) is similar to that of the generic two-level system that was repeatedly discussed in this course - first

[^766]time in Sec. 2.6 and then in Chapters 4-6. In particular, if the composite system had been initially prepared to be in one component state, for example $|\uparrow\rangle \otimes|0\rangle$ (i.e. the atom excited, while the cavity in its ground state) and allowed to evolve on its own, after some time interval it may be found in the counterpart state $|\downarrow\rangle \otimes|1\rangle$, including the first excited Fock state $n=1$ of the field mode. This is one more (resonant) version of the same method for generation of Fock states of electromagnetic field which was discussed in Sec. 3.43

Unfortunately, my time devoted to cavity QED is over, and for further reading I have to refer the reader to special literature. ${ }^{44}$

### 9.5. The Klein-Gordon and relativistic Schrödinger equations

Now let us discuss the basics of relativistic quantum mechanics of particles with a nonvanishing rest mass $m$ - i.e., in terms of Eq. (1), the intermediate range of energies: $E \sim m c^{2}$, i.e. for $p \sim m c$. Historically, the first attempt ${ }^{45}$ to extend the non-relativistic wave mechanics into the relativistic energy range was based on performing the same transitions from classical observables to their quantummechanical operators as in the non-relativistic limit:

$$
\begin{equation*}
\mathbf{p} \rightarrow \hat{\mathbf{p}}=-i \hbar \nabla, \quad E \rightarrow \hat{H}=i \hbar \frac{\partial}{\partial t} \tag{9.83}
\end{equation*}
$$

Substitution of these operators, acting on the Schrödinger-picture wavefunction $\Psi(\mathbf{r}, t)$, into the classical relation between the energy $E$ and momentum $\mathbf{p}$ (for of a free particle) leads to the following equations:

Table 9.1. Deriving the Klein-Gordon equation for a free relativistic particle. ${ }^{46}$

|  | Non-relativistic limit | Relativistic case |
| :---: | :---: | :---: |
| Classical <br> mechanics | $E=\frac{1}{2 m} p^{2}$ | $E^{2}=c^{2} p^{2}+\left(m c^{2}\right)^{2}$ |
| Wave <br> mechanics | $i \hbar \frac{\partial}{\partial t} \Psi=\frac{1}{2 m}(-i \hbar \nabla)^{2} \Psi$ | $\left(i \hbar \frac{\partial}{\partial t}\right)^{2} \Psi=c^{2}(-i \hbar \nabla)^{2} \Psi+\left(m c^{2}\right)^{2} \Psi$ |

[^767]The resulting equation for the non-relativistic limit is just the usual Schrödinger equation (1.28) for a free particle. Its relativistic generalization, usually rewritten as

Klein-
Gordon
equation

$$
\begin{equation*}
\left(\frac{1}{c^{2}} \frac{\partial^{2}}{\partial t^{2}}-\nabla^{2}\right) \Psi+\mu^{2} \Psi=0, \quad \text { with } \mu \equiv \frac{m c}{\hbar} \tag{9.84}
\end{equation*}
$$

is called the Klein-Gordon (or sometimes "Klein-Gordon-Fock") equation. The most fundamental solutions of this equation are the same plane, monochromatic waves

$$
\begin{equation*}
\Psi(\mathbf{r}, t) \propto \exp \{i(\mathbf{k} \cdot \mathbf{r}-\omega t)\} . \tag{9.85}
\end{equation*}
$$

as in the non-relativistic case. Indeed, such waves are eigenstates of operators (83), with eigenvalues

$$
\begin{equation*}
\mathbf{p}=\hbar \mathbf{k}, \quad E=\hbar \omega \tag{9.86}
\end{equation*}
$$

so that their substitution into Eq. (84) immediately returns us to Eq. (1) with replacements (86):

$$
\begin{equation*}
E_{ \pm}=\hbar \omega_{ \pm}= \pm\left[(\hbar c k)^{2}+\left(m c^{2}\right)^{2}\right]^{1 / 2} \tag{9.87}
\end{equation*}
$$

Though one may say that this dispersion relation is just a simple combination of the classical relation (1) and the same basic quantum-mechanical relations (86) as in non-relativistic limit, it attracts our attention to the fact that energy $\hbar \omega$ as a function of momentum $\hbar \mathbf{k}$ has two rather than one branches, with $E_{-}(\mathbf{p})=-E_{+}(\mathbf{p})-$ see Fig. 6a.

(b)

Fig. 9.6. (a) Free-particle dispersion relation resulting from the Klein-Gordon and Dirac equations, and (b) creation of a particle-antiparticle pair from the vacuum.

Historically, this fact has played a very important role for spurring the fundamental idea of particle-antiparticle pairs. In this idea (very similar to the concept of electrons and holes in semiconductors, which was discussed in Sec. 2.8), what we call the vacuum actually corresponds to all states of the lower branch, with energies $E(\mathbf{p})<0$, being filled, while the states on the upper branch, with energies $E_{+}(\mathbf{p})>0$, being empty. Then an externally supplied energy

$$
\begin{equation*}
\Delta E=E_{+}-E_{-}=E_{+}+\left(-E_{-}\right) \geq 2 m c^{2}>0 \tag{9.88}
\end{equation*}
$$

may bring the system from the lower branch to the upper one (Fig. 6b). The resulting excited state is interpreted as a combination of a particle (formally, of the infinite spatial extension) with energy $E_{+}$and momentum $\mathbf{p}$, and a "hole" (antiparticle) of positive energy ( $-E_{-}$) and momentum $-\mathbf{p}$. This idea ${ }^{47}$ has led

[^768]to a search for, and discovery of the positron: electron's antiparticle with charge $q=+e$, in 1932, and later of the antiproton and other antiparticles.

Free particles of a finite spatial extension may be described, in this approach, just in the nonrelativistic Schrödinger equation, by wave packets: linear superpositions of de-Broglie waves (85) with close wave vectors $\mathbf{k}$, and $\omega$ given by Eq. (87), with the positive sign for the "usual" particles, and negative sign for antiparticles - see Fig. 6a above. Note that in order to form, from a particle's wave packet, a similar wave packet for the antiparticle, with the same phase and group velocities (2.33) in each direction, we need to change the sign not only before $\omega$, but also before $\mathbf{k}$, i.e. to replace all component wavefunctions (85), and hence the full wavefunction, with their complex conjugates.

Of more formal properties of the equation, it is easy to prove that its solutions satisfy the same continuity equation (1.52) with the probability current density $\mathbf{j}$ still given by Eq. (1.47), but a different expression for the probability density $w$ - which becomes very similar to that for $\mathbf{j}$ :

$$
\begin{equation*}
w=\frac{i \hbar}{2 m c^{2}}\left(\Psi^{*} \frac{\partial \Psi}{\partial t}-\text { c.c. }\right), \quad \mathbf{j}=\frac{i \hbar}{2 m}\left(\Psi \nabla \Psi^{*}-\text { c.c. }\right) . \tag{9.89}
\end{equation*}
$$

(In the non-relativistic limit $v / c \rightarrow 0$, Eq. (84) allows a reduction of the first relation to Eq. (1.22): $w \rightarrow$ $\Psi \Psi^{*}$.)

The Klein-Gordon equation may be readily generalized to describe a single particle moving in external fields; for example, the electromagnetic field effects on a particle with charge $q$ may be described by the same replacement as in the non-relativistic limit (see Sec. 3.1):48

$$
\begin{equation*}
\hat{\mathbf{p}} \rightarrow \hat{\mathbf{P}}-q \mathbf{A}(\mathbf{r}, t), \quad \hat{H} \rightarrow \hat{H}-q \phi(\mathbf{r}, t) \tag{9.90}
\end{equation*}
$$

where $\hat{\mathbf{P}}=-i \hbar \nabla$ is the canonical momentum operator (3.25), and the vector- and scalar potentials, $\mathbf{A}$ and $\phi$, should be treated appropriately - either as $c$-number functions if the electromagnetic field quantization is unimportant, or as operators (see Secs. 1-4 above) if it is.

However, the practical value of the relativistic Schrödinger equation is rather limited, because of two main reasons. First of all, it does not give the correct description of particles with spin. For example, for the hydrogen-like atom, i.e. the motion of an electron with electric charge $-e$ in the Coulomb central field (3.182) of an immobile nucleus with charge $+Z e$, the equation may be readily solved exactly ${ }^{49}$ and yields the following spectrum of (doubly-degenerate) energy levels:

$$
\begin{equation*}
E=m c^{2}\left(1+\frac{Z^{2} \alpha^{2}}{\lambda^{2}}\right)^{-1 / 2}, \quad \text { with } \lambda \equiv n+\left[\left(l+\frac{1}{2}\right)^{2}-Z^{2} \alpha^{2}\right]^{1 / 2}-\left(l+\frac{1}{2}\right) \tag{9.91}
\end{equation*}
$$

where $n=1,2, \ldots$ and $l=0,1, \ldots, n-1$ are the same quantum numbers as in the non-relativistic theory (see Sec. 3.6), and $\alpha \equiv e^{2} / 4 \pi \varepsilon_{0} \hbar c \approx 1 / 137$ is the fine structure constant - see Eq. (6.62). The three leading terms of the Taylor expansion of this result in small parameter $Z \alpha$ are as follows:

$$
\begin{equation*}
E \approx m c^{2}\left[1-\frac{Z^{2} \alpha^{2}}{2 n^{2}}-\frac{Z^{4} \alpha^{4}}{2 n^{4}}\left(\frac{n}{l+1 / 2}-\frac{3}{4}\right)\right] . \tag{9.92}
\end{equation*}
$$

[^769]The first of these terms is just the rest energy of the particle. The second term,

$$
\begin{equation*}
E_{n}=-m c^{2} \frac{Z^{2} \alpha^{2}}{2 n^{2}}=-\frac{m Z^{2} e^{4}}{\left(4 \pi \varepsilon_{0}\right)^{2} \hbar^{2}} \frac{1}{2 n^{2}}=-\frac{E_{0}}{2 n^{2}}, \quad \text { with } E_{0}=Z^{2} E_{\mathrm{H}} \tag{9.93}
\end{equation*}
$$

reproduces the non-relativistic Bohr's formula (3.191). Finally, the third term,

$$
\begin{equation*}
-m c^{2} \frac{Z^{4} \alpha^{4}}{2 n^{4}}\left(\frac{n}{l+1 / 2}-\frac{3}{4}\right)=-\frac{2 E_{n}^{2}}{m c^{2}}\left(\frac{n}{l+1 / 2}-\frac{3}{4}\right) \tag{9.94}
\end{equation*}
$$

is just the kinetic-relativistic contribution (6.52) to the fine structure of the Bohr levels (93). However, as we already know from Sec. 6.3, for a spin $-1 / 2$ particle such as the electron, the spin-orbit interaction (6.56) gives an additional contribution of the same order to the fine structure, so that the net result, confirmed by experiment, is given by Eq. (6.60), i.e. different from Eq. (94). This is very natural, because the relativistic Schrödinger equation does not have the very notion of spin.

Second, even for massive spinless particles (such as $Z^{0}$ bosons), for which this equation is believed to be valid, the most important problems are related to particle interactions at high energies of the order of $\Delta E \sim 2 m c^{2}$ (88) and beyond. Due to possibility of creation and annihilation of particleantiparticle pairs at such energies, the number of particles participating in such interactions is typically considerable (and variable), and its adequate description of the system is given not by the relativistic Schrödinger equation (which is formulated in single-particle terms), but by the quantum field theory - to which I will devote just a few sentences in the very end of this chapter.

### 9.6. Dirac's theory

The real breakthrough toward the quantum relativistic theory of electrons (and any spin- $1 / 2$ fermions) was achieved in 1928 by P. A. M. Dirac. For that time, the structure of his theory was highly nontrivial. Namely, while formally preserving, in the coordinate representation, the same Schrödingerpicture equation of quantum dynamics as in the non-relativistic quantum mechanics, ${ }^{50}$

$$
\begin{equation*}
i \hbar \frac{\partial \Psi}{\partial t}=\hat{H} \Psi \tag{9.95}
\end{equation*}
$$

it postulates that wavefunction $\Psi$ is not a scalar complex function of time and coordinates, but a fourcomponent column-vector (sometimes called the bispinor) of such functions, its Hermitian-conjugate bispinor $\Psi^{\dagger}$ being a 4-component row-vector of their complex conjugates:

$$
\Psi=\left(\begin{array}{l}
\Psi_{1}(\mathbf{r}, t)  \tag{9.96}\\
\Psi_{2}(\mathbf{r}, t) \\
\Psi_{3}(\mathbf{r}, t) \\
\Psi_{4}(\mathbf{r}, t)
\end{array}\right), \quad \Psi^{\dagger}=\left(\begin{array}{lll}
\left.\Psi_{1}^{*}(\mathbf{r}, t) \quad \Psi_{2}^{*}(\mathbf{r}, t) \quad \Psi_{3}^{*}(\mathbf{r}, t) \quad \Psi_{4}^{*}(\mathbf{r}, t)\right), ~, ~
\end{array}\right.
$$

[^770]and that the Hamiltonian participating in Eq. (95) is a $4 \times 4$ matrix in the Hilbert space of bispinors $\Psi$. For a free particle, the postulated Hamiltonian looks amazingly simple: ${ }^{51}$
\[

$$
\begin{equation*}
\hat{H}=c \hat{\boldsymbol{\alpha}} \cdot \hat{\mathbf{p}}+\hat{\beta} m c^{2} \tag{9.97}
\end{equation*}
$$

\]

where $\hat{\mathbf{p}}=-i \hbar \nabla$ is the same 3D vector of momentum component operators as in the non-relativistic case, while operators $\hat{\boldsymbol{\alpha}}$ and $\hat{\beta}$ may be presented in the following shorthand $2 \times 2$ form:

$$
\hat{\boldsymbol{\alpha}} \equiv\left(\begin{array}{cc}
0 & \hat{\boldsymbol{\sigma}}  \tag{9.98a}\\
\hat{\boldsymbol{\sigma}} & 0
\end{array}\right), \quad \hat{\beta} \equiv\left(\begin{array}{cc}
\hat{I} & 0 \\
0 & -\hat{I}
\end{array}\right)
$$

Dirac operators

Operator $\hat{\boldsymbol{\alpha}}$, composed of the Pauli vector operators $\hat{\boldsymbol{\sigma}}$, is also a vector in the usual 3D space, so that each of its 3 Cartesian components is a $4 \times 4$ matrix. The particular form of the $2 \times 2$ matrices corresponding to operators $\hat{\boldsymbol{\sigma}}$ and $\hat{I}$ in Eq. (98a) depends on the basis selected for representation of the spin states of the particle; for example, in the standard $z$-basis, in which the Cartesian components $\hat{\sigma}_{x}$, $\hat{\sigma}_{y}$, and $\hat{\sigma}_{z}$ of $\hat{\boldsymbol{\sigma}}$ are represented by the Pauli matrices (4.105), the full matrix form of Eq. (98a) is

$$
\alpha_{x}=\left(\begin{array}{cccc}
0 & 0 & 0 & 1  \tag{9.98b}\\
0 & 0 & 1 & 0 \\
0 & 1 & 0 & 0 \\
1 & 0 & 0 & 0
\end{array}\right), \quad \alpha_{y}=\left(\begin{array}{cccc}
0 & 0 & 0 & -i \\
0 & 0 & i & 0 \\
0 & -i & 0 & 0 \\
i & 0 & 0 & 0
\end{array}\right), \quad \alpha_{z}=\left(\begin{array}{cccc}
0 & 0 & 1 & 0 \\
0 & 0 & 0 & -1 \\
1 & 0 & 0 & 0 \\
0 & -1 & 0 & 0
\end{array}\right), \quad \beta=\left(\begin{array}{cccc}
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & -1 & 0 \\
0 & 0 & 0 & -1
\end{array}\right) .
$$

(According to the second of Eq. (98a), $\beta$ has this form in any spin basis.) It is straightforward to use Eqs. (98) to verify that matrices $\alpha_{x}, \alpha_{y}, \alpha_{z}$ and $\beta$ satisfy the following relations:

$$
\begin{gather*}
\alpha_{x}^{2}=\alpha_{y}^{2}=\alpha_{z}^{2}=\beta^{2}=1,  \tag{9.99}\\
\alpha_{x} \alpha_{y}+\alpha_{y} \alpha_{x}=\alpha_{y} \alpha_{z}+\alpha_{z} \alpha_{y}=\alpha_{z} \alpha_{x}+\alpha_{x} \alpha_{z}=\alpha_{x} \beta+\beta \alpha_{x}=\alpha_{y} \beta+\beta \alpha_{y}=\alpha_{z} \beta+\beta \alpha_{z}=0, \tag{9.100}
\end{gather*}
$$

i.e. anticommute.

Acting essentially as in Sec. 4.1, but using commutation relations (99)-(100), it is straightforward to show that any solution to the Dirac equation obeys the probability conservation law, i.e. the continuity equation (1.52), with the probability density,
${ }^{51}$ Moreover, if the time derivative participating in Eq. (95) and the three coordinate derivatives participating (via the momentum operator) in Eq. (97), are merged into one 4 -vector operator $\partial / \partial x_{k} \equiv\{\nabla, \partial / \partial(c t)\}$, the Dirac equation (95) may be rewritten in an even simpler, manifestly Lorentz-invariant 4 -vector form (with the implicit summation over the repeated index $k=1, \ldots, 4-\mathrm{see}$, e,g., EM Sec. 9.4):

$$
\left(\hat{\gamma}_{k} \frac{\partial}{\partial x_{k}}+\mu\right) \Psi=0, \quad \text { where } \hat{\boldsymbol{\gamma}} \equiv\left\{\hat{\gamma}_{1}, \hat{\gamma}_{2}, \hat{\gamma}_{3}\right\}=\left(\begin{array}{cc}
0 & -i \hat{\boldsymbol{\sigma}} \\
i \hat{\boldsymbol{\sigma}} & 0
\end{array}\right), \quad \hat{\gamma}_{4}=\hat{\boldsymbol{\beta}},
$$

where $\mu \equiv m c / \hbar$ - just as in Eq. (84). Note also that, very counter-intuitively, the Dirac Hamiltonian (97) is linear in momentum, while the non-relativistic Hamiltonian of a particle, as well as the relativistic Schrödinger equation, are quadratic in $\mathbf{p}$. In my humble opinion, the Dirac theory (including the concept of antiparticles) may compete for the title of the most revolutionary theoretical idea in physics, despite such heavy contenders as the Newton laws, the Maxwell equations, the Einstein's relativity, the Bohr atom, and the Gibbs' statistical distributions.

$$
\begin{equation*}
w=\Psi^{\dagger} \Psi \tag{9.101}
\end{equation*}
$$

and the probability current,

$$
\begin{equation*}
\mathbf{j}=c \Psi^{\dagger} \hat{\boldsymbol{\alpha}} \Psi \tag{9.102}
\end{equation*}
$$

looking almost as in the non-relativistic theory - cf. Eqs. (1.22) and (1.47). Note, however, the Hermitian conjugation used in these formulas instead of the complex conjugation, in order to form scalars $w, j_{x}, j_{y}$, and $j_{z}$ from 4-component vectors (96).

This qualified similarity is extended to the fundamental, plane-wave solutions of the Dirac equations is free space. Indeed, plugging such solution, in the form

$$
\Psi=\mathrm{u} e^{i(\mathbf{k} \cdot \mathbf{r}-\omega t)}=\left(\begin{array}{l}
u_{1}  \tag{9.103}\\
u_{2} \\
u_{3} \\
u_{4}
\end{array}\right) e^{i(\mathbf{k} \cdot \mathbf{r}-\omega t)}
$$

into Eqs. (95) and (97), we get a system of 4 coupled, linear algebraic equations for 4 complex $c$-number amplitudes $u_{1,2,3,4}$. The condition of their consistency yields the same dispersion relation (87), i.e. the same two-branch diagram shown in Fig. 6, as follows from the Klein-Gordon equation. The difference is that plugging each value of $\omega$, given by Eq. (87), back into the system of equations for amplitudes $u$, we get two solutions for vector $u$ for each of the energy branches. In the standard spin $z$-basis they may be presented as:

$$
\begin{align*}
& \text { for } E=E_{+}>0: \quad \mathbf{u}_{+\uparrow}=c_{+\uparrow}\left(\begin{array}{c}
1 \\
0 \\
\frac{c p_{z}}{E_{+}+m c^{2}} \\
\frac{c\left(p_{x}+i p_{y}\right)}{E_{+}+m c^{2}}
\end{array}\right), \quad \mathbf{u}_{+\downarrow}=c_{+\downarrow}\left(\begin{array}{c}
0 \\
\frac{c\left(p_{x}-i p_{y}\right)}{E_{+}+m c^{2}} \\
\frac{-c p_{z}}{E_{+}+m c^{2}}
\end{array}\right),  \tag{9.104a}\\
& \text { for } E=E_{-}<0: \quad \mathrm{u}_{-\uparrow}=c_{\uparrow}\left(\begin{array}{c}
\frac{c p_{z}}{E_{-}-m c^{2}} \\
\frac{c\left(p_{x}+i p_{y}\right)}{E_{-}-m c^{2}} \\
1 \\
0
\end{array}\right), \quad \mathbf{u}_{-\downarrow}=c_{\downarrow}\left(\begin{array}{c}
\frac{c\left(p_{x}-i p_{y}\right)}{E_{-}-m c^{2}} \\
\frac{-c p_{z}}{E_{-}-m c^{2}} \\
0 \\
1
\end{array}\right), \tag{9.104b}
\end{align*}
$$

where $c$ are normalization coefficients.
The simplest interpretation of these solutions is that Eq. (103) with vectors $u_{+}$, given by Eq. (104a), represents a spin- $1 / 2$ particle (say, an electron), while that with vectors u. given by Eq. (104b) represents an antiparticle (a positron), and two solutions for each particle correspond to two opposite directions of spin, $\sigma_{z}= \pm 1, S_{z}= \pm \hbar / 2$. This interpretation is indeed solid in the non-relativistic limit, when two last components of vector (104a) and two first components of vector (104b) are negligibly small:

$$
u_{+\uparrow} \rightarrow\left(\begin{array}{l}
1  \tag{9.105}\\
0 \\
0 \\
0
\end{array}\right), \quad \mathbf{u}_{+\downarrow} \rightarrow\left(\begin{array}{l}
0 \\
1 \\
0 \\
0
\end{array}\right), \quad \mathbf{u}_{-\uparrow} \rightarrow\left(\begin{array}{l}
0 \\
0 \\
1 \\
0
\end{array}\right), \quad \mathbf{u}_{-\downarrow} \rightarrow\left(\begin{array}{l}
0 \\
0 \\
0 \\
1
\end{array}\right), \quad \text { at } \frac{p_{k}}{m c} \rightarrow 0
$$

In order to show this, let us use the Dirac equation to calculate the Heisenberg-picture law of time evolution of operators of the Cartesian components of the orbital angular momentum $\mathbf{L} \equiv \mathbf{r} \times \mathbf{p}$, for example of $L_{x}=y p_{z}-z p_{y}$, taking into account that operators (98a) commute with those of $\mathbf{r}$ and $\mathbf{p}$, and also the Heisenberg commutation relations (2.14):

$$
\begin{equation*}
i \hbar \frac{\partial \hat{L}_{x}}{\partial t}=\left[\hat{L}_{x}, \hat{H}\right]=c \hat{\boldsymbol{a}} \cdot\left[\left(\hat{y} \hat{p}_{z}-\hat{z} \hat{p}_{y}\right), \hat{\mathbf{p}}\right]=-i \hbar c\left(\hat{\alpha}_{z} \hat{p}_{y}-\hat{\alpha}_{y} \hat{p}_{z}\right) \tag{9.106}
\end{equation*}
$$

with similar relations for two other Cartesian components of the operator. Since the right-hand part of these equations is different from zero, the orbital momentum is generally not conserved - even for a free particle! Let us, however, consider the following vector operator,

$$
\hat{\mathbf{S}} \equiv \frac{\hbar}{2}\left(\begin{array}{ll}
\hat{\boldsymbol{\sigma}} & 0  \tag{9.107a}\\
0 & \hat{\boldsymbol{\sigma}}
\end{array}\right)
$$

whose Cartesian components, in the $z$-basis, are represented by $4 \times 4$ matrices

$$
\mathrm{S}_{x}=\frac{\hbar}{2}\left(\begin{array}{cccc}
0 & 1 & 0 & 0  \tag{9.107b}\\
1 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 \\
0 & 0 & 1 & 0
\end{array}\right), \quad \mathrm{S}_{y}=\frac{\hbar}{2}\left(\begin{array}{cccc}
0 & -i & 0 & 0 \\
i & 0 & 0 & 0 \\
0 & 0 & 0 & -i \\
0 & 0 & i & 0
\end{array}\right), \quad \mathrm{S}_{z}=\frac{\hbar}{2}\left(\begin{array}{cccc}
1 & 0 & 0 & 0 \\
0 & -1 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & -1
\end{array}\right)
$$

and calculate the Heisenberg-picture law of time evolution of these components, for example

$$
\begin{equation*}
i \hbar \frac{\partial \hat{S}_{x}}{\partial t}=\left[\hat{S}_{x}, \hat{H}\right]=c\left[\hat{S}_{x},\left(\hat{\alpha}_{x} \hat{p}_{x}+\hat{\alpha}_{y} \hat{p}_{y}+\hat{\alpha}_{z} \hat{p}_{z}\right)\right] \tag{9.108}
\end{equation*}
$$

A direct calculation of the commutators of matrices (98) and (107) yields

$$
\begin{equation*}
\left[\hat{S}_{x}, \hat{\alpha}_{x}\right]=0, \quad\left[\hat{S}_{x}, \hat{\alpha}_{y}\right]=i \hbar \hat{\alpha}_{z}, \quad\left[\hat{S}_{x}, \hat{\alpha}_{z}\right]=-i \hbar \hat{\alpha}_{y} \tag{9.109}
\end{equation*}
$$

so that we finally get

$$
\begin{equation*}
i \hbar \frac{\partial \hat{S}_{x}}{\partial t}=i \hbar c\left(\hat{\alpha}_{z} \hat{p}_{y}-\hat{\alpha}_{y} \hat{p}_{z}\right) \tag{9.110}
\end{equation*}
$$

with similar expressions for other two components of the operator. Comparing this result with Eq. (106), we see that any Cartesian component of operator (5.198),

$$
\begin{equation*}
\hat{\mathbf{J}} \equiv \hat{\mathbf{L}}+\hat{\mathbf{S}} \tag{9.111}
\end{equation*}
$$

is an integral of motion, ${ }^{52}$ so that this operator may be interpreted as the one presenting the total angular momentum. Hence, operator (104) may be interpreted as the spin operator of a spin-1/2 particle (e.g., electron). As it follows from the last of Eq. (107b), columns (105) represent the eigenkets of the $z$ component of that operator, with eigenstates $S_{z}= \pm \hbar / 2$, depending on the arrow index. So, the Dirac theory provides a justification for spin- $1 / 2$ - or, somewhat more humbly, replaces the spin hypothesis by an assumption of a simpler (and hence more plausible), Lorentz-invariant Hamiltonian (97).

Note, however, that this fact is not true for the exact solutions (103)-(104), so that generally the eigenstates of the Dirac Hamiltonian are certain linear (coherent) superpositions of component wavefunctions describing the particle and its antiparticle - each with both directions of spin. This fact leads to several interesting effects, including the so-called Klien paradox at reflection of a particle from a tunnel barrier. ${ }^{53}$ It is curious that some of these effects may be reproduced in such non-relativistic systems as electron moving in a 2D honeycomb lattice (e.g., in graphene), since they also feature a (locally) linear dispersion relation - see Eq. (3.122). ${ }^{54}$

### 9.7. Low-energy limit

The generalization of the Dirac's theory to the case of a particle with electric charge $q$, moving in a classically-described electromagnetic field may be obtained using the same Eqs. (90). As a result, Eq. (95) becomes

$$
\begin{equation*}
\left[c \hat{\boldsymbol{\alpha}} \cdot(-i \hbar \nabla-q \mathbf{A})+m c^{2} \hat{\beta}+(q \phi-\hat{H})\right] \Psi=0 \tag{9.112}
\end{equation*}
$$

where the Hamiltonian operator $\hat{H}$ is understood in the sense of Eq. (95), i.e. as the partial time derivative with multiplier $i \hbar$. Let us prepare this equation for a low-energy approximation by acting on its left-hand part by a similar square bracket (also an operator!), but with the opposite sign before the last parentheses. Using relations (99) and (100), and the fact that space- and time-independent operators $\hat{\boldsymbol{\alpha}}$ and $\hat{\beta}$ commute with the spin-independent functions $\mathbf{A}(\mathbf{r}, t)$ and $\phi(\mathbf{r}, t)$, as well as with the Hamiltonian operator $i \hbar \partial / \partial t$, the result is

$$
\begin{equation*}
\left\{c^{2}[\hat{\boldsymbol{\alpha}} \cdot(-i \hbar \nabla-q \mathbf{A})]^{2}+\left(m c^{2}\right)^{2}-c[\hat{\boldsymbol{\alpha}} \cdot(-i \hbar \nabla-q \mathbf{A}),(q \phi-\hat{H})]-(q \phi-\hat{H})^{2}\right\} \Psi=0 . \tag{9.113}
\end{equation*}
$$

A direct calculation of the first square bracket, using Eqs. (98) and (107), yields

$$
\begin{equation*}
[\hat{\boldsymbol{\alpha}} \cdot(-i \hbar \nabla-q \mathbf{A})]^{2}=(-i \hbar \nabla-q \mathbf{A})^{2}-2 q \hat{\mathbf{S}} \cdot \nabla \times \mathbf{A} . \tag{9.114}
\end{equation*}
$$

But according to the last of Eqs. (3.21), the last vector product in the right-hand part is just the magnetic field

$$
\begin{equation*}
\boldsymbol{B}=\nabla \times \mathbf{A} . \tag{9.115}
\end{equation*}
$$

Similarly, we may use the first of Eqs. (3.21), for the electric field,

$$
\begin{equation*}
\varepsilon=-\nabla \phi-\frac{\partial \mathbf{A}}{\partial t} \tag{9.116}
\end{equation*}
$$

[^771]to simplify the commutator participating in Eq. (9.113):
\[

$$
\begin{equation*}
[\hat{\boldsymbol{\alpha}} \cdot(-i \hbar \nabla-q \mathbf{A}),(q \phi-\hat{H})]=-q \hat{\boldsymbol{\alpha}} \cdot[\hat{H}, \mathbf{A}]-i \hbar q \hat{\boldsymbol{\alpha}} \cdot[\nabla, \phi]=-i \hbar q \frac{\partial \mathbf{A}}{\partial t}-i \hbar \hat{\boldsymbol{\alpha}} \cdot \nabla \phi=i \hbar q \hat{\boldsymbol{\alpha}} \cdot \boldsymbol{\varepsilon} . \tag{9.117}
\end{equation*}
$$

\]

As a result, Eq. (110) becomes

$$
\begin{equation*}
\left\{c^{2}(-i \hbar \nabla-q \mathbf{A})^{2}+(q \phi-\hat{H})^{2}-\left(m c^{2}\right)^{2}-2 q c^{2} \hat{\mathbf{S}} \cdot \boldsymbol{B}+i \hbar c q \hat{\boldsymbol{\alpha}} \cdot \boldsymbol{\varepsilon}\right\} \Psi=0 . \tag{9.118}
\end{equation*}
$$

So far, this is an exact result, equivalent to Eq. (112), but more convenient for an analysis of the low-energy limit in that not only the offset energy $E-m c^{2}$ (which is the energy used in non-relativistic quantum mechanics), but also the electrostatic energy of the particle, $|q\langle\phi\rangle|$, are much smaller than the rest energy $m c^{2}$. In this limit, the second and third terms of Eq. (118) almost cancel, and introducing the offset Hamiltonian

$$
\begin{equation*}
\hat{\tilde{H}} \equiv \hat{H}-m c^{2} \hat{I} \tag{9.119}
\end{equation*}
$$

we may approximate their difference, up to the first nonvanishing term, as

$$
\begin{equation*}
(q \phi \hat{I}-\hat{H})^{2}-\left(m c^{2}\right)^{2} \hat{I} \equiv\left(q \phi \hat{I}-m c^{2} \hat{I}-\hat{\tilde{H}}\right)^{2}-\left(m c^{2}\right)^{2} \hat{I} \approx 2 m c^{2}(\hat{\tilde{H}}-q \phi \hat{I}) . \tag{9.120}
\end{equation*}
$$

As a result, after division of all terms by $2 m c^{2}$, Eq. (118) may be approximated as

$$
\begin{equation*}
\hat{\tilde{H}} \Psi=\left[\frac{1}{2 m}(-i \hbar \nabla-q \mathbf{A})^{2}+q \phi-\frac{q}{m} \hat{\mathbf{S}} \cdot \boldsymbol{B}+\frac{i \hbar q}{2 m c} \hat{\boldsymbol{\alpha}} \cdot \boldsymbol{\varepsilon}\right] \Psi . \tag{9.121}
\end{equation*}
$$

Let us discuss this important result. The first two terms in the square brackets give the Hamiltonian (3.26) that was extensively used in Chapter 3 for the discussion of non-relativistic motion of charged particles. Note again that the contribution of the vector-potential $\mathbf{A}$ into that Hamiltonian is essentially relativistic, in the following sense: when used for the description of magnetic interaction of two charged particles, due to their orbital motion with speed $v \ll c$, the magnetic interaction is a factor of $(v / c)^{2}$ smaller than the electrostatic interaction of the particles. ${ }^{55}$ The reason why we did discuss the effects of $\mathbf{A}$ in Chapter 3 was that is was used there to describe external magnetic fields, keeping our analysis valid even for the cases when that field is strong by being produced by relativistic effects - such as aligned spins in a permanent magnet.

The next, third term in the square brackets is also familiar to the reader: it was introduced informally in Sec. 4.1, and then formally in Sec. 4.4 to describe the effect of magnetic field on particle's spin - see Eqs. (4.3), (4.5), and (4.163). When justifying this form of interaction, I referred mostly to results of Stern-Gerlach-type experiments, but it is extremely pleasing that this result ${ }^{56}$ follows from such a fundamental relativistic treatment as Dirac's theory. As we already know from the discussion of

[^772]the Zeeman effect in Sec. 6.4, the effects of magnetic field on the orbital motion of an electron (described by orbital angular momentum $\mathbf{L}$ ) and its spin $\mathbf{S}$ are of the same order, i.e. present an essentially relativistic effect.

Finally, the last term in the square brackets of Eq. (121) is also not quite new for us: in particular it describes the spin-orbit interaction. Indeed, in the case of classical, spherical-symmetric electric field $\varepsilon$ with potential $\phi(r)=U(r) / q$, the term may be reduced to Eq. (6.56b):

$$
\begin{equation*}
\hat{H}_{\mathrm{so}}=\frac{1}{2 m^{2} c^{2}} \hat{\mathbf{S}} \cdot \hat{\mathbf{L}} \frac{1}{r} \frac{d U}{d r}=-\frac{q}{2 m^{2} c^{2}} \hat{\mathbf{S}} \cdot \hat{\mathbf{L}} \frac{1}{r} \varepsilon . \tag{9.122}
\end{equation*}
$$

The proof of this correspondence requires a bit of additional work, ${ }^{57}$ because in Eq. (121), the term responsible for the spin-orbit interaction acts on 4-component wavefunctions, while Hamiltonian (122) is supposed to act on non-relativistic wavefunctions with account of spin, whose coordinate representation is given by 2 -component columns - spinors: ${ }^{58}$

$$
\begin{equation*}
\psi=\binom{\psi_{\uparrow}}{\psi_{\downarrow}} . \tag{9.123}
\end{equation*}
$$

The simplest way to prove the identity of the two formulas is not to use Eq. (121) directly, but to return to the Dirac equation (112), for the particular case of motion in a stationary electric field with no magnetic field, when Dirac's Hamiltonian is reduced to

$$
\begin{equation*}
\hat{H}=c \hat{\boldsymbol{\alpha}} \cdot \hat{\mathbf{p}}+\hat{\beta} m c^{2}+U(\mathbf{r}) \tag{9.124}
\end{equation*}
$$

Since this Hamiltonian is time-independent, we may look for its 4-component eigenfunctions in the form

$$
\begin{equation*}
\Psi(\mathbf{r}, t)=\binom{\psi_{+}(\mathbf{r})}{\psi_{-}(\mathbf{r})} \exp \left(-i \frac{E}{\hbar} t\right) \tag{9.125}
\end{equation*}
$$

where each of $\psi_{ \pm}$is a 2-component column of the type (123), representing two spin states of the particle (index + ) and antiparticle (index -). Plugging Eq. (125) into Eq. (124), and using Eq. (98a), we get the following system of two linear equations:

$$
\begin{align*}
& {\left[E-m c^{2}-U(\mathbf{r})\right] \psi_{+}-c \hat{\boldsymbol{\sigma}} \cdot \hat{\mathbf{p}} \psi_{-}=0}  \tag{9.126}\\
& {\left[E+m c^{2}-U(\mathbf{r})\right] \psi_{-}-c \hat{\boldsymbol{\sigma}} \cdot \hat{\mathbf{p}} \psi_{+}=0}
\end{align*}
$$

[^773]Expressing $\psi$ - from the latter equation, and plugging the result into the former one, we get the following single equation for particle's spinor:

$$
\begin{equation*}
\left[E-m c^{2}-U(\mathbf{r})-c^{2} \hat{\boldsymbol{\sigma}} \cdot \hat{\mathbf{p}} \frac{1}{E+m c^{2}-U(\mathbf{r})} \hat{\boldsymbol{\sigma}} \cdot \hat{\mathbf{p}}\right] \psi_{+}=0 . \tag{9.127}
\end{equation*}
$$

So far, this is an exact equation for eigenstates and eigenvalues of Hamiltonian (124). It may be substantially simplified in the low-energy limit when both the potential energy ${ }^{59}$ and the non-relativistic eigenenergy

$$
\begin{equation*}
\widetilde{E} \equiv E-m c^{2} \tag{9.128}
\end{equation*}
$$

are much less than $m c^{2}$. Indeed, in this case the expression in denominator of the last term in the brackets of Eq. (127) is close to $2 m c^{2}$. Since $\sigma^{2}=1$, with that replacement, Eq. (127) is reduced to the non-relativistic Schrödinger equation, similar for both spin components of $\psi_{+}$, and hence giving spindegenerate energy levels. In order to recover small relativistic and spin-orbit effects, we need a slightly more accurate approximation:

$$
\begin{equation*}
\frac{1}{E+m c^{2}-U(\mathbf{r})} \equiv \frac{1}{2 m c^{2}+\widetilde{E}-U(\mathbf{r})}=\frac{1}{2 m c^{2}}\left[1+\frac{\widetilde{E}-U(\mathbf{r})}{2 m c^{2}}\right]^{-1} \approx \frac{1}{2 m c^{2}}\left[1-\frac{\widetilde{E}-U(\mathbf{r})}{2 m c^{2}}\right] \tag{9.129}
\end{equation*}
$$

in which Eq. (127) is reduced to

$$
\begin{equation*}
\left[\widetilde{E}-U(\mathbf{r})-\frac{\hat{p}^{2}}{2 m}+\hat{\boldsymbol{\sigma}} \cdot \hat{\mathbf{p}} \frac{\widetilde{E}-U(\mathbf{r})}{\left(2 m c^{2}\right)^{2}} \hat{\boldsymbol{\sigma}} \cdot \hat{\mathbf{p}}\right] \psi_{+}=0 . \tag{9.130}
\end{equation*}
$$

As follows from Eqs. (5.46)-(5.47), the operators of momentum and of a function of coordinates commute as

$$
\begin{equation*}
[\hat{\mathbf{p}}, U(\mathbf{r})]=-i \hbar \nabla U, \tag{9.131}
\end{equation*}
$$

so that the last term in square brackets of Eq. (130) may be rewritten as

$$
\begin{equation*}
\hat{\boldsymbol{\sigma}} \cdot \hat{\mathbf{p}} \frac{\widetilde{E}-U(\mathbf{r})}{(2 m c)^{2}} \hat{\boldsymbol{\sigma}} \cdot \hat{\mathbf{p}}=\frac{\widetilde{E}-U(\mathbf{r})}{(2 m c)^{2}} \hat{p}^{2}-\frac{i \hbar}{(2 m c)^{2}}(\hat{\boldsymbol{\sigma}} \cdot \nabla U)(\hat{\boldsymbol{\sigma}} \cdot \hat{\mathbf{p}}) . \tag{9.132}
\end{equation*}
$$

Since in the low-energy limit both terms in the right-hand part of this relation are much smaller than the three leading terms of Eq. (130), in the first of them we may replace the numerator with its nonrelativistic value $\hat{p}^{2} / 2 m$. With this replacement, the term coincides with the first relativistic correction to the kinetic energy operator - see Eqs. (6.47) and (6.49a). The second term, proportional to the electric field $\varepsilon=-\nabla \phi=-\nabla U / q$, may be transformed further on, using a readily verifiable relation

$$
\begin{equation*}
(\hat{\boldsymbol{\sigma}} \cdot \nabla U)(\hat{\boldsymbol{\sigma}} \cdot \hat{\mathbf{p}})=(\nabla U) \cdot \hat{\mathbf{p}}+i \hat{\boldsymbol{\sigma}} \cdot[(\nabla U) \times \hat{\mathbf{p}}] . \tag{9.133}
\end{equation*}
$$

Of the two terms in the right-hand part, only the second one depends on spin, ${ }^{60}$ giving the following spin-orbital interaction contribution to the Hamiltonian,

[^774]\[

$$
\begin{equation*}
\hat{H}_{\mathrm{so}}=\frac{\hbar}{(2 m c)^{2}} \hat{\boldsymbol{\sigma}} \cdot[(\nabla U) \times \hat{\mathbf{p}}]=\frac{q}{2 m^{2} c^{2}} \hat{\mathbf{S}} \cdot[(\nabla \phi) \times \hat{\mathbf{p}}] . \tag{9.134}
\end{equation*}
$$

\]

For a central electric field with $\phi(\mathbf{r})=\phi(r)$, the potential gradient has only one, radial component: $\nabla \phi=$ $(d \phi / d r) \mathbf{r} / \mathbf{r}=-\varepsilon \mathbf{r} / r$, and with the angular momentum definition $\hat{\mathbf{L}} \equiv \mathbf{r} \times \hat{\mathbf{p}}$, Eq. (134) is reduced to Eq. (122).

As was shown in Sec. 6.3, the perturbative treatment of Eq. (122), together with the kineticrelativistic correction (6.49), in the hydrogen-like atom problem, leads to the fine structure of each Bohr level $E_{n}$, given by Eq. (6.60):

$$
\begin{equation*}
\Delta E_{\mathrm{so}}=-\frac{2 E_{n}}{m c^{2}}\left(3-\frac{4 n}{j+1 / 2}\right) . \tag{9.135}
\end{equation*}
$$

This result gets a confirmation from the surprising fact that for the hydrogen-like atom problem, the Dirac equation may be solved exactly - without any assumptions. I do not have time/space to reproduce the solution, ${ }^{61}$ and will list just the final result for the energy spectrum:

H-like
atom's eigenenergies

$$
\begin{equation*}
\frac{E}{m c^{2}}=\left\{1+\frac{Z^{2} \alpha^{2}}{\left[n+\left\{(j+1 / 2)^{2}-Z^{2} \alpha^{2}\right\}^{1 / 2}-(j+1 / 2)\right]^{2}}\right\}^{-1 / 2} . \tag{9.136}
\end{equation*}
$$

Here $n=1,2, \ldots$ is the same main quantum number as in Bohr's theory, while $j$ is the quantum number specifying eigenvalues (5.203) of the total angular momentum's square $J^{2}$ in the units of $\hbar^{2}$, taking halfinteger values: $j=l \pm 1 / 2=1 / 2,3 / 2,5 / 2, \ldots$ - see Eq. (5.215). Such set of quantum numbers is rather natural, because due to the spin-orbit interaction, the orbital and spin angular momenta are not conserved, while their vector sum, $\mathbf{J}=\mathbf{L}+\mathbf{S}$, is - in the absence of external magnetic field. Each energy level (136) is doubly-degenerate, with two eigenstates representing two directions of spin - i.e. two values of $l=j \mp 1 / 2$ at fixed j .

Since according to Eq. (1.9), the square of the fine-structure constant $\alpha \equiv e^{2} / 4 \pi \varepsilon_{0} \hbar \mathrm{c}$ may be presented as the ratio $E_{\mathrm{H}} / m c^{2}$, the low-energy limit $\left(E-m c^{2} \sim E_{\mathrm{H}} \ll m c^{2}\right)$ may be pursued by expanding Eq. (136) into the Taylor series in $(Z \alpha)^{2} \ll 1$. The result,

$$
\begin{equation*}
E \approx m c^{2}\left[1-\frac{Z^{2} \alpha^{2}}{2 n^{2}}-\frac{Z^{4} \alpha^{4}}{2 n^{4}}\left(\frac{n}{j+1 / 2}-\frac{3}{4}\right)\right], \tag{9.137}
\end{equation*}
$$

has the same structure, and allows the same interpretation as Eq. (92), but with the last term coinciding with Eq. (6.52) - and with experimental results. Historically, this correct description of the fine structure of atomic levels provided a decisive proof of Dirac's theory.

However, even such an impressive theory does not have too many direct applications. The main reason for that was already discussed in brief in the end of Sec. 5: due to the possibility of creation and

[^775]annihilation of particle-antiparticle pairs at energies higher than $2 m c^{2}$, the number of particles participating in high-energy interactions is not fixed. An adequate general description of such situation is given by the quantum field theory, in which the particle wavefunction is treated as a field to be quantized, using so-called field operators $\hat{\Psi}(\mathbf{r}, t)$ - very much as the electromagnetic field was treated in Secs. 1-4 above. (The Dirac equation follows from the quantum field theory in the single-particle approximation.)

As was mentioned above on several occasions, the quantum field theory is beyond the scope of this course, and I have to stop here, referring the interested reader to one of several excellent available textbooks on this discipline. ${ }^{62}$ (I would strongly encourage the student going in this direction to start with playing with the field operators on this or her own, taking clues from Eqs. (16), but replacing the creation / annihilations operators $\hat{a}_{j}^{\dagger}$ and $\hat{a}_{j}$ of the harmonic oscillator with those of the general second quantization formalism outlined in Sec. 8.3.)

### 9.8. Exercise problems

9.1.* Prove the Casimir formula (23) for the attraction force $F=-P A$ between two perfectly conducting parallel plates of area $A$, separated by a narrow vacuum gap $d \ll A^{1 / 2}$.

Hint: You may like to use the Euler-Maclaurin formula. ${ }^{63}$
9.2. Radiation of some single-mode quantum sources may have such a high degree of coherence that it is possible to observe interference from two independent sources with virtually the same frequency, incident on one detector.
(i) Generalize Eq. (29) to this case.
(ii) Use the generalized expression to show that incident waves in different Fock states do not create an interference pattern.
9.3. Calculate the zero-delay value $g^{(2)}(0)$ of the second-order correlation function of a singlemode electromagnetic field in the so-called Schrödinger-cat state: a coherent superposition of two Glauber states, with equal amplitudes, equal but sign-opposite parameters $\alpha$, and a certain phase shift between them.
9.4. Calculate the zero-delay value $g^{(2)}(0)$ of the second-order correlation function of singlemode electromagnetic field in the squeezed ground state $=$ defined by Eq. (5.172).
9.5. Calculate the rate of spontaneous photon emission (into the unrestricted free space) by a hydrogen atom, initially in the $2 p$ state $(n=2, l=1)$ with $m=0$. Would the result be different for $m= \pm$

[^776]1? for the $2 s$ state $(n=2, l=0, m=0)$ ? Discuss the relation between these quantum-mechanical results and those given by the classical theory of radiation, using the simplest classical model of the atom.
9.6. An electron has been placed at the lowest excited level of a spherically-symmetric, quadratic potential well $U(\mathbf{r})=m_{e} \omega^{2} r^{2} / 2$. Calculate the rate of its relaxation to the ground state, with emission of a photon (to the free space). Compare the rate with that for a similar transition of the hydrogen atom, for the case when the radiation frequencies of these two systems are equal.
9.7. Derive an analog of Eq. (53) for the spontaneous photon emission into the free space, due to a change of its magnetic dipole moment $\mathbf{m}$ of a small-size system.
9.8. A spin- $1 / 2$ particle, with the gyromagnetic ratio $\gamma$, is in its orbital ground state in a dc magnetic field $\boldsymbol{B}_{0}$. Calculate the rate of its spontaneous transition from the higher to the lower energy level, with the emission of a photon into the free space. Evaluate the rate for in an electron in a field of 10 T , and discuss the implications of this result for experiments with electron spins.
9.9. Calculate the rate of spontaneous transitions between the two sublevels of the ground state of a hydrogen atom, formed as a result of its hyperfine splitting. Discuss the implications of the result for the width of the $21-\mathrm{cm}$ spectral line.
9.10. Find the eigenstates and eigenvalues of the Janes-Cummings Hamiltonian (78), and discuss their behavior near the resonance point $\omega=\Omega$.
9.11. Analyze the Purcell effect, mentioned in Secs. 3 and 4, qualitatively; in particular, calculate the so-called Purcell factor $F_{\mathrm{P}}$, defined as the ratio of the spontaneous emission rates $\Gamma_{s}$ of an atom in a resonant cavity (tuned exactly to the quantum transition frequency) and that in the free space.
9.12. Prove that the Klein-Gordon equation (9.84) may be rewritten in the form similar to the non-relativistic Schrödinger equation,

$$
i \hbar \frac{\partial \psi}{\partial t}=\hat{H} \psi
$$

for a two-component wavefunction $\psi,{ }^{64}$ with the Hamiltonian represented (in the usual $z$-basis) by the following $2 \times 2$-matrix:

$$
\mathrm{H}=-\left(\sigma_{z}+i \sigma_{y}\right) \frac{\hbar^{2}}{2 m} \nabla^{2}+m c^{2} \sigma_{z} .
$$

Use your solution to discuss the physical meaning of the wavefunction's components.
9.13. Calculate and discuss the energy spectrum of a relativistic, spinless, charged particle placed into an external uniform, time-independent magnetic field $\mathcal{B}$. Use the result to formulate the condition of validity of the non-relativistic theory.

[^777]Hint: Reduce the relativistic Schrödinger equation, describing the problem, to the non-relativistic one describing the same problem, with some effective parameter(s).
9.14. Prove Eq. (91) for the energy spectrum of a hydrogen-line atom, calculated from the relativistic Schrödinger equation.

Hint: Use the fact that, as a mathematical analysis of Eq. (3.184) shows, its eigenvalues are given by Eq. (3.191), $\varepsilon_{n}=-1 / 2 n^{2}$, with $n=l+1+n_{r}$, where $n_{r}=0,1,2, \ldots$, even if $l$ is not integer. ${ }^{65}$
9.15. Derive the general expression for the differential cross-section of the elastic scattering of a spinless relativistic particle by a static potential $U(\mathbf{r})$, in the Born approximation, and formulate the conditions of its validity. Use these results to calculate the differential cross-section of scattering of a particle with electric charge $-e$ by the Coulomb electrostatic potential $\phi(\mathbf{r})=Z e / 4 \pi \varepsilon_{0} r$.
9.16. Calculate the commutator of operator $\hat{L}^{2}$ and the Dirac Hamiltonian of a free particle. Compare the result with that for the non-relativistic Hamiltonian of a free particle, and interpret the difference.
9.17.* In the Heisenberg picture of quantum dynamics, derive an equation describing time evolution of free electron's velocity in the Dirac theory. Solve the equation for the simplest state, with constant energy and momentum, and discuss the solution.
9.18. ${ }^{*}$ Calculate the eigenstates and eigenenergies of a spin- $1 / 2$ particle with charge $q$, placed into a uniform, time-independent external magnetic field $B$. Compare the calculated energy spectrum with those following from the non-relativistic theory and the relativistic Schrödinger equation.
9.19. ${ }^{*}$ Following the recommendation in the end of Chapter 9 of the lecture notes, introduce the quantum field operators $\hat{\psi}$, which would be related to the usual wavefunctions $\psi$ just as the EM field operators (9.16) are related to the classical electromagnetic fields, and explore the basic properties of these operators. (For this preliminary study, consider just the fixed-time situation.)

[^778]
## Chapter 10. Making Sense of Quantum Mechanics

This (very cryptic) chapter addresses the issues of quantum mechanics interpretation that are still a subject of debate - fortunately not affecting practical applications of the quantum theory.

### 10.1. Hidden variables and local reality

Only now, with a quantitative understanding of the principles of quantum mechanics, we are ready to proceed to the discussion of its interpretation ${ }^{1}$ - the issue which is very closely related to problems of measurements, already discussed in Sec. 7.7. As was already mentioned in that section, the founding fathers of quantum mechanics have not left much guidance on these topics, because in the first years after the advent of this exciting new theory they gave understandable preference to using it for deriving new particular results, and then were much distracted by the development of nuclear physics and its applications. This is why, after a very important but inconclusive discussion between A. Einstein and N . Bohr in the mid-30s, the debates of quantum measurements and the related conceptual issues of quantum mechanics have resumed only in the 1950s. They have led to a key contribution by J. Bell in the early 1960s, and an important experimental work on verifying Bell's inequalities (see below), but besides that work, the recent progress is marginal, and opinions of even prominent physicists on certain issues are still very much different.

Perhaps the central controversial issue is question (iii) posed in Sec. 7.7: what (if any :-) is the "real" state of a quantum-mechanical system before a nearly-perfect measurement giving a certain outcome? In order to be specific, let us focus again on the simplest example of Stern-Gerlach measurements of spin $-1 / 2$ particles - because of their physical transparency and technical simplicity. ${ }^{2}$ As the reader knows very well by now, even in a pure quantum spin state (for example, $\uparrow$ ), i.e. the least uncertain state of the system, the results of the Stern-Gerlach measurements of other spin component are still uncertain. Indeed, as we know from Sec. 4.4, the ket-vector of this state may be presented as

$$
\begin{equation*}
|\uparrow\rangle=\frac{1}{\sqrt{2}}(|\rightarrow\rangle+|\leftarrow\rangle), \tag{10.1}
\end{equation*}
$$

so that the probabilities of measuring any of values $S_{x}=+\hbar / 2$ and $S_{x}=-\hbar / 2$ equal $50 \%$. So, has the spin had a certain value of $S_{x}$ a split second before the Stern-Gerlach measurement that gave a certain outcome, for example $S_{x}=+\hbar / 2$ ? For a classical system, with perfect detectors, the answer is definitely yes. In this case, the pre-measurement probability of $50 \%$ just reflects the degree of our ignorance about the real state of the system, and the detector merely reveals it.

However, the situation in quantum mechanics is different, and such interpretation is impossible, as was clearly shown in the famous EPR paper published in 1935 by A. Einstein, B. Podolsky, and N.

[^779]Rosen. Its original discussed thought experiments with a pair of 1D particles prepared in a quantum state in that both the sum of their momenta and difference of their coordinates are exactly fixed: $p_{1}+p_{2}$ $=0, x_{1}-x_{2}=a .{ }^{3}$ However, usually the discussion is recast into an equivalent Stern-Gerlach experiment shown in Fig. 1a. ${ }^{4}$ A source emits rare pairs of spin- $1 / 2$ particles, propagating in opposite directions, with exactly zero net spin, but otherwise in random spin states. After the spatial separation of the particles has become sufficiently large (see below), the spin state of each of them is measured with a SternGerlach detector, one of them (Fig. 1, detector $\mathrm{SG}_{1}$ ) somewhat closer to the particle source, so it makes the measurement first, at time $t_{1}<t_{2}$.

Fig. 10.1. (a) General scheme of two-particle Stern-Gerlach experiments, and (b) the orientation of the detectors, assumed at the devivation of Bell's inequality (14).

First, let the detectors be oriented say along the same direction, say axis z. Evidently, the probability of each detector to give any of values $S_{z}= \pm \hbar / 2$ is $50 \%$. However, if the first detector had given result $S_{z}=-\hbar / 2$, even before the second detector's measurement, we know that it will give result $S_{z}$ $=+\hbar / 2$ with $100 \%$ probability. So far, the result allows for a classical interpretation, just for the singleparticle measurements discussed in Secs. 2.5 and 7.7. Thus we may fancy that the second particle really has a definite spin before the measurement, and the first measurement has just removes our ignorance about that reality. In other words, the change of probability is due to the statistical ensemble redefinition: the $50 \%$ probability belongs to the ensemble of all experiments, while the $100 \%$ probability, to the sub-ensemble of experiments with the $S_{z}=-\hbar / 2$ outcome of the first experiment.

However, let the source generate the particle pairs in the entangled, singlet state (8.19),

$$
\begin{equation*}
\left|s_{12}\right\rangle=\frac{1}{\sqrt{2}}(|\uparrow \downarrow\rangle-|\downarrow \uparrow\rangle), \tag{10.2}
\end{equation*}
$$

that certainly satisfies the above assumptions: the probability of each $S_{z}$ value of any particle is $50 \%$, the sum of both $S_{z}$ is exactly zero, and if the first detector's result is $S_{z}=-\hbar / 2$, then the state of the remaining particle is $\uparrow$, with zero uncertainty. Now let us use Eq. (1), and its counterpart for vector $|\downarrow\rangle,{ }^{5}$ to present the same initial state (2) in the form

[^780]\[

$$
\begin{equation*}
\left|s_{12}\right\rangle=\frac{1}{\sqrt{2}}\left[\frac{1}{\sqrt{2}}(|\rightarrow\rangle+|\leftarrow\rangle) \frac{1}{\sqrt{2}}(|\rightarrow\rangle-|\leftarrow\rangle)-\frac{1}{\sqrt{2}}(|\rightarrow\rangle-|\leftarrow\rangle) \frac{1}{\sqrt{2}}(|\rightarrow\rangle+|\leftarrow\rangle)\right] . \tag{10.3}
\end{equation*}
$$

\]

Opening the parentheses (without swapping the ket-vector order!), we get an expression similar to Eq. (2), but now for the $x$-basis:

$$
\begin{equation*}
\left|s_{12}\right\rangle=\frac{1}{\sqrt{2}}(|\rightarrow \leftarrow\rangle-|\leftarrow \rightarrow\rangle) . \tag{10.4}
\end{equation*}
$$

Hence if we use the first detector (closest to the particle source) to measure $S_{x}$ rather than $S_{z}$, then after it had given as certain result (say, $S_{x}=-\hbar / 2$ ), we know for sure, before the second particle spin's measurement, that its $S_{x}$ component equals $+\hbar / 2$.

So, depending on the experiment performed on the first particle, the second particle turns out to be in one of two states - either with a definite component $S_{z}$ or with a definite component $S_{x}$, in each case without any uncertainty. Evidently, this situation cannot be interpreted in classical terms if the particles do not interact during the measurements. A. Einstein in was deeply unhappy with such situation, because it did not satisfy the general requirement to any theory, which nowadays is called the local reality. His definition of this requirement was as follows:
"The real factual situation of system 2 is independent of what is done with system 1 that is spatially separated from the former".
(Here the term "separated" in this sentence is a bit uncertain, but from the context it is clear that Einstein meant the detector separation by a superluminal interval, i.e. by distance

$$
\begin{equation*}
\left|\mathbf{r}_{1}-\mathbf{r}_{2}\right|>c\left|t_{1}-t_{2}\right|, \tag{10.5}
\end{equation*}
$$

where the measurement time difference, participating in the right-hand part, includes the measurement duration.) In Einstein's view, since quantum mechanics does not satisfy the local reality condition, it cannot be considered a complete theory of Nature.

This situation naturally raises the question whether something (usually called hidden variables) may be added to the quantum-mechanical description in order to satisfy the local reality requirement. The first definite statement in this regards was J. von Neumann's "proof" (first famous, then infamous :-) that such variables cannot be introduced; for a while his work satisfied quantum mechanics practitioners. ${ }^{7}$ A major new contribution to the problem was made only in the 1960s by J. Bell. ${ }^{8}$ First of all, he has found an elementary (in his words, "foolish") error in von Neumann's logic, which voids his "proof". Second, he demonstrated that Einstein’s local reality condition is incompatible with conclusions of quantum mechanics - that had been, by that time, confirmed by too many experiments to be seriously questioned. Since no hidden variable introduction can change this situation, in this sense such introduction is impossible.

[^781]Let me describe a particular version of Bell's proof (suggested by E. Wigner), using the same EPR pair experiment (Fig. 1a), in that each SG detector may be oriented in any of 3 directions: $a, b$, or $c$ - see Fig. 1b. As we know from Chapter 4, if a fully-polarized beam of spin-1/2 particles is passed through a Stern-Gerlach apparatus forming angle $\phi$ with the polarization axis, the probabilities of two counterpart outcomes of the experiment are

$$
\begin{equation*}
W\left(\phi_{+}\right)=\cos ^{2} \frac{\phi}{2}, \quad W\left(\phi_{-}\right)=\sin ^{2} \frac{\phi}{2} . \tag{10.6}
\end{equation*}
$$

Let us use this formula to calculate all joint probabilities of measurement outcomes, starting from the detectors 1 and 2 oriented, respectively, in directions $a$ and $c$. Since the angle between negative direction of axis $a$ and positive direction of axis $c$ is $\phi_{a+, c-}=\pi-\varphi$ (see the dashed arrow in Fig. 1b), we get

$$
\begin{equation*}
W\left(a_{+}, c_{+}\right)=W\left(a_{+}\right) W\left(c_{+} \mid a_{+}\right)=\frac{1}{2} \cos ^{2} \frac{\phi_{a-, c+}}{2}=\frac{1}{2} \cos ^{2} \frac{\pi-\varphi}{2}=\frac{1}{2} \sin ^{2} \frac{\varphi}{2} . \tag{10.7}
\end{equation*}
$$

Absolutely similarly,

$$
\begin{gather*}
W\left(c_{+}, b_{+}\right)=W\left(c_{+}\right) W\left(b_{+} \mid c_{+}\right)=\frac{1}{2} \sin ^{2} \frac{\varphi}{2},  \tag{10.8}\\
W\left(a_{+}, b_{+}\right)=W\left(a_{+}\right) W\left(b_{+} \mid a_{+}\right)=\frac{1}{2} \cos ^{2} \frac{\pi-2 \varphi}{2}=\frac{1}{2} \sin ^{2} \varphi . \tag{10.9}
\end{gather*}
$$

Now note that for any angle $\varphi$ smaller than $\pi / 2$ (as in the case shown in Fig. 1b),

$$
\begin{equation*}
\frac{1}{2} \sin ^{2} \varphi \geq \frac{1}{2} \sin ^{2} \frac{\varphi}{2}+\frac{1}{2} \sin ^{2} \frac{\varphi}{2} \equiv \sin ^{2} \frac{\varphi}{2} . \tag{10.10}
\end{equation*}
$$

(For example, for $\varphi \rightarrow 0$ the left-hand part of this relation tends to $\varphi^{2} / 2$, while the right-hand part, to $\varphi^{2} / 4$.) Hence the quantum-mechanical result gives, in particular,

$$
\begin{equation*}
W\left(a_{+}, b_{+}\right) \geq W\left(a_{+}, c_{+}\right)+W\left(c_{+}, b_{+}\right), \quad \text { for }|\varphi| \leq \pi / 2 . \tag{10.11}
\end{equation*}
$$

On the other hand, we may compose another inequality for the same probabilities without calculating them from any particular theory, but using the local reality assumption. Let us list all possible outcomes of detector measurements, taking into account the zero net spin:

| $W\left(a_{+}, b_{+}\right) \xrightarrow{W\left(a_{+}, c_{+}\right) \longrightarrow} \xrightarrow{\bullet}$ | Detector 1 results | Detector 2 results | Probability |
| :---: | :---: | :---: | :---: |
|  | $a_{+}, b_{+}, c_{+}$ | $a_{\text {-, }}, b_{\text {-, }}, c_{\text {- }}$ | $W_{1}$ |
|  | $a_{+}, b_{+}, c_{-}$ | $a_{\text {-, }}, b_{\text {-, }} c_{+}$ | $W_{2}$ |
|  | $a_{+}, b_{-}, c_{+}$ | $a_{\text {-, }}, b_{+}, c_{-}$ | $W_{3}$ |
|  | $a_{+}, b_{-}, c_{-}$ | $a_{\text {-, }}, b_{+}, c_{+}$ | $W_{4}$ |
|  | $a_{\text {a }}, b_{+}, c_{+}$ | $a_{+}, b_{-}, c_{-}$ | $W_{5}$ |
|  | $a_{\text {. }}, b_{+}, c_{\text {- }}$ | $a_{+}, b_{-}, c_{+}$ | $W_{6}$ |
|  | $a_{\text {-, }}, b_{-}, c_{+}$ | $a_{+}, b_{+}, c_{-}$ | $W_{7}$ |
|  | $a_{\text {- , }}, b_{-}, c_{\text {- }}$ | $a_{+}, b_{+}, c_{+}$ | $W_{8}$ |

Quantummechanical result for joint probabilities

From the local reality point of view, these measurement options are independent, so we may write:

$$
\begin{equation*}
W\left(a_{+}, c_{+}\right)=W_{2}+W_{4}, \quad W\left(c_{+}, b_{+}\right)=W_{3}+W_{7}, \quad W\left(a_{+}, b_{+}\right)=W_{3}+W_{4} . \tag{10.12}
\end{equation*}
$$

On the other hand, since no probability may be negative (by its very definition), we may always write

$$
\begin{equation*}
W_{3}+W_{4} \leq\left(W_{2}+W_{4}\right)+\left(W_{3}+W_{7}\right) \tag{10.13}
\end{equation*}
$$

Plugging into this inequality the values of these two parentheses, given by Eq. (12), we get

Bell's inequality for local-reality theories

$$
\begin{equation*}
W\left(a_{+}, b_{+}\right) \leq W\left(a_{+}, c_{+}\right)+W\left(c_{+}, b_{+}\right) . \tag{10.14}
\end{equation*}
$$

This is (one of several possible forms of) the Bell's inequality that has to be satisfied by any local-reality theory; it directly contradicts the quantum-mechanical result (11).

Though experimental tests of the Bell's inequalities had been started in the late 1960s, the interpretation of first results was vulnerable to two criticisms:
(i) The detectors were not fast enough and not far enough to have relation (5) satisfied. This is why, as the matter of principle, there was a chance that information on one measurement had been transferred (by some, mostly implausible) means to particles before the second measurement - the socalled locality loophole.
(ii) Particle detection efficiencies were too low to have sufficiently small error bars for both parts of the inequality - the detection loophole.

Gradually, these loopholes have been closed. ${ }^{9}$ As expected, substantial violations of Bell inequalities equivalent to Eq. (14) have been proved, essentially rejecting any possibility to reconcile quantum mechanics with Einstein's local reality requirement.

### 10.2. Interpretations of quantum mechanics

The fact that quantum mechanics is incompatible with local reality, makes it reconciliation with our (classically-bred) "common sense" rather challenging. Here is a brief list of the major interpretations of quantum mechanics, that try to provide at least a partial reconciliation of this kind:
(i) The so-called Copenhagen interpretation, to which most physicists subscribe. This "interpretation" does not really interpret anything; it just states the internal randomness of measurement results in quantum mechanics, essentially saying: "Do not worry; this is just how it is; live with it". For me personally, this interpretation, at least in its most frequently repeated forms, has only one, rather pedagogical weakness: though it implies statistical ensembles (otherwise, how would you define the probability?), but does not put a sufficient emphasis on their role, in particular the possible ensemble

[^782]redefinition as the only key point of human involvement in the measurement process. ${ }^{10}$ Perhaps the most impressive objection to the Copenhagen interpretation was given by A. Einstein during his 1935 discussion with N. Bohr: "God does not play dice." OK, when Einstein speaks, we all should listen, but perhaps when God speaks (through the experimental results), we have to pay even more attention.
(ii) Non-local reality. After the dismissal of von Neumann's "proof" by J. Bell, to the best of my knowledge, there has been no proof that hidden parameters could not be introduced, provided that they do not imply the local reality. Of constructive approaches, perhaps the most notable contribution was made by D. Bohm ${ }^{11}$ who developed the L. de Broglie's interpretation of the wavefunction as a "pilot wave", making it quantitative. In the wave mechanics version of this concept, the wavefunction, governed by the Schrödinger equation, just guides a real, point-like classical particle whose coordinates serve as hidden variables. However, this concept does not satisfy the notion of local reality. Namely, the measurement of particle's coordinate at a certain point $\mathbf{r}_{1}$ has to instantly change the wavefunction everywhere, including points $\mathbf{r}_{2}$ in the superluminal interval range (4). So, Bohm's hidden variables would hardly make A. Einstein happy. After having recognized this problem, D. Bohm abandoned his theory - in J. Bell's view, perhaps too early. In my personal taste, however, the assumption of such (in Einstein's words) "spooky action at a distance" is too large a sacrifice to save the classical determinism.
(iii) The many-world interpretation introduced in 1957 by H . Everitt and popularized in the 1960s and 1970s by B. de Witt. In this interpretation, all possible measurement outcomes do happen, splitting the Universe into the corresponding number of "parallel" Universes, so that from one of them, other Universes and hence other outcomes cannot be observed. Let me leave to the reader an estimate of the rate at which the parallel Universes being constantly generated (say, per second), taking into account that such generation should take place not only at explicit lab experiments, but at any irreversible process such as fission of any atom nucleus or absorption of a photon, everywhere in each Universe whether its result is recorded or not. Even the main proponent of this interpretation, B. de Witt, has confessed: "The idea is not easy to reconcile with common sense". I agree.
(iv) The quantum logic. In desperation, some physicists turned philosophers have decided to dismiss the very logic we are using - in science and elsewhere, so that a statement like "the Bell inequalities are violated" would not make any definite sense. OK, if we dismiss the formal logic, I do not know how we can use any scientific theory and make any predictions - until the quantum logic experts tell us what to replace the classical logic with. To the best of my knowledge, so far they have not done that, at least for the measurement process. I personally trust J. Bell's opinion: "It is my impression that the whole vast subject of Quantum Logic has arisen [...] from the misuse of a word."

The weakness of all interpretations of quantum mechanics is that, as far as I know, neither of them has yet provided any suggestion how this particular interpretation might be tested experimentally to exclude other ones. On the positive side, there is a consensus that quantum mechanics makes correct, if sometimes probabilistic, predictions of all reliable experimental results we are aware of. Maybe, this is not that bad for a scientific theory. ${ }^{12}$

# Part CM: Statistical Mechanics 

Last corrections: 2019/08/01

A revised version of this material is now published by the IOP under the title "Statistical Mechanics: Lecture notes" (Essential Advanced Physics - Volume 7, ISBN 978-0-7503-1416-6), with the model solutions of the exercise problems published under the title

## Table of Contents

## Chapter 1. Review of Thermodynamics ( 24 pp .)

1.1. Introduction: Statistical physics and thermodynamics
1.2. The $2^{\text {nd }}$ law of thermodynamics, entropy, and temperature
1.3. The $1^{\text {st }}$ and $3^{\text {rd }}$ laws of thermodynamics, and heat capacity
1.4. Thermodynamic potentials
1.5. Systems with variable number of particles
1.6. Thermal machines
1.7. Exercise problems (16)

## Chapter 2. Principles of Physical Statistics (44 pp.)

2.1. Statistical ensemble and probability
2.2. Microcanonical ensemble and distribution
2.3. Maxwell's Demon, information, and computing
2.4. Canonical ensemble and the Gibbs distribution
2.5. Harmonic oscillator statistics
2.6. Two important applications
2.7. Grand canonical ensemble and distribution
2.8. Systems of independent particles
2.9. Exercise problems (32)

Chapter 3. Ideal and Not-so-Ideal Gases (34 pp.)
3.1. Ideal classical gas
3.2. Calculating $\mu$
3.3. Degenerate Fermi gas
3.4. The Bose-Einstein condensation
3.5. Gases of weakly interacting particles
3.6. Exercise problems (29)

## Chapter 4. Phase Transitions (36 pp.)

4.1. First order phase transitions
4.2. Continuous phase transitions
4.3. Landau's mean-field theory
4.4. Ising model: Weiss molecular-field theory
4.5. Ising model: Exact and numerical results
4.6. Exercise problems (18)

Chapter 5. Fluctuations (44 pp.)
5.1. Characterization of fluctuations
5.2. Energy and the number of particles
5.3. Volume and temperature
5.4. Fluctuations as functions of time
5.5. Fluctuations and dissipation
5.6. The Kramers problem and the Smoluchowski equation
5.7. The Fokker-Planck equation
5.8. Back to the correlation function
5.9. Exercise problems (21)

## Chapter 6. Elements of Kinetics (38 pp.)

6.1. The Liouville theorem and the Boltzmann equation
6.2. The Ohm law and the Drude formula
6.3. Electrochemical potential and drift-diffusion equation
6.4. Charge carriers in semiconductors: Statics and kinetics
6.5. Thermoelectric effects
6.6. Exercise problems (14)

Exercise and Test Problems with Model Solutions (130 + 25 = 155 problems; 236 pp.)

## Chapter 1. Review of Thermodynamics

This chapter starts from a brief discussion of the subject of statistical physics and thermodynamics, and the relation between these two disciplines. Then I proceed to a review of the basic notions and relations of thermodynamics. Most of this material is supposed to be known to the reader from his or her undergraduate studies, ${ }^{1}$ so the discussion is rather brief.

### 1.1. Introduction: Statistical physics and thermodynamics

Statistical physics (alternatively called "statistical mechanics") and thermodynamics are two different approaches to the same goal: a description of internal dynamics of large physical systems, notably those consisting of many, $N \gg 1$, identical particles - or other components. The traditional example of such a system is a human-scale portion of a gas, with the number $N$ of molecules of the order of the Avogadro number $N_{\mathrm{A}} \sim 10^{23} .^{2}$ The "internal dynamics" is an (admittedly loose) term meaning all the physics unrelated to the motion of the system as a whole. The most important example of the internal dynamics is the thermal motion of atoms and molecules.

The motivation for the statistical approach to such systems is straightforward: even if the laws governing the dynamics of each particle and their interactions were exactly known, and we had infinite computing resources at our disposal, calculating the exact evolution of the system in time would be impossible, at least because it is completely impracticable to measure the exact initial state each component, e.g., the initial position and velocity of each particle. The situation is further exacerbated by the phenomena of chaos and turbulence, ${ }^{3}$ and the quantum-mechanical uncertainty, ${ }^{4}$ which do not allow the exact calculation of final positions and velocities of the component particles even if their initial state is known with the best possible precision. As a result, in most situations only statistical predictions about behavior of such systems may be made, with the probability theory becoming a major part of the mathematical tool arsenal.

However, the statistical approach is not as bad as it may look. Indeed, it is almost self-evident that any measurable macroscopic variable characterizing a stationary system of $N \gg 1$ particles as a whole (think, e.g., about pressure $P$ of a gas contained in a fixed volume $V$ ) is almost constant in time. Indeed, we will see below that, besides certain exotic exceptions, the relative fluctuations - either in time, or among macroscopically similar systems - of such a variable are of the order of $1 / \sqrt{ } N$, i.e. for $\mathrm{N} \sim$ $N_{\mathrm{A}}$ are extremely small. As a result, the average values of macroscopic variables may characterize the state of the system rather well. Their calculation is the main task of statistical physics. (Though the analysis of fluctuations is also an important task, but due to the fluctuation smallness, the analysis in most cases may be based on perturbative approaches - see Chapter 5.)

[^784]Let us have a look at typical macroscopic variables the statistical physics and thermodynamics should operate with. Since I have already mentioned pressure $P$ and volume $V$, let me start with this famous pair. First of all, note that volume is an extensive variable, i.e. a variable whose value for a system consisting of several non-interacting (or weakly interacting) parts is the sum of those of its parts. On the other hand, pressure is an example of intensive variables whose value is the same for different parts of a system - if they are in equilibrium. In order to understand why $P$ and $V$ form a natural pair of variables, let us consider the classical playground of thermodynamics, a portion of a gas contained in a cylinder, closed with a movable piston of area $A$ (Fig. 1). Neglecting friction between the walls and the piston, and assuming that it is being moved slowly enough (so that the pressure $P$, at any instant, is virtually the same for all parts of the volume), the elementary work of the external force $\neq P A$, compressing the gas, at a small piston displacement $d x=-d V / A$, is

$$
\begin{equation*}
d w=7 d x=(7 / A)(A d x)=-P d V \tag{1.1}
\end{equation*}
$$

It is clear that the last expression is more general than the model shown in Fig. 1, and does not depend on the particular shape of the system surface.

Fig. 1.1. Compressing a gas.

From the point of analytical mechanics, ${ }^{5} \quad V$ and $(-P)$ is just one of many possible canonical pairs of generalized coordinates $q_{j}$ and generalized forces $\mathcal{Z}_{j}$, whose products $d w_{j}=\mathcal{Z}_{j} d q_{j}$ give independent contributions to the total work of the environment on the system under analysis. For example, the reader familiar with the basics of electrostatics knows that if the spatial distribution $\mathscr{E}(\mathbf{r})$ of an external electric field does not depend on the electric polarization $\mathscr{P}(\mathbf{r})$ of the dielectric medium placed into the field, its elementary work on the medium is

$$
\begin{equation*}
d w=\int \mathscr{E}(\mathbf{r}) \cdot d \mathscr{P}(\mathbf{r}) d^{3} r \equiv \int \sum_{j=1}^{3} \mathscr{E}_{j}(\mathbf{r}) d \mathscr{T}_{j}(\mathbf{r}) d^{3} r . \tag{1.2a}
\end{equation*}
$$

The most important cases when this condition is fulfilled (and hence Eq. (2a) is valid) are, first, long cylindrical samples in a parallel external field (see, e.g., EM Fig. 3.13) and, second, the polarization of a sample (of any shape) due to that of discrete dipoles $\boldsymbol{\mu}_{\mathrm{k}}$, whose electric interaction is negligible. In the latter case, Eq. (2a) may be also rewritten as the sum over the single dipoles, located at points $\mathbf{r}_{\mathrm{k}}$ :

$$
\begin{equation*}
d w=\sum_{k} d w_{k}, \quad \text { with } d w_{k}=\mathscr{E}\left(\mathbf{r}_{k}\right) \cdot d \boldsymbol{p}_{k} . \tag{1.2b}
\end{equation*}
$$

Very similarly, and at the similar conditions upon the external magnetic field $\mathscr{H}(\mathbf{r})$, its elementary work on a magnetic medium may be also represented in either of two forms:

$$
\begin{equation*}
d w=\mu_{0} \int \mathscr{H}(\mathbf{r}) \cdot d \mathscr{M}(\mathbf{r}) d^{3} r \equiv \mu_{0} \int \sum_{j=1}^{3} \mathscr{H}_{j}(\mathbf{r}) d \mathscr{M}_{j}(\mathbf{r}) d^{3} r \tag{1.3a}
\end{equation*}
$$

[^785]\[

$$
\begin{equation*}
d w=\sum_{k} d w_{k}, \quad \text { with } d w_{k}=\mu_{0} \mathscr{H}\left(\mathbf{r}_{k}\right) \cdot d \boldsymbol{m}_{k} \tag{1.3b}
\end{equation*}
$$

\]

where $\mathscr{M}$ and $\boldsymbol{m}$ are the vectors of, respectively, the magnetization and the moment of a single magnetic dipole. These expressions show that the roles of generalized coordinates may be played by Cartesian components of the vectors $\mathscr{P}$ (or $\boldsymbol{\mu}$ ) and $\mathscr{M}$ (or $\boldsymbol{m}$ ), with the components of the electric and magnetic fields serving as the corresponding generalized forces. This list may be extended to other interactions (such as gravitation, surface tension in fluids, etc.).

Again, the specific relations between the variables of each pair listed above are typically affected by the statistics of the components (particles) of a body, but their definition is not based on statistics. The situation is very different for a very specific pair of variables, temperature $T$ and entropy $S$, although these "sister variables" participate in many formulas of thermodynamics exactly like one more canonical pair $\left\{\mathcal{Z}_{j}, q_{j}\right\}$. However, the very existence of these two variables is due to statistics. Temperature $T$ is an intensive variable that characterizes the degree of thermal "agitation" of system components. On the contrary, entropy $S$ is an extensive variable that in most cases evades immediate perception by human senses; it is a qualitative measure of disorder of the system, i.e. the degree of our ignorance about its exact microscopic state. ${ }^{6}$

The reason for the appearance of the $\{T, S\}$ pair of variables in formulas is that the statistical approach to large systems of particles brings some qualitatively new results, most notably the notion of irreversible time evolution of collective (macroscopic) variables describing the system. On one hand, such irreversibility looks absolutely natural in such phenomena as the diffusion of an ink drop in a glass of water. In the beginning, the ink molecules are located in a certain small part of system's volume, i.e. to some extent ordered, while at the late stages of diffusion, the position of each molecule is essentially random. However, as a second thought, the irreversibility is rather surprising, ${ }^{7}$ taking into account that it takes place even if the laws governing the motion of system's components are time-reversible - such as the Newton laws or the basic laws of quantum mechanics. Indeed, if, at a late stage of the diffusion process, we exactly reversed the velocities of all molecules simultaneously, the ink molecules would again gather (for a moment) into the original spot. ${ }^{8}$ The problem is that getting the information necessary for the exact velocity reversal is not practicable. This example shows a deep connection between the statistical mechanics and the information theory.

A qualitative discussion of the reversibility-irreversibility dilemma requires a strict definition of the basic notion of statistical mechanics (and indeed the probability theory), the statistical ensemble, and I would like to postpone it until the beginning of Chapter 2. In particular, in that chapter we will see that the basic law of irreversible behavior is the increase of entropy $S$ in any closed system. Thus, statistical mechanics, without defying the "microscopic" laws governing evolution of system's components,

[^786]introduces on top of them some new "macroscopic" laws, intrinsically related to the evolution of information, i.e. the degree of our knowledge of the microscopic state of the system.

To conclude this brief discussion of variables, let me mention that as in all fields of physics, a very special role in statistical mechanics is played by energy $E$. In order to emphasize the commitment to disregard the motion of the system as a whole, in thermodynamics it is frequently called the internal energy, though for brevity, I will mostly skip the adjective. Its simplest example is the kinetic energy of the thermal motion of molecules in a dilute gas, but in general $E$ also includes not only the individual energies of all system's components, but also their interactions with each other. Besides a few pathological cases of very-long-range interactions (such as the Coulomb interactions in plasma with uncompensated charge density), the interactions may be treated as local; in this case the internal energy is proportional to $N$, i.e. is an extensive variable. As will be shown below, other extensive variables with the dimension of energy are often very useful, including the (Helmholtz) free energy $F$, the Gibbs energy $G$, enthalpy $H$, and grand potential $\Omega$. (The collective name for such variables is thermodynamic potentials.)

Now, we are ready for a brief discussion of the relation between statistical physics and thermodynamics. While the task of statistical physics is to calculate the macroscopic variables discussed above, ${ }^{9}$ using this or that particular microscopic model of the system, the main role of thermodynamics is to derive some general relations between the average values of the macroscopic variables (called thermodynamic variables) that do not depend on specific models. Surprisingly, it is possible to accomplish such a feat using a few either evident or very plausible general assumptions (sometimes called the laws of thermodynamics), which find their proof in statistical physics. ${ }^{10}$ Such general relations allow us to reduce rather substantially the amount of calculations we have to do in statistical physics; in many cases it is sufficient to calculate from statistics just one or two variables, and then use thermodynamic relations to calculate all other properties of interest. Thus the thermodynamics, sometimes snubbed at as a phenomenology, deserves every respect not only as a discipline which is, in a certain sense, more general than statistical physics as such, but also as a very useful science. This is why the balance of this chapter is devoted to a brief review of thermodynamics.

### 1.2. The $2^{\text {nd }}$ law of thermodynamics, entropy, and temperature

Thermodynamics accepts a phenomenological approach to entropy $S$, postulating that there is such a unique extensive measure of disorder, and that in a closed system, ${ }^{11}$ it may only grow in time, reaching its constant (maximum) value at equilibrium: ${ }^{12}$

$$
\begin{equation*}
d S \geq 0 \tag{1.4}
\end{equation*}
$$

This postulate is called the $2^{\text {nd }}$ law of thermodynamics - arguably its only substantial new law.

[^787]Surprisingly, this law, together with the additivity of $S$ in composite systems of non-interacting parts (as an extensive variable), is sufficient for a formal definition of temperature, and a derivation of its basic properties that comply with our everyday notion of this variable. Indeed, let us consider a particular case: a closed system consisting of two fixed-volume subsystems (Fig. 2) whose internal relaxation is very fast in comparison with the rate of the thermal flow (i.e. the energy and entropy exchange) between the parts. In this case, on the latter time scale, each part is always in some quasiequilibrium state, which may be described by a unique relation $E(S)$ between its energy and entropy. ${ }^{13}$

Fig. 1.2. Composite thermodynamic system.
Neglecting the interaction energy between the parts (which is always possible at $N \gg 1$, in the absence of long-range interactions), we may use the extensive character of variables $E$ and $S$ to write

$$
\begin{equation*}
E=E_{1}\left(S_{1}\right)+E_{2}\left(S_{2}\right), \quad S=S_{1}+S_{2}, \tag{1.5}
\end{equation*}
$$

for the full energy and entropy of the system. Now let us calculate the following derivative:

$$
\begin{equation*}
\frac{d S}{d E_{1}}=\frac{d S_{1}}{d E_{1}}+\frac{d S_{2}}{d E_{1}}=\frac{d S_{1}}{d E_{1}}+\frac{d S_{2}}{d E_{2}} \frac{d E_{2}}{d E_{1}}=\frac{d S_{1}}{d E_{1}}+\frac{d S_{2}}{d E_{2}} \frac{d\left(E-E_{1}\right)}{d E_{1}} . \tag{1.6}
\end{equation*}
$$

Since the total energy $E$ of the system is fixed and hence independent of its re-distribution between the sub-systems, $d E / d E_{1}=0$, and we get

$$
\begin{equation*}
\frac{d S}{d E_{1}}=\frac{d S_{1}}{d E_{1}}-\frac{d S_{2}}{d E_{2}} \tag{1.7}
\end{equation*}
$$

According to the $2^{\text {nd }}$ law of thermodynamics, when the two parts reach the thermodynamic equilibrium, the total entropy $S$ reaches its maximum, so that $d S / d E_{1}=0$, and Eq. (7) yields

$$
\begin{equation*}
\frac{d S_{1}}{d E_{1}}=\frac{d S_{2}}{d E_{2}} \tag{1.8}
\end{equation*}
$$

Thus we see that if a thermodynamic system may be partitioned into weakly interacting macroscopic parts, their derivatives $d S / d E$ should be equal in the equilibrium. The reciprocal of such derivative is called temperature. Taking into account that our analysis pertains to the situation (Fig. 2) when both volumes $V_{1,2}$ are fixed, we may write this definition as

$$
\begin{equation*}
\left(\frac{\partial E}{\partial S}\right)_{V} \equiv T \tag{1.9}
\end{equation*}
$$

[^788]subscript $V$ meaning that volume is kept constant at differentiation. (Such notation is common and very useful in thermodynamics, with its broad range of variables.)

Note that according to Eq. (9), if temperature is measured in energy units (as I will do in this course for the brevity of notation), $S$ is dimensionless. ${ }^{14}$ The transfer to the SI or Gaussian units, i.e. to temperature $T_{\mathrm{K}}$ measured in kelvins (not "Kelvins", not "degrees Kelvin", please!), is given by relation $T=k_{\mathrm{B}} T_{\mathrm{K}}$, where the Boltzmann constant $k_{\mathrm{B}} \approx 1.38 \times 10^{-23} \mathrm{~J} / \mathrm{K}=1.38 \times 10^{-16} \mathrm{erg} / \mathrm{K} .{ }^{15}$ In these units, the entropy becomes dimensional: $S_{\mathrm{K}}=k_{\mathrm{B}} S$.

The definition of temperature, given by Eq. (9), is of course in a sharp contract with the popular notion of $T$ as a measure of the average energy per particle. However, as we will repeatedly see below, is most cases these two notions may be reconciled. In particular, let us list some properties of $T$, which are in accordance with our everyday notion of temperature:
(i) according to Eq. (9), temperature is an intensive variable (since both $E$ and $S$ are extensive), i.e., in a system of similar particles, independent of the particle number $N$;
(ii) temperatures of all parts of a system are equal at equilibrium - see Eq. (8);
(iii) in a closed system whose parts are not in equilibrium, thermal energy (heat) always flows from a warmer part (with higher $T$ ) to the colder part.

In order to prove the last property, let us come back to the closed, composite system shown in Fig. 2, and consider another derivative:

$$
\begin{equation*}
\frac{d S}{d t}=\frac{d S_{1}}{d t}+\frac{d S_{2}}{d t}=\frac{d S_{1}}{d E_{1}} \frac{d E_{1}}{d t}+\frac{d S_{2}}{d E_{2}} \frac{d E_{2}}{d t} . \tag{1.10}
\end{equation*}
$$

If the internal state of each part is very close to equilibrium (as was assumed from the very beginning) at each moment of time, we can use Eq. (9) to replace derivatives $d S_{1,2} / d E_{1,2}$ for $1 / T_{1,2}$ and get

$$
\begin{equation*}
\frac{d S}{d t}=\frac{1}{T_{1}} \frac{d E_{1}}{d t}+\frac{1}{T_{2}} \frac{d E_{2}}{d t} \tag{1.11}
\end{equation*}
$$

Since in a closed system $E=E_{1}+E_{2}=$ const, these time derivatives are related as $d E_{2} / d t=-d E_{1} / d t$, and Eq. (11) yields

$$
\begin{equation*}
\frac{d S}{d t}=\left(\frac{1}{T_{1}}-\frac{1}{T_{2}}\right) \frac{d E_{1}}{d t} \tag{1.12}
\end{equation*}
$$

But in accordance with the $2^{\text {nd }}$ law of thermodynamics, the derivative cannot be negative: $d S / d t \geq 0$. Hence,

$$
\begin{equation*}
\left(\frac{1}{T_{1}}-\frac{1}{T_{2}}\right) \frac{d E_{1}}{d t} \geq 0 \tag{1.13}
\end{equation*}
$$

[^789]For example, if $T_{1}>T_{2}$ (i.e. $1 / T_{1}<1 / T_{2}$ ), then $d E_{1} / d t \leq 0$, i.e. the warmer part gives energy to its colder counterpart.

Note also that at such a heat exchange, at fixed volumes $V_{1,2}$, and $T_{1} \neq T_{2}$, increases the total system entropy, without performing any "useful" mechanical work.

### 1.3. The $1^{\text {st }}$ and $3^{\text {rd }}$ laws of thermodynamics, and heat capacity

Now let us consider a thermally insulated system whose volume $V$ may be changed by a deterministic force - see, for example, Fig. 1. Such system is different from the fully closed one, because its energy $E$ may be changed by the external force's work - see Eq. (1):

$$
\begin{equation*}
d E=d w=-P d V . \tag{1.14}
\end{equation*}
$$

Let the volume change be so slow $(d V / d t \rightarrow 0)$ that the system is virtually at equilibrium at any instant without much error. Such a slow process is called reversible, and in this particular case of a thermally insulated system, it is also called adiabatic. If pressure $P$ (or any a generalized external force $7_{j}$ ) is deterministic, i.e. is a predetermined function of time independent on the state of the system under analysis, it may be considered as coming from a fully ordered system, i.e. the one having zero entropy, with the total system completely closed. Since according to the second of Eqs. (5), the entropy of the total closed system should stay constant, $S$ of the system under analysis should stay constant on its own. Thus we arrive at a very important conclusion: an adiabatic process, the entropy of a system cannot change. ${ }^{16}$ This means that we can use Eq. (14) to write

$$
\begin{equation*}
P=-\left(\frac{\partial E}{\partial V}\right)_{S} . \tag{1.15}
\end{equation*}
$$

Let us now consider an even more general thermodynamic system that may also exchange thermal energy ("heat") with the environment (Fig. 3).

Fig. 1.3. General thermodynamic process involving both the mechanical work and heat exchange with the environment.

For such a system, our previous conclusion about the entropy constancy is not valid, so that $S$, in equilibrium, may be a function of not only energy $E$, but also of volume $V$. Let us resolve this relation for energy: $E=E(S, V)$, and write the general mathematical expression for the full differential of $E$ as a function of these two independent arguments:

$$
\begin{equation*}
d E=\left(\frac{\partial E}{\partial S}\right)_{V} d S+\left(\frac{\partial E}{\partial V}\right)_{S} d V \tag{1.16}
\end{equation*}
$$

[^790]This formula, based on the stationary relation $E=E(S, V)$, is evidently valid not only in equilibrium, but also for very slow, reversible ${ }^{17}$ processes. Now, using Eqs. (9) and (15), we may rewrite Eq. (16) as

$$
\begin{equation*}
d E=T d S-P d V \tag{1.17}
\end{equation*}
$$

[^791]The second term in the right-hand part of this equation is just the work of the external force, so that due to the conservation of energy, ${ }^{18}$ the first term has to be equal to the heat $d Q$ transferred from the environment to the system (see Fig. 3):

$$
\begin{gather*}
d E=d Q+d w  \tag{1.18}\\
d Q=T d S \tag{1.19}
\end{gather*}
$$

[^792]The last relation, divided by $T$ and then integrated along an arbitrary (but reversible!) process,

$$
\begin{equation*}
S=\int \frac{d Q}{T}+\text { const }, \tag{1.20}
\end{equation*}
$$

is sometimes used as an alternative definition of entropy $S$ - provided that temperature is defined not by Eq. (9), but in some independent way. It is useful to recognize that entropy (like energy) may be defined to an arbitrary constant, which does not affect any other thermodynamic observables. The common convention is to take

$$
\begin{equation*}
S \rightarrow 0 \text { at } T \rightarrow 0 . \tag{1.21}
\end{equation*}
$$

This condition is sometimes called the $3^{\text {rd }}$ law of thermodynamics, but it is important to realize that this is just a convention rather than a real law. ${ }^{19}$ Indeed, the convention corresponds well to the notion of the full order at $T=0$ in some systems (e.g., perfect crystals), but creates ambiguity for other systems, e.g., amorphous solids (like the usual glasses) that may remain, for "astronomic" times, highly disordered even at $T \rightarrow 0$.

Now let us discuss the notion of heat capacity that, by definition, is the ratio $d Q / d T$, where $d Q$ is the amount of heat that should be given to a system to raise its temperature by a small amount $d T .{ }^{20}$ (This notion is very important, because it may be most readily measured experimentally.) The heat capacity depends, naturally, on whether the heat $d Q$ goes only into an increase of the internal energy $d E$

[^793]of the system (as it does if volume $V$ is constant), or also into the mechanical work ( $-d w$ ) that may be performed at expansion - as it happens, for example, if pressure $P$, rather than volume $V$, is fixed (the socalled isobaric process - see Fig. 4). ${ }^{21}$

Fig. 1.4. The simplest implementation of an isobaric process.

Hence we should discuss two different quantities, the heat capacity at fixed volume,

$$
\begin{equation*}
C_{V} \equiv\left(\frac{\partial Q}{\partial T}\right)_{V} \tag{1.22}
\end{equation*}
$$

and heat capacity at fixed pressure

$$
\begin{equation*}
C_{P} \equiv\left(\frac{\partial Q}{\partial T}\right)_{P}, \tag{1.23}
\end{equation*}
$$

and expect that for all "normal" (mechanically stable) systems, $C_{P} \geq C_{V}$. The difference between $C_{P}$ and $C_{V}$ is rather minor for most liquids and solids, but may be very substantial for gases - see Sec. 4.

### 1.4. Thermodynamic potentials

A technical disadvantage of Eqs. (22) and (23) is that $\partial Q$ is not a differential of a function of state of the system, ${ }^{22}$ and hence (in contrast with temperature and pressure) does not allow an immediate calculation of heat capacity, even if the relation between $E, S$, and $V$ is known. For $C_{V}$ the situation is immediately correctable, because at fixed volume, $d w=-P d V=0$ and hence, according to Eq. (18), $d Q$ $=d E$. Hence we may write

$$
\begin{equation*}
C_{V}=\left(\frac{\partial E}{\partial T}\right)_{V} . \tag{1.24}
\end{equation*}
$$

[^794]so that in order to calculate $C_{V}$ from a certain statistical-physics model, we only need to calculate $E$ as a function of temperature and volume.

If we want to write similarly a convenient expression for $C_{P}$, the best way is to introduce a new notion of so-called thermodynamic potentials - whose introduction and effective use is perhaps one of the most impressive formalisms of thermodynamics. For that, let us combine Eqs. (1) and (18) to write the " $1^{\text {st }}$ law of thermodynamics" in its most common form

$$
\begin{equation*}
d Q=d E+P d V \tag{1.25}
\end{equation*}
$$

At an isobaric process (Fig. 4), i.e. at $P=$ const, this expression is equivalent to

$$
\begin{equation*}
(d Q)_{P}=d E+d(P V)=d(E+P V)_{P} \tag{1.26}
\end{equation*}
$$

Thus, if we introduce a new function with the dimensionality of energy: ${ }^{23}$

$$
\begin{equation*}
H \equiv E+P V \tag{1.27}
\end{equation*}
$$

called enthalpy (or, more rarely, the "heat function" or "heat contents"), ${ }^{24}$ we may rewrite Eq. (23) as

$$
\begin{equation*}
C_{P}=\left(\frac{\partial H}{\partial T}\right)_{P} \tag{1.28}
\end{equation*}
$$

Comparing Eq. (28) with (24) we see that for the heat capacity, enthalpy $H$ plays the same role at fixed pressure as the internal energy $E$ plays at fixed volume.

Now let us explore properties of the enthalpy for an arbitrary reversible process, i.e. lifting the restriction $P=$ const, but still keeping definition (27). Differentiating it, we get

$$
\begin{equation*}
d H=d E+P d V+V d P \tag{1.29}
\end{equation*}
$$

so that plugging in Eq. (17) for $d E$, we see that two terms $P d V$ cancel, yielding a very simple expression

$$
\begin{equation*}
d H=T d S+V d P \tag{1.30}
\end{equation*}
$$

Enthalpy: definition

This equation shows that if $H$ has been found (say, experimentally measured or calculated for a certain microscopic model) as a function of entropy $S$ and pressure $P$, we can find temperature $T$ and volume $V$ by simple partial differentiation:

$$
\begin{equation*}
T=\left(\frac{\partial H}{\partial S}\right)_{P}, \quad V=\left(\frac{\partial H}{\partial P}\right)_{S} \tag{1.31}
\end{equation*}
$$

The comparison of the first of these relations with Eq. (9) shows that not only for the heat capacity, but for temperature as well, enthalpy plays the same role at fixed pressure as played by the intrinsic energy at fixed volume. Moreover, the comparison of the second of Eqs. (31) with Eq. (15) shows that the transfer between $E$ to $H$ corresponds to a simple swap of $(-P)$ and $V$ in the expressions for the differentials of these variables.

[^795]This success immediately raises the question whether we could develop it further on, by defining other useful thermodynamic potentials - variables with the dimensionality of energy that would have similar properties, first of all a potential which would enable a similar swap of $T$ and $S$ in its full differential. We already know that the adiabatic processes is the reversible process with fixed entropy, so that now we should analyze a reversible process with fixed temperature. Such isothermal process may be implemented, for example, by placing the system under consideration into a thermal contact with a much larger system (called either the heat bath, or "heat reservoir", or "thermostat") that remains in thermodynamic equilibrium at all times - see Fig. 5.

Fig. 1.5. The simplest implementation of an isothermal process.

Due to its large size, the heat bath temperature $T$ does not depend on what is being done with our system, and if the change is being done slowly enough (i.e. reversibly), that temperature is also the temperature of our system - see Eq. (8) and its discussion. Let us calculate the elementary work $d w$ for such a reversible isothermal process. According to the general Eq. (18), $d w=d E-d Q$. Plugging in $d Q$ from Eq. (19), for $T=$ const we get

$$
\begin{equation*}
(d w)_{T}=d E-T d S=d(E-T S)=d F \tag{1.32}
\end{equation*}
$$

where the following combination,

Free
energy: definition

$$
\begin{equation*}
F \equiv E-T S \tag{1.33}
\end{equation*}
$$

is called the free energy (or the "Helmholtz free energy", or just the "Helmholtz energy"25). Just as we have done for the enthalpy, let us establish properties of this new thermodynamic potential for an arbitrary (not necessarily isothermal) small reversible variation of variables, while keeping definition (33). Differentiating this relation and using Eq. (17), we get

$$
\begin{equation*}
d F=-S d T-P d V \tag{1.34}
\end{equation*}
$$

Thus, if we know function $F(T, V)$, we can calculate $S$ and $P$ by simple differentiation:

$$
\begin{equation*}
S=-\left(\frac{\partial F}{\partial T}\right)_{V}, \quad P=-\left(\frac{\partial F}{\partial V}\right)_{T} . \tag{1.35}
\end{equation*}
$$

It is easy to see that we can make the derivative system full and symmetric if we introduce one more thermodynamic potential. Indeed, we have shown that each of three already introduced thermodynamic potentials $(E, H$, and $F$ ) has especially simple full differential if it is considered a

[^796]function of two canonical arguments: one of "thermal variables" (either $S$ or $T$ ) and one of "mechanical variables" (either $P$ or $V$ ): ${ }^{26}$
\[

$$
\begin{equation*}
E=E(S, V), \quad H=H(S, P), \quad \text { and } \quad F=F(T, V) . \tag{1.36}
\end{equation*}
$$

\]

In this list of pair of 4 arguments, only one pair is missing: $(T, P)$. The thermodynamic function of this pair, which gives two other variables ( $S$ and $V$ ) by simple differentiation, is called the Gibbs energy (or sometimes the "Gibbs free energy"): $G=G(T, P)$. The way to define it in a symmetric way is evident from the so-called circular diagram shown in Fig. 6.

(b)

Fig. 1.6. (a) Circular diagram and (b) its use for variable calculation. The thermodynamic potentials are shown in boldface, each flanked by its two canonical arguments.

In this diagram, each thermodynamic potential is placed between its two canonical arguments see Eq. (36). The left two arrows in Fig. 6a show the way the potentials $H$ and $F$ have been obtained from energy $E$ - see Eqs. (27) and (33). This diagram hints that $G$ has to be defined as shown by the right two arrows on that panel, i.e. as

$$
\begin{equation*}
G \equiv E-T S+P V=H-T S=F+P V \tag{1.37}
\end{equation*}
$$

Gibbs
energy: definition
so that if we know the function $G(T, P)$, we can indeed readily calculate entropy and volume:

$$
\begin{equation*}
S=-\left(\frac{\partial G}{\partial T}\right)_{P}, \quad V=\left(\frac{\partial G}{\partial P}\right)_{T} \tag{1.39}
\end{equation*}
$$

The circular diagram completed in this way is a good mnemonic tool for describing Eqs. (9), (15), (31), (35), and (39), which express thermodynamic variables as partial derivatives of the thermodynamic potentials. Indeed, the variable in any corner of the diagram may be found as a derivative of any of two potentials that are not its immediate neighbors, over the variable in the opposite corner. For example, the red line in Fig. 6b corresponds to the second of Eqs. (39), while the blue line, to the second of Eqs. (31). At this, the derivatives giving variables of the upper row ( $S$ and $P$ ) have to be

[^797]taken with negative signs, while those giving the variables of the bottom row ( $V$ and $T$ ), with positive signs. ${ }^{27}$

Now I have to justify the collective name "thermodynamic potentials" used for $E, H, F$, and $G$. For that, let us consider an irreversible process, for example, a direct thermal contact of two bodies with different initial temperatures. As we have seen in Sec. 2, at such a process, the entropy may grow even without the external heat flow: $d S \geq 0$ at $d Q=0$ - see Eq. (12). For a more general process with $d Q \neq 0$, this means that entropy may grow faster than predicted by Eq. (19), which has been derived for a reversible process, so that

$$
\begin{equation*}
d S \geq \frac{d Q}{T} \tag{1.40}
\end{equation*}
$$

with the equality approached in the reversible limit. Plugging Eq. (40) into Eq. (18) (which, being just the energy conservation law, remains valid for irreversible processes as well), we get

$$
\begin{equation*}
d E \leq T d S-P d V \tag{1.41}
\end{equation*}
$$

Now we can use this relation to have a look at the behavior of other thermodynamic potentials in irreversible situations, still keeping their definitions given by Eqs. (27), (33), and (37). Let us start from the (very common) case when both temperature $T$ and volume $V$ are kept constant. If the process was reversible, according to Eq. (34), the full time derivative of free energy $F$ would equal zero. Equation (41) says that at the irreversible process it is not necessarily so: if $d T=d V=0$, then

$$
\begin{equation*}
\frac{d F}{d t}=\frac{d}{d t}(E-T S)=\frac{d E}{d t}-T \frac{d S}{d t} \leq T \frac{d S}{d t}-T \frac{d S}{d t}=0 . \tag{1.42}
\end{equation*}
$$

Hence, in the general (irreversible) situation, function $F$ can only decrease, but not increase in time. This means that $F$ eventually approaches its minimum value $F(T, S)$, which is given by the equations of reversible thermodynamics.

Thus in the case $T=$ const, $V=$ const, the free energy $F$, i.e. the difference $E-T S$, plays the role of the potential energy in the classical mechanics of dissipative processes: its minimum corresponds to the (in the case of $F$, thermodynamic) equilibrium of the system. This is one of the key results of thermodynamics, and I invite the reader to give it some thought. One of its possible handwaving interpretations is that the heat bath with fixed $T>0$, i.e. with a substantial thermal agitation of its components, "wants" to impose thermal disorder in the system immersed in it by "rewarding" it (by lowering its $F$ ) for any increase of disorder.

Repeating the calculation for the case $T=$ const, $P=$ const, it is easy to see that in this case the same role is played by the Gibbs energy:

$$
\begin{equation*}
\frac{d G}{d t}=\frac{d}{d t}(E-T S+P V)=\frac{d E}{d t}-T \frac{d S}{d t}+P \frac{d V}{d t} \leq\left(T \frac{d S}{d t}-P \frac{d V}{d t}\right)-T \frac{d S}{d t}+P \frac{d V}{d t}=0, \tag{1.43}
\end{equation*}
$$

[^798]so that the thermal equilibrium now corresponds to the minimum of $G$ rather than $F$. One can argue very convincingly that the difference, $G-F=P V$ between these two potentials (also equal to $H-E$ ) has very little to do with thermodynamics at all, because this difference exists (although not much advertised) in classical mechanics as well. ${ }^{28}$ Indeed, the difference may be generalized as $G-F=-\mathcal{Z}_{j} q_{j}$, where $q_{j}$ is any generalized coordinate and $z_{j}$ is the corresponding generalized force - see Eq. (1) and its discussion. In this case the minimum of $F$ corresponds to the equilibrium of an autonomous system (with $\mathcal{F}_{j}=0$ ), while the equilibrium position of the same system under the action of external force $z_{j}$ is given by the minimum of $G$. Thus the external force "wants" the system to subdue to its effect, "rewarding" it by lowering its $G$. (The analogy with the "disorder pressure" by a heat bath, discussed in the last paragraph, is evident.)

For two remaining thermodynamic potentials, $E$ and $H$, the calculations similar to Eqs. (42) and (43) make less sense, because that would require taking $S=$ const (with $V=$ const for $E$, and $P=$ const for $H$ ), but it is hard to prevent the entropy from growing if initially it had been lower than its equilibrium value, at least on the long-term basis. ${ }^{29}$ Thus the circular diagram is not so symmetric after all: $G$ and/or $F$ are somewhat more useful for most practical calculations than $E$ and $H$.

One more important conceptual question is why the main task of statistical physics should be the calculation of thermodynamic potentials, rather than just a relation between $P, V$, and $T$. (Such relation is called the equation of state of the system.) Let us explore this issue on the example of an ideal classical gas in thermodynamic equilibrium, for which the equation of state should be well known to the reader from undergraduate physics (in Chapter 3, we will be derived from statistics):

$$
\begin{equation*}
P V=N T, \tag{1.44}
\end{equation*}
$$

where $N$ is the number of particles in volume $V .{ }^{30}$ Let us try to use it for the calculation of all thermodynamic potentials, and all other thermodynamic variables discussed above. We may start, for example, from the calculation of the free energy $F$. Indeed, solving Eq. (44) for pressure, $P=N T / V$, and integrating the second of Eqs. (35), we get

$$
\begin{equation*}
F=-\left.\int P d V\right|_{T}=-N T \int \frac{d V}{V}=-N T \int \frac{d(V / N)}{(V / N)}=-N T \ln \frac{V}{N}+N f(T), \tag{1.45}
\end{equation*}
$$

where I have divided $V$ by $N$ in both instances just to present $F$ as a manifestly extensive variable, in this uniform system proportional to $N$. The integration "constant" $f(T)$ is some function of temperature that cannot be recovered from the equation of state. This function also affects all other thermodynamic potentials, and entropy. Indeed, using the first of Eqs. (35) together with Eq. (45), we get

[^799]\[

$$
\begin{equation*}
S=-\left(\frac{\partial F}{\partial T}\right)_{V}=N\left[\ln \frac{V}{N}-\frac{d f}{d T}\right] \tag{1.46}
\end{equation*}
$$

\]

and now can combine Eqs. (33) and (46) to calculate the (internal) energy,

$$
\begin{equation*}
E=F+T S=\left(-N T \ln \frac{V}{N}+N f\right)+T\left(N \ln \frac{V}{N}-N \frac{d f}{d T}\right)=N\left(f-T \frac{d f}{d T}\right) \tag{1.47}
\end{equation*}
$$

then use Eqs. (27), (44) and (47) to calculate enthalpy,

$$
\begin{equation*}
H=E+P V=E+N T=N\left(f-T \frac{d f}{d T}+T\right) \tag{1.48}
\end{equation*}
$$

and, finally, plug Eqs. (44), and (45) into Eq. (37) to calculate the Gibbs energy

$$
\begin{equation*}
G=F+P V=N\left(-T \ln \frac{V}{N}+f+T\right) \tag{1.49}
\end{equation*}
$$

In particular, Eq. (47) describes a very important property of the ideal classical gas: its energy depends only on temperature, but not on volume or pressure. One might question whether function $f(T)$ may be physically insignificant, just like the arbitrary constant that may be always added to the potential energy in non-relativistic mechanics. In order to address this concern, let us calculate, from Eqs. (24) and (28), both heat capacities, that are readily measurable quantities:

$$
\begin{gather*}
C_{V}=\left(\frac{\partial E}{\partial T}\right)_{V}=-N T \frac{d^{2} f}{d T^{2}},  \tag{1.50}\\
C_{P}=\left(\frac{\partial H}{\partial T}\right)_{P}=N\left(-T \frac{d^{2} f}{d T^{2}}+1\right)=C_{V}+N . \tag{1.51}
\end{gather*}
$$

We see that function $f(T)$, or at least its second derivative, is measurable. ${ }^{31}$ (In Chapter 3, we will calculate this function for two simple "microscopic" models of the ideal classical gas.) The meaning of this function is evident from the physical picture of the ideal gas: pressure $P$ exerted on the walls of the containing volume is produced only by the translational motion of the gas molecules, while their internal energy $E$ (and hence other thermodynamic potentials) may be also contributed by the internal motion of the molecules - their rotations, vibrations, etc. Thus, the equation of state does not give the full thermodynamic description of a system, while the thermodynamic potentials do.

### 1.5. Systems with variable number of particles

Now we have to consider one more important case when the number $N$ of particles in a system is not rigidly fixed, but may change as a result of a thermodynamic process. Typical examples of such a system is a gas sample separated from the environment by a penetrable partition (Fig. 7), and a gas in a contact with the liquid of the same molecules.

[^800]environment

Fig. 1.7. Example of a system with variable number of particles.

Let us analyze this situation for the simplest case when all the particles are similar (though the analysis may be readily extended to systems with particle of several sorts). In this case we can consider $N$ as an independent thermodynamic variable whose variation may change energy $E$ of the system, so that (for a slow, reversible process) Eq. (17) should be now generalized as

$$
\begin{equation*}
d E=T d S-P d V+\mu d N \tag{1.52}
\end{equation*}
$$

Chemical potential: definition
where $\mu$ is a new function of state, called the chemical potential. ${ }^{32}$ Keeping the definitions of other thermodynamic potentials, given by Eqs. (27), (33), and (37) intact, we see that expressions for their differentials should be generalized as

$$
\begin{align*}
& d H=T d S+V d P+\mu d N  \tag{1.53a}\\
& d F=-S d T-P d V+\mu d N  \tag{1.53b}\\
& d G=-S d T+V d P+\mu d N \tag{1.53c}
\end{align*}
$$

so that the chemical potential may be calculated as either of the following derivatives: ${ }^{33}$

$$
\begin{equation*}
\mu=\left(\frac{\partial E}{\partial N}\right)_{S, V}=\left(\frac{\partial H}{\partial N}\right)_{S, P}=\left(\frac{\partial F}{\partial N}\right)_{T, V}=\left(\frac{\partial G}{\partial N}\right)_{T, P} \tag{1.54}
\end{equation*}
$$

Despite their similarity, one of Eqs. (53)-(54) is more consequential than the others. Indeed, the Gibbs energy $G$ is the only thermodynamic potential that is a function of two intensive parameters, $T$ and $P$. However, as all thermodynamic potentials, $G$ has to be extensive, so that in a system of similar particles it has to be proportional to $N$ :

$$
\begin{equation*}
G=N f(T, P) . \tag{1.55}
\end{equation*}
$$

Plugging this expression into the last of Eqs. (54), we see that $\mu$ equals $f(T, P)$. In other words,

$$
\begin{equation*}
\mu=\frac{G}{N} \tag{1.56}
\end{equation*}
$$

so that the chemical potential is just the Gibbs energy per particle.

[^801]In order to demonstrate how vital the notion of chemical potential may be, let us consider the situation (parallel to that shown in Fig. 2) when a system consists of two parts, with equal pressure and temperature, that can exchange particles at a relatively slow rate (much slower than the speed of internal relaxation inside each of the parts). Then we can write two equations similar to Eq. (5):

$$
\begin{equation*}
N=N_{1}+N_{2}, \quad G=G_{1}+G_{2}, \tag{1.57}
\end{equation*}
$$

where $N=$ const, and Eq. (56) may be used to describe each component of $G$ :

$$
\begin{equation*}
G=\mu_{1} N_{1}+\mu_{2} N_{2} . \tag{1.58}
\end{equation*}
$$

Plugging $N_{2}$ expressed from the first of Eqs. (57), $N_{2}=N-N_{1}$, into Eq. (58), we see that

$$
\begin{equation*}
\frac{d G}{d N_{1}}=\mu_{1}-\mu_{2} \tag{1.59}
\end{equation*}
$$

so that the minimum of $G$ is achieved at $\mu_{1}=\mu_{2}$. Hence, in the conditions of fixed temperature and pressure, i.e. when $G$ is the appropriate thermodynamic potential, the chemical potentials of the system parts should be equal - the so-called chemical equilibrium.

Later we will also run into cases when volume $V$ of a system, its temperature $T$, and the chemical potential $\mu$ are all fixed. (The last condition may be readily implemented by allowing the system of interest to exchange particles with a reservoir so large that its $\mu$ stays constant.) A thermodynamic potential appropriate for this case may be obtained from the free energy $F$ by subtraction of the product $\mu N$, resulting is the so-called grand thermodynamic potential (or the "Landau potential")

Grand potential: definition and full differential

Indeed, for a reversible process, the full differential of this potential is

$$
\begin{equation*}
d \Omega=d F-d(\mu N)=(-S d T-P d V+\mu d N)-(\mu d N+N d \mu)=-S d T-P d V-N d \mu \tag{1.61}
\end{equation*}
$$

so that if $\Omega$ has been calculated as a function of $T, V$ and $\mu$, other thermodynamic variables may be found as

$$
\begin{equation*}
S=-\left(\frac{\partial \Omega}{\partial T}\right)_{V, \mu}, \quad P=-\left(\frac{\partial \Omega}{\partial V}\right)_{T, \mu}, \quad N=-\left(\frac{\partial \Omega}{\partial \mu}\right)_{T, V} \tag{1.62}
\end{equation*}
$$

For an irreversible process, acting exactly as we have done with other potentials, it is straightforward to prove that in the conditions of fixed $T, V$, and $\mu, d \Omega / d t \leq 0$, so that system's equilibrium indeed corresponds to the minimum of the grand potential $\Omega$.

### 1.6. Thermal machines

In order to complete this brief review of thermodynamics, I cannot pass the topic of thermal machines - not because it will be used much in this course, but mostly because of its practical and historic significance. (Indeed, the whole field of thermodynamics was spurred by the famous 1824 work by S. Carnot, which in particular gave an alternative, indirect form of the $2^{\text {nd }}$ law of thermodynamics see below.)

Figure 8a shows the generic scheme of a thermal machine that may perform mechanical work on the environment (in the notation of Eq. (1), equal to $-\mathscr{W}$ ) during each cycle of the expansion/compression of the "working gas", by transferring different amounts of heat from a high-temperature heat bath $\left(Q_{H}\right)$ and to the low-temperature bath $\left(Q_{L}\right)$. One relation between three amounts $Q_{H}, Q_{L}$, and $\mathcal{W}$ is immediately given by the energy conservation (i.e. by "the $1^{\text {st }}$ law of thermodynamics"):

$$
\begin{equation*}
Q_{H}-Q_{L}=-w . \tag{1.63}
\end{equation*}
$$

From Eq. (1), the mechanical work during the cycle may be calculated as

$$
\begin{equation*}
-w=\oint P d V \tag{1.64}
\end{equation*}
$$

i.e. equals the area circumvented by the representing point on the $[P, V]$ plane - see Fig. $8 b .{ }^{34}$ Hence, the work depends on the exact form of the cycle, which in turn depends not only on $T_{H}$ and $T_{L}$, but also on working gas' properties.

Fig. 1.8. (a) The simplest implementation of a thermal machine, and (b) the graphic presentation of the mechanical work it performs. On panel (b), solid arrow indicates the heat engine cycle direction, while the dashed arrow, the refrigerator cycle direction.

An exception from this rule is the famous Carnot cycle, consisting of two isothermal and two adiabatic processes (all reversible!). In its heat engine's form, the cycle starts from an isothermic expansion of the gas in contact with the hot bath (i.e. at $T=T_{H}$ ), followed by its additional adiabatic expansion until $T$ drops to $T_{\mathrm{L}}$. Then an isothermal compression of the gas is performed in its contact with the cold bath (at $T=T_{L}$ ), followed by its additional adabatic compression to raise its temberature to $T_{H}$ again, after which the cycle is repeated again and again. (Note that during this cycle the working gas is never in contact with both heat baths simultaneously, thus avoiding the irreversible heat transfer between them.) The cycle's shape on the $[V, P]$ plane depends on exact properties of the working gas and may be rather complicated. However, since the entropy is constant at any adabatic process, the Carnot cycle shape on the [ $S, T]$ plane is always rectangular - see Fig. 9. ${ }^{35}$

[^802]

(b)

Fig. 1.9. Representation of the Carnot cycle (a) on the [ $S, T]$ plane and (b) the $[V, P]$ plane (schematically). The meaning of arrows is the same as in Fig. 8.

Since during each isotherm, the working gas is brought into thermal contact only with the corresponding heat bath, Eq. (19), $d Q=T d S$ may be immediately integrated to yield

$$
\begin{equation*}
Q_{H}=T_{H}\left(S_{2}-S_{1}\right), \quad Q_{L}=T_{L}\left(S_{2}-S_{1}\right) . \tag{1.65}
\end{equation*}
$$

Hence the ratio of these two heat flows is completely determined by their temperature ratio:

$$
\begin{equation*}
\frac{Q_{H}}{Q_{L}}=\frac{T_{H}}{T_{L}}, \tag{1.66}
\end{equation*}
$$

regardless of the working gas properties. Equations (63) and (66) are sufficient to find the ratio of work $-w$ to any of $Q_{H}$ and $Q_{L}$. For example, the main figure-of-merit of a thermal machine used as a heat engine $\left(Q_{H}>0, Q_{L}>0,-\mathcal{W}=|\mathcal{W}|>0\right)$, is its efficiency
engine efficiency: definition

$$
\begin{equation*}
\eta \equiv \frac{|w|}{Q_{H}}=\frac{Q_{H}-Q_{L}}{Q_{H}}=1-\frac{Q_{L}}{Q_{H}} \leq 1 \tag{1.67}
\end{equation*}
$$

For the Carnot cycle, Eq. (66) immediately yields the famous relation,

Carnot cycle's
efficiency

$$
\begin{equation*}
\eta_{\text {Carnot }}=1-\frac{T_{L}}{T_{H}} \tag{1.68}
\end{equation*}
$$

which shows that at given $T_{L}$ (that is typically the ambient temperature $\sim 300 \mathrm{~K}$ ), the efficiency may be increased, ultimately to 1 , by raising temperature of the heat source.

On the other hand, if the cycle is reversed (see the dashed arrows in Figs. 8 and 9), the same thermal machine may serve as a refrigerator, providing the heat removal from the low-temperature bath $\left(Q_{L}<0\right)$ for the cost of consuming external work: $w>0$. This reversal does not affect the basic relation (63) that may be used to calculate the relevant figure-of-merit, called the cooling coefficient of performance ( $\mathrm{COP}_{\text {cooling }}$ )

$$
\begin{equation*}
\mathrm{COP}_{\text {cooling }} \equiv \frac{\left|Q_{L}\right|}{w}=\frac{Q_{L}}{Q_{H}-Q_{L}} . \tag{1.69}
\end{equation*}
$$

Notice that this coefficient may readily be above unity; in particular, for the Carnot cycle we may use Eq. (66) (which is also unaffected by the cycle reversal) to get
nuclear spins by external magnetic field. In such refrigerators (to be further discussed in the next chapter), the role of the $\{-P, V\}$ pair of variables is played by the $\{\mathcal{H}, B\}$ pair - see Eq. (3).

$$
\begin{equation*}
\left(\mathrm{COP}_{\text {cooling }}\right)_{\text {Carnot }}=\frac{T_{L}}{T_{H}-T_{L}} \tag{1.70}
\end{equation*}
$$

so that the $\mathrm{COP}_{\text {cooling }}$ is larger than 1 at $T_{H}<2 T_{L}$, and even may be very large when the temperature difference $\left(T_{H}-T_{L}\right)$, sustained by the refrigerator, tends to zero. For example, in a typical airconditioning system, $T_{H}-T_{L} \sim T_{L} / 30$, so that the Carnot value of $\mathrm{COP}_{\text {cooling }}$ is as high as $\sim 30$, while in the state-of-the-art commercial HVAC systems it is the range for 3 to 4 . This is why the term "cooling efficiency", used in some textbooks instead of (COP) $)_{\text {cooling, }}$, may be misleading.

Since in the reversed cycle $Q_{H}=-w+Q_{L}<0$, the system also provides heat flow into the hotter heat bath, and thus may be used as a heat pump. However, the figure-of-merit appropriate for this application is different:

$$
\begin{equation*}
\mathrm{COP}_{\text {heating }} \equiv \frac{\left|Q_{H}\right|}{w}=\frac{Q_{H}}{Q_{H}-Q_{L}} \tag{1.71}
\end{equation*}
$$

so that for the Carnot cycle

$$
\begin{equation*}
\left(\mathrm{COP}_{\text {heating }}\right)_{\text {Carnot }}=\frac{T_{H}}{T_{H}-T_{L}} . \tag{1.72}
\end{equation*}
$$

Note that this COP is always larger than 1, meaning that the Carnot heat pump is always more efficient than the direct conversion of work into heat (where $Q_{H}=-\mathcal{W}$, and $\mathrm{COP}_{\text {heating }}=1$ ), though practical electricity-driven heat pumps are substantially more complex (and hence more expensive) than, say, simple electric heaters. Such heat pumps, with typical $\mathrm{COP}_{\text {heating }}$ values around 4 in summer and 2 in winter, are frequently used for heating large buildings.

I have dwelled so long on the Carnot cycle, because it has a remarkable property: the highest possible efficiency of all heat-engine cycles. Indeed, in the Carnot cycle the transfer of heat between any heat bath and the working gas is performed reversibly, when their temperatures are equal. If this is not so, heat might flow from a hotter to colder system without performing any work. Hence the result (68) also yields the maximum efficiency of any heat engine. In particular, it shows that $\eta_{\max }=0$ at $T_{H}=T_{L}$, i.e., no heat engine can perform any mechanical work in the absence of temperature gradients. ${ }^{36}$ In some alternative axiomatic systems of thermodynamics, this fact, i.e. the impossibility of the direct conversion of heat to work, is postulated, and serves the role of the $2^{\text {nd }}$ law.

Note also that according to Eq. (70), $\mathrm{COP}_{\text {cooling }}$ of the Carnot cycle tends to zero at $T_{\mathrm{L}} \rightarrow 0$, making it impossible to reach the absolute zero of temperature, and hence illustrating the meaningful (Nernst's) formulation of the $3^{\text {rd }}$ law of thermodynamics. Indeed, let us prescribe a certain (but very large) heat capacity $C(T)$ to the low-temperature bath, and use the definition of this variable to write the following evident expression for the (very small) change of its temperature as a result of a relatively large number $d n$ of similar refrigeration cycles:

$$
\begin{equation*}
C\left(T_{L}\right) d T_{L}=Q_{L} d n . \tag{1.73}
\end{equation*}
$$

[^803]Together with Eq. (66), this relation yields

$$
\begin{equation*}
C\left(T_{L}\right) d T_{L}=-\frac{\left|Q_{H}\right|}{T_{H}} T_{L} d n, \tag{1.74}
\end{equation*}
$$

so that if we perform many $(n)$ cycles (with constant $Q_{H}$ and $T_{H}$ ), the initial and final values of $T_{L}$ obey the following equation

$$
\begin{equation*}
\int_{T_{\mathrm{ini}}}^{T_{\mathrm{fin}}} \frac{C(T) d T}{T}=-\frac{\left|Q_{H}\right|}{T_{H}} n . \tag{1.75}
\end{equation*}
$$

For example, if $C(T)$ is a constant, Eq. (75) yields an exponential law,

$$
\begin{equation*}
T_{\mathrm{fin}}=T_{\mathrm{ini}} \exp \left\{-\frac{\left|Q_{H}\right|}{C T_{H}} n\right\}, \tag{1.76}
\end{equation*}
$$

with the absolute zero not reached as any finite $n$. Relation (75) proves the Nernst theorem if $C(T)$ does not vanish at $T \rightarrow 0$, but for such metastable systems as glasses the situation is more complicated. ${ }^{37}$ Fortunately, this issue does not affect other aspects of statistical physics - at least those to be discussed in this course.

### 1.7. Exercise problems

1.1. Two bodies, with negligible thermal expansion coefficients and constant heat capacities $C_{1}$ and $C_{2}$, are placed into a weak thermal contact, at different initial temperatures $T_{1}$ and $T_{2}$. Calculate the full change of entropy of the system before it reaches the full thermal equilibrium.
1.2. A gas has the following properties:
(i) $C_{V}=a T^{b}$, and
(ii) the work $w_{T}$ needed for its isothermal compression from $V_{2}$ to $V_{1}$ equals $c T \ln \left(V_{2} / V_{1}\right)$,
where $a, b$, and $c$ are constants. Find the equation of state of the gas, and calculate the temperature dependences of its entropy $S$, and thermodynamic potentials $E, H, F, G$ and $\Omega$.
1.3. A vessel with an ideal classical gas of indistinguishable molecules is separated by a partition so that the number $N$ of molecules in both parts is the same but their volumes are different. The gas is in thermal equilibrium, and its pressure in one part is $P_{1}$, and in another, $P_{2}$. Calculate the change of entropy caused by a fast removal of the partition. Analyze the result.
1.4. An ideal classical gas of $N$ particles, is initially confined to volume $V$, and let alone to reach the thermal equilibrium with a heat bath of temperature $T$. Then the gas is allowed to expand to volume $V^{\prime}>V$ in one the following ways:

[^804](i) The expansion slow, so that due to the thermal contact with the heat bath, the gas temperature remains equal to $T$ all the time.
(ii) The partition separating volumes $V$ and $\left(V^{\prime}-V\right)$ is removed very fast, allowing the gas to expand rapidly.

For each process, calculate the changes of pressure, temperature, energy, and entropy of the gas during its expansion.
1.5. For an ideal classical gas with temperature-independent specific heat, derive the relation between $P$ and $V$ at the adiabatic expansion/compression.
1.6. Calculate the speed and wave impedance of acoustic waves in an ideal classical gas with temperature-independent $C_{P}$ and $C_{V}$, in the limits when that the wave propagation may be treated as:
(i) an isothermal process,
(ii) an adiabatic process.

Which of these limits corresponds to higher wave frequencies?
1.7. As will be discussed in Sec. 3.5, the so-called "hardball" models of classical particle interaction yield the following equation of state of a gas of such particles:

$$
P=T \varphi(n)
$$

where $n=N / V$ is the particle density, and function $\varphi(n)$ is generally different from that $\left(\varphi_{\text {ideal }}(n)=n\right)$ of the ideal gas. For such a gas, with temperature-independent $c_{V}$, calculate:
(i) the energy of the gas, and
(ii) its pressure as a function of $n$ at adiabatic compression.
1.8. For an arbitrary thermodynamic system with a fixed number of particles, prove the following Maxwell relations (already mentioned in Sec. 1.4):

$$
\text { (i): }\left(\frac{\partial S}{\partial V}\right)_{T}=\left(\frac{\partial P}{\partial T}\right)_{V}, \quad \text { (ii): }\left(\frac{\partial V}{\partial S}\right)_{P}=\left(\frac{\partial T}{\partial P}\right)_{S}, \quad \text { (iii): }\left(\frac{\partial S}{\partial P}\right)_{T}=-\left(\frac{\partial V}{\partial T}\right)_{P}, \quad \text { (iv): }\left(\frac{\partial P}{\partial S}\right)_{V}=-\left(\frac{\partial T}{\partial V}\right)_{S} .
$$

1.9. A process, performed with a fixed portion of an ideal gas, may be represented with a straight line on the $[P, V]$ plane - see Fig. on the right. Find the point at which the heat flow into/out of the gas changes its direction.

1.10. Two bodies have equal and constant heat capacities $C$, but different temperatures, $T_{1}$ and $T_{2}$. Calculate the maximum mechanical work obtainable from this system, using a heat engine.
1.11. Express the efficiency of a heat engine that uses the "Joule cycle" consisting of two adiabatic and two isobaric processes (see Fig. on the right), via the minimum and maximum values of pressure, and compare the result with that for the Carnot cycle. Assume an ideal classical working gas with constant $C_{P}$ and $C_{V}$.

1.12. Calculate the efficiency of a heat engine using the "Otto cycle", ${ }^{38}$ which consists of two adiabatic and two isochoric (constantvolume) processes - see Fig. on the right. Explore how does the efficiency depend on the ratio $r \equiv V_{\max } / V_{\min }$, and compare it with Carnot cycle's efficiency. Assume an ideal working gas with temperature-independent specific heat.

1.13. A heat engine's cycle consists of two isothermal ( $T=$ const) and two isochoric ( $V=$ const) reversible processes - see Fig. on the right.
(i) Assuming that the working gas is an ideal classical gas of $N$ particles, calculate the mechanical work performed by the engine during one cycle.
(ii) Are the specified conditions sufficient to calculate engine's efficiency?

[^805]

## Chapter 2. Principles of Physical Statistics

This chapter is the key part of this course. It is started with a brief discussion of such basic notions of statistical physics as statistical ensembles, probability, and ergodicity. Then the so-called microcanonical distribution postulate is formulated in parallel with the statistical definition of entropy. The next step is the derivation of the Gibbs distribution, which is frequently considered the summit of the statistical physics, and one more, grand canonical distribution, which is more convenient for some tasks - in particular for the derivation of the Boltzmann, Fermi-Dirac, and Bose-Einstein statistics for systems of independent particles.

### 2.1. Statistical ensembles and probability

As has been already discussed in Sec. 1.1, statistical physics deals with systems in conditions when either the unknown initial conditions, or the system complexity, or the laws of motion (as in the case of quantum mechanics) do not allow a definite prediction of measurement results. The main formalism for the analysis of such systems is the probability theory, so let me start with a very brief review of its basic concepts using informal "physical" language - less rigorous but (hopefully) more transparent than a standard mathematical treatment. ${ }^{1}$

Consider $N \gg 1$ independent similar experiments carried out with apparently similar systems (i.e. systems with identical macroscopic parameters such as volume, pressure, etc.), but still giving, by any of the reasons outlined above, different results of measurements. Such a collection of experiments, together with the fixed method of result processing, is a good example of a statistical ensemble. Let us start from the case when the experiments may have $M$ different discrete outcomes, and the number of experiments giving the corresponding different results is $N_{1}, N_{2}, \ldots, N_{M}$, so that

$$
\begin{equation*}
\sum_{m=1}^{M} N_{m}=N . \tag{2.1}
\end{equation*}
$$

The probability of each outcome, for the given statistical ensemble, is then defined as

$$
\begin{equation*}
W_{m} \equiv \lim _{N \rightarrow \infty} \frac{N_{m}}{N} . \tag{2.2}
\end{equation*}
$$

Though this definition is so close to our everyday experience that it is almost self-evident, a few remarks may still be relevant.

First, probabilities $W_{m}$ depend on the exact statistical ensemble they are defined for, notably including the method of result processing. As an example, consider the standard coin tossing. For the ensemble of all tossed coins, the probabilities of both the heads and tails outcomes equal $1 / 2$. However, nothing prevents us from defining another statistical ensemble as a set of coin-tossing experiments with the heads-up outcome. Evidently, the probability of finding coins with tails up in this new ensemble is not $1 / 2$ but 0 . Still, this set of experiments is not only legitimate but also a rather meaningful statistical

[^806]ensemble; for example, the exact position and orientation of the tossed coins on the floor, within this restricted ensemble, may be rather random.

Second, a statistical ensemble does not necessarily require $N$ different physical systems, e.g., $N$ different coins. It is intuitively clear that tossing the same coin $N$ times constitutes an ensemble with similar statistical properties. More generally, a set of $N$ experiments with the same system provides a statistical ensemble equivalent to the set of experiments with $N$ different systems, provided that the experiments are kept independent, i.e. that outcomes of past experiments do not affect those of the experiments to follow. Moreover, for most physical systems of interest any special preparation is unnecessary, and $N$ different experiments, separated by sufficiently long time intervals, form a "good" statistical ensemble - the property called ergodicity. ${ }^{2}$

Third, the reference to infinite $N$ in Eq. (2) does not strip the notion of probability from its practical relevance. Indeed, it is easy to prove (see Chapter 5) that, at very general conditions, at finite but sufficiently large $N$, numbers $N_{m}$ are approaching their average (or expectation) values ${ }^{3}$

$$
\begin{equation*}
\left\langle N_{m}\right\rangle \equiv W_{m} N \tag{2.3}
\end{equation*}
$$

with the relative deviation scale decreasing as $1 /\left\langle N_{m}\right\rangle^{1 / 2}$.
Now let me list those properties of probabilities that we will immediately need. First, dividing Eq. (1) by $N$ and following the limit $N \rightarrow \infty$, we get the well-known normalization condition

$$
\begin{equation*}
\sum_{m=1}^{M} W_{m}=1 \tag{2.4}
\end{equation*}
$$

just remember that it is true only if each experiment definitely yields one of outcomes $N_{1}, N_{2}, \ldots, N_{M}$. Next, if we have an additive function of results,

$$
\begin{equation*}
f=\frac{1}{N} \sum_{m=1}^{M} N_{m} f_{m}, \tag{2.5}
\end{equation*}
$$

where $f_{m}$ are some definite (deterministic) coefficients, we may define the statistical average (also called the expectation value) of the function as

$$
\begin{equation*}
\langle f\rangle \equiv \lim _{N \rightarrow \infty} \frac{1}{N} \sum_{m=1}^{M}\left\langle N_{m}\right\rangle f_{m}, \tag{2.6}
\end{equation*}
$$

[^807]so that using Eq. (3) we get
\[

$$
\begin{equation*}
\langle f\rangle=\sum_{m=1}^{M} W_{m} f_{m} \tag{2.7}
\end{equation*}
$$

\]

Notice that Eq. (3) may be considered as the particular form of this general result, for all $f_{m}=1$.
Next, the spectrum of possible experimental outcomes is frequently continuous. (Think, for example, about the positions of the marks left by bullets fired into a target from a far.) The above formulas may be readily generalized to this case; let us start from the simplest situation when all different outcomes may be described by one continuous variable $q$, which replaces the discrete index $m$ in Eqs. (1)-(7). The basic relation for this case is the self-evident fact that the probability $d W$ of having an outcome within a very small interval $d q$ near point $q$ is proportional to the magnitude of that interval:

$$
\begin{equation*}
d W=w(q) d q \tag{2.8}
\end{equation*}
$$

Function $w(q)$, which does not depend on $d q$, is called the probability density. Now all the above formulas may be recast by replacing probabilities $W_{m}$ by products (8), and the summation over $m$, by integration over $q$. In particular, instead of Eq. (4) the normalization condition now becomes

$$
\begin{equation*}
\int w(q) d q=1 \tag{2.9}
\end{equation*}
$$

where the integration should be extended over the whole range of possible values of $q$. Similarly, instead by Eq. (5), it is natural to consider a function $f(q)$. Then instead of Eq. (7), the expectation value of the function may be calculated as

$$
\begin{equation*}
\langle f\rangle=\int w(q) f(q) d q \tag{2.10}
\end{equation*}
$$

It is straightforward to generalize these formulas to the case of more variables. For example, results of measurements of a particle with 3 degrees of freedom may be described by the probability density $w$ defined in the 6D space of its generalized radius-vector $\mathbf{q}$ and momentum $\mathbf{p}$. As a result, the expectation value of a function of these variables may be expressed as a 6D integral

$$
\begin{equation*}
\langle f\rangle=\int w(\mathbf{q}, \mathbf{p}) f(\mathbf{q}, \mathbf{p}) d^{3} q d^{3} p \tag{2.11}
\end{equation*}
$$

Some systems considered in this course consist of components whose quantum properties cannot be ignored, so let us discuss how $\langle f\rangle$ should be calculated in this case. If by $f_{m}$ we mean measurement results, Eq. (7) (and its generalizations) of course remains valid, but since these numbers themselves may be affected by the intrinsic quantum-mechanical uncertainty, it may make sense to have a bit deeper look into this situation. Quantum mechanics tells us ${ }^{4}$ that the most general expression for the expectation value of an observable $f$ in a certain ensemble of macroscopically similar systems is

$$
\begin{equation*}
\langle f\rangle=\sum_{m, m^{\prime}} W_{m m^{\prime}} f_{m^{\prime} m} \equiv \operatorname{Tr}(\mathrm{Wf}) \tag{2.12}
\end{equation*}
$$

Here $f_{m m}$, are the matrix elements of the quantum-mechanical operator $\hat{f}$ corresponding to the observable $f$, in a full basis of orthonormal states $m$,

$$
\begin{equation*}
f_{m m^{\prime}}=\langle m| \hat{f}\left|m^{\prime}\right\rangle, \tag{2.13}
\end{equation*}
$$

[^808]while coefficients $W_{m m}$ are elements of the so-called density matrix W , which represents, in the same basis, a density operator $\hat{W}$ describing properties of this ensemble. Equation (12) is evidently more general than Eq. (7), and is reduced to it only if the density matrix is diagonal:
\[

$$
\begin{equation*}
W_{m m^{\prime}}=W_{m} \delta_{m m^{\prime}}, \tag{2.14}
\end{equation*}
$$

\]

(where $\delta_{m m}$, is the Kronecker symbol), when the diagonal elements $W_{m}$ play the role of probabilities of the corresponding states.

Thus the largest difference between the quantum and classical description is the presence, in Eq. (12), of the off-diagonal elements of the density matrix. They have largest values in the pure (also called "coherent") ensemble, in which the state of the system may be described with state vectors, e.g., the ketvector

$$
\begin{equation*}
|\alpha\rangle=\sum_{m} \alpha_{m}|m\rangle \tag{2.15}
\end{equation*}
$$

where $\alpha_{m}$ are some complex coefficients. In this simple case, the density matrix elements are merely

$$
\begin{equation*}
W_{m m^{\prime}}=\alpha_{m}^{*} \alpha_{m^{\prime}}, \tag{2.16}
\end{equation*}
$$

so that the off-diagonal elements are of the same order as the diagonal elements. For example, in the very important particular case of a two-level system, the pure-state density matrix is

$$
\mathrm{W}=\left(\begin{array}{ll}
\alpha_{1}^{*} \alpha_{1} & \alpha_{1}^{*} \alpha_{2}  \tag{2.17}\\
\alpha_{2}^{*} \alpha_{1} & \alpha_{2}^{*} \alpha_{2}
\end{array}\right)
$$

so that the product of its off-diagonal components is as large as that of the diagonal components. In the most important basis of stationary states, i.e. eigenstates of system's time-independent Hamiltonian, coefficients $\alpha_{m}$ oscillate in time as ${ }^{5}$

$$
\begin{equation*}
\alpha_{m}(t)=\alpha_{m}(0) \exp \left\{-i \frac{E_{m}}{\hbar} t\right\}=\left|\alpha_{m}\right| \exp \left\{-i \frac{E_{m}}{\hbar} t+i \varphi_{m}\right\}, \tag{2.18}
\end{equation*}
$$

where $E_{m}$ are the corresponding eigenenergies, and $\varphi_{m}$ are constant phase shifts. This means that while the diagonal terms of the density matrix (16) remain constant, its off-diagonal components are oscillating functions of time:

$$
\begin{equation*}
W_{m m^{\prime}}=\alpha_{m^{\prime}}^{*} \alpha_{m}=\left|\alpha_{m^{\prime}} \alpha_{m}\right| \exp \left\{i \frac{E_{m}-E_{m^{\prime}}}{\hbar} t\right\} \exp \left\{i\left(\varphi_{m^{\prime}}-\varphi_{m}\right)\right\} . \tag{2.19}
\end{equation*}
$$

Due to the extreme smallness of the Planck constant (on the human scale of things), a miniscule random perturbations of eigenenergies are equivalent to substantial random changes of the phase multiplier, so that the time average of any off-diagonal matrix element tends to zero. Moreover, even if our statistical ensemble consists of systems with exactly the same $E_{m}$, but different values $\varphi_{m}$ (which are typically hard to control at the initial preparation of the system), the average values of all $W_{m m^{\prime}}$ (with $m \neq m^{\prime}$ ) vanish again.

[^809]This is why, besides some very special cases, typical statistical ensembles of quantum particles are far from being pure, and in most cases (certainly including the thermodynamic equilibrium), a good approximation for their description is given by the opposite limit of the so-called classical mixture in which all off-diagonal matrix elements of the density matrix equal zero, and its diagonal elements $W_{m m}$ are merely the probabilities $W_{m}$ of the corresponding eigenstates. In this case, for observables compatible with energy, Eq. (12) is reduced to Eq. (7), with $f_{m}$ being the eigenvalues of variable $f$.

### 2.2. Microcanonical ensemble and distribution

Let us start with the discussion of physical statistics with the simplest, microcanonical statistical ensemble ${ }^{6}$ that is defined a set of macroscopically similar closed (isolated) systems with virtually the same total energy $E$. Since in quantum mechanics the energy of a closed system is quantized, it is convenient to include into the ensemble all systems with energies $E_{m}$ within a narrow interval $\Delta E \ll E$, that is nevertheless much larger than the average distance $\delta E$ between the energy levels, so that the number $M$ of different quantum states within interval $\Delta E$ is large, $M \gg 1$. Such choice of $\Delta E$ is only possible if $\delta E \ll E$; however, the reader should not worry too much about this condition, because the most important applications of the microcanonical ensemble are for very large systems (or very high energies) when the energy spectrum is very dense. ${ }^{7}$

Fig. 2.1. Very schematic image of the microcanonical ensemble. (Actually, the ensemble deals with quantum states rather than energy levels. An energy level may be degenerate, i.e. correspond to several states.)

This ensemble serves as the basis for the formulation of a postulate which is most frequently called the microcanonical distribution (or sometimes the "main statistical hypothesis"): in the thermodynamic equilibrium, all possible states of the microcanonical ensemble have equal probability,

$$
\begin{equation*}
W_{m}=\frac{1}{M}=\text { const. } \tag{2.20}
\end{equation*}
$$

Though in some constructs of statistical mechanics this equality is derived from other axioms, which look more plausible to their authors, I believe that Eq. (20) may be taken as the starting point of the statistical physics, supported "just" by the compliance of all its corollaries with experimental observations. ${ }^{8}$

Note that postulate (20) sheds a light on the nature of the macroscopic irreversibility of microscopically reversible (closed) systems: if such a system was initially in a certain state, its time

[^810]evolution with just miniscule interactions with environment (which is necessary for reaching the thermodynamic equilibrium) would eventually lead to the uniform distribution of its probability among all states with the essentially same energy. Each of these states is not "better" than the initial one; rather, in a macroscopic system, there are just so many of these states that the chance to find the system in the initial state is practically nil - again, think about the ink drop diffusion into a glass of water.

Now let us find a suitable definition of entropy $S$ of a microcanonical ensemble member - for now, in the thermodynamic equilibrium only. Since $S$ is a measure of disorder, it should be related to the amount of information lost when the system goes from the full order to the full disorder, i.e. into the microcanonical distribution (20), or, in other words, the amount of information ${ }^{9}$ necessary to find the exact state of your system in a microcanonical ensemble.

In the information theory, the amount of information necessary to make a definite choice between two options with equal probabilities (Fig. 2a) is defined as

$$
\begin{equation*}
I(2) \equiv \log _{2} 2=1 \tag{2.21}
\end{equation*}
$$

This unit of information is called a bit. Now, if we need to make a choice between 4 equally probable opportunities, it can be made in two similar steps (Fig. 2b), each requiring one bit of information, so that the total amount of information necessary for the choice is

$$
\begin{equation*}
I(4)=2 I(2)=2=\log _{2} 4 . \tag{2.22}
\end{equation*}
$$

An obvious extension of this process to the choice between $M=2^{m}$ states gives

$$
\begin{equation*}
I(M)=m I(2)=m=\log _{2} M . \tag{2.23}
\end{equation*}
$$

(b)

Fig. 2.2. "Logarithmic trees" of binary decisions for making a choice between (a) 2 and (b) 4 opportunities with equal probabilities.

This measure, if extended naturally to any integer $M$, is quite suitable for the definition of entropy at equilibrium, with the only difference that, following tradition, the binary logarithm is replaced with the natural one: ${ }^{10}$

[^811]\[

$$
\begin{equation*}
S \equiv \ln M \tag{2.24a}
\end{equation*}
$$

\]

Using Eq. (20), we may recast this definition in the most frequently used form

$$
\begin{array}{r}
\text { Entropy } \\
\text { in }  \tag{2.24b}\\
\text { equilibrium }
\end{array}
$$

$$
S=\ln \frac{1}{W_{m}}=-\ln W_{m}
$$

(Again, please note that Eq. (24) is valid in the thermodynamic equilibrium only!)
Equation (24) satisfies the major condition for the entropy definition in thermodynamics, i.e. to be a unique characteristics of disorder. Indeed, according to Eq. (20), number $M$ (and hence any function of $M$ ) are the only possible measures characterizing the microcanonical distribution. We also need this function of $M$ to satisfy another requirement to the entropy, of being an extensive thermodynamic variable, and Eq. (24) does satisfy this requirement as well. Indeed, mathematics says that for two independent systems the joint probability is just a product of their partial probabilities, and hence, according to Eq. (24b), their entropies just add up.

Now let us see whether Eqs. (20) and (24) are compatible with the $2^{\text {nd }}$ law of thermodynamics. For that, we need to generalize Eq. (24) for $S$ to an arbitrary state of the system (generally, out of thermodynamic equilibrium), with arbitrary state probabilities $W_{m}$. For that, let us first recognize that $M$ in Eq. (24) is just the number of possible ways to commit a particular system to a certain state $m$ ( $m=1$, $2, \ldots M)$, in a statistical ensemble where each state is equally probable. Now let us consider a more general ensemble, still consisting of a large number $N \gg 1$ of similar systems, but with a certain number $N_{m}=W_{m} N \gg 1$ of systems in each of $M$ states, with $W_{m}$ not necessarily equal. In this case the evident generalization of Eq. (24) is that the entropy $S_{N}$ of the whole ensemble is

$$
\begin{equation*}
S_{N} \equiv \ln M\left(N_{1}, N_{2}, . .\right), \tag{2.25}
\end{equation*}
$$

where $M\left(N_{1}, N_{2}, \ldots\right)$ is the number of ways to commit a particular system to a certain state $m$, while keeping all numbers $N_{m}$ fixed. Such number $M\left(N_{1}, N_{2}, \ldots\right)$ is clearly equal to the number of ways to distribute $N$ distinct balls between $M$ different boxes, with the fixed number $N_{m}$ of balls in each box, but in no particular order within it. Comparing this description with the definition of the so-called multinomial coefficients, ${ }^{11}$ we get

$$
\begin{equation*}
M\left(N_{1}, N_{2}, \ldots\right)={ }^{N} C_{N_{1}, N_{2}, \ldots, N_{M}} \equiv \frac{N!}{N_{1}!N_{2}!\ldots N_{M}!}, \quad \text { with } N=\sum_{m=1}^{M} N_{m} \tag{2.26}
\end{equation*}
$$

In order to simplify the resulting expression for $S_{N}$, we can use the famous Stirling formula in its crudest, de Moivre's form ${ }^{12}$ whose accuracy is suitable for most purposes of statistical physics:

$$
\begin{equation*}
\ln (N!)_{\mid N \rightarrow \infty} \rightarrow N(\ln N-1) . \tag{2.27}
\end{equation*}
$$

When applied to our current problem, this gives the following average entropy per system, ${ }^{13}$

[^812]\[

$$
\begin{align*}
S \equiv & \frac{S_{N}}{N}=\frac{1}{N} \ln \left({ }^{N} C_{N_{1}, N_{2}, \ldots, N_{M}}\right)=\frac{1}{N}\left[\ln (N!)-\sum_{m=1}^{M} \ln \left(N_{m}!\right)\right] \\
& \rightarrow \frac{1}{N}\left[N(\ln N-1)-\sum_{m=1}^{M} N_{m}\left(\ln N_{m}-1\right)\right]=\ln N-\frac{1}{N} \sum_{m=1}^{M} N_{m} \ln N_{m}=-\sum_{m=1}^{M} \frac{N_{m}}{N} \ln \frac{N_{m}}{N} . \tag{2.28}
\end{align*}
$$
\]

and since this result is only valid in the limit $N_{m} \rightarrow \infty$ anyway, we may use Eq. (2) to present it as

$$
\begin{equation*}
S=-\sum_{m=1}^{M} W_{m} \ln W_{m}=\sum_{m=1}^{M} W_{m} \ln \frac{1}{W_{m}} . \tag{2.29}
\end{equation*}
$$

Entropy
out of equilibrium

This extremely important formula ${ }^{14}$ may be interpreted as the average of the entropy values given by Eq. (24), weighed with specific probabilities $W_{m}$ in accordance with the general formula (7). ${ }^{15}$

Now let us find what distribution of probabilities $W_{m}$ provides the largest value of entropy (29). The answer is almost evident from a single glance at Eq. (29). For example, if coefficients $W_{m}$ are constant (and hence equal to $1 / M^{\prime}$ ) for a subgroup of $M^{\prime} \leq M$ states and equal zero for all others, all $M^{\prime}$ nonvanishing terms in the sum (29) are equal to each other, so that

$$
\begin{equation*}
S=M^{\prime} \frac{1}{M^{\prime}} \ln M^{\prime}=\ln M^{\prime} \tag{2.30}
\end{equation*}
$$

so that the closer $M^{\prime}$ to its maximum number $M$ the larger $S$. Hence, the maximum of $S$ is reached at the uniform distribution given by Eq. (24).

In order to prove this important fact more strictly, let us find the maximum of function given by Eq. (29). If its arguments $W_{1}, W_{2}, \ldots W_{M}$ were completely independent, this could be done by finding the point (in the $M$-dimensional space of coefficients $W_{m}$ ) where all partial derivatives $\partial S / \partial W_{m}$ are equal to zero. However, since the probabilities are constrained by condition (4), the differentiation has to be carried out more carefully, taking into account this interdependence:

$$
\begin{equation*}
\left[\frac{\partial}{\partial W_{m}} S\left(W_{1}, W_{2}, \ldots\right)\right]_{\mathrm{cond}}=\frac{\partial S}{\partial W_{m}}+\sum_{m^{\prime} \neq m} \frac{\partial S}{\partial W_{m^{\prime}}} \frac{\partial W_{m^{\prime}}}{\partial W_{m}} . \tag{2.31}
\end{equation*}
$$

At the maximum of function $S$, all such expressions should be equal to zero simultaneously. This condition may be presented as $\partial S / \partial W_{m}=\lambda$, where the so-called Lagrange multiplier $\lambda$ is independent of $m$. Indeed, at such point Eq. (31) becomes

$$
\begin{equation*}
\left[\frac{\partial}{\partial W_{m}} S\left(W_{1}, W_{2}, \ldots\right)\right]_{\mathrm{cond}}=\lambda+\sum_{m^{\prime} \neq m} \lambda \frac{\partial W_{m^{\prime}}}{\partial W_{m}}=\lambda\left(\frac{\partial W_{m}}{\partial W_{m}}+\sum_{m^{\prime} \neq m} \frac{\partial W_{m^{\prime}}}{\partial W_{m}}\right)=\lambda \frac{\partial}{\partial W_{m}}(1)=0 . \tag{2.32}
\end{equation*}
$$

[^813]For the particular expression (29), condition $\partial S / \partial W_{m}=\lambda$ yields

$$
\begin{equation*}
\frac{\partial S}{\partial W_{m}} \equiv \frac{d}{d W_{m}}\left[-W_{m} \ln W_{m}\right]=-\ln W_{m}-1=\lambda . \tag{2.33}
\end{equation*}
$$

Equation (33) may hold for all $m$ (and hence the entropy reach its maximum value) only if $W_{m}$ is independent on $m$. Thus entropy (29) indeed reaches its maximum value (24) at equilibrium.

To summarize, we see that definition (24) of entropy in statistical physics does fit all the requirements imposed on this variable by thermodynamics. ${ }^{16}$ In particular, we have been able to prove the $2^{\text {nd }}$ law of thermodynamics, starting from that definition and a more fundamental postulate (20). Now let me discuss one possible point of discomfort with that definition: it depends on the accepted energy interval of the microcanonical ensemble, for whose width $\Delta E$ no exact guidance is offered. However, if the interval $\Delta E$ contains many states, $M \gg 1$, then with a very small relative error (vanishing in the limit $M \rightarrow \infty$ ), $M$ may be presented as

$$
\begin{equation*}
M=g(E) \Delta E \tag{2.34}
\end{equation*}
$$

where $g(E)$ is the density of states of the system:

$$
\begin{equation*}
g(E) \equiv \frac{d \Sigma(E)}{d E} \tag{2.35}
\end{equation*}
$$

$\Sigma(E)$ being the total number of states with energies below $E$. (Note that the average interval $\delta E$ between energy levels, mentioned in the beginning of this section, is just $\delta E=\Delta E / M=1 / g$.) Plugging Eq. (34) into Eq. (24), we get

$$
\begin{equation*}
S=\ln M=\ln g(E)+\ln \Delta E \tag{2.36}
\end{equation*}
$$

so that the only effect of a particular choice of $\Delta E$ is an offset of entropy by a constant, and in Chapter 1 we have seen that such a shift does not affect any measurable quantity. Of course, Eq. (34), and hence Eq. (36) are only precise in the limit when density of states $g(E)$ is so large that the range available for the appropriate choice of $\Delta E$,

$$
\begin{equation*}
g^{-1}(E) \ll \Delta E \ll E, \tag{2.37}
\end{equation*}
$$

is sufficiently broad: $g(E) E=E / \delta E \gg 1$.
In order to get some feeling of the functions $g(E)$ and $S(E)$ and the feasibility of condition (37), and also to see whether the microcanonical distribution may be directly used for calculations of thermodynamic variables in particular systems, let us apply it to a microcanonical ensemble of many sets of $N \gg 1$ independent, similar harmonic oscillators with eigenfrequency $\omega$. (Please note that the requirement of a virtually fixed energy is applied, in this case, the total energy $E_{N}$ of the set, rather to a single oscillator - whose energy $E$ may be virtually arbitrary, though certainly less than $E_{N} \sim N E$.) Basic quantum mechanics ${ }^{17}$ teaches us that the eigenenergies of such an oscillator form a discrete, equidistant spectrum:

[^814]\[

$$
\begin{equation*}
E_{m}=\hbar \omega\left(m+\frac{1}{2}\right), \quad \text { where } m=0,1,2, \ldots \tag{2.38}
\end{equation*}
$$

\]

If $\omega$ is kept constant, the zero-point energy $\hbar \omega / 2$ does not contribute to any thermodynamic properties of the system and may be ignored, ${ }^{18}$ so that for the sake of simplicity we may take that point as the energy origin, and replace Eq. (38) with $E_{m}=m \hbar \omega$. Let us carry out an approximate analysis of the system for the case when its average energy per oscillator,

$$
\begin{equation*}
E=\frac{E_{N}}{N}, \tag{2.39}
\end{equation*}
$$

is much larger than the energy quantum $\hbar \omega$. For one oscillator, the number of states with energy $\varepsilon_{1}$ below certain value $=E_{1} \gg \hbar \omega$ is evidently $\Sigma\left(E_{1}\right) \approx E_{1} / \hbar \omega$ (Fig. 3a). For two oscillators, all possible values of the total energy $\left(\varepsilon_{1}+\varepsilon_{2}\right)$ below some level $E_{2}$ correspond to the points of a 2D square grid within the right triangle shown in Fig. 3b, giving $\Sigma\left(E_{2}\right) \approx(1 / 2)\left(E_{2} / \hbar \omega\right)^{2}$. For three oscillators, the possible values of the total energy $\left(\varepsilon_{1}+\varepsilon_{2}+\varepsilon_{3}\right)$ correspond to those points of the 3D cubic mesh, that fit inside the right pyramid shown in Fig. 3c, giving $\Sigma\left(E_{3}\right) \approx(1 / 2)(1 / 3)\left(E_{3} / \hbar \omega\right)^{3}=(1 / 3!)\left(E_{3} / \hbar \omega\right)^{3}$, etc.

Fig. 2.3. Calculating functions $\Sigma\left(\mathrm{E}_{N}\right)$ for the systems of (a) one, (b) two and (c) three quantum oscillators.
An evident generalization of these formulas to arbitrary $N$ gives the number of states

$$
\begin{equation*}
\Sigma\left(E_{N}\right) \approx \frac{1}{N!}\left(\frac{E_{N}}{\hbar \omega}\right)^{N} \tag{2.40}
\end{equation*}
$$

where coefficient $1 / N$ ! has the geometrical meaning of the (hyper)volume of the $N$-dimensional right pyramid with unit sides. Differentiating Eq. (40), we get

$$
\begin{equation*}
g\left(E_{N}\right)=\frac{d \Sigma\left(E_{N}\right)}{d E_{N}}=\frac{1}{(N-1)!} \frac{E_{N}^{N-1}}{(\hbar \omega)^{N}} \tag{2.41}
\end{equation*}
$$

so that

[^815]\[

$$
\begin{equation*}
S_{N}\left(E_{N}\right)=\ln g\left(E_{N}\right)+\text { const }=-\ln [(N-1)!]+(N-1) \ln E_{N}-N \ln (\hbar \omega)+\text { const. } \tag{2.42}
\end{equation*}
$$

\]

For $N \gg 1$ we can ignore the difference between $N$ and $(N-1)$ in both instances, and use the Stirling formula (27) to simplify this result as

$$
\begin{equation*}
S_{N}(E)-\text { const } \approx N\left(\ln \frac{E_{N}}{N \hbar \omega}+1\right) \approx N\left(\ln \frac{E}{\hbar \omega}\right)=\ln \left[\left(\frac{E}{\hbar \omega}\right)^{N}\right] \tag{2.43}
\end{equation*}
$$

(The second approximation is only valid at very high $E / \hbar \omega$ ratios, when the logarithm in Eq. (43) is substantially larger than 1 , i.e. is rather crude. ${ }^{19}$ ) Returning for a second to the density of states, we see that in the limit $N \rightarrow \infty$, it is exponentially large:

$$
\begin{equation*}
g\left(E_{N}\right)=e^{S_{N}} \approx\left(\frac{E}{\hbar \omega}\right)^{N} \tag{2.44}
\end{equation*}
$$

so that both conditions (37) may be satisfied within a very broad range of $\Delta E$.
Now we can use Eq. (43) to find all thermodynamic properties of the system, though only in the limit $E \gg \hbar \omega$. Indeed, according to thermodynamics (see Sec. 1.2), if the system volume and number of particles are fixed, the derivative $d S / d E$ is nothing more than the reciprocal temperature - see Eqs. (1.9) or (1.15). In our current case, we imply that the harmonic oscillators are distinct, for example by their spatial positions. Hence, even if we can speak of some volume of the system, it is certainly fixed. ${ }^{20}$ Differentiating Eq. (43) over energy $E$, we get

## Average energy of a classical

 oscillator$$
\begin{equation*}
\frac{1}{T}=\frac{d S_{N}}{d E_{N}}=\frac{N}{E_{N}}=\frac{1}{E} \tag{2.45}
\end{equation*}
$$

Reading this result backwards, we see that the average energy $E$ of a harmonic oscillator equals $T$ (i.e. $k_{\mathrm{B}} T_{\mathrm{K}}$ is SI units). As we will show in Sec. 5 below, this is the correct asymptotic form of the exact result, valid in our current limit $E \gg \hbar \omega$.

Result (45) may be readily generalized. Indeed, in quantum mechanics a harmonic oscillator with eigenfrequency $\omega$ may by described by Hamiltonian

$$
\begin{equation*}
\hat{H}=\frac{\hat{p}^{2}}{2 m}+\frac{\kappa \hat{q}^{2}}{2} \tag{2.46}
\end{equation*}
$$

where $q$ is some generalized coordinate, and $p$ the corresponding generalized momentum, $m$ is oscillator's mass, ${ }^{21}$ and $\kappa$ is the spring constant, so that $\omega=(\kappa / m)^{1 / 2}$. Since in thermodynamic equilibrium the density matrix is always diagonal (see Sec. 1 above) in basis of stationary states $m$, quantum-mechanical averages of the kinetic and potential energies may be found from Eq. (7):

[^816]\[

$$
\begin{equation*}
\left\langle\frac{p^{2}}{2 m}\right\rangle=\sum_{m=0}^{\infty} W_{m}\langle m| \frac{\hat{p}^{2}}{2 m}|m\rangle, \quad\left\langle\frac{\kappa q^{2}}{2}\right\rangle=\sum_{m=0}^{\infty} W_{m}\langle m| \frac{\kappa \hat{q}^{2}}{2}|m\rangle, \tag{2.47}
\end{equation*}
$$

\]

where $W_{m}$ is the probability to occupy $m$-th energy level, and bra- and ket-vectors describe the stationary state corresponding to that level. ${ }^{22}$ However, both classical and quantum mechanics teach us that for any $m$, the bra-kets under the sums in Eqs. (47), which present the average kinetic and mechanical energies of the oscillator on its $m^{\text {th }}$ energy level, are equal to each other, and hence each of them is equal to $E_{m} / 2$. Hence, even though we do not know the probability distribution $W_{m}$ yet (it will be calculated in Sec. 5 below), we may conclude that in the "classical limit" $T \gg \hbar \omega$,

$$
\begin{equation*}
\left\langle\frac{p^{2}}{2 m}\right\rangle=\left\langle\frac{\kappa q^{2}}{2}\right\rangle=\frac{T}{2} \tag{2.48}
\end{equation*}
$$

Now let us consider a system with an arbitrary number of degrees of freedom, described by a more general Hamiltonian: ${ }^{23}$

$$
\begin{equation*}
\hat{H}=\sum_{j} \hat{H}_{j}, \quad \hat{H}_{j}=\frac{\hat{p}_{j}^{2}}{2 m_{j}}+\frac{\kappa_{j} \hat{q}_{j}^{2}}{2} \tag{2.49}
\end{equation*}
$$

with (generally, different) eigenfrequencies $\omega_{j}=\left(\kappa_{j} / m_{j}\right)^{1 / 2}$. Since the "modes" (effective harmonic oscillators), contributing into this Hamiltonian, are independent, result (48) is valid for each of the modes. This is the famous equipartition theorem: at thermal equilibrium with $T \gg \hbar \omega_{j}$, the average energy of each so-called half-degree of freedom (which are defined as variables $p_{j}$ or $q_{j}$, giving a quadratic term to the system's Hamiltonian), is equal to $T / 2 .{ }^{24}$ In particular, for each Cartesian coordinate $q_{j}$ of a free-moving, non-interacting particle this theorem is valid for any temperature, because such coordinates may be considered as 1D harmonic oscillators with vanishing potential energy, i.e. $\omega_{j}=0$, so that condition $T \gg \hbar \omega_{j}$ is fulfilled at any temperature.

At this point, a first-time student of thermodynamics should be very much relieved to see that the counter-intuitive thermodynamic definition (1.9) of temperature does indeed correspond to what we all have known about this notion from our kindergarten physics courses.

I believe that our case study of quantum oscillator systems has been a fair illustration of both the strengths and weaknesses of the microcanonical ensemble approach. ${ }^{25}$ On one hand, we could calculate virtually everything we wanted in the classical limit $T \gg \hbar \omega$, but calculations for arbitrary $T \sim \hbar \omega$, though possible, are difficult, because for that, all vertical steps of function $\Sigma\left(E_{N}\right)$ have to be carefully

[^817]counted. In Sec. 4, we will see that other statistical ensembles are much more convenient for such calculations.

Let me conclude this discussion of entropy with a short notice on deterministic classical systems with a few degrees of freedom (and even simpler mathematical objects called "maps") that may exhibit essentially disordered behavior, called the deterministic chaos. ${ }^{26}$ Such chaotic system may be approximately characterized by an entropy defined similarly to Eq. (29), where $W_{m}$ are probabilities to find it in different small regions of phase space, at well separated time intervals. On the other hand, one can use an equation slightly more general than Eq. (29) to define the so-called Kolmogorov (or "Kolmogorov-Sinai") entropy $K$ that characterizes the speed of loss of information about the initial state of the system, and hence what is called the "chaos' depth". In the definition of $K$, the sum over $m$ is replaced with the summation over all possible permutations $\{m\}=m_{0}, m_{1}, \ldots, m_{N-1}$ of small space regions, and $W_{m}$ is replaced with $W_{\{m\}}$, the probability of finding the system in the corresponding regions $m$ at time moment $t_{m}$, with $t_{m}=m \tau$, in the limit $\tau \rightarrow 0$, with $N \tau=$ const. For chaos in the simplest objects, 1D maps, $K$ is equal to the Lyapunov exponent $\lambda>0 .{ }^{27}$ For systems of higher dimensionality, which are characterized by several Lyapunov exponents $\lambda$, the Kolmogorov entropy is equal to the phase-space average of the sum of all positive $\lambda$. These facts provide a much more practicable way of (typically, numerical) calculation of the Kolmogorov entropy than the direct use of its definition. ${ }^{28}$

### 2.3. Maxwell's Demon, information, and computation

Before proceeding to other statistical distributions, I would like to address one more popular concern about Eq. (24), the direct relation between the entropy and information. Some physicists are still uneasy with entropy being nothing else than the (deficit of) information, ${ }^{29}$ though to the best of my knowledge, nobody has yet been able to suggest any experimentally verifiable difference between these two notions. Let me give one example of their direct relation, that is essentially a development of the thought experiment suggested by Maxwell as early as in 1867.

Consider a volume containing just one molecule (considered as a point particle), and separated to two equal halves by a movable partition with a door that may be opened and closed at will, at no energy cost (Fig. 4a). If the door is open and the system is in thermodynamic equilibrium, we do not know on which side of the door partition the molecule is. Here the disorder (and hence entropy) are largest, and there is no way to get, from a large ensemble of such systems, any useful mechanical energy.

Now, let us consider that we (as instructed by, in Lord Kelvin's formulation, an omniscient Maxwell's Demon) know which side of the partition the molecule is currently located. Then we may

[^818]close the door, so that molecule's impacts on the partition create, on the average, a pressure force 7 directed toward the empty part of the volume (in Fig. 4b, the right one). Now we can get from the molecule some mechanical work, say by allowing force $\boldsymbol{7}$ to move the partition to the right, and picking up the resulting mechanical energy by some deterministic external mechanism. After the partition has been moved to the right end of the volume, we can open the door again (Fig. 4c), equalizing the molecule's average pressure on both sides of the partition, and then slowly move the partition back to the middle of the volume, without doing any substantial work. With the kind help by Maxwell's Demon, we can repeat the cycle again and again, and hence make the system to do unlimited mechanical work, fed "only" by information and thermal motion, and thus implementing the perpetual motion machine of the $2^{\text {nd }}$ kind - see Sec. 1.6. The fact that such heat engines do not exist means that the Maxwell's Demon does not either: getting any new information, at nonvanishing temperature (i.e. at thermal agitation of particles) has a finite energy cost.

Fig. 2.4. The Maxwell's Demon paradox: the volume with a single molecule (a) before and (b) after closing the door, and (c) after opening the door in the end of the expansion stage.

In order to evaluate this cost, let us calculate the maximum work per cycle made by the Maxwell's heat engine (Fig. 4), assuming that it is constantly in thermal equilibrium with a heat bath of temperature $T$. Formula (21) tells us that the information supplied by the demon (what exactly half of the volume contains the molecule) is exactly one bit, $I(2)=1$. According to Eq. (24), this means that by getting this information we are changing the entropy by

$$
\begin{equation*}
\Delta S_{I}=-\ln 2 \tag{2.50}
\end{equation*}
$$

Now, it would be a mistake to plug this (negative) entropy change into Eq. (1.19). First, that relation is only valid for slow, reversible processes. Moreover (and more importantly), this equation, as well as its irreversible version (1.41), is only valid for a fixed statistical ensemble. The change $\Delta S_{I}$ does not belong to this category, and may be formally described by the change of the statistical ensemble - from the one consisting of all similar systems (experiments) with an unknown location of the molecule, to the new ensemble consisting of the systems with the molecule in its certain (in Fig. 4, left) half. ${ }^{30}$

Now let us consider the slow expansion of the "gas" after the door had been closed. At this stage, we do not need the demon's help any longer (i.e. the statistical ensemble is fixed), and we can use relation (1.19). At the assumed isothermal conditions ( $T=$ const), this relation may be integrated over the whole expansion process, getting $\Delta Q=T \Delta S$. At the final position, the system's entropy should be the same as initially, i.e. before the door had been opened, because we again do not know where in the volume the molecule is. This means that the entropy was replenished, during the reversible expansion,

[^819]from the heat bath, by $\Delta S=-\Delta S_{\mathrm{I}}=+\ln 2$, so that $\Delta Q=T \Delta S=T \ln 2$. Since by the end of the whole cycle the internal energy $E$ of the system is the same as before, all this heat should have gone into the mechanical energy obtained during the expansion. Thus the obtained work per cycle (i.e. for each obtained information bit) is $T \ln 2\left(k_{\mathrm{B}} T_{\mathrm{K}} \ln 2\right.$ in SI units), about $4 \times 10^{-21}$ Joule at room temperature. This is exactly the minimum energy cost of getting one bit of new information about a system at temperature $T$.

The smallness of that amount on the everyday human scale has left the Maxwell's Demon paradox an academic exercise for almost a century. However, its discussion resumed in the 1960s in the context of energy consumption at numerical calculations, motivated by the exponential (Moore's-law) progress of the digital integrated circuits, which leads in particular, to a fast reduction of energy $\Delta E$ "spent" (turned into heat) per one binary logic operation. In the current generations of semiconductor digital integrated circuits, $\Delta E$ is of the order of $\sim 10^{-16} \mathrm{~J},{ }^{31}$ i.e. still exceeds the room-temperature value of $T \ln 2=k_{\mathrm{B}} T_{\mathrm{K}} \ln 2 \approx 3 \times 10^{-21} \mathrm{~J}$ by more than 4 orders of magnitude. Still, some engineers believe that thermodynamics imposes an important lower limit on $\Delta E$ and hence presents an insurmountable obstacle to the future progress of computation, ${ }^{32}$ so that the issue deserves a discussion.

Let me believe that the reader of these notes understands that, in contrast to naïve popular thinking, computers do not create any new information; all they can do it to reshape (process) it, loosing most of input information on the go. Indeed, any digital computation algorithm may be decomposed into simple, binary logical operations, each of them performed by a certain logic circuit called the logic gate. Some of these gates (e.g., logical NOT performed by inverters, as well as memory READ and WRITE operations) do not change the amount of information in the computer. On the other hand, such information-irreversible logic gates as two-input NAND (or NOR, or XOR, etc.) actually erase one bit at each operation, because they turn two input bits into one output bit (Fig. 5a).

(b)

Fig. 2.5. Simple examples of (a) irreversible and (b) potentially reversible logic circuits. Each rectangle presents a circuit storing one bit of information.

In 1961, R. Landauer arrived at the conclusion that each logic operation should turn into heat at least energy

[^820]\[

$$
\begin{equation*}
\Delta E_{\min }=T \ln 2 \equiv k_{\mathrm{B}} T_{\mathrm{K}} \ln 2 \tag{2.51}
\end{equation*}
$$

\]

This result may be illustrated with the Maxwell's Demon machine shown in Fig. 4, operating as heat pump. At the first stage, with the door closed, it uses external mechanical work $\Delta E=T \ln 2$ to reduce the volume in which of the molecule is confined from $V$ to $V / 2$, pumping heat $-\Delta Q=\Delta E$ into the heat bath. To model a logically-irreversible logic gate, let us now open the door in the partition, and thus loose 1 bit of information about molecule's position. Then we will never get work $T \ln 2$ back, because moving the partition back to the right, with door open, takes place at zero average pressure. Hence, Eq. (51) gives a fundamental limit for energy loss (per bit) at the logically irreversible computation.

However, in 1973 C. Bennett came up with convincing arguments that it is possible to avoid such energy loss by using only operations that are reversible not only physically, but also logically. ${ }^{33}$ For that, one has to avoid any loss of information, i.e. any erasure of intermediate results, for example in the way shown in Fig. 5b. (For that, gate F should be physically reversible, with no substantial static power consumption.) In the end of all calculations, after the result has been copied into a memory, the intermediate results may be "rolled back" through reversible gate to be eventually merged into a copy of input data, again without erasing a single bit. The minimal energy dissipation at such reversible calculation tends to zero as the operation speed is decreased, so that the average energy loss per bit may be less than the perceived "fundamental thermodynamic limit" (51). ${ }^{34}$ The price to pay for this ultralow dissipation is an enormous (exponential) complexity of hardware necessary for storage of all intermediate results. However, using irreversible gates sparely, it may be possible to reduce the complexity dramatically, so that in future the mostly reversible computation may be able to reduce energy consumption in practical digital electronics. ${ }^{35}$

Before we leave Maxwell's Demon behind, let me use it to discuss, for one more time, the relation between the reversibility of the classical and quantum mechanics of Hamiltonian systems and the irreversibility possible in thermodynamics and statistical physics. In our (or rather Lord Kelvin's :-) gedanken experiment shown in Fig. 4, the laws of mechanics governing the motion of the molecule are reversible all times. Still, at partition's motion to the right, driven by molecule's impacts, the entropy grows, because the molecule picks up heat $\Delta Q>0$, and hence entropy $\Delta S=\Delta Q / T>0$, from the heat bath. The physical mechanism of this irreversible entropy (read: disorder) growth is the interaction of the molecule with uncontrollable components of the heat bath, and the resulting loss of information about the motion of the molecule. Philosophically, the emergence of irreversibility in large systems is a strong argument against the reductionism - a naïve belief that knowing the exact laws of Nature at one level of its complexity, we can readily understand all the phenomena on the higher levels of its organization. In reality, the macroscopic irreversibility of large systems is a wonderful example of a new law (in this case, the $2^{\text {nd }}$ law of thermodynamics) that becomes relevant on the substantially new level of complexity - without defying the lower-level laws. Without such new laws, very little of the higher level organization of Nature may be understood.

[^821]
### 2.4. Canonical ensemble and the Gibbs distribution

As we have seen in Sec. 2, the microcanonical distribution may be directly used for solving some simple problems, ${ }^{36}$ but a further development of this approach (also due to J. Gibbs) turns out to be much more convenient for calculations. Let us consider that a statistical ensemble of similar systems we are studying, each in thermal equilibrium with a much larger heat bath of temperature $T$ (Fig. 6a). Such an ensemble is called canonical.
(a)

(b)

Fig. 2.6. (a) System in a heat bath (a canonical ensemble member) and (b) energy spectrum of the composite system (including the heat bath).

Next, it is intuitively evident that if the heat bath is sufficiently large, any thermodynamic variables characterizing the system under study should not depend on heat bath's environment. In particular, we may assume that the heat bath is thermally insulated; then the total energy $E_{\Sigma}$ of the composite system (consisting of the system of our interest, plus the heat bath) does not change in time. For example, if our system of interest is in its certain (say, $m^{\text {th }}$ ) quantum state, then the sum

$$
\begin{equation*}
E_{\Sigma}=E_{m}+E_{\mathrm{HB}} \tag{2.52}
\end{equation*}
$$

is time-independent. Now let us partition the canonical ensemble of such systems into much smaller sub-ensembles, each being a microcanonical ensemble of composite systems whose time-independent total energy $E_{\Sigma}$ is the same - as discussed in Sec. 2, within a certain very small energy interval $\Delta E_{\Sigma} \ll$ $E_{\Sigma}$. According to the microcanonical distribution, probabilities to find the composite system, within this new ensemble, in any state are equal. Still, heat bath energies $E_{\mathrm{HB}}=E_{\Sigma}-E_{m}$ (Fig. 6b) of members of this microcanonical sub-ensemble may be different due to the difference in $E_{m}$.

The probability $W\left(E_{m}\right)$ to find the system of our interest (within the selected sub-ensemble) in a state with energy $E_{m}$ is proportional to the number $\Delta M$ of such systems in the sub-ensemble. Due to the very large size of the heat bath in comparison with that of the system under study, the heat bath' density of states $g_{\mathrm{HB}}$ is very high, and $\Delta E_{\Sigma}$ may be selected so that

$$
\begin{equation*}
\frac{1}{g_{\mathrm{HB}}} \ll \Delta E_{\Sigma} \ll\left|E_{m}-E_{m^{\prime}}\right| \ll E_{\mathrm{HB}}, \tag{2.53}
\end{equation*}
$$

where $m$ and $m$ ' are any states of the system of our interest. As Fig. 6b shows, in this case we may write $\Delta M=g_{\mathrm{HB}}\left(E_{\mathrm{HB}}\right) \Delta E_{\Sigma}$. As a result, within the microcanonical ensemble with the total energy $E_{\Sigma}$,

[^822]\[

$$
\begin{equation*}
W_{m} \propto \Delta M=g_{\mathrm{HB}}\left(E_{\mathrm{HB}}\right) \Delta E_{\Sigma}=g_{\mathrm{HB}}\left(E_{\Sigma}-E_{m}\right) \Delta E_{\Sigma} . \tag{2.54}
\end{equation*}
$$

\]

Let us simplify this expression further, using the Taylor expansion with respect to relatively small $E_{m} \ll E_{\Sigma}$. However, here we should be careful. As we have seen in Sec. 2, the density of states of a large system is an extremely rapidly growing function of energy, so that if we applied the Taylor expansion directly to Eq. (54), the Taylor series would converge for very small $E_{m}$ only. A much broader applicability range may be obtained by taking logarithm of both parts of Eq. (54) first:

$$
\begin{equation*}
\ln W_{m}=\mathrm{const}+\ln \left[g_{\mathrm{HB}}\left(E_{\Sigma}-E_{m}\right)\right]+\ln \Delta E_{\Sigma}=\mathrm{const}+S_{\mathrm{HB}}\left(E_{\Sigma}-E_{m}\right), \tag{2.55}
\end{equation*}
$$

where the second equality results from application of Eq. (36) to the heat bath, and $\ln \Delta E_{\Sigma}$ has been incorporated into the constant. Now, we can Taylor-expand the (much more smooth) function of energy in the right-hand part, and limit ourselves to the two leading terms of the series:

$$
\begin{equation*}
\ln W_{m} \approx \mathrm{const}+\left.S_{\mathrm{HB}}\right|_{E_{m}=0}-\left.\frac{d S_{\mathrm{HB}}}{d E_{\mathrm{HB}}}\right|_{E_{m}=0} E_{m} . \tag{2.56}
\end{equation*}
$$

But according to Eq. (1.9), the derivative participating in this expression is nothing else than the reciprocal heat bath temperature that (due to the large bath size) does not depend on whether $E_{m}$ is equal to zero or not. Since our system of interest is in the thermal equilibrium with the bath, this is also the temperature $T$ of the system - see Eq. (1.8). Hence Eq. (56) is merely

$$
\begin{equation*}
\ln W_{m}=\text { const }-\frac{E_{m}}{T} . \tag{2.57}
\end{equation*}
$$

This equation describes a substantial decrease of $W_{m}$ as $E_{m}$ is increased by several $T$, and hence our linear approximation (56) is virtually exact as soon as $E_{\mathrm{HB}}$ is much larger than $T$ - the condition that is rather easy to satisfy, because as we have seen in Sec. 2, the average energy of each particle is of the order of $T$.

Now we should be careful again, because so far we have only derived Eq. (57) for a subensemble with fixed $E_{\Sigma}$. However, since the right-hand part of Eq. (57) includes only $E_{m}$ and $T$ that are independent of $E_{\Sigma}$, this relation is valid for all sub-ensembles of the canonical ensemble, and hence for the later ensemble as the whole. ${ }^{37}$ Hence for the total probability to find our system of interest in state with energy $E_{m}$, in the canonical ensemble with temperature $T$, we can write

$$
\begin{equation*}
W_{m}=\text { const } \times \exp \left\{-\frac{E_{m}}{T}\right\} \equiv \frac{1}{Z} \exp \left\{-\frac{E_{m}}{T}\right\} . \tag{2.58}
\end{equation*}
$$

This is the famous Gibbs distribution (sometimes called the "canonical distribution"), ${ }^{38}$ which is frequently arguably the summit of statistical physics, ${ }^{39}$ because it may be used for a straightforward (or at least conceptually straightforward :-) calculation of all statistical and thermodynamic variables.

[^823]Before I illustrate this, let me first calculate the coefficient $Z$ participating in Eq. (58) for the general case. Requiring, in accordance with Eq. (4), the sum of all $W_{m}$ to be equal 1, we get

Statistical
sum

$$
\begin{equation*}
Z=\sum_{m} \exp \left\{-\frac{E_{m}}{T}\right\} \tag{2.59}
\end{equation*}
$$

where the summation is formally extended to all quantum states of the system, though in practical calculations, the sum may be truncated to include only the states that are noticeably occupied. This apparently humble normalization coefficient $Z$ turns out to be so important for the relation between the Gibbs distribution (i.e. statistics) and thermodynamics that it has a special name - or actually, two names: either the statistical sum or the partition function. To demonstrate how important $Z$ is, let us use the general Eq. (29) for entropy to calculate its value for the particular case of the canonical ensemble, i.e. the Gibbs distribution of probabilities $W_{n}$ :

$$
\begin{equation*}
S=-\sum_{m} W_{m} \ln W_{m}=\frac{\ln Z}{Z} \sum_{m} \exp \left\{-\frac{E_{m}}{T}\right\}+\frac{1}{Z T} \sum_{m} E_{m} \exp \left\{-\frac{E_{m}}{T}\right\} . \tag{2.60}
\end{equation*}
$$

According to the general rule (7), the thermodynamic (i.e. ensemble-average) value $E$ of the internal energy of the system is

$$
\begin{equation*}
E=\sum_{m} W_{m} E_{m}=\frac{1}{Z} \sum_{m} E_{m} \exp \left\{-\frac{E_{m}}{T}\right\}, \tag{2.61a}
\end{equation*}
$$

so that the second term in the right-hand part of Eq. (60) is just $E / T$, while the first term equals just $\ln Z$, due to the normalization condition (59). (As a parenthetic remark, using the notion of reciprocal temperature $\beta \equiv 1 / T$, Eq. (61a), with account of Eq. (59), may be also rewritten as

$$
\begin{equation*}
E=-\frac{\partial(\ln Z)}{\partial \beta} \tag{2.61b}
\end{equation*}
$$

This formula is very convenient for calculations if our prime interest is the average energy $E$ rather than $F$ or $W_{n}$.) With these substitutions, Eq. (60) yields a very simple relation between the statistical sum and entropy:

$$
\begin{equation*}
S=\frac{E}{T}+\ln Z . \tag{2.62}
\end{equation*}
$$

Using Eq. (1.33), we see that Eq. (62) gives a straightforward way to calculate the free energy $F$ of the system from nothing else than its statistical sum:

$$
\begin{equation*}
F \equiv E-T S=T \ln \frac{1}{Z} \tag{2.63}
\end{equation*}
$$

[^824]Now, using the general thermodynamic relations (see especially the circular diagram shown in Fig. 1.7b, and its discussion) we can calculate all thermodynamic potentials of the system, and all other variables of interest. Let me only note that in order to calculate pressure $P$ - e.g., from the second of Eqs. (1.35) - we would need to know the explicit dependence of $F$, and hence of the statistical sum $Z$ on the system volume $V$. This would require the calculation, by appropriate methods of either classical or quantum mechanics, of the volume dependence of eigenenergies $E_{m}$. I will give numerous examples of such calculations later in the course. ${ }^{40}$

As the final note of this section, Eqs. (59) and (63) may be combined to give a very elegant expression,

$$
\begin{equation*}
\exp \left\{-\frac{F}{T}\right\}=\sum_{m} \exp \left\{-\frac{E_{m}}{T}\right\} \tag{2.64}
\end{equation*}
$$

which offers a convenient interpretation of free energy as a (rather specific) average of eigenenergies of the system. One more convenient formula may be obtained by using Eq. (64) to rewrite the Gibbs distribution (58) in the form

$$
\begin{equation*}
W_{m}=\exp \left\{\frac{F-E_{m}}{T}\right\} . \tag{2.65}
\end{equation*}
$$

In particular, this expression shows that that since all probabilities $W_{m}$ are below $1, F$ is always lower than the lowest energy level. Also, note that probabilities $W_{m}$ do not depend on the energy reference choice, i. e. on an arbitrary constant added to all $E_{m}$ (and hence to $E$ and $F$ ).

### 2.5. Harmonic oscillator statistics

The last property may be immediately used in our first example of the Gibbs distribution application to a particular, but very important system - the harmonic oscillator, for the more general case then was done in Sec. 2, namely for a "quantum oscillator" with an arbitrary relation between $T$ and $\hbar \omega .{ }^{41}$ Let us consider a canonical ensemble of similar oscillators, each in a contact with a heat bath of temperature $T$. Selecting the zero-point energy $\hbar \omega / 2$ for the origin of $E$, oscillator eigenenergies (38) become $E_{m}=m \hbar \omega(m=0,1, \ldots)$, so that the Gibbs distribution for probabilities of these states is

$$
\begin{equation*}
W_{m}=\frac{1}{Z} \exp \left\{-\frac{E_{m}}{T}\right\}=\frac{1}{Z} \exp \left\{-\frac{m \hbar \omega}{T}\right\} \tag{2.66}
\end{equation*}
$$

[^825]with the statistical sum
\[

$$
\begin{equation*}
Z \equiv \sum_{m=0}^{\infty} \exp \left\{-\frac{m \hbar \omega}{T}\right\}=\sum_{m=0}^{\infty} \lambda^{m}, \quad \text { where } \lambda \equiv \exp \left\{-\frac{\hbar \omega}{T}\right\} \leq 1 \tag{2.67}
\end{equation*}
$$

\]

This is just the well-known infinite geometric progression (the "geometric series"), ${ }^{42}$ with the sum

$$
\begin{equation*}
Z=\frac{1}{1-\lambda}=\frac{1}{1-e^{-\hbar \omega / T}} \tag{2.68}
\end{equation*}
$$

Quantum oscillator's statistics

(a)

(b)

Fig. 2.7. Statistical and thermodynamic parameters of a harmonic oscillator, as functions of temperature.

This average energy may be calculated in any of two ways: either using Eq. (7):

$$
\begin{equation*}
E=\sum_{m=0}^{\infty} E_{m} W_{m}=\left(1-e^{-\hbar \omega / T}\right) \sum_{m=0}^{\infty} m \hbar \omega e^{-m \hbar \omega / T}, \tag{2.70}
\end{equation*}
$$

or (simpler) using Eq. (61b), as

[^826]\[

$$
\begin{equation*}
E=-\frac{\partial}{\partial \beta} \ln Z=\frac{\partial}{\partial \beta} \ln (1-\exp \{-\beta \hbar \omega\}), \quad \beta \equiv \frac{1}{T} . \tag{2.71}
\end{equation*}
$$

\]

Both methods give (of course) the same famous result, ${ }^{43}$

$$
\begin{equation*}
E=E(\omega, T)=\hbar \omega \frac{1}{e^{\hbar \omega / T}-1}, \tag{2.72}
\end{equation*}
$$

Quantum
which is valid for arbitrary temperature and plays the key role in many fundamental problems of physics. The red line in Fig. 7b shows this $E$ as a function of normalized temperature. At low temperatures, $T \ll \hbar \omega$, the oscillator is predominantly in its lowest (ground) state, and its energy (on top of the constant zero-point energy $\hbar \omega / 2$ !) is exponentially small: $E \approx \hbar \omega \exp \{-\hbar \omega / T\} \ll T$, $\hbar \omega$. On the other hand, in the high-temperature limit the energy tends to $T$. This is exactly the result (a particular case of the equipartition theorem) that was obtained in Sec. 2 from the microcanonical distribution. Please note how much simpler is the calculation starting from the Gibbs distribution, even for an arbitrary ratio $T / \hbar \omega$.

To complete the discussion of thermodynamic properties of the harmonic oscillator, we can calculate its free energy using Eq. (63):

$$
\begin{equation*}
F=T \ln \frac{1}{Z}=T \ln \left(1-e^{-\hbar \omega / T}\right) \tag{2.73}
\end{equation*}
$$

Now entropy may be found from thermodynamics: either from the first of Eqs. (1.35), $S=-(\partial F / \partial T)_{V}$, or (even more easily) from Eq. (1.33): $S=(E-F) / T$. Both relations give, of course, the same result:

$$
\begin{equation*}
S=\frac{\hbar \omega}{T} \frac{1}{e^{\hbar \omega / T}-1}-\ln \left(1-e^{-\hbar \omega / T}\right) \tag{2.74}
\end{equation*}
$$

Finally, since in the general case the dependence of the oscillator properties (essentially, $\omega$ ) on volume $V$ in this problem is not specified, such variables as $P, \mu, G, W$, and $\Omega$ are not defined, and we may calculate only the average heat capacity $C$ per one oscillator:

$$
\begin{equation*}
C=\frac{\partial E}{\partial T}=\left(\frac{\hbar \omega}{T}\right)^{2} \frac{e^{\hbar \omega / T}}{\left(e^{\hbar \omega / T}-1\right)^{2}}=\left[\frac{\hbar \omega / 2 T}{\sinh (\hbar \omega / 2 T)}\right]^{2} \tag{2.75}
\end{equation*}
$$

The calculated thermodynamic variables are shown in Fig. 7b. In the low-temperature limit ( $T$ $\ll \hbar \omega$ ), they all tend to zero. On the other hand, in the high temperature limit ( $T \gg \hbar \omega$ ), $F \rightarrow-T$ $\ln (T / \hbar \omega) \rightarrow-\infty, S \rightarrow \ln (T / \hbar \omega) \rightarrow+\infty$, and $C \rightarrow 1$ (in SI units, $C \rightarrow k_{\mathrm{B}}$ ). Note that the last limit is the direct corollary of the equipartition theorem: each of two "half-degrees of freedom" of the oscillator gives, in the classical limit, a contribution $C=1 / 2$ into its heat capacity.

Now let us use Eq. (69) to discuss the statistics of the quantum oscillator described by Hamiltonian (46), in the coordinate representation. Again using density matrix' diagonality at thermodynamic equilibrium, we may use a relation similar to Eqs. (47) to calculate the probability density to find the oscillator at coordinate $q$ :

[^827]\[

$$
\begin{equation*}
w(q)=\sum_{m=0}^{\infty} W_{m} w_{m}(q)=\sum_{m=0}^{\infty} W_{m}\left|\psi_{m}(q)\right|^{2}=\left(1-e^{-\hbar \omega / T}\right) \sum_{m=0}^{\infty} e^{-m \hbar \omega / T}\left|\psi_{m}(q)\right|^{2}, \tag{2.76}
\end{equation*}
$$

\]

where $\psi_{m}(q)$ is the eigenfunction of $m$-th stationary state of the oscillator. Since each $\psi_{m}(q)$ is proportional to the Hermite polynomial ${ }^{44}$ that requires at least $m$ elementary functions for its representation, working out the sum in Eq. (76) is a bit tricky, ${ }^{45}$ but the final result is rather simple: $w(q)$ is just a normalized Gaussian distribution (the "bell curve"),

$$
\begin{equation*}
w(q)=\frac{1}{(2 \pi)^{1 / 2} \delta q} \exp \left\{-\frac{q^{2}}{2(\delta q)^{2}}\right\}, \tag{2.77}
\end{equation*}
$$

with $\langle q\rangle=0$, and

$$
\begin{equation*}
\left\langle q^{2}\right\rangle=\frac{\hbar}{2 m \omega} \operatorname{coth} \frac{\hbar \omega}{2 T} . \tag{2.78}
\end{equation*}
$$

Since coth $\xi$ tends to 1 at $\xi \rightarrow \infty$, and diverges as $1 / \xi$ at $\xi \rightarrow 0$, Eq. (78) shows that the width of coordinate distribution is constant (and equal to that, $\hbar / 2 m \omega$, of the ground-state wavefunction $\psi_{0}$ ) at $T$ $\ll \hbar \omega$, and grows as $T / m \omega^{2}$ at $T / \hbar \omega \rightarrow \infty$.

As a sanity check, we may use Eq. (78) to write the following expression,

$$
\langle U\rangle \equiv\left\langle\frac{\kappa q^{2}}{2}\right\rangle=\frac{\hbar \omega}{4} \operatorname{coth} \frac{\hbar \omega}{2 T} \rightarrow \begin{cases}\hbar \omega / 4, & \text { at } T \ll \hbar \omega  \tag{2.79}\\ T / 2, & \text { at } \hbar \omega \ll T\end{cases}
$$

for the average potential energy of the oscillator. In order to comprehend this result, let us notice that Eq. (72) for the average full energy $E$ was obtained by counting it from the ground state energy $\hbar \omega / 2$ of the oscillator. ${ }^{46}$ If we add this energy to the result, we get

$$
\begin{equation*}
E=\frac{\hbar \omega}{e^{\hbar \omega / T}-1}+\frac{\hbar \omega}{2}=\frac{\hbar \omega}{2} \operatorname{coth} \frac{\hbar \omega}{2 T} \tag{2.80}
\end{equation*}
$$

We see that for arbitrary temperature, $\langle U\rangle=E / 2$, as we already concluded from Eq. (47). This means that the average kinetic energy, equal to $E-\langle U\rangle$, is also the same:

$$
\begin{equation*}
\left\langle\frac{p^{2}}{2 m}\right\rangle=\left\langle\frac{\kappa q^{2}}{2}\right\rangle=\frac{E}{2}=\frac{\hbar \omega}{4} \operatorname{coth} \frac{\hbar \omega}{2 T} . \tag{2.81}
\end{equation*}
$$

In the classical limit $T \gg \hbar \omega$, both energies equal $T / 2$, reproducing the equipartition theorem result (48).

### 2.6. Two important applications

The results of the previous section, especially Eq. (72), have enumerable applications in physics, but I will have time for a brief discussion of only two of them.

[^828](i) Blackbody radiation. Let us consider a free-space volume $V$ limited by non-absorbing (i.e. ideally reflecting) walls. Electrodynamics tells us ${ }^{47}$ that electromagnetic field in such a cavity may be presented as a sum of "modes" with time evolution similar to that of the usual harmonic oscillator, and quantum mechanics says ${ }^{48}$ that the energy of such electromagnetic oscillator is quantized in accordance with Eq. (38), so that at thermal equilibrium the average energy is described by Eq. (72). If volume $V$ is large enough, ${ }^{49}$ the number of these modes within a small range $d k$ of the wavevector magnitude $k$ is ${ }^{50}$
\[

$$
\begin{equation*}
d N=\frac{g V}{(2 \pi)^{3}} d^{3} k=\frac{g V}{(2 \pi)^{3}} 4 \pi k^{2} d k \tag{2.82}
\end{equation*}
$$

\]

where for electromagnetic waves, the degeneracy factor $g=2$, due to their two different (e.g., linear) polarizations for the same wave vector $\mathbf{k}$. With the isotropic dispersion relation for waves in vacuum, $k$ $=\omega / c$, the elementary volume $d^{3} k$ corresponding to a small interval $d \omega$ is a spherical shell of small thickness $d k=d \omega / c$, and Eq. (82) yields

$$
\begin{equation*}
d N=\frac{2 V}{(2 \pi)^{3}} 4 \pi \frac{\omega^{2} d \omega}{c^{3}}=V \frac{\omega^{2}}{\pi^{2} c^{3}} d \omega . \tag{2.83}
\end{equation*}
$$

Using Eq. (72), we see that the spectral density of electromagnetic wave energy, per unit volume, is

$$
\begin{equation*}
u(\omega) \equiv \frac{E}{V} \frac{d N}{d \omega}=\frac{\hbar \omega^{3}}{\pi^{2} c^{3}} \frac{1}{e^{\hbar \omega / T}-1} \tag{2.84}
\end{equation*}
$$

This is the famous Planck's blackbody radiation law. ${ }^{51}$ To understand why its name mentions radiation, let us consider a small planar part, of area $d A$, of a surface that completely absorbs electromagnetic waves incident from any direction. (Such "perfect black body" approximation may be closely approached in special experimental structures, especially in limited frequency intervals.) Figure 8 shows that if the arriving wave was planar, with the incidence angle $\theta$, then power $d \mathcal{P}_{d}(\omega)$ absorbed by the surface within a small frequency interval $d \omega$ (i.e. energy arriving at the surface within unit time interval), would be equal to the radiation energy within the same frequency interval and inside a cylinder of height $c$, base area $d A \cos \theta$, and hence volume $d V=c d A \cos \theta$ :

$$
\begin{equation*}
d P_{\theta}(\omega)=u(\omega) d \omega d V=u(\omega) d \omega c d A \cos \theta \tag{2.85}
\end{equation*}
$$

Since the thermally-induced field is isotropic, i.e. propagates equally in all directions, this results should be averaged over all solid angles within the polar angle interval $0 \leq \theta \leq \pi / 2$ :

$$
\begin{equation*}
\frac{d \mathcal{P}(\omega)}{d A d \omega}=\frac{1}{4 \pi} \int \frac{d P_{\theta}(\omega)}{d A d \omega} d \Omega=c u(\omega) \frac{1}{4 \pi} \int_{0}^{\pi / 2} \sin \theta d \theta \int_{0}^{2 \pi} d \varphi \cos \theta=\frac{c}{4} u(\omega) \tag{2.86}
\end{equation*}
$$

[^829]Hence the Planck's expression (84), multiplied by $c / 4$, gives the power absorbed by such "blackbody" surface. But at thermal equilibrium, this absorption has to be exactly balanced by the surface's own radiation, due to its finite temperature $T$.

Fig. 2.8. Calculating the relation between $d \mathcal{P}(\omega)$ and $u(\omega) d \omega$.

I am confident that the reader is familiar with the main features of the Planck law (84), including its general shape (Fig. 9), with the low-frequency asymptote $u(\omega) \propto \omega^{2}$ (due to its historic significance bearing the special name of the Rayleigh-Jeans law), the exponential drop at high frequencies (the Wien law), and the resulting maximum of function $u(\omega)$, reached at frequency $\omega_{\max }$,

$$
\begin{equation*}
\hbar \omega_{\max } \approx 2.82 T \tag{2.87}
\end{equation*}
$$

i.e. at wavelength $\lambda_{\max }=2 \pi / k_{\max }=2 \pi c / \omega_{\max } \approx 2.22 c \hbar / T$. Still, I cannot help mentioning two particular values corresponding to visible light ( $\lambda_{\text {max }} \sim 500 \mathrm{~nm}$ ) for Sun's surface temperature $T_{\mathrm{K}} \approx 6,000 \mathrm{~K}$, and to mid-infrared range $\left(\lambda_{\max } \sim 10 \mu \mathrm{~m}\right)$ for the Earth's surface temperature $T_{\mathrm{K}} \approx 300 \mathrm{~K}$. The balance of these two radiations, absorbed and emitted by the Earth, determines its surface temperature, and hence has the key importance for all life on our planet. As one more example, the cosmic microwave background (CMB) radiation, closely following the Planck law with $T_{\mathrm{K}}=2.726 \mathrm{~K}$ (and hence having maximum density at $\lambda_{\max } \approx 1.9 \mathrm{~mm}$ ), and in particular its weak anisotropy, is a major source of data for all modern cosmology. ${ }^{52}$

Fig. 2.9. Frequency dependence of the blackbody radiation density, normalized by $u_{0} \equiv$ $T^{3} / \pi^{2} \hbar^{2} c^{3}$, according to the Planck law (red line) and the Rayleigh-Jeans law (blue line).

[^830]Now let us calculate the total energy $E$ of this radiation in some volume $V$. It may be found from Eq. (72) by integration its over all frequencies: ${ }^{53}$

$$
\begin{equation*}
E=V \int_{0}^{\infty} u(\omega) d \omega=V \int_{0}^{\infty} \frac{\hbar \omega^{3}}{\pi^{2} c^{3}} \frac{d \omega}{e^{\hbar \omega / T}-1}=\frac{V T^{4}}{\pi^{2} \hbar^{3} c^{3}} \int_{0}^{\infty} \frac{\xi^{3} d \xi}{e^{\xi}-1}=V \frac{\pi^{2}}{15 \hbar^{3} c^{3}} T^{4} . \tag{2.88}
\end{equation*}
$$

(The last transition in Eq. (88) uses a table integral equal to $\left.\Gamma(4) \zeta(4)=(3!)\left(\pi^{4} / 90\right)=\pi^{4} / 15 .{ }^{54}\right)$ Using Eq. (86) to recast Eq. (88) into the total power radiated by a blackbody surface, we get the well-known Stefan (or "Stefan-Boltzmann") law

$$
\begin{equation*}
\frac{d \mathcal{P}}{d A}=\frac{\pi^{2}}{60 \hbar^{3} c^{2}} T^{4}=\sigma T_{\mathrm{K}}^{4}, \tag{2.89a}
\end{equation*}
$$

where $\sigma$ is the Stefan-Boltzmann constant

$$
\begin{equation*}
\sigma \equiv \frac{\pi^{2}}{60 \hbar^{3} c^{2}} k_{\mathrm{B}}^{4} \approx 5.67 \times 10^{-8} \frac{\mathrm{~W}}{\mathrm{~m}^{2} \mathrm{~K}^{4}} \tag{2.89b}
\end{equation*}
$$

By this time, the thoughtful reader should have an important concern ready: Eq. (84) and hence Eq. (88) are based on Eq. (72) for the average energy of each oscillator, counted from its ground energy $\hbar \omega / 2$. However, the radiation power should not depend on the energy origin; why have not we included the ground energy of each oscillator into integration (88), as we have done in Eq. (80)? The answer is that usual radiation detectors only measure the difference between power $\mathcal{P}_{\text {in }}$ of the incident radiation (say, that of a blackbody surface with temperature $T$ ) and their own back-radiation $P_{\text {out }}$ with power corresponding to some effective temperature $T_{d}$ of the detector (Fig. 10). But however low $T_{d}$ is, the temperature-independent ground state energy contribution $\hbar \omega / 2$ to the back radiation is always there. Hence, the $\hbar \omega / 2$ drops out from the difference, and cannot be detected - at least in this simple way. This is the reason why we had the right to ignore this contribution in Eq. (88) - very fortunately, because it would lead to the integral's divergence at its upper limit. However, let me repeat again that the groundstate energy of the electromagnetic field oscillators is physically real - and important.

Fig. 2.10. Generic scheme of the electromagnetic radiation power measurement.

[^831]One more interesting result may be deduced from the free energy $F$ of the electromagnetic radiation, which may be also calculated by integration of Eq. (73) over all the modes, with the appropriate weight:

$$
\begin{equation*}
F=\sum_{\omega} T \ln \left(1-e^{-\hbar \omega / T}\right) \rightarrow \int_{0}^{\infty} T \ln \left(1-e^{-\hbar \omega / T}\right) \frac{d N}{d \omega} d \omega=\int_{0}^{\infty} T \ln \left(1-e^{-\hbar \omega / T}\right)\left(V \frac{\omega^{2}}{\pi^{2} c^{3}}\right) d \omega \tag{2.90}
\end{equation*}
$$

Presenting $\omega^{2} d \omega$ as $d\left(\omega^{3}\right) / 3$, this integral may be readily worked out by parts, and reduced to a table integral similar to that in Eq. (88), yielding a surprisingly simple result:

$$
\begin{equation*}
F=-V \frac{\pi^{2}}{45 \hbar^{3} c^{3}} T^{4}=-\frac{E}{3} \tag{2.91}
\end{equation*}
$$

Now we can use the second of general thermodynamic equations (1.35) to calculate pressure:

$$
\begin{equation*}
P=-\left(\frac{\partial F}{\partial V}\right)_{T}=\frac{\pi^{2}}{45 \hbar^{3} c^{3}} T^{4}=\frac{E}{3 V} . \tag{2.92a}
\end{equation*}
$$

This result might be, of course, derived by the integration of the expression for the forces exerted by each mode of the electromagnetic on confining the walls confining it to volume $V,{ }^{55}$ but notice how much simpler the thermodynamic calculation is. Rewritten in the form,

$$
\begin{equation*}
P V=\frac{E}{3} \tag{2.92b}
\end{equation*}
$$

this result may be considered as the equation of state of the electromagnetic field, i.e. from the quantummechanical point of view, the photon gas. As we will prove in the next chapter, the equation of state (1.44) of the ideal classical gas may be presented in a similar form, but with a coefficient generally different from Eq. (92). In particular, according to the equipartition theorem, for an ideal gas of nonrelativistic atoms whose internal degrees of freedom are in their ground state, whose whole energy is that of three translational "half-degrees of freedom", $E=3 N(T / 2)$, the factor before $E$ is twice larger than in Eq. (92). On the other hand, a relativistic treatment of the classical gas shows that Eq. (92) is valid for any gas in the ultra-relativistic limit, $T \gg m c^{2}$, where $m$ is the rest mass of the gas particle. Evidently, photons (i.e. particles with $m=0$ ) satisfy this condition. ${ }^{56}$

Finally, let me note that Eq. (92) allows the following interesting interpretation. The last of Eqs. (1.60), being applied to Eq. (92), shows that in this particular case the grand potential $\Omega$ equals ( $-E / 3$ ). But according to the definition of $\Omega$, the first of Eqs. (1.60), this means that the chemical potential of the electromagnetic field excitations vanishes:

$$
\begin{equation*}
\mu=\frac{F-\Omega}{N}=0 . \tag{2.93}
\end{equation*}
$$

In Sec. 8 below, we will see that the same result follows from Eq. (72) and the Bose-Einstein distribution, and discuss its physical sense.

[^832](ii) Specific heat of solids. The heat capacity of solids is readily measurable, and in the early 1900s its experimentally observed temperature dependence served as an important test for emerging quantum theories. However, theoretical calculation of $C_{V}$ is not simple, ${ }^{57}$ even for isolators whose specific heat is due to thermally-induced vibrations of their crystal lattice alone. ${ }^{58}$ Indeed, a solid may be treated as an elastic continuum only at low relatively frequencies. Such continuum supports three different modes of mechanical waves with the same frequency $\omega$, that obey similar, linear dispersion laws, $\omega=v k$, but velocity $v=v_{l}$ for one of these modes (the longitudinal sound) is higher than that $\left(v_{t}\right)$ of two other modes (the transverse sound). ${ }^{59}$ At such frequencies the wave mode density may be described by an evident modification of Eq. (83):
\[

$$
\begin{equation*}
d N=V \frac{1}{(2 \pi)^{3}}\left(\frac{1}{v_{l}^{3}}+\frac{2}{v_{t}^{3}}\right) 4 \pi \omega^{2} d \omega . \tag{2.94a}
\end{equation*}
$$

\]

For what follows, it is convenient to rewrite this relation in a form similar to Eq. (83):

$$
\begin{equation*}
d N=\frac{3 V}{(2 \pi)^{3}} 4 \pi \frac{\omega^{2} d \omega}{v^{3}}, \quad \text { with } v \equiv\left[\frac{1}{3}\left(\frac{1}{v_{l}^{3}}+\frac{2}{v_{t}^{3}}\right)\right]^{-1 / 3} . \tag{2.94b}
\end{equation*}
$$

However, wave theory shows ${ }^{60}$ that as frequency $\omega$ of a sound wave in a periodic structure is increased so that its half-wavelength $\pi / k$ approaches the crystal period $d$, the dispersion law $\omega(k)$ becomes nonlinear before the frequency reaches a maximum at $k=\pi / d$. To make the things even more complex, 3D crystals are generally anisotropic, so that the dispersion law is different in different directions of wave propagation. As a result, the exact statistics of thermally excited sound waves, and hence the heat capacity of crystals, is rather complex and specific for each particular crystal type.

In 1912, P. Debye suggested an approximate theory of the temperature dependence of the specific heat, which is in a surprisingly good agreement with experiment for many insulators, including polycrystalline and amorphous materials. In his model, the linear (acoustic) dispersion law $\omega=v k$, with the effective sound velocity $v$, defined by the latter of Eqs. (94b), is assumed to be exact all the way up to some cutoff frequency $\omega_{\mathrm{D}}$, the same for all three wave modes. This cutoff frequency may be defined by the requirement that the total number of acoustic modes, calculated within this model from Eq. (94b),

$$
\begin{equation*}
N=V \frac{1}{(2 \pi)^{3}} \frac{3}{v^{3}} \int_{0}^{\omega_{D}} 4 \pi \omega^{2} d \omega=\frac{V \omega_{D}^{3}}{2 \pi^{2} v^{3}}, \tag{2.95}
\end{equation*}
$$

is equal to the universal number $N=3 n V$ of degrees of freedom (and hence of independent oscillation modes) in a system of $n V$ elastically coupled particles, where $n$ is the atomic density of the crystal, i.e. the number of atoms per unit volume. Within this model, Eq. (72) immediately yields the following expression for the average energy and specific heat (in thermal equilibrium at temperature $T$ ):

[^833]Debye law

$$
\begin{gather*}
E=V \frac{1}{(2 \pi)^{3}} \frac{3}{v^{3}} \int_{0}^{\omega_{\mathrm{D}}} \frac{\hbar \omega}{e^{\hbar \omega / T}-1} 4 \pi \omega^{2} d \omega=3 n V T \cdot D(x)_{x=T_{\mathrm{D}} / T},  \tag{2.96}\\
c_{V} \equiv \frac{C_{V}}{n V}=\frac{1}{n V}\left(\frac{\partial E}{\partial T}\right)_{V}=3\left[D(x)-x \frac{d D(x)}{d x}\right]_{x=T_{\mathrm{D}} / T}, \tag{2.97}
\end{gather*}
$$

where $T_{\mathrm{D}} \equiv \hbar \omega_{\mathrm{D}}$ is called the Debye temperature, ${ }^{61}$ and

$$
D(x) \equiv \frac{3}{x^{3}} \int_{0}^{x} \frac{\xi^{3} d \xi}{e^{\xi}-1} \rightarrow \begin{cases}1, & \text { at } x \rightarrow 0  \tag{2.98}\\ \pi^{4} / 5 x^{3}, & \text { at } x \rightarrow \infty\end{cases}
$$

the Debye function. Red lines in Fig. 11 show the temperature dependence of the specific heat $c_{V}$ (per atom) within the Debye model. At high temperatures, it approaches a constant value of 3, corresponding to energy $E=3 n V T$, in accordance with the equipartition theorem for each of 3 degrees of freedom of each atom. (This model-insensitive value of $c_{V}$ is known as the Dulong-Petit law.) In the opposite limit of low temperatures, the specific heat is much smaller:

$$
\begin{equation*}
c_{V} \approx \frac{12 \pi^{4}}{5}\left(\frac{T}{T_{D}}\right)^{3} \ll 1 \tag{2.99}
\end{equation*}
$$

reflecting the reduction of the number of excited waves with $\hbar \omega<T$ as the temperature is decreased.

Fig. 2.11. Temperature dependence of the specific heat in the Debye (red lines) and Einstein (blue lines) models.

As a historic curiosity, P. Debye's work followed one by A. Einstein, who had suggested (in 1907) a simpler model of crystal vibrations. In this model, all $3 n V$ independent oscillatory modes of $n V$ atoms of the crystal have approximately the same frequency, say $\omega_{\mathrm{E}}$, and Eq. (72) immediately yields

[^834]\[

$$
\begin{equation*}
E=3 n V \frac{\hbar \omega_{\mathrm{E}}}{e^{\hbar \omega_{\mathrm{E}} / T}-1}, \tag{2.100}
\end{equation*}
$$

\]

so that the specific heat is functionally similar to Eq. (75):

$$
\begin{equation*}
c_{V} \equiv \frac{1}{n V}\left(\frac{\partial E}{\partial T}\right)_{V}=3\left[\frac{\hbar \omega_{\mathrm{E}} / 2 T}{\sinh \left(\hbar \omega_{\mathrm{E}} / 2 T\right)}\right]^{2} \tag{2.101}
\end{equation*}
$$

This dependence $c_{V}(T)$ is shown with blue lines in Fig. 11 (assuming, for the sake of simplicity, $\hbar \omega_{\mathrm{E}}=T_{\mathrm{D}}$ ). At high temperatures, this result does satisfy the universal Dulong-Petit law ( $c_{V}=3$ ), but at low temperatures the Einstein's model predicts a much faster (exponential) drop of the specific heart as the temperature is reduced. (The difference between the Debye and Einstein models is not too spectacular on the linear scale, but in the log-log plot, shown on the right panel of Fig. 11, it is rather dramatic. ${ }^{62}$ ) The Debye model is in a much better agreement with experimental data for simple, monoatomic crystals, thus confirming the conceptual correctness of his wave-based approach.

Note, however, that when a genius such as A. Einstein makes an error, there is probably some deep and important reason behind it. Indeed, crystals with the basic cell consisting of atoms of two or more types (such as NaCl , etc.), feature two or more separate branches of the dispersion law $\omega(k)$ - see, e.g., Fig. $12 .{ }^{63}$

Fig. 2.12. Dispersion relation for longitudinal waves in a simple 1D model of a solid, with similar interparticle distances $d$, but alternating particle masses, plotted for a particular mass ratio $r=5$.

While the lower "acoustic" branch is virtually similar to those for monoatomic crystals, and may be approximated by the Debye model, $\omega=v k$, reasonably well, the upper ("optical" ${ }^{64}$ ) branch does approach $\omega=0$ at any $k$. Moreover, for large values of the atom mass ratio $r$, the optical branches are almost flat, with virtually $k$-independent frequencies $\omega_{0}$ that correspond to simple oscillations of each light atom between its heavy counterparts. For thermal excitations of such oscillations, and their

[^835]contribution to the specific heat, the Einstein model (with $\omega_{\mathrm{E}}=\omega_{0}$ ) gives a very good approximation, so that the specific heat may be well described by a sum of the Debye and Einstein laws (97) and (101), with appropriate weights.

### 2.7. Grand canonical ensemble and distribution

As we have seen, the Gibbs distribution is a very convenient way to calculate statistical and thermodynamic properties of systems with a fixed number $N$ of particles. However, for systems in which $N$ may vary, another distribution is preferable for some applications. Several examples of such situations (as well as the basic thermodynamics of such systems) have already been discussed in Sec. 1.5. Perhaps even more importantly, statistical distributions for systems with variable $N$ are also applicable to the ensembles of independent particles on a certain single-particle energy level - see the next section.

With this motivation, let us consider what is called the grand canonical ensemble (Fig. 13). It is similar to the canonical ensemble discussed in the previous section (Fig. 6) in all aspects, besides that now the system under study and the heat bath (in this case typically called the environment) may exchange not only heat but also particles. In all system members of the ensemble, the environments are in both the thermal and chemical equilibrium, and their temperatures $T$ and chemical potentials $\mu$ are equal.

Fig. 2.13. Member of a grand canonical ensemble.

Now let us assume that the system of interest is also in the chemical and thermal equilibrium with its environment. Then using exactly the same arguments as in Sec. 4 (including the specification of a microcanonical sub-ensemble with fixed $E_{\Sigma}$ and $N_{\Sigma}$ ), we may generalize Eq. (55), taking into account that entropy $S_{\text {env }}$ of the environment is now a function of not only its energy $E_{\text {env }}=E_{\Sigma}-E_{m, N},{ }^{65}$ but also the number of particles $N_{\mathrm{E}}=N_{\Sigma}-N$, with $E_{\Sigma}$ and $N_{\Sigma}$ fixed:

$$
\begin{align*}
\ln W_{m, N} & \propto \ln M=\ln g_{\mathrm{env}}\left(E_{\Sigma}-E_{m, N}, N_{\Sigma}-N\right)+\ln \Delta E_{\Sigma}=S_{\mathrm{env}}\left(E_{\Sigma}-E_{m, N}, N_{\Sigma}-N\right)+\mathrm{const} \\
& \approx S_{\mathrm{env}}\left|E_{\Sigma}, N_{\Sigma}-\frac{\partial S_{\mathrm{env}}}{\partial E_{\mathrm{env}}}\right| E_{\Sigma}, \left.N_{\Sigma} E_{m, N}-\frac{\partial S_{\mathrm{env}}}{\partial N_{\mathrm{env}}} \right\rvert\, E_{\Sigma}, N_{\Sigma} N+\mathrm{const} . \tag{2.102}
\end{align*}
$$

In order to simplify this relation, we may rewrite Eq. (1.52) in the equivalent form

[^836]\[

$$
\begin{equation*}
d S=\frac{1}{T} d E+\frac{P}{T} d V-\frac{\mu}{T} d N \tag{2.103}
\end{equation*}
$$

\]

Hence, if entropy $S$ of a system is expressed as a function of $E, V$, and $N$, then

$$
\begin{equation*}
\left(\frac{\partial S}{\partial E}\right)_{V, N}=\frac{1}{T}, \quad\left(\frac{\partial S}{\partial V}\right)_{E, N}=\frac{P}{T}, \quad\left(\frac{\partial S}{\partial N}\right)_{E, V}=-\frac{\mu}{T} \tag{2.104}
\end{equation*}
$$

Applying the first one and the last one of these relations to Eq. (102), and using the equality, of the temperatures $T$ and chemical potentials $\mu$ of the system under study and its environment, at their equilibrium, discussed in Sec. 1.5, we get

$$
\begin{equation*}
\ln W_{m, N}=S_{\mathrm{env}}\left(E_{\Sigma}, N_{\Sigma}\right)-\frac{1}{T} E_{m, N}+\frac{\mu}{T} N+\text { const } . \tag{2.105}
\end{equation*}
$$

Again, exactly as at the derivation of the Gibbs distribution in Sec. 4, we may argue that since $E_{m, N}, T$ and $\mu$ do not depend on the choice of environment's size, i.e. on $E_{\Sigma}$ and $N_{\Sigma}$, the probability $W_{m, N}$ for a system to have $N$ particles and be in $m$-th quantum state in the whole grand canonical ensemble should also obey a relation similar to Eq. (105). As a result, we get the so-called grand canonical distribution:

$$
\begin{equation*}
W_{m, N}=\frac{1}{Z_{G}} \exp \left\{\frac{\mu N-E_{m, N}}{T}\right\} \tag{2.106}
\end{equation*}
$$

Just as in the case of the Gibbs distribution, constant $Z_{G}$ (most often called the grand statistical sum, but sometimes the "grand partition function") should be determined from the probability normalization condition, now with the summation of probabilities $W_{m, N}$ over all possible values of both $m$ and $N$ :

$$
\begin{equation*}
Z_{G}=\sum_{m, N} \exp \left\{\frac{\mu N-E_{m, N}}{T}\right\} \tag{2.107}
\end{equation*}
$$

Now, using the general Eq. (29) to calculate entropy for distribution (106) (exactly like we did it for the canonical ensemble), we get the following expression,

$$
\begin{equation*}
S=-\sum_{m, N} W_{m, N} \ln W_{m, N}=\ln Z_{G}+\frac{E}{T}-\frac{\mu\langle N\rangle}{T}, \tag{2.108}
\end{equation*}
$$

which is evidently a generalization of Eq. (62). ${ }^{66} \mathrm{We}$ see that now the grand thermodynamic potential $\Omega$ (rather than the free energy $F$ ) may be expressed directly via the normalization coefficient $Z_{G}$ :

$$
\begin{equation*}
\Omega \equiv F-\mu\langle N\rangle=E-T S-\mu\langle N\rangle=T \ln \frac{1}{Z_{G}}=-T \ln \sum_{m, N} \exp \left\{\frac{\mu N-E_{m, N}}{T}\right\} . \tag{2.109}
\end{equation*}
$$

Finally, solving the last equality for $Z_{G}$, and plugging the result back into Eq. (106), we can rewrite the grand canonical distribution in the form

[^837]Grand
canonical
sum

$$
\begin{equation*}
W_{m, N}=\exp \left\{\frac{\Omega+\mu N-E_{m, N}}{T}\right\}, \tag{2.110}
\end{equation*}
$$

similar to Eq. (65) for the Gibbs distribution. Indeed, in the particular case when the number $N$ of particles is fixed, $N=\langle N\rangle$, so that $\Omega+\mu N=\Omega+\mu\langle N\rangle \equiv F$, Eq. (110) is reduced right to Eq. (65).

### 2.8. Systems of independent particles

Now we will use the general statistical distributions discussed above to a simple but very important case when each system we are considering consists of many similar particles whose explicit (physical) interaction is negligible. As a result, each particular energy value $E_{m, N}$ of such a system may be presented as a sum of energies $\varepsilon_{k}$ of its particles, where index $k$ numbers single-particle energy levels (rather than of the whole system, as index $m$ does).

Let us start with the classical limit. In classical mechanics, the quantization effects are negligible, i.e. there is a virtually infinite number of states $k$ within each finite energy interval. However, it is convenient to keep, for the time being, the discrete-state language, with understanding that the average number $\left\langle N_{k}\right\rangle$ of particles in each of these states, frequently called the state occupancy, is very small. In this case, we may apply the Gibbs distribution to the canonical ensemble of single particles, and hence use it with the substitution $E_{m, N} \rightarrow \varepsilon_{k}$, so that Eq. (58) becomes

$$
\begin{equation*}
\left\langle N_{k}\right\rangle=c \exp \left\{-\frac{\varepsilon_{k}}{T}\right\} \ll 1 \tag{2.111}
\end{equation*}
$$

where constant $c$ should be found from the normalization condition:

$$
\begin{equation*}
\sum_{k}\left\langle N_{k}\right\rangle=1 . \tag{2.112}
\end{equation*}
$$

This is the famous Boltzmann distribution. ${ }^{67}$ Despite its superficial similarity to the Gibbs distribution (58), let me emphasize the conceptual difference between these two results. The Gibbs distribution describes the probability to find the whole system on energy level $E_{m}$, and it is always valid more exactly, for a canonical ensemble of systems in thermodynamic equilibrium. On the other hand, the Boltzmann distribution describes occupancy of an energy level of a single particle, and for systems of identical particles is valid only in the classical limit $\left\langle N_{k}\right\rangle \ll 1$, even if the particles do not interact directly.

The last fact may be surprising, because it may seem that as soon as particles of the system are independent, nothing prevents us from using the Gibbs distribution to derive Eq. (111), regardless of the value of $\left\langle N_{k}\right\rangle$. This is indeed true if the particles are distinguishable, i.e. may be distinguished from each other - say by their fixed spatial positions, or by the states of certain internal degrees of freedom (say, spin), or any other "pencil mark". However, it is an experimental fact that elementary particles of each particular type (say, electrons) are identical to each other, i.e. cannot be "pencil-marked". For such particles we have to be more careful: even if they do not interact explicitly, there is still some implicit

[^838]dependence in their behavior, which is especially evident for the so-called fermions (fundamental particles with semi-integer spin) they obey the Pauli exclusion principle that forbids two identical particles to be in the same quantum state, even if they do not interact explicitly. ${ }^{68}$

Note that here the term "the same quantum state" carries a heavy meaning load here. For example, if two particles are confined to stay in different spatial positions (say, reliably locked in different boxes), they are distinguishable even if they are internally identical. Thus the Pauli principle, as well as other identity effects such as Bose-Einstein condensation, to be discussed in the next chapter, are important only when identical particles may move in the same spatial region. In order to describe this case, instead of "identical", it is much better to use a more precise (though ugly) term indistinguishable particles. ${ }^{69}$

In order to take these effects into account, let us examine the effects of nonvanishing occupancy $\left\langle N_{k}\right\rangle \sim 1$ on statistical properties of a system of many non-interacting but indistinguishable particles (at the first stage of calculation, either fermions or bosons) in equilibrium, and apply the grand canonical distribution (109) to a very interesting particular grand canonical ensemble: a subset of particles in the same quantum state $k$ (Fig. 14).
single-particle energy levels:

Fig. 2.14. Grand canonical ensemble of particles in the same quantum state (with eigenenergy $\varepsilon_{k}$ ).

In this ensemble, the role of the environment is played by the particles in all other states $k^{\prime} \neq k$, because due to infinitesimal interactions, the particles may change their states. In equilibrium, the chemical potential $\mu$ and temperature $T$ of the system should not depend on the state number $k$, but the grand thermodynamic potential $\Omega_{k}$ of the chosen particle subset may. Replacing $N$ with $N_{k}$ - the particular (not average!) number of particles in $k^{\text {th }}$ state, and the particular energy value $E_{m, N}$ with $\varepsilon_{k} N_{k}$, we may reduce Eq. (109) to

$$
\begin{equation*}
\Omega_{k}=-T \ln \left(\sum_{N_{k}} \exp \left\{\frac{\mu N_{k}-\varepsilon_{k} N_{k}}{T}\right\}\right)=-T \ln \left[\sum_{N_{k}}\left(\exp \left\{\frac{\mu-\varepsilon_{k}}{T}\right\}\right)^{N_{k}}\right] \tag{2.113}
\end{equation*}
$$

[^839]where the summation should be carried out over all possible values of $N_{k}$. For the final calculation of this sum, the elementary particle type becomes essential.

In particular, for fermions, obeying the Pauli principle, numbers $N_{k}$ in Eq. (113)may take only two values, either 0 (state $k$ is unoccupied) or 1 (the state is occupied), and the summation gives

$$
\begin{equation*}
\Omega_{k}=-T \ln \left[\sum_{N_{k}=0,1}\left(\exp \left\{\frac{\mu-\varepsilon_{k}}{T}\right\}\right)^{N_{k}}\right]=-T \ln \left(1+\exp \left\{\frac{\mu-\varepsilon_{k}}{T}\right\}\right) . \tag{2.114}
\end{equation*}
$$

Now the average occupancy may be calculated from the last of Eqs. (1.62) - in this case, with $N$ replaced with $\left\langle N_{k}\right\rangle$ :

$$
\begin{equation*}
\left\langle N_{k}\right\rangle=-\left(\frac{\partial \Omega_{k}}{\partial \mu}\right)_{T, V}=\frac{1}{e^{\left(\varepsilon_{k}-\mu\right) / T}+1} \tag{2.115}
\end{equation*}
$$

This is the famous Fermi-Dirac distribution, derived in 1926 independently by E. Fermi and P. Dirac.
On the other hand, bosons do not obey the Pauli principle, and for them numbers $N_{k}$ can take any non-negative integer values. In this case, Eq. (113) turns into the following equality:

$$
\begin{equation*}
\Omega_{k}=-T \ln \sum_{N_{k}=0}^{\infty}\left(\exp \left\{\frac{\mu-\varepsilon_{k}}{T}\right\}\right)^{N_{k}}=-T \ln \sum_{N_{k}=0}^{\infty} \lambda^{N_{k}}, \quad \text { with } \lambda \equiv \exp \left\{\frac{\mu-\varepsilon_{k}}{T}\right\} \tag{2.116}
\end{equation*}
$$

This sum is just the usual geometric progression again, which converges if $\lambda<1$, giving

$$
\begin{equation*}
\Omega_{k}=-T \ln \frac{1}{1-\lambda}=-T \ln \frac{1}{1-e^{\left(\mu-\varepsilon_{k}\right) / T}}, \quad \text { for } \mu<\varepsilon_{k} . \tag{2.117}
\end{equation*}
$$

In this case the average occupancy, again calculated using Eq. (1.62) with $N$ replaced with $\left\langle N_{k}\right\rangle$, obeys the Bose-Einstein distribution,

Bose-
Einstein distribution

$$
\begin{equation*}
\left\langle N_{k}\right\rangle=-\left(\frac{\partial \Omega_{k}}{\partial \mu}\right)_{T, V}=\frac{1}{e^{\left(\varepsilon_{k}-\mu\right) / T}-1}, \quad \text { for } \mu<\varepsilon_{k} \tag{2.118}
\end{equation*}
$$

which was derived in 1924 by S. Bose (for the particular case $\mu=0$ ) and generalized in 1925 by A. Einstein for an arbitrary chemical potential. In particular, comparing Eq. (118) with Eq. (72), we see that harmonic oscillator excitations, ${ }^{70}$ each with energy $\hbar \omega$, may be considered as bosons, with zero chemical potential. We have already obtained this result $(\mu=0)$ in a different way - see Eq. (93). Its physical interpretation is that the oscillator excitations may be created inside the system, so that there is no energy cost $\mu$ of moving them into the system from its environment.

The simple form of Eqs. (115) and (118), and their similarity (besides "only" the difference of the signs before unity in their denominators), is one of most beautiful results of physics. This similarity should not disguise the facts that the energy dependences of $\left\langle N_{k}\right\rangle$, given by these two formulas, are rather different - see Fig. 15. In the Fermi-Dirac statistics, the average level occupancy is finite (and

[^840]below 1) at any energy, while in the Bose-Einstein it may be above 1 , and even diverges at $\varepsilon_{k} \rightarrow \mu$. However, for any of these distributions, as temperature is increased, it eventually becomes much larger than the difference $\left(\varepsilon_{k}-\mu\right)$ for all $k$. In this limit, $\left\langle N_{k}\right\rangle \ll 1$, both distributions coincide with each other, as well as with the Boltzmann distribution (111) with $c=\exp \{\mu / T\}$. The last distribution, therefore, serves as the high-temperature limit for quantum particles of both sorts.

A natural question now is how to find the chemical potential $\mu$ participating in Eqs. (115) and (118). In the grand canonical ensemble as such (Fig. 13), with number of particles variable, the value of $\mu$ is imposed by system's environment. However, both the Fermi-Dirac and Bose-Einstein distributions are also applicable to equilibrium systems with a fixed but large number $N$ of particles. In these conditions, the role of the environment for some subset of $N^{\prime} \ll N$ particles is played by the remaining $N-N^{\prime}$ particles. In this case, $\mu$ may be found by calculation of $\langle N\rangle$ from the corresponding distribution, and then requiring it to be equal to the genuine number of particles in the system. In the next section, we will perform such calculations for several particular systems.

Fig. 2.15. Fermi-Dirac (blue line) and Bose-Einstein (red line) distributions, and the Boltzmann distribution with $c=\exp \{\mu / T\}$ (black line).

$$
\left(\varepsilon_{k}-\mu\right) / T
$$

For those and other applications, it will be convenient for us to have ready expressions for entropy $S$ of a general (i.e. not necessarily equilibrium) state of systems of independent Fermi or Bose particles, expressed not as a function of $W_{m}$ of the whole system - as Eq. (29) does, but as a function of the average occupancy numbers $\left\langle N_{k}\right\rangle$. For that, let us consider a composite system, each consisting of $M$ $\gg 1$ similar but distinct component systems, numbered by index $m=1,2, \ldots M$, with independent (i.e. not explicitly interacting) particles. We will assume that though in each of $M$ component systems, the number $N_{k}^{(m)}$ of particles in its $k$-th quantum state may be different (Fig. 16), but their total number $N_{k}^{(\Sigma)}$ in the composite system is fixed:

$$
\begin{equation*}
\sum_{m=1}^{M} N_{k}^{(m)}=N_{k}^{(\Sigma)} \tag{2.119}
\end{equation*}
$$

Fig. 2.16. Composite system with a certain distribution of $N_{k}^{(2)}$ particles in $k$-th state between $M$ component systems.

As a result, the total energy of the composite system is fixed as well,

$$
\begin{equation*}
\sum_{m=1}^{M} N_{k}^{(m)} \varepsilon_{k}=N_{k}^{(\Sigma)} \varepsilon_{k}=\text { const } \tag{2.120}
\end{equation*}
$$

so that an ensemble of many such composite systems (with the same $k$ ), in equilibrium, is microcanonical. According to Eq. (24a), the average entropy $S_{k}$ per component system may be calculated as

$$
\begin{equation*}
S_{k}=\lim _{M, N_{k} \rightarrow \infty} \frac{\ln M_{k}}{M}, \tag{2.121}
\end{equation*}
$$

where $M_{k}$ is the number of possible different ways such composite system (with fixed $N_{k}^{(\Sigma)}$ ) may be implemented.

Let us start the calculation of $M_{k}$ with Fermi particles - for which the Pauli principle is valid. Here the level occupancies $N_{k}{ }^{(m)}$ may be only equal 0 or 1 , so that the distribution problem is solvable only if $N_{k}^{(\Sigma)} \leq M$, and evidently equivalent to the choice of $N_{k}^{(\Sigma)}$ balls (in arbitrary order) from the total number of $M$ distinct balls. Comparing this formulation with the binomial coefficient definition, ${ }^{71}$ we immediately have

$$
\begin{equation*}
M_{k}={ }^{M} C_{N_{k}^{(\Sigma)}}=\frac{M!}{\left(M-N_{k}^{(\Sigma)}\right)!N_{k}^{(\Sigma)}!} . \tag{2.122}
\end{equation*}
$$

From here, using the Stirling formula (again, in its simplest form (27)), we get

$$
\begin{equation*}
S_{k}=-\left\langle N_{k}\right\rangle \ln \left\langle N_{k}\right\rangle-\left(1-\left\langle N_{k}\right\rangle\right) \ln \left(1-\left\langle N_{k}\right\rangle\right) \tag{2.123}
\end{equation*}
$$

where

$$
\begin{equation*}
\left\langle N_{k}\right\rangle \equiv \lim _{M, N_{k} \rightarrow \infty} \frac{N_{k}^{(\Sigma)}}{M} \tag{2.124}
\end{equation*}
$$

is exactly the average occupancy of the $k$-th single-particle level in each system that was discussed earlier in this section. Since for a Fermi system, $\left\langle N_{k}\right\rangle$ is always somewhere between 0 and 1 , so that entropy (123) is always positive.

In the Bose case, where the Pauli limitation is not valid, the number $N_{k}{ }^{(m)}$ of particles on the $k$-th level in each of the systems is an arbitrary (positive) integer. Let us consider $N_{k}{ }^{(\Sigma)}$ particles and ( $M-1$ ) partitions (shown by vertical lines in Fig. 16) between $M$ systems as $\left(M-1+N_{k}^{(\Sigma)}\right)$ similar mathematical objects ordered along one axis. Then $M_{k}$ may be calculated as the number of possible ways to distribute the $(M-1)$ indistinguishable partitions among these $\left(M-1+N_{k}^{(\Sigma)}\right)$ distinct objects, i.e. as the following binomial coefficient: ${ }^{72}$

$$
\begin{equation*}
M_{k}={ }^{M+N_{k}-1} C_{M-1}=\frac{\left(M-1+N_{k}^{(\Sigma)}\right)!}{(M-1)!N_{k}^{(\Sigma)}!} . \tag{2.125}
\end{equation*}
$$

[^841]Applying the Stirling formula (27) again, we get the following result,

$$
\begin{equation*}
S_{k}=-\left\langle N_{k}\right\rangle \ln \left\langle N_{k}\right\rangle+\left(1+\left\langle N_{k}\right\rangle\right) \ln \left(1+\left\langle N_{k}\right\rangle\right) \tag{2.126}
\end{equation*}
$$

which again differs from the Fermi case (123) "only" by the signs in the second term, and is valid for any positive $\left\langle N_{k}\right\rangle$.

Expressions (123) and (126) are valid for an arbitrary (possibly non-equilibrium) case; they may be also used for an alternative derivation of the Fermi-Dirac (115) and Bose-Einstein (118) distributions valid in equilibrium. For that, we may use the method of Lagrange multipliers, requiring (just like it was done in Sec. 2) the total entropy of a system of $N$ independent, similar particles,

$$
\begin{equation*}
S=\sum_{k} S_{k} \tag{2.127}
\end{equation*}
$$

as a function of state occupancies $\left\langle N_{k}\right\rangle$, to attain its maximum, with the conditions of fixed total number of particles $N$ and the total energy $E$ :

$$
\begin{equation*}
\sum_{k}\left\langle N_{k}\right\rangle=N=\text { const }, \quad \sum_{k}\left\langle N_{k}\right\rangle \varepsilon_{k}=E=\mathrm{const} . \tag{2.128}
\end{equation*}
$$

The completion of this calculation is left for reader's exercise.
In the classical limit, when the average occupancies $\left\langle N_{k}\right\rangle$ of all states are small, both the Fermi and Bose expressions for $S_{k}$ tend to the same limit

$$
\begin{equation*}
S_{k}=-\left\langle N_{k}\right\rangle \ln \left\langle N_{k}\right\rangle, \quad \text { for }\left\langle N_{k}\right\rangle \ll 1 . \tag{2.129}
\end{equation*}
$$

This expression, frequently referred to as the Boltzmann (or "classical") entropy, might be also obtained, for arbitrary $\left\langle N_{k}\right\rangle$, directly from Eq. (29) by considering an ensemble of systems, each consisting of just one classical particle, so that $E_{m} \rightarrow \varepsilon_{k}$ and $W_{m} \rightarrow\left\langle N_{k}\right\rangle$. Let me emphasize again that for indistinguishable particles, such identification is generally (i.e. at $\left\langle N_{k}\right\rangle \sim 1$ ) illegitimate even if they do not interact explicitly. As we will see in the next chapter, the indistinguishability affects statistical properties of even classical particles.

### 2.9. Exercise problems

2.1. A famous example of the macroscopic irreversibility was suggested in 1907 by P. Ehrenfest. Two dogs share $2 N \gg 1$ fleas. Each flea may jump to another dog, and the rate (i.e. the probability of jumping per unit time) $\Gamma$ of such an event does not depend on time, and on the location of other fleas. Find the time evolution of the average number of fleas on a dog, and of the flea-related part of dogs' entropy (at arbitrary initial conditions), and prove that the entropy can only grow. ${ }^{73}$
2.2. Use the microcanonical distribution to calculate thermodynamic properties (including entropy, all relevant thermodynamic potentials, and heat capacity), of an ensemble of similar two-level

[^842]Boltzmann entropy
systems, in thermodynamic equilibrium at temperature $T$ that is comparable with the energy gap $\Delta$. For each variable, sketch its temperature dependence, and find its asymptotic values (or trends) in the lowtemperature and high-temperature limits.

Hint: The two-level system is generally defined as any system with just two relevant states whose energies, say $E_{0}$ and $E_{1}$, are separated by a finite gap $\Delta \equiv E_{1}-E_{0}$. Its most popular (but not the only!) example is a spin- $1 / 2$ particle, e.g., an electron, in an external magnetic field.
2.3. Solve the previous problem using the Gibbs distribution. Also, calculate the probabilities of the energy level occupation, and give physical interpretations of your results, in both temperature limits.
2.4. Calculate the low-field magnetic susceptibility $\chi_{m}$ of a dilute set of non-interacting, spontaneous magnetic dipoles $\mathbf{m}$, in thermal equilibrium at temperature $T$, within two models:
(i) the dipole moment $\mathbf{m}$ is a classical vector of fixed magnitude $m_{0}$, but arbitrary orientation, and
(ii) the dipole moment $\mathbf{m}$ belongs to a quantum spin- $1 / 2$ particle, and is described by vector operator $\hat{\mathbf{m}}=\gamma \hat{\mathbf{S}}$, where $\gamma$ is the gyromagnetic ratio, and $\hat{\mathbf{S}}$ is the vector operator of particle's spin. ${ }^{74}$

Hint: The low-field magnetic susceptibility of an isotropic medium is defined ${ }^{75}$ as

$$
\chi_{m} \equiv \frac{\partial M_{z}}{\partial H}
$$

where $\mathbf{M}$ is the (average) magnetization of a unit volume, and axis $z$ is aligned with the direction of the external magnetic field $\mathbb{Z}$.
2.5. Calculate the low-field magnetic susceptibility of a set of non-interacting, distinguishable particles with an arbitrary $\operatorname{spin} s$, neglecting their orbital motion. Compare the result with the solution of the previous problem.

Hint: Quantum mechanics ${ }^{76}$ tells us that the Cartesian component $m_{z}$ of the magnetic moment of such a particle, in the direction of the applied field, may take $(2 s+1)$ values

$$
m_{z}=\gamma \hbar s_{m}, \quad \text { where } s_{m}=-s,-s+1, \ldots, s-1, s,
$$

where $\gamma$ is the gyromagnetic ratio of the particle, and $\hbar$ is the Planck's constant.
2.6. Derive a general expression for the average interaction potential between two similar magnetic dipoles with fixed magnitude $m$ but arbitrary orientation, at thermal equilibrium. Spell out the result in the low-temperature and high-temperature limits.
2.7.* Analyze the possibility of using a system of non-interacting spin-1/2 particles in magnetic field for refrigeration.

Hint: See a footnote in Sec. 1.6.

[^843]2.8. Use the microcanonical distribution to calculate the average entropy, energy, and pressure of a single classical particle of mass $m$, with no internal degrees of freedom, free to move in volume $V$, at temperature $T$.

Hint: Try to make a more accurate calculation than has been done in Sec. 2.2 for the system of $N$ harmonic oscillators. For that you will need to know the volume $V_{d}$ of an $d$-dimensional hypersphere of the unit radius. To avoid being too cruel, I am giving it to you:

$$
V_{d}=\pi^{d / 2} / \Gamma\left(\frac{d}{2}+1\right),
$$

where $\Gamma(\xi)$ is the gamma-function. ${ }^{77}$
2.9. Solve the previous problem starting from the Gibbs distribution.
2.10. Calculate the average energy, entropy, free energy, and the equation of state of a classical 2D particle (without internal degrees of freedom), free to move within area $A$, at temperature $T$, starting from:
(i) the microcanonical distribution, and
(ii) the Gibbs distribution.

Hint: Make the appropriate modification of the notion of pressure.
2.11. A quantum particle of mass $m$ is confined to free motion along a 1 D segment of length $a$. Using any approach you like, find the average force the particle exerts on walls of such a " 1 D quantum well" in thermal equilibrium, and analyze its temperature dependence, focusing on the low-temperature and high-temperature limits.

Hint: You may consider series $\Theta(\xi) \equiv \sum_{n=1}^{\infty} e^{-\xi n^{2}}$ as a known function of $\xi .{ }^{78}$
2.12. Rotational properties of diatomic molecules (such as $\mathrm{N}_{2}, \mathrm{CO}$, etc.) may be reasonably well described using a "dumbbell" model: two point particles, of masses $m_{1}$ and $m_{2}$, with a fixed distance $d$ between them. Ignoring the translational motion of the molecule as the whole, use this model to calculate its heat capacity, and spell out the result in the limits of low and high temperatures. (Quantify the conditions.)
2.13. Calculate the heat capacity of a diatomic molecule, using the simple model described in the previous problem, but now assuming that the rotation is confined to one plane. ${ }^{79}$

[^844]2.14. Low-temperature specific heat of some solids has a considerable contribution from thermal excitation of spin waves, whose dispersion law scales as $\omega \propto k^{2}$ at $\omega \rightarrow 0 .{ }^{80}$ Find the temperature dependence of this contribution to $C_{V}$ at low temperatures and discuss conditions of its experimental observation.
2.15. A rudimentary "zipper" model of DNA replication is a chain of $N$ links that may be either open or closed - see Fig. on the right. Opening a link increases system's energy by $\Delta>0$, and a link may change its state (either open or close) only if all links to the left of it are already open.
 Calculate the average number of open links at thermal equilibrium, and analyze its temperature dependence in detail, especially for the case $N \gg 1$.
2.16. An ensemble of classical 1D particles of mass $m$, residing in the potential wells
$$
U(x)=\alpha|x|^{\gamma}, \quad \text { with } \gamma>0
$$
is in thermal equilibrium at temperature $T$. Calculate the average values of its potential energy $U$ and the full energy $E$ using two approaches:
(i) directly from the Gibbs distribution, and
(ii) using the virial theorem of classical mechanics. ${ }^{81}$
2.17. For a thermally-equilibrium ensemble of slightly anharmonic classical 1D oscillators, with mass $m$ and potential energy
$$
U(q)=\frac{\kappa}{2} x^{2}+\alpha x^{3},
$$
with small coefficient $\alpha$, calculate $\langle x\rangle$ in the first approximation in low temperature $T$.
2.18.* A small conductor (in this context, usually called the single-electron $b o x)$ is placed between two conducting electrodes, with voltage $V$ applied between them. The gap between one of the electrodes and the island is so narrow that electrons may tunnel quantum-mechanically through this gap ("weak tunnel junction") - see Fig. on the right. Calculate the average charge of the island as a function of $V$.

Hint: The quantum-mechanical tunneling of electrons through weak junctions ${ }^{82}$ between macroscopic conductors, and its subsequent energy relaxation
 inside the conductor, may be considered as a single inelastic (energy-dissipating) event, so that the only energy relevant for the thermal equilibrium of the system is its electrostatic potential energy.

[^845]2.19. An $L C$ circuit (see Fig. on the right) is at thermodynamic equilibrium with the environment. Find the r.m.s. fluctuation $\delta \mathscr{V} \equiv\left\langle V^{2}\right\rangle^{1 / 2}$ of the voltage across it, for an arbitrary ratio $T / \hbar \omega$, where $\omega=(L C)^{-1 / 2}$ is the
 resonance frequency of this "tank circuit".
2.20. Derive Eq. (92) from simplistic arguments, representing the blackbody radiation as an ideal gas of photons, treated as ultra-relativistic particles. What do similar arguments give for an ideal gas of classical, non-relativistic particles?
2.21. Calculate the enthalpy, the entropy, and the Gibbs energy of the blackbody electromagnetic radiation with temperature $T$, and then use these results to find the law of temperature and pressure drop at an adiabatic expansion of the radiation.
2.22. As was mentioned in Sec. 2.6(i) of the lecture notes, the relation between the visible temperatures $T_{\oplus}$ of Sun's surface and Earth's surface $T_{\mathrm{o}}$ follows from the balance of the thermal radiation they emit. Prove that this relation indeed follows, with a good precision, from a simple model in which the surfaces radiate as perfect black bodies with a constant, average temperature.

Hint: You may pick up the experimental values you need from any (reliable :-) source.
2.23. If a surface is not perfectly radiation-absorbing ("black"), the electromagnetic power of its thermal radiation differs from the Stefan law (2.89a) by a frequency-dependent factor $\varepsilon<1$, called emissivity:

$$
\frac{\mathcal{P}}{A}=\varepsilon \sigma T^{4} .
$$

Prove that such surface reflects $(1-\varepsilon)$ part of incident radiation.
2.24. If two black surfaces, facing each other, have different temperatures (see Fig. on the right), then according to the Stefan radiation law (2.89), there is a net flow of thermal radiation, from a warmer surface to the colder one:

$$
\frac{P_{\text {net }}}{A}=\sigma\left(T_{1}^{4}-T_{2}^{4}\right) .
$$

For many applications (including low temperature experiments) this flow is detrimental. One way to reduce it is to reduce the emissivity $e(\omega)$ of both surfaces - say by covering them with shiny metallic films. An alternative way toward the same goal is to place, between the surfaces, a thin layer (usually called the thermal shield), with a low emissivity of both surfaces, and disconnected from any heat bath see dashed line in Fig. above. Assuming that the emissivity is the same in both cases, find out which way is more efficient.

Hint: The definition of emissivity may be found, for example, in the previous problem.
2.25. Two parallel, well conducting plates of area $A$ are separated by a free-space gap of a constant thickness $t \ll A^{1 / 2}$. Calculate the energy of the spontaneous electromagnetic field inside the gap
at thermal equilibrium with temperature $T$. Specify the validity limits of your result. Does the radiation push the plates apart?
2.26. Use the Debye theory to estimate the specific heat of aluminum at room temperature (say, 300 K ), and express the result in the following popular units:
(i) $\mathrm{eV} / \mathrm{K}$ per atom,
(ii) $J / K$ per mole, and
(iii) $\mathrm{J} / \mathrm{K}$ per gram.

Compare the last number with the experimental value (from a reliable book or online source).
2.27. Use the general Eq. (123) to re-derive the Fermi-Dirac distribution (115) for a system in equilibrium.
2.28. Each of two similar particles, not interacting directly, may take two quantum states, with single-particle energies $\varepsilon$ equal to 0 and $\Delta$. Write down the statistical sum $Z$ of the system, and use it to calculate its average total energy $E$ of the system, for the cases when the particles are:
(i) distinguishable;
(ii) indistinguishable fermions;
(iii) indistinguishable bosons.

Analyze and interpret the temperature dependence of $\langle E\rangle$ for each case, assuming that $\Delta>0$.
2.29. Calculate the chemical potential of a system of $N \gg 1$ independent fermions, kept at fixed temperature $T$, provided that each particle has two non-degenerate energy levels, separated by gap $\Delta$.

## Chapter 3. Ideal and Not-So-Ideal Gases

In this chapter, the general approaches discussed in the previous chapters are applied to calculate statistical and thermodynamic properties of gases, i.e. collections of identical particles (say, atoms or molecules) that are free to move inside a certain volume, either not interacting or weakly interacting with each other.

### 3.1. Ideal classical gas

Interactions of typical atoms and molecules are well localized, i.e. rapidly decreasing with distance $r$ between them, becoming negligible at certain distance $r_{0}$. In a gas of $N$ particles inside volume $V$, the average distance $\langle r\rangle$ between the particles is of the order of $(V / N)^{1 / 3}$. As a result, if the gas density $n \equiv N / V \sim\langle r\rangle^{-3}$ is much lower than $r_{0}{ }^{-3}$, i.e. if $n r_{0}{ }^{3} \ll 1$, the chance for its particles to approach each other and interact is rather small. The model in which such interactions are completely ignored is called the ideal gas.

Let us start with a classical ideal gas, which may be defined as the gas in whose behavior the quantum effects are negligible. As we saw in Sec. 2.8 , the condition of that is to have the average occupancy of each quantum state low:

$$
\begin{equation*}
\left\langle N_{k}\right\rangle \ll 1 . \tag{3.1}
\end{equation*}
$$

It may seem that we have already found properties of such a system, in particular the equilibrium occupancy of its states - see Eq. (2.111):

$$
\begin{equation*}
\left\langle N_{k}\right\rangle=\text { const } \times \exp \left\{-\frac{\varepsilon_{k}}{T}\right\} . \tag{3.2}
\end{equation*}
$$

In some sense it is true, but we still need, first, to see what exactly does Eq. (2) means for the gas, i.e. a system with an essentially continuous energy spectrum, and, second, to show that, rather surprisingly, particles' indistinguishability affects some properties of even classical gases.

The first of these tasks is evidently the easiest for a gas out of external fields, and with no internal degrees of freedom. ${ }^{1}$ In this case $\varepsilon_{k}$ is just the kinetic energy of the particle obeys the isotropic and parabolic dispersion law

$$
\begin{equation*}
\varepsilon_{k}=\frac{p^{2}}{2 m}=\frac{p_{x}^{2}+p_{y}^{2}+p_{z}^{2}}{2 m} . \tag{3.3}
\end{equation*}
$$

Now we have to use two facts from other fields of physics. First, in quantum mechanics, momentum $\mathbf{p}$ is associated with wavevector $\mathbf{k}$ of the de Broglie wave, $\mathbf{p}=\hbar \mathbf{k} .{ }^{2}$ Second, eigenvalues of $\mathbf{k}$ for any waves (including de Broglie waves) in free space are uniformly distributed in the momentum space, with a constant density of states, given by Eq. (2.82)

[^846]\[

$$
\begin{equation*}
\frac{d N_{\text {states }}}{d^{3} k}=\frac{g V}{(2 \pi)^{3}}, \quad \text { i.e. } \frac{d N_{\text {states }}}{d^{3} p}=\frac{g V}{(2 \pi \hbar)^{3}}, \tag{3.4}
\end{equation*}
$$

\]

where $g$ is the degeneracy of particle's internal states (say, for electrons, the spin degeneracy $g=2$ ).
Even regardless of the exact proportionality coefficient between $d N_{\text {states }}$ and $d^{3} p$, the very fact of this proportionality means that the probability $d W$ to find the particle in a small region $d^{3} p=d p_{1} d p_{2} d p_{3}$ of the momentum space is proportional to the right-hand part of Eq. (2), with $\varepsilon_{k}$ given by Eq. (3):

$$
\begin{equation*}
d W=C \exp \left\{-\frac{p^{2}}{2 m T}\right\} d^{3} p=C \exp \left\{-\frac{p_{1}^{2}+p_{2}^{2}+p_{3}^{2}}{2 m T}\right\} d p_{1} d p_{2} d p_{3} . \tag{3.5}
\end{equation*}
$$

Maxwell distribution

This is the famous Maxwell distribution. ${ }^{3}$ The normalization constant $C$ may be readily found from the last form of Eq. (5), by requiring that the integral of $d W$ over all the momentum space to equal 1 , and using the equality of all 1D integrals over the each Cartesian component $p_{j}$ of the momentum $(j=$ $1,2,3$ ), which may be reduced to the well-known dimensionless Gaussian integral: ${ }^{4}$

$$
\begin{equation*}
C=\left[\int_{-\infty}^{+\infty} \exp \left\{-\frac{p_{j}^{2}}{2 m T}\right\} d p_{j}\right]^{-3}=\left[(2 m T)^{1 / 2} \int_{-\infty}^{+\infty} e^{-\xi^{2}} d \xi\right]^{-3}=(2 \pi m T)^{-3 / 2} \tag{3.6}
\end{equation*}
$$

As a sanity check, let us use the Maxwell distribution to calculate the average energy corresponding to each half-degree of freedom:

$$
\begin{equation*}
\left\langle\frac{p_{j}^{2}}{2 m}\right\rangle=\int \frac{p_{j}^{2}}{2 m} d W=\left[C^{1 / 3} \int_{-\infty}^{+\infty} \frac{p_{j}^{2}}{2 m} \exp \left\{-\frac{p_{j}^{2}}{2 m T}\right\} d p_{j}\right]\left[C^{1 / 3} \int_{-\infty}^{+\infty} \exp \left\{-\frac{p_{j^{\prime}}^{2}}{2 m T}\right\} d p_{j^{\prime}}\right]^{2}=\frac{T}{\pi^{1 / 2}} \int_{-\infty}^{+\infty} \xi^{2} e^{-\xi^{2}} d \xi . \tag{3.7}
\end{equation*}
$$

The last integral ${ }^{5}$ equals $\sqrt{ } \pi / 2$, so that, finally,

$$
\begin{equation*}
\left\langle\frac{p_{j}^{2}}{2 m}\right\rangle \equiv\left\langle\frac{m v_{j}^{2}}{2}\right\rangle=\frac{T}{2} \tag{3.8}
\end{equation*}
$$

This result is (fortunately :-) in agreement with the equipartition theorem (2.48). It also means that the r.m.s. velocity of the particles is

$$
\begin{equation*}
\delta v \equiv\left\langle v^{2}\right\rangle^{1 / 2}=\left\langle\sum_{j=1}^{3} v_{j}^{2}\right\rangle^{1 / 2}=\left\langle 3 v_{j}^{2}\right\rangle^{1 / 2}=\left(3 \frac{T}{m}\right)^{1 / 2} . \tag{3.9}
\end{equation*}
$$

[^847]For a typical gas (say, $\mathrm{N}_{2}$ ), with $m \approx 28 m_{p} \approx 4.7 \times 10^{-26} \mathrm{~kg}$ at room temperature ( $T=k_{\mathrm{B}} T_{\mathrm{K}} \approx$ $k_{\mathrm{B}} \times 300 \mathrm{~K} \approx 4.1 \times 10^{-21} \mathrm{~J}$ ), this velocity is about $500 \mathrm{~m} / \mathrm{s}$ - comparable with the sound velocity in the same gas (and the muzzle velocity of typical handgun bullets). Still, it is measurable using simple table-top equipment (say, a set of two concentric, rapidly rotating cylinders with a thin slit collimating an atomic beam emitted at the axis) that was available already in the end of the $19^{\text {th }}$ century. Experiments using such equipment gave convincing confirmations of Maxwell's theory.

This is all very simple (isn't it?), but actually the thermodynamic properties of a classical gas, especially its entropy, are more intricate. To show that, let us apply the Gibbs distribution to gas portions consisting of $N$ particles each, rather than just one of them. If the particles are exactly similar, the eigenenergy spectrum $\left\{\varepsilon_{k}\right\}$ of each of them is also exactly the same, and each value $E_{m}$ of the total energy is just the sum of particular energies $\varepsilon_{k(l)}$ of the particles, where $k(l)$, with $l=1,2, \ldots N$, is the number of the energy level of $l^{\text {th }}$ particle. Moreover, since the gas is classical, $\left\langle N_{k}\right\rangle \ll 1$, the probability of having two or more particles in any state may be ignored. As a result, we can use Eq. (2.59) to write

$$
\begin{equation*}
Z=\sum_{m} \exp \left\{-\frac{E_{m}}{T}\right\}=\sum_{k(l)} \exp \left\{-\frac{1}{T} \sum_{l} \varepsilon_{k(l)}\right\}=\sum_{k(1)} \sum_{k(2)} \ldots \sum_{k(N)} \prod_{l} \exp \left\{-\frac{\varepsilon_{k(l)}}{T}\right\} \tag{3.10}
\end{equation*}
$$

where the summation has to be carried over all possible states of each particle. Since the summation over each set $\{k(l)\}$ concerns only one of the operands of the product of exponents under the sum, it is tempting to complete the calculation as follows:

$$
\begin{equation*}
Z \rightarrow Z_{\text {dist }}=\sum_{k(1)} \exp \left\{-\frac{\varepsilon_{k(1)}}{T}\right\} \cdot \sum_{k(2)} \exp \left\{-\frac{\varepsilon_{k(2)}}{T}\right\} \ldots \cdot \sum_{k(N)} \exp \left\{-\frac{\varepsilon_{k(N)}}{T}\right\}=\left(\sum_{k} \exp \left\{-\frac{\varepsilon_{k}}{T}\right\}\right)^{N} \tag{3.11}
\end{equation*}
$$

where the final summation is over all states of one particle. This formula is indeed valid for distinguishable particles. ${ }^{6}$ However, if particles are indistinguishable (again, meaning that they are identical and free to move within the same spatial region), Eq. (11) has to be modified by what is called the correct Boltzmann counting:

Correct Boltzmann counting

$$
\begin{equation*}
Z=\frac{1}{N!}\left(\sum_{k} \exp \left\{-\frac{\varepsilon_{k}}{T}\right\}\right)^{N} \tag{3.12}
\end{equation*}
$$

that considers all quantum states, differing only by particle permutations in the gas portion, as one.
Now let us take into account that the fundamental relation (4) implies the following rule for the replacement of a sum over quantum states with an integral in the classical limit - whose exact conditions are still to be specified: ${ }^{7}$

$$
\begin{equation*}
\sum_{k}(\ldots) \rightarrow \int(\ldots) d N_{\text {states }}=\frac{g V}{(2 \pi)^{3}} \int(\ldots) d^{3} k=\frac{g V}{(2 \pi \hbar)^{3}} \int(\ldots) d^{3} p \tag{3.13}
\end{equation*}
$$

In application to Eq. (12), this rule yields

[^848]\[

$$
\begin{equation*}
Z=\frac{1}{N!}\left(\frac{g V}{(2 \pi \hbar)^{3}}\left[\int_{-\infty}^{+\infty} \exp \left\{-\frac{p_{j}^{2}}{2 m T}\right\} d p_{j}\right]^{3}\right)^{N} \tag{3.14}
\end{equation*}
$$

\]

The integral in square brackets is the same one as in Eq. (6), i.e. equal to $(2 \pi m T)^{1 / 2}$, so that finally

$$
\begin{equation*}
Z=\frac{1}{N!}\left(\frac{g V}{(2 \pi \hbar)^{3}}(2 \pi m T)^{3 / 2}\right)^{N}=\frac{1}{N!}\left[g V\left(\frac{m T}{2 \pi \hbar^{2}}\right)^{3 / 2}\right]^{N} \tag{3.15}
\end{equation*}
$$

Now, assuming that $N \gg 1,{ }^{8}$ and applying the Stirling formula, we can calculate gas' free energy,

$$
\begin{equation*}
F=T \ln \frac{1}{Z}=-N T \ln \frac{V}{N}+N f(T) \tag{3.16a}
\end{equation*}
$$

with

$$
\begin{equation*}
f(T) \equiv-T\left\{\ln \left[g\left(\frac{m T}{2 \pi \hbar^{2}}\right)^{3 / 2}\right]+1\right\} . \tag{3.16b}
\end{equation*}
$$

The first of these relations is exactly Eq. (1.45) which was derived, in Sec. 1.4, from the equation of state $P V=N T$, using thermodynamic identities. At that stage this equation of state was just postulated, but now we can finally derive it by calculating pressure from the second of Eqs. (1.35), and Eq. (16a):

$$
\begin{equation*}
P=-\left(\frac{\partial F}{\partial V}\right)_{T}=\frac{N T}{V} \tag{3.17}
\end{equation*}
$$

So, the equation of state of the ideal classical gas, with density $n \equiv N / V$, is indeed given by Eq. (1.44):

$$
\begin{equation*}
P=\frac{N T}{V} \equiv n T . \tag{3.18}
\end{equation*}
$$

Hence we may use Eqs. (1.46)-(1.51), derived from this equation of state, to calculate all other thermodynamic variables of the gas. As one more sanity check, let us start with energy. Using Eq. (1.47) with $f(T)$ given by Eq. (16b), we immediately get

$$
\begin{equation*}
E=N\left(f-T \frac{d f}{d T}\right)=\frac{3}{2} N T \tag{3.19}
\end{equation*}
$$

in full agreement with Eq. (8) and hence with the equipartition theorem. Much less trivial is the result for entropy, which may be obtained by combining Eqs. (1.46) and (15):

$$
\begin{equation*}
S=-\left(\frac{\partial F}{\partial T}\right)_{V}=N\left[\ln \frac{V}{N}-\frac{d f(T)}{d T}\right] \tag{3.20}
\end{equation*}
$$

[^849]This formula, ${ }^{9}$ in particular, provides the means to resolve the following gas mixing paradox (sometimes called the "Gibbs paradox"). Consider two volumes, $V_{1}$ and $V_{2}$, separated by a partition, each filled with the same gas, with the same density $n$, at the same temperature $T$. Now let us remove the partition and let the gases mix; would the total entropy change? According to Eq. (20), it would not, because the ration $V / N=n$, and hence the expression in square brackets is the same in the initial and the final state, so that the entropy is additive (extensive). This makes full sense if the gas particles in the both parts of the volume are identical, i.e. the partition's removal does not change our information about the system. However, let us assume that all particles are distinguishable; then the entropy should clearly increase, because the mixing would certainly decrease our information about the system, i.e. increase its disorder. A quantitative description of this effect may be obtained using Eq. (11). Repeating for $Z_{\text {dist }}$ all the calculations made above for $Z$, we readily get a different formula for entropy:

$$
\begin{equation*}
S_{\text {dist }}=N\left[\ln V-\frac{d f_{\text {dist }}(T)}{d T}\right], \quad f_{\text {dist }}(T) \equiv-T \ln \left[g\left(\frac{m T}{2 \pi \hbar^{2}}\right)^{3 / 2}\right] \tag{3.21}
\end{equation*}
$$

Notice that in contrast to the $S$ given by Eq. (20), entropy $S_{\text {dist }}$ is not proportional to $N$ (at fixed temperature $T$ and density $N / V$ ). While for distinguishable particles this fact does not present any conceptual problem, for indistinguishable particles it would mean that entropy were not an extensive variable, i.e. would contradict the basic assumptions of thermodynamics. This fact emphasizes again the necessity of the correct Boltzmann counting in the latter case.

Comparing Eqs. (20) and (21), we can calculate the change of entropy due to mixing of distinguishable particles:

$$
\begin{equation*}
\Delta S_{\text {dist }}=\left(N_{1}+N_{2}\right) \ln \left(V_{1}+V_{2}\right)-\left(N_{1} \ln V_{1}+N_{2} \ln V_{2}\right)=N_{1} \ln \frac{V_{1}+V_{2}}{V_{1}}+N_{2} \ln \frac{V_{1}+V_{2}}{V_{2}}>0 . \tag{3.22}
\end{equation*}
$$

Note that for a particular case, $V_{1}=V_{2}=V / 2$, Eq. (22) reduces to the simple result $\Delta S_{\text {dist }}=\left(N_{1}+N_{2}\right) \ln 2$, which may be readily understood from the point of view of information theory. Indeed, allowing each particle of $N=N_{1}+N_{2}$ to spread to twice larger volume, we loose one bit of information per particle, i.e. $\Delta I=\left(N_{1}+N_{2}\right)$ bits for the whole system.

Let me leave it for the reader to show that result (22) is also valid if particles in each sub-volume are indistinguishable from each other, but different from those in another sub-volume, i.e. for mixing of two different gases. ${ }^{10}$ However, it is certainly not applicable to the system where all particles are identical, stressing again that the correct Boltzmann counting (12) does indeed affect entropy, even though it is not essential for either the Maxwell distribution (5), or the equation of state (18), or average energy (19).

In this context, one may wonder whether the change (22) (called the mixing entropy) is experimentally observable. The answer is yes. For example, after free mixing of two different gases one can use a thin movable membrane that is semipermeable, i.e. penetrable by particles of one type only, to

[^850]separate them again, thus reducing the entropy back to the initial value, and measure either the necessary mechanical work $\Delta \mathcal{W}=T \Delta S_{\text {dist }}$ or the corresponding heat discharge into the heat bath. Practically, measurements of this type are easier in weak solutions, ${ }^{11}$ systems with a small concentration $c \ll 1$ of particles of one sort (solute) within much more abundant particles of another sort (solvent). The mixing entropy also affects thermodynamics of chemical reactions in gases and liquids. ${ }^{12}$ It is curious that besides purely thermal measurements, mixing entropy in some conducting solutions (electrolytes) is also measurable by a purely electrical method, called cyclic voltammetry, in which a low-frequency ac voltage, applied between solid-state electrodes embedded in the solution, is used to periodically separate different ions, and then mix them again. ${ }^{13}$

Now let us briefly discuss two generalizations of our results for ideal classical gases. First, let us consider the ideal classical gas in an external field of potential forces. It may be described by replacing Eq. (3) with

$$
\begin{equation*}
\varepsilon_{k}=\frac{p_{k}^{2}}{2 m}+U\left(\mathbf{r}_{k}\right), \tag{3.23}
\end{equation*}
$$

where $\mathbf{r}_{k}$ is the position of the particular particle, and $U(\mathbf{r})$ is the potential energy per particle. In this cases, Eq. (4) is applicable only to small volumes, $V \rightarrow d V=d^{3} r$ whose linear size is much smaller than the spatial scale of variations of macroscopic parameters of the gas- say, pressure. Hence, instead of Eq. (5), we may only write the probability $d W$ of finding the particle in a small volume $d^{3} r d^{3} p$ of the 6dimensional phase space:

$$
\begin{equation*}
d W=w(\mathbf{r}, \mathbf{p}) d^{3} r d^{3} p, \quad w(\mathbf{r}, \mathbf{p})=\text { const } \times \exp \left\{-\frac{p^{2}}{2 m T}-\frac{U(\mathbf{r})}{T}\right\} . \tag{3.24}
\end{equation*}
$$

Hence, the Maxwell distribution of particle velocities is still valid at each point $\mathbf{r}$, and a more interesting issue here is the spatial distribution of the total density,

$$
\begin{equation*}
n(\mathbf{r}) \equiv N \int w(\mathbf{r}, \mathbf{p}) d^{3} p \tag{3.25}
\end{equation*}
$$

of all gas particles, regardless of their momentum. For this variable, Eq. (24) yields ${ }^{14}$

$$
\begin{equation*}
n(\mathbf{r})=n(0) \exp \left\{-\frac{U(\mathbf{r})}{T}\right\} \tag{3.26}
\end{equation*}
$$

[^851]where the potential energy reference is at the origin. As we will see in Chapter 6, in a non-uniform gas the equation of state (18) is valid locally if particles' mean free path $l$ is much smaller than the spatial scale of changes of function $n(\mathbf{r}) .{ }^{15}$ In this case, the local gas pressure may be still calculated from Eq. (18):
\[

$$
\begin{equation*}
P(\mathbf{r})=n(\mathbf{r}) T=P(0) \exp \left\{-\frac{U(\mathbf{r})}{T}\right\} . \tag{3.27}
\end{equation*}
$$

\]

An important example of application of Eq. (27) is an approximate description of the Earth atmosphere. At all heights $h \ll R_{\mathrm{E}} \sim 6 \times 10^{6} \mathrm{~m}$ above the Earth's surface (say, the sea level), we may describe the Earth gravity effect by potential $U=m g h$, and Eq. (27) yields the so-called barometric formula

$$
\begin{equation*}
P(h)=P(0) \exp \left\{-\frac{h}{h_{0}}\right\}, \quad \text { with } h_{0} \equiv \frac{T}{m g}=\frac{k_{\mathrm{B}} T_{\mathrm{K}}}{m g} . \tag{3.28}
\end{equation*}
$$

For the same $\mathrm{N}_{2}$ (the main component of the atmosphere) at $T_{\mathrm{K}}=300 \mathrm{~K}, h_{0} \approx 7 \mathrm{~km}$. This gives the right order of magnitude of the Earth atmosphere's thickness, though the exact law of pressure change differs somewhat from Eq. (28) because of a certain drop of the absolute temperature $T$ with height, by about $20 \%$ at $h \sim h_{0} .{ }^{16}$

The second generalization I would like to mention is to particles with internal degrees of freedom. Ignoring, for simplicity, the potential energy $U(\mathbf{r})$, we may describe them by replacing Eq. (3) for

$$
\begin{equation*}
\varepsilon_{k}=\frac{p^{2}}{2 m}+\varepsilon_{k}^{\prime}, \tag{3.29}
\end{equation*}
$$

where $\varepsilon_{k}$ ' describes the internal energy of the $k$-th particle. If the particles are similar, we may repeat all above calculations, and see that all the results (including the Maxwell distribution) are still valid, with the only exception of Eq. (16) that now becomes

$$
\begin{equation*}
f(T)=-T\left\{\ln \left[g\left(\frac{m T}{2 \pi \hbar^{2}}\right)^{3 / 2} \times \sum_{\varepsilon_{k^{\prime}}} \exp \left\{-\frac{\varepsilon_{k}^{\prime}}{T}\right\}\right]+1\right\} \tag{3.30}
\end{equation*}
$$

As we already know from Eq. (1.51), this change may affect both heat capacities of the gas, $C_{V}$ and $C_{P}$, but not their difference (equal to $N$ ).

### 3.2. Calculating $\mu$

Now let us return to Eq. (3), i.e. neglect the external field effects, as well as thermal activation of the internal degrees of freedom, and discuss properties of ideal gases of indistinguishable quantum

[^852]particles in more detail, paying special attention to the chemical potential $\mu$ - which, as you may recall, was a little bit mysterious aspect of the Fermi and Bose distributions.

Let us start from the classical gas, and recall the conclusion of thermodynamics that $\mu$ is the Gibbs potential per unit particle - see Eq. (1.56). Hence we can calculate $\mu=G / N$ from Eqs. (1.49) and (16b). The result,

$$
\begin{equation*}
\mu=-T \ln \frac{V}{N}+f(T)+T=T \ln \left[\frac{N}{g V}\left(\frac{2 \pi \hbar^{2}}{m T}\right)^{3 / 2}\right] \tag{3.31}
\end{equation*}
$$

which may be rewritten as

$$
\begin{equation*}
\exp \left\{\frac{\mu}{T}\right\}=\frac{N}{g V}\left(\frac{2 \pi \hbar^{2}}{m T}\right)^{3 / 2} \tag{3.32}
\end{equation*}
$$

is very important, because it gives us some information about $\mu$ not only for a classical gas, but for quantum (Fermi and Bose) gases as well. Indeed, we already know that for indistinguishable particles the Boltzmann distribution (2.111) is valid only if $\left\langle N_{k}\right\rangle \ll 1$. Comparing this condition with quantum statistics (2.115) and (2.118), we see that the condition of gas' classicity may be expressed as

$$
\begin{equation*}
\exp \left\{\frac{\mu-\varepsilon_{k}}{T}\right\} \ll 1 \tag{3.33}
\end{equation*}
$$

for all $\varepsilon_{k}$. Since the lowest value of $\varepsilon_{k}$ given by Eq. (3) is zero, Eq. (33) for a gas may be satisfied only if $\exp \{\mu / T\} \ll 1$. This means that the chemical potential of the classical has to be not just negative, but also "strongly negative" in the sense

$$
\begin{equation*}
-\mu \gg T \tag{3.34}
\end{equation*}
$$

According to Eq. (32), this condition may be presented as

$$
\begin{equation*}
T \gg T_{0} \tag{3.35}
\end{equation*}
$$

with $T_{0}$ defined as

$$
\begin{equation*}
T_{0} \equiv \frac{\hbar^{2}}{m}\left(\frac{n}{g}\right)^{2 / 3}=\frac{\hbar^{2}}{g^{2 / 3} m r_{A}^{2}}, \quad \text { with } r_{A} \equiv \frac{1}{n^{1 / 3}}=\left(\frac{V}{N}\right)^{1 / 3} . \tag{3.36}
\end{equation*}
$$

Condition (35) is very transparent physically: disregarding factor $g^{2 / 3}$ (which is typically not much larger than 1), it means that the average thermal energy of a particle (which is of the order of $T$ ) has to be much larger than the energy of quantization of particle's motion at length $r_{A}$ - the average distance between the particles. An alternative form of this condition is ${ }^{17}$

$$
\begin{equation*}
r_{A} \gg g^{-1 / 3} r_{c}, \quad \text { with } r_{c} \equiv \frac{\hbar}{(m T)^{1 / 2}} . \tag{3.37}
\end{equation*}
$$

[^853]For a typical gas (say, $\mathrm{N}_{2}$, with $m \approx 14 m_{p} \approx 2.3 \times 10^{-26} \mathrm{~kg}$ ) at the standard room temperature ( $T=$ $\left.k_{\mathrm{B}} \times 300 \mathrm{~K} \approx 4.1 \times 10^{-21} \mathrm{~J}\right), r_{c} \approx 10^{-11} \mathrm{~m}$, i.e. is significantly smaller than the physical size $a \sim 3 \times 10^{-10} \mathrm{~m}$ of the molecule. This estimate shows that at room temperature, as soon as any practical gas is rare enough to be ideal $\left(r_{A} \gg a\right)$, it is classical, i.e. the only way to observe the quantum effects in the translation motion of molecules is a very deep refrigeration. According to Eq. (36), for the same nitrogen molecule, taking $r_{A} \sim 10^{3} a \sim 10^{-7} \mathrm{~m}$ (to ensure that direct interaction effects are negligible), $T_{0}$ should be well below $1 \mu \mathrm{~K}$.

In order to analyze quantitatively what happens with gases when $T$ is reduced to such low values, we need to calculate $\mu$ for an arbitrary ideal gas of indistinguishable particles. Let us use the lucky fact that the Fermi-Dirac and the Bose-Einstein statistics may be represented with one formula:

$$
\begin{equation*}
\langle N(\varepsilon)\rangle=\frac{1}{e^{(\varepsilon-\mu) / T} \pm 1} \tag{3.38}
\end{equation*}
$$

where (and everywhere in the balance of this section) the top sign stands for fermions and the lower one is for bosons, to discuss the fermionic and bosonic gases on the same breath.

If we deal with a member of the grand canonical ensemble (Fig. 2.13), in which $\mu$ is externally fixed, we may apply Eq. (39) to calculate the average number $N$ of particles in volume $V$. If the volume is so large that $N \gg 1$, we may use the general state counting rule (13):

$$
\begin{equation*}
N=\frac{g V}{(2 \pi)^{3}} \int\langle N(\varepsilon)\rangle d^{3} k=\frac{g V}{(2 \pi \hbar)^{3}} \int \frac{d^{3} p}{e^{[\varepsilon(p)-\mu] / T} \pm 1}=\frac{g V}{(2 \pi \hbar)^{3}} \int_{0}^{\infty} \frac{4 \pi p^{2} d p}{e^{[\varepsilon(p)-\mu] / T} \pm 1} \tag{3.39}
\end{equation*}
$$

In most practical cases, however, the number $N$ of gas particles is fixed by particle confinement (i.e. the gas portion under study is a member of the canonical ensemble - see Fig. 2.6), and hence $\mu$ rather than $N$ should be calculated. Here comes the main trick: if $N$ is very large, the relative fluctuation of the particle number is negligibly small $(\sim 1 / \sqrt{ } N \ll 1)$, and the relation between the average values of $N$ and $\mu$ should not depend which of these variables is exactly fixed. Hence, Eq. (39), with $\mu$ having the sense of the average chemical potential, should be valid even if $N$ is exactly fixed, so that small fluctuations of $N$ are replaced with (equally small) fluctuations of $\mu$. Physically (as was already mentioned in Sec. 2.8), in this case the role of the $\mu$-fixing environment for any gas sub-portion is played by the rest of the gas, and Eq. (39) expresses the condition of self-consistency of such mutual particle exchange.

In this situation, Eq. (39) may be used for calculating the average $\mu$ as a function of two independent parameters: $N$ (i.e. of the gas density $n=N / V$ ) and temperature $T$. For carrying out this calculation, it is convenient to convert the right-hand part of Eq. (39) to an integral over particle's energy $\varepsilon(p)=p^{2} / 2 m$, so that $p=(2 m \varepsilon)^{1 / 2}$, and $d p=(m / 2 \varepsilon)^{1 / 2} d \varepsilon$ :

$$
\begin{equation*}
N=\frac{g V m^{3 / 2}}{\sqrt{2} \pi^{2} \hbar^{3}} \int_{0}^{\infty} \frac{\varepsilon^{1 / 2} d \varepsilon}{e^{(\varepsilon-\mu) / T} \pm 1} \tag{3.40}
\end{equation*}
$$

This key result may be presented in two more convenient forms. First, Eq. (40), derived for our current (3D, isotropic and parabolic-dispersion) approximation (3), is just particular case of a general relation

$$
\begin{equation*}
N=\int_{0}^{\infty} g(\varepsilon)\langle N(\varepsilon)\rangle d \varepsilon, \tag{3.41}
\end{equation*}
$$

where

$$
\begin{equation*}
g(\varepsilon) \equiv \frac{d N_{\text {states }}}{d \varepsilon} \tag{3.42}
\end{equation*}
$$

is the temperature-independent density of all quantum states of a particle - regardless of whether they are occupied or not. Indeed, according to the general Eq. (4), for our simple model (3),

$$
\begin{equation*}
g(\varepsilon)=g_{3}(\varepsilon) \equiv \frac{d N_{\text {states }}}{d \varepsilon}=\frac{d}{d \varepsilon}\left(\frac{g V}{(2 \pi \hbar)^{3}} \frac{4 \pi}{3} p^{3}\right)=\frac{4 \pi g V}{3(2 \pi \hbar)^{3}} \frac{d\left(p^{3}\right)}{d \varepsilon}=\frac{g V m^{3 / 2}}{\sqrt{2} \pi^{2} \hbar^{3}} \varepsilon^{1 / 2} \tag{3.43}
\end{equation*}
$$

so that we return to Eq. (39). On the other hand, for some calculations, it is convenient to introduce a dimensionless energy variable $\xi \equiv \varepsilon / T$ to express Eq. (40) via a dimensionless integral:

$$
\begin{equation*}
N=\frac{g V(m T)^{3 / 2}}{\sqrt{2} \pi^{2} \hbar^{3}} \int_{0}^{\infty} \frac{\xi^{1 / 2} d \xi}{e^{\xi-\mu / T} \pm 1} \tag{3.44}
\end{equation*}
$$

As a sanity check, in the classical limit (34), the exponent in the denominator of the fraction under the integral is much larger than 1, and Eq. (44) reduces to

$$
\begin{equation*}
N=\frac{g V(m T)^{3 / 2}}{\sqrt{2} \pi^{2} \hbar^{3}} \int_{0}^{\infty} \frac{\xi^{1 / 2} d \xi}{e^{\xi-\mu / T}} \approx \frac{g V(m T)^{3 / 2}}{\sqrt{2} \pi^{2} \hbar^{3}} \exp \left\{\frac{\mu}{T} \int_{0}^{\infty} \xi^{1 / 2} e^{-\xi} d \xi, \quad \text { at }-\mu \gg T .\right. \tag{3.45}
\end{equation*}
$$

By the definition of gamma-function $\Gamma(\xi),{ }^{18}$ this dimensionless integral is just $\Gamma(3 / 2)=\sqrt{ } \pi / 2$, and we get

$$
\begin{equation*}
\exp \left\{\frac{\mu}{T}\right\}=N \frac{\sqrt{2} \pi^{2} \hbar^{3}}{g V(m T)^{3 / 2}} \frac{2}{\sqrt{\pi}}=\left(2 \pi \frac{T_{0}}{T}\right)^{3 / 2}, \tag{3.46}
\end{equation*}
$$

which is exactly the same result as given by Eq. (34), which has been obtained in a rather different way - from the Boltzmann distribution and thermodynamic identities.

Unfortunately, in the general case of arbitrary $\mu$ the integral in Eq. (44) cannot be worked out analytically. ${ }^{19}$ The best we can do is to use temperature $T_{0}$, defined by Eq. (37), to rewrite Eq. (44) as

$$
\begin{equation*}
\frac{T}{T_{0}}=\left[\frac{1}{\sqrt{2} \pi^{2}} \int_{0}^{\infty} \frac{\xi^{1 / 2} d \xi}{e^{\xi-\mu / T} \pm 1}\right]^{-2 / 3} \tag{3.47}
\end{equation*}
$$

We may use this relation to calculate ratio $T / T_{0}$, and then ratio $\mu / T_{0} \equiv(\mu / T) \times\left(T / T_{0}\right)$, as functions of $\mu / T$ numerically, and then plot the results versus each other, thinking of the former ratio as the argument.

Figure 1 shows the resulting plot. It shows that at large temperatures, $T \gg T_{0}$, the chemical potential is negative and approaches the classical behavior given by Eq. (46) for both fermions and bosons - just as we could expect. For fermions, the reduction of temperature leads to $\mu$ changing its sign from negative to positive, and then approaching a constant positive value called the Fermi energy, $\varepsilon_{\mathrm{F}} \approx$ $7.595 T_{0}$ at $T \rightarrow 0$. On the contrary, the chemical potential of a gas of bosons stays negative, and turns

[^854]into zero at certain critical temperature $T_{c} \approx 3.313 T_{0}$. Both these limits, which are very important for applications, may (and will be :-) explored analytically, but separately for each statistics.

Fig. 3.1. Chemical potential of an ideal gas of $N \gg 1$ indistinguishable quantum particles, as a function of temperature (at fixed gas density $n \equiv N / V$, which fixes parameter $T_{0} \propto$ $n^{3 / 2}$ ), for two different quantum statistics. The dashed line shows the classical approximation (46) valid at $T \gg T_{0}$.

Before doing that (in the next two sections), let me show that, rather surprisingly, for any (but non-relativistic!) quantum gas, the product $P V$ expressed in terms of energy,

$$
\begin{equation*}
P V=\frac{2}{3} E \tag{3.48}
\end{equation*}
$$

is the same as follows from Eqs. (18) and (19) for the classical gas, and hence does not depend on particle's statistics. In order to prove this, it is sufficient to use Eqs. (2.114) and (2.117) for the grand thermodynamic potential of each quantum state, which may be conveniently represented by a single formula,

$$
\begin{equation*}
\Omega_{k}=\mp T \ln \left(1 \pm e^{\left(\mu-\varepsilon_{k}\right) / T}\right) \tag{3.49}
\end{equation*}
$$

and sum them over all states $k$, using the general summation formula (13). The result for the total grand potential of a 3D gas with the dispersion law (3) is

$$
\begin{equation*}
\Omega=\mp T \frac{g V}{(2 \pi \hbar)^{3}} \int_{0}^{\infty} \ln \left(1 \pm e^{\left(\mu-p^{2} / 2 m\right) / T}\right) 4 \pi p^{2} d p=\mp T \frac{g V m^{3 / 2}}{\sqrt{2} \pi^{2} \hbar^{3}} \int_{0}^{\infty} \ln \left(1 \pm e^{(\mu-\varepsilon) / T}\right) \varepsilon^{1 / 2} d \varepsilon \tag{3.50}
\end{equation*}
$$

Working out this integral by parts, exactly as we did it with the one in Eq. (2.90), we get

$$
\begin{equation*}
\Omega=-\frac{2}{3} \frac{g V m^{3 / 2}}{\sqrt{2} \pi^{2} \hbar^{3}} \int_{0}^{\infty} \frac{\varepsilon^{3 / 2} d \varepsilon}{e^{(\varepsilon-\mu) / T} \pm 1}=-\frac{2}{3} \int_{0}^{\infty} \varepsilon g_{3}(\varepsilon)\langle N(\varepsilon)\rangle d \varepsilon . \tag{3.51}
\end{equation*}
$$

But the last integral is just the total energy $E$ of the gas:

$$
\begin{equation*}
E=\frac{g V}{(2 \pi \hbar)^{3}} \int_{0}^{\infty} \frac{p^{2}}{2 m} \frac{4 \pi p^{2} d p}{e^{[\varepsilon(p)-\mu] / T} \pm 1}=\frac{g V m^{3 / 2}}{\sqrt{2} \pi^{2} \hbar^{3}} \int_{0}^{\infty} \frac{\varepsilon^{3 / 2} d \varepsilon}{e^{(\varepsilon-\mu) / T} \pm 1}=\int_{0}^{\infty} \varepsilon g_{3}(\varepsilon)\langle N(\varepsilon)\rangle d \varepsilon, \tag{3.52}
\end{equation*}
$$

so that for any temperature and any particle type, $\Omega=-(2 / 3) E$. But since, from thermodynamics, $\Omega=-$ $P V$, we have Eq. (48) proved. This universal relation will be repeatedly used below.

### 3.3. Degenerate Fermi gas

The analysis of low-temperature properties of a Fermi gas is very simple in the limit $T=0$. Indeed, in this limit, the Fermi-Dirac distribution (2.115) is just a step function:

$$
\langle N(\varepsilon)\rangle= \begin{cases}1, & \text { for } \varepsilon<\mu  \tag{3.53}\\ 0, & \text { for } \mu<\varepsilon\end{cases}
$$

- see by the bold line in Fig. 2a. Since $\varepsilon=p^{2} / 2 m$ is isotropic in the momentum space, this means that at $T$ $=0$, in that space the particles fully occupy all possible quantum states within a sphere (frequently called either the Fermi sphere or the Fermi sea) with some radius $p_{\text {F }}$ (Fig. 2b), while all states above the sea surface are empty. Such degenerate Fermi gas is a striking manifestation of the Pauli principle: though at thermodynamic equilibrium at $T=0$ all particles try to lower their energies as much as possible, only $g$ of them may occupy each quantum state within the Fermi sphere. As a result, the sphere's volume is proportional to the particle number $N$, or rather to their density $n=N / V$.

Fig. 3.2. Representation of the Fermi sea: (a) on the energy axis and (b) in the momentum space.

Indeed, radius $p_{\mathrm{F}}$ may be readily related to the number of particles $N$ using Eq. (40) whose integral in this case is just the Fermi sphere volume:

$$
\begin{equation*}
N=\frac{g V}{(2 \pi \hbar)^{3}} \int_{0}^{p_{\mathrm{F}}} 4 \pi p^{2} d p=\frac{g V}{(2 \pi \hbar)^{3}} \frac{4 \pi}{3} p_{\mathrm{F}}^{3} . \tag{3.54}
\end{equation*}
$$

Now we can use Eq. (3) to express via $N$ the chemical potential $\mu$ (which is this limit, $T \rightarrow 0$, bears the special name of the Fermi energy $\left.\varepsilon_{\mathrm{F}}\right)^{20}$ :

$$
\begin{equation*}
\left.\varepsilon_{\mathrm{F}} \equiv \mu\right|_{T=0}=\frac{p_{\mathrm{F}}^{2}}{2 m}=\frac{\hbar^{2}}{2 m}\left(6 \pi^{2} \frac{N}{g V}\right)^{2 / 3}=\left(\frac{9 \pi^{4}}{2}\right)^{1 / 3} T_{0} \approx 7.595 T_{0}, \tag{3.55a}
\end{equation*}
$$

where $T_{0}$ is the quantum temperature scale defined by Eq. (36). This formula quantifies the lowtemperature trend of function $\mu(T)$, clearly visible in Fig. 1, and in particular explains the ratio $\varepsilon_{\mathrm{F}} / T$ mentioned in Sec. 2. Note also a useful and simple relation,

$$
\begin{equation*}
\varepsilon_{\mathrm{F}}=\frac{3}{2} \frac{N}{g_{3}\left(\varepsilon_{\mathrm{F}}\right)}, \tag{3.55b}
\end{equation*}
$$

which may be obtained immediately from Eqs. (43) and (54).

[^855]The total energy of the gas may be (equally easily) calculated from Eq. (52):

$$
\begin{equation*}
E=\frac{g V}{(2 \pi \hbar)^{3}} \int_{0}^{p_{\mathrm{F}}} \frac{p^{2}}{2 m} 4 \pi p^{2} d p=\frac{g V}{(2 \pi \hbar)^{3}} \frac{4 \pi}{2 m} \frac{p_{\mathrm{F}}^{5}}{5}=\frac{3}{5} \varepsilon_{\mathrm{F}} N \tag{3.56}
\end{equation*}
$$

showing that the average energy, $\langle\varepsilon\rangle \equiv E / N$, of a particle inside the Fermi sea is equal to $3 / 5=60 \%$ of that $\left(\varepsilon_{\mathrm{F}}\right)$ of the most energetic occupied states, on the Fermi surface. Since, according to the formulas of Chapter 1, at zero temperature $H=G=N \mu$, and $F=E$, the only thermodynamic variable still to be calculated is pressure $P$. For that, we could use any of thermodynamic relations $P=(H-E) / V$ or $P=-$ $(\partial F / \partial V)_{T}$, but it is even easier to use our recent result (48). Together with Eq. (56), it yields

$$
\begin{equation*}
P=\frac{2}{3} \frac{E}{V}=\frac{2}{5} \varepsilon_{F} \frac{N}{V}=\left(\frac{36 \pi^{4}}{125}\right)^{1 / 3} P_{0} \approx 3.035 P_{0}, \quad \text { where } P_{0} \equiv n T_{0}=\frac{\hbar^{2}}{m g^{2 / 3}} n^{5 / 3} \tag{3.57}
\end{equation*}
$$

From here, it is easy to calculate the bulk modulus (reciprocal compressibility), ${ }^{21}$

$$
\begin{equation*}
K \equiv-V\left(\frac{\partial P}{\partial V}\right)_{T}=\frac{2}{3} \varepsilon_{\mathrm{F}} \frac{N}{V} \tag{3.58}
\end{equation*}
$$

which is simpler to measure experimentally.
Perhaps the most important example ${ }^{22}$ of the degenerate Fermi gas are the conduction electrons in metals - the electrons that belong to outer shells of the isolated atoms but become common in solid metals and can move through the crystal lattice almost freely. Though electrons (which are fermions with spin $s=1 / 2$ and hence the spin degeneracy $g=2 s+1=2$ ) are negatively charged, the Coulomb interaction of conduction electrons with each other is substantially compensated by the positively charged ions of the atomic lattice, so that they follow the simple formulas derived above reasonably well. This is especially true for alkali metals (forming Group 1 of the periodic table of elements), whose experimentally measured Fermi surfaces are spherical within $1 \%$ even within $0.1 \%$ for Na. Table 1 lists, in particular, the experimental values of the bulk modulus for such metals, together with the values given by Eq. (58) using $\varepsilon_{\mathrm{F}}$ calculated from Eq. (55) with the experimental density of conduction electrons. Evidently, the agreement is pretty good, taking into account that the simple theory described above completely ignores such factors as the Coulomb and exchange interactions of the electrons. This agreement implies that, surprisingly, the rigidity of solids (or at least metals) is predominantly due to the kinetic energy of conduction electrons, complemented with the Pauli principle, rather than any electrostatic interactions - though, to be fair, these interactions are the crucial factor defining the equilibrium value of $n$. Numerical calculations using more accurate approximations (e.g., the density functional theory ${ }^{23}$ ) that agree with experiment with a few percent accuracy, confirm this conclusion. ${ }^{24}$

[^856]Table 3.1. Experimental and theoretical parameters of electron's Fermi sea in some alkali metals ${ }^{25}$

| Metal | $\mathcal{E}_{\mathrm{F}}(\mathrm{eV})$ <br> Eq. $(55)$ | $K(\mathrm{GPa})$ <br> Eq. (58) | $K(\mathrm{GPa})$ <br> experiment | $\gamma\left(\mathrm{mcal} / \mathrm{mole} \cdot \mathrm{K}^{2}\right)$ <br> Eq. (69) | $\gamma\left(\mathrm{mcal} / \mathrm{mole} \cdot \mathrm{K}^{2}\right)$ <br> experiment |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Na | 3.24 | 923 | 642 | 0.26 | 0.35 |
| K | 2.12 | 319 | 281 | 0.40 | 0.47 |
| Rb | 1.85 | 230 | 192 | 0.46 | 0.58 |

Now looking at the values of $\varepsilon_{\mathrm{F}}$ listed in the table, note that room temperatures ( $T_{\mathrm{K}} \sim 300 \mathrm{~K}$ ) correspond to $T \sim 25 \mathrm{meV}$. As a result, virtually all experiments with metals, at least in their solid or liquid form, are performed in the limit $T \ll \mathcal{E}_{\mathrm{F}}$. According to Eq. (39), at such temperatures the occupancy step described by the Fermi-Dirac distribution has a finite but relatively small width $\sim T-$ see the dashed line in Fig. 2a. Calculations in this case are much facilitated by the so-called Sommerfeld expansion formula ${ }^{26}$ for integrals like (40) and (52):

$$
\begin{equation*}
I(T) \equiv \int_{0}^{\infty} \varphi(\varepsilon)\langle N(\varepsilon)\rangle d \varepsilon \approx \int_{0}^{\mu} \varphi(\varepsilon) d \varepsilon+\frac{\pi^{2}}{6} T^{2} \frac{d \varphi(\mu)}{d \mu}, \quad \text { at } T \ll \mu, \tag{3.59}
\end{equation*}
$$

Sommerfeld expansion
where $\varphi(\varepsilon)$ is an arbitrary function that is sufficiently smooth at $\varepsilon=\mu$ and integrable at $\varepsilon=0$. In order to prove this formula, let us introduce another function

$$
\begin{equation*}
f(\varepsilon) \equiv \int_{0}^{\varepsilon} \varphi\left(\varepsilon^{\prime}\right) d \varepsilon^{\prime}, \quad \text { so that } \varphi(\varepsilon)=\frac{d f(\varepsilon)}{d \varepsilon} \tag{3.60}
\end{equation*}
$$

and work out the integral $I(T)$ by parts:

$$
\begin{equation*}
I(T)=\int_{0}^{\infty} \frac{d f(\varepsilon)}{d \varepsilon}\langle N(\varepsilon)\rangle d \varepsilon=\int_{\varepsilon=0}^{\varepsilon=\infty}\langle N(\varepsilon)\rangle d f=[\langle N(\varepsilon)\rangle f]_{\varepsilon=0}^{\varepsilon=\infty}-\int_{\varepsilon=0}^{\varepsilon=\infty} f(\varepsilon) d\langle N(\varepsilon)\rangle=\int_{0}^{\infty} f(\varepsilon)\left(-\frac{\partial\langle N(\varepsilon)\rangle}{\partial \varepsilon}\right) d \varepsilon . \tag{3.61}
\end{equation*}
$$

As evident from Eq. (39) and/or Fig. 2a, at $T \ll \mu$, function ( $-\partial\langle N(\varepsilon)\rangle / \partial \varepsilon$ ) approaches zero for all energies, besides a narrow peak, of unit area, at $\varepsilon \approx \mu$. Hence, if we expand function $f(\varepsilon)$ in the Taylor series near this point, just a few leading terms of the expansion should give us a good approximation:

$$
\begin{align*}
I(T) & \approx \int_{0}^{\infty}\left[f(\mu)+\left.\frac{d f}{d \varepsilon}\right|_{\varepsilon=\mu}(\varepsilon-\mu)+\left.\frac{1}{2} \frac{d^{2} f}{d \varepsilon^{2}}\right|_{\varepsilon=\mu}(\varepsilon-\mu)^{2}\right]\left(-\frac{\partial\langle N(\varepsilon)\rangle}{\partial \varepsilon}\right) d \varepsilon  \tag{3.62}\\
& =\int_{0}^{\mu} \varphi\left(\varepsilon^{\prime}\right) d \varepsilon^{\prime} \int_{0}^{\infty}\left(-\frac{\partial\langle N(\varepsilon)\rangle}{\partial \varepsilon}\right) d \varepsilon+\varphi(\mu) \int_{0}^{\infty}(\varepsilon-\mu)\left(-\frac{\partial\langle N(\varepsilon)\rangle}{\partial \varepsilon}\right) d \varepsilon+\frac{1}{2} \frac{d \varphi(\mu)}{d \mu} \int_{0}^{\infty}(\varepsilon-\mu)^{2}\left(-\frac{\partial\langle N(\varepsilon)\rangle}{\partial \varepsilon}\right) d \varepsilon
\end{align*}
$$

[^857]In the last form of this relation, the first integral over $\varepsilon$ equals $\langle N(\varepsilon=0)\rangle-\langle N(\varepsilon=\infty\rangle=1$, the second one vanishes (because the function under it is asymmetric about point $\varepsilon=\mu$ ), and only the last one needs to be dealt with explicitly, by working it out by parts and then using a table integral:27

$$
\begin{equation*}
\int_{0}^{\infty}(\varepsilon-\mu)^{2}\left(-\frac{\partial\left\langle N_{k}\right\rangle}{\partial \varepsilon}\right) d \varepsilon \approx T^{2} \int_{-\infty}^{+\infty} \xi^{2} \frac{d}{d \xi}\left(-\frac{1}{e^{\xi}+1}\right) d \xi=4 T^{2} \int_{0}^{+\infty} \frac{\xi d \xi}{e^{\xi}+1}=4 T^{2} \frac{\pi^{2}}{12} \tag{3.63}
\end{equation*}
$$

Being plugged into Eq. (62), this result proves the Sommerfeld formula (59).
The last preparatory step we need is to take into account a possible small difference (as we will see below, also proportional to $T^{2}$ ) between the temperature-dependent chemical potential $\mu(T)$ and the Fermi energy defined as $\varepsilon_{\mathrm{F}} \equiv \mu(0)$, in the largest (first) term in the right-hand part of Eq. (62), to write

$$
\begin{equation*}
I(T) \approx \int_{0}^{\varepsilon_{\mathrm{F}}} \varphi(\varepsilon) d \varepsilon+\left(\mu-\varepsilon_{\mathrm{F}}\right) \varphi(\mu)+\frac{\pi^{2}}{6} T^{2} \frac{d \varphi(\mu)}{d \mu}=I(0)+\left(\mu-\varepsilon_{\mathrm{F}}\right) \varphi(\mu)+\frac{\pi^{2}}{6} T^{2} \frac{d \varphi(\mu)}{d \mu} . \tag{3.64}
\end{equation*}
$$

Now, applying this formula to Eq. (41) and the last form of Eq. (52), we get the following results (which are valid for any dispersion law $\varepsilon(\mathbf{p})$ and even any dimensionality of the gas):

$$
\begin{gather*}
N(T)=N(0)+\left(\mu-\varepsilon_{\mathrm{F}}\right) g(\mu)+\frac{\pi^{2}}{6} T^{2} \frac{d g(\mu)}{d \mu},  \tag{3.65}\\
E(T)=E(0)+\left(\mu-\varepsilon_{\mathrm{F}}\right) \mu g(\mu)+\frac{\pi^{2}}{6} T^{2} \frac{d}{d \mu}[\mu g(\mu)] . \tag{3.66}
\end{gather*}
$$

However, the number of particles does not change with temperature, $N(T)=N(0)$, so that Eq. (65) gives an equation for finding the temperature-induced change of $\mu$ :

$$
\begin{equation*}
\mu-\varepsilon_{\mathrm{F}}=-\frac{\pi^{2}}{6} T^{2} \frac{1}{g(\mu)} \frac{d g(\mu)}{d \mu} . \tag{3.67}
\end{equation*}
$$

Note that the change is quadratic in $T$ and negative, in agreement with the numerical results shown with the red line in Fig. 1. Plugging this expression (which is only valid when the magnitude of the change is much smaller than $\varepsilon_{\mathrm{F}}$ ) into Eq. (66), we finally get the finite-temperature correction to energy:

$$
\begin{equation*}
E(T)-E(0)=\frac{\pi^{2}}{6} g(\mu) T^{2} \tag{3.68}
\end{equation*}
$$

where within the accuracy of our approximation, $\mu$ may be replaced with $\varepsilon_{\mathrm{F}}$. (Due to the universal relation (48), Eq. (68) also gives the temperature correction to pressure.) Now we may use Eq. (68) to calculate the heat capacity of the degenerate Fermi gas:

$$
\begin{equation*}
C_{V} \equiv\left(\frac{\partial E}{\partial T}\right)_{V}=\gamma T, \quad \gamma=\frac{\pi^{2}}{3} g\left(\varepsilon_{\mathrm{F}}\right) . \tag{3.69}
\end{equation*}
$$

According to Eq. (55b), in the particular case of a 3D gas with the isotropic and parabolic dispersion law (3), Eq. (69) reduces to

[^858]\[

$$
\begin{equation*}
\gamma=\frac{\pi^{2}}{2} \frac{N}{\varepsilon_{\mathrm{F}}}, \text { i.e. } C_{V}=\frac{\pi^{2}}{2} N \frac{T}{\varepsilon_{\mathrm{F}}} \ll N . \tag{3.70}
\end{equation*}
$$

\]

This important result deserves a discussion. First, note that within the range of validity of the Sommerfeld approximation ( $T \ll \varepsilon_{\mathrm{F}}$ ), the specific heat of the degenerate gas is much smaller than that of the classical gas, even without internal degrees of freedom, $C_{V}=(3 / 2) N$-see Eq. (19). The reason for such a small heat capacity is that particles deep inside the Fermi sea cannot pick up thermal excitations with available energies of the order of $T \ll \varepsilon_{\mathrm{F}}$, because all states around them are already occupied. The only particles (or rather quantum states) that may be excited with such small energies are those at the very Fermi surface, more exactly within a surface layer of thickness $\Delta \varepsilon \sim T \ll \varepsilon_{\mathrm{F}}$, and Eq. (69) presents a very vivid expression of this fact.

The second important feature of Eqs. (69)-(70) is the linear dependence of the heat capacity on temperature, which decreases with a reduction of $T$ much slower than that of crystal vibrations - see Eq. (2.99) and it discussion. This means that in metals the specific heat at temperatures $T \ll T_{\mathrm{D}}$ is dominated by the conduction electrons. Indeed, experiments confirm not only the linear dependence (70) of the specific heat, ${ }^{28}$ but also the values of the proportionality coefficient $\gamma \equiv C_{V} / T$ for cases when $\varepsilon_{\mathrm{F}}$ can be calculated independently, for example for alkali metals - see the right two columns of Table 1. More typically, Eq. (69) is used for the experimental measurement of the density of states on the Fermi surface, $g\left(\varepsilon_{\mathrm{F}}\right)$ - the factor which participates in many theoretical results, in particular in transport properties of degenerate Fermi gases (see Chapter 6 below).

### 3.4. Bose-Einstein condensation

Now let us explore what happens at cooling of an ideal gas of bosons. Figure 3a shows on a more appropriate, log-log scale, the same plot as Fig. 1b, i.e. the numerical solution of Eq. (47) with the appropriate (negative) sign in the denominator. One can see that that the chemical potential $\mu$ indeed tends to zero at some finite "critical temperature" $T_{c}$. This temperature may be found by taking $\mu=0$ in Eq. (47), which is then reduced to a table integral: ${ }^{29}$

$$
\begin{equation*}
T_{c}=T_{0}\left[\frac{1}{\sqrt{2} \pi^{2}} \int_{0}^{\infty} \frac{\xi^{1 / 2} d \xi}{e^{\xi}-1}\right]^{-2 / 3}=T_{0}\left[\frac{1}{\sqrt{2} \pi^{2}} \Gamma\left(\frac{3}{2}\right) \zeta\left(\frac{3}{2}\right)\right]^{-2 / 3} \approx 3.313 T_{0} \tag{3.71}
\end{equation*}
$$

the result explaining the $T_{c} / T_{0}$ ratio mentioned in Sec. 2.
Hence we must have a good look at the temperature interval $0<T<T_{c}$, which may look rather mysterious. Indeed, within this range, chemical potential $\mu$ cannot be either negative or zero, because then Eq. (41) would give a value of $N$ fewer than the number of particles we actually have. On the other hand, $\mu$ cannot be positive either, because integral (41) would diverge at $\varepsilon \rightarrow \mu$ due to the divergence of $\langle N(\varepsilon)\rangle$ - see, e.g., Fig. 2.15. The only possible resolution of the paradox, suggested by A. Einstein, is as follows: at $T<T_{c}$, the chemical potential of each particle still equals exactly zero, but a certain number

[^859]( $N_{0}$ of $N$ ) of them are in the ground state (with $\varepsilon \equiv p^{2} / 2 m=0$ ), forming the so-called Bose-Einstein condensate, very frequently referred to as BEC.

(a)

Fig. 3.3. The Bose-Einstein condensation: (a) chemical potential of the gas and (b) its pressure, as functions of temperature. The dashed line corresponds to the classical gas.

Since the condensate particles do not contribute to Eq. (41) (because of the factor $\varepsilon^{1 / 2}=0$ ), their number $N_{0}$ may be calculated by using Eq. (44), with $\mu=0$, to find the number ( $N-N_{0}$ ) of particles still remaining in the gas, i.e. having energy $\varepsilon>0$ :

$$
\begin{equation*}
N-N_{0}=\frac{g V(m T)^{3 / 2}}{\sqrt{2} \pi^{2} \hbar^{3}} \int_{0}^{\infty} \frac{\xi^{1 / 2} d \xi}{e^{\xi}-1} . \tag{3.72}
\end{equation*}
$$

This result is even simpler than it may look. Indeed, let us write it for case $T=T_{c}$, when $N_{0}=0: 30$

$$
\begin{equation*}
N=\frac{g V\left(m T_{c}\right)^{3 / 2}}{\sqrt{2} \pi^{2} \hbar^{3}} \int_{0}^{\infty} \frac{\xi^{1 / 2} d \xi}{e^{\xi}-1} . \tag{3.73}
\end{equation*}
$$

Since the dimensionless integrals in both equations are similar, we may just divide them, getting an extremely simple and elegant result:

$$
\begin{equation*}
\frac{N-N_{0}}{N}=\left(\frac{T}{T_{c}}\right)^{3 / 2}, \quad \text { so that } \quad N_{0}=N\left[1-\left(\frac{T}{T_{c}}\right)^{3 / 2}\right], \quad \text { at } T \leq T_{c} . \tag{3.74a}
\end{equation*}
$$

Please note that this result is only valid for the particles whose motion, within volume $V$, is free in other words, for the particles trapped in a rigid-wall box of volume $V$. In typical experiments with the Bose-Einstein condensation of diluted gases of neutral (and hence weakly interacting) atoms, particles

[^860]are trapped at the bottom of a "soft" potential well, which may be well approximated by a 3D quadratic parabola: $U(\mathbf{r})=m \omega^{2} r^{2} / 2$. It is straightforward to show (and hence left for reader's exercise) that in this case the temperature dependence of $N_{0}$ is somewhat different:
\[

$$
\begin{equation*}
N_{0}=N\left[1-\left(\frac{T}{T_{c}^{*}}\right)^{3}\right], \quad \text { at } T \leq T_{c}^{*} \tag{3.74b}
\end{equation*}
$$

\]

where $T_{c}{ }^{*}$ is a critical temperature that depends on $\hbar \omega$, i.e. the confining potential's "steepness", rather than on the gas' volume (which in this case is not fixed). Figure 4 shows one of the first sets of experimental data for the Bose-Einstein condensation of dilute gases of neutral atoms. Taking into account the finite number of particles in the experiment, the agreement with the simple theory is surprisingly good.

Fig. 3.4. Total number $N$ of trapped ${ }^{87} \mathrm{Rb}$ atoms (inset) and their ground-state fraction $N_{0} / N$, as functions of the ratio $T / T_{c}$, as measured by J. Ensher et al., Phys. Rev. Lett. 77, 4984 (1996). In this experiment, $T_{c}{ }^{*}$ was as low as $0.28 \times 10^{-6} \mathrm{~K}$. The solid line shows the simple theoretical dependence $N(T)$, given by Eq. (74b), while other lines correspond to more complex theories taking into account the finite number $N$ of trapped atoms. © 1996 APS.

Now returning to the rigid-wall box model, let us explore what happens at the critical temperature and below it with other gas parameters. Equation (52) with the appropriate (lower) sign shows that approaching this point from higher temperatures, gas energy and hence its pressure do not vanish (Fig. 3b). Indeed, at $T=T_{\mathrm{c}}$ (where $\mu=0$ ), that equation yields ${ }^{31}$

$$
\begin{equation*}
E\left(T_{c}\right)=g V \frac{m^{3 / 2} T_{c}^{5 / 2}}{\sqrt{2} \pi^{2} \hbar^{3}} \int_{0}^{\infty} \frac{\xi^{3 / 2} d \xi}{e^{\xi}-1}=g V \frac{m^{3 / 2} T_{c}^{5 / 2}}{\sqrt{2} \pi^{2} \hbar^{3}} \Gamma\left(\frac{5}{2}\right) \zeta\left(\frac{5}{2}\right)=\frac{3}{2} \frac{\zeta(5 / 2)}{\zeta(3 / 2)} N T_{c} \approx 0.7701 N T_{c}, \tag{3.75}
\end{equation*}
$$

so that using the universal relation (48), we get a pressure value,

$$
\begin{equation*}
P\left(T_{c}\right)=\frac{2}{3} \frac{E\left(T_{c}\right)}{V}=\frac{\zeta(5 / 2)}{\zeta(3 / 2)} \frac{N}{V} T_{c} \approx 0.5134 \frac{N}{V} T_{c} \approx 1.701 P_{0}, \tag{3.76}
\end{equation*}
$$

which is somewhat lower than, but comparable to $P(0)$ for the fermions - cf. Eq. (57). Now we can use the same Eq. (52), also with $\mu=0$, to calculate the energy of the gas at $T<T_{\mathrm{c}}$,

[^861]\[

$$
\begin{equation*}
E(T)=g V \frac{m^{3 / 2} T^{5 / 2}}{\sqrt{2} \pi^{2} \hbar^{3}} \int_{0}^{\infty} \frac{\xi^{3 / 2} d \xi}{e^{\xi}-1} \tag{3.77}
\end{equation*}
$$

\]

Comparing this relation with the first form of Eq. (75), which features the same integral, we immediately get one more simple temperature dependence:

$$
\begin{equation*}
E(T)=E\left(T_{c}\right)\left(\frac{T}{T_{c}}\right)^{5 / 2}, \quad \text { at } T \leq T_{c} \tag{3.78}
\end{equation*}
$$

From the universal relation (48), we immediately see that pressure follows the same dependence:

$$
\begin{equation*}
P(T)=P\left(T_{c}\right)\left(\frac{T}{T_{c}}\right)^{5 / 2}, \quad \text { at } T \leq T_{c} \tag{3.79}
\end{equation*}
$$

This temperature dependence of pressure is shown with the blue line in Fig. 3b. The plot shows that for all temperatures (both below and above $T_{c}$ ) the pressure of bosonic gas is below that of the classical gas of the same density. Note also that since, according to Eqs. (57) and (76), $P\left(T_{c}\right) \propto P_{0} \propto V^{5 / 3}$, while, according to Eqs. (37) and (71), $T_{c} \propto T_{0} \propto V^{2 / 3}$, pressure (79) does not depend on volume at all! The physics of this result (that is valid at $T<T_{\mathrm{c}}$ only) is that as we decrease the volume at fixed total number of particles, more and more of them go to the condensate, decreasing the number $\left(N-N_{0}\right)$ of particles in the gas phase, but not changing its pressure. Such behavior is very typical for phase transitions - see, in particular, the next chapter.

The last thermodynamic variable of major interest is the heat capacity, because it may be readily measured in many systems. For temperatures $T \leq T_{c}$, it may be easily calculated from Eq. (78):

$$
\begin{equation*}
C_{V}(T) \equiv\left(\frac{\partial E}{\partial T}\right)_{N, V}=E\left(T_{c}\right) \frac{5}{2} \frac{T^{3 / 2}}{T_{c}^{5 / 2}} \tag{3.80}
\end{equation*}
$$

so that below $T_{c}$, the capacity increases, at the critical temperature reaching the value,

$$
\begin{equation*}
C_{V}\left(T_{c}\right)=\frac{5}{2} \frac{E\left(T_{c}\right)}{T_{c}} \approx 1.925 \mathrm{~N} \tag{3.81}
\end{equation*}
$$

which is approximately $28 \%$ above that ( $3 N / 2$ ) of the classical gas - in both cases ignoring the possible contributions from the internal degrees of freedom. The analysis for $T \geq T_{c}$ is a little bit more cumbersome, because differentiating $E$ over temperature - say, using Eq. (52) - one should also take into account the temperature dependence of $\mu$ that follows from Eq. (40) - see also Fig. 1b. However, the most important feature of the result may be predicted without the calculation (which is being left for reader's exercise). Since at $T \gg T_{c}$ the heat capacity has to approach the classical value, it must decrease at $T>T_{c}$, thus forming a sharp maximum (a "cusp") at the critical point $T=T_{c}-$ see Fig. 5.

Such a cusp is good indication of the Bose-Einstein condensation in virtually any experimental system, especially because inter-particle interactions (unaccounted for in our simple discussion) typically make this feature even more substantial, turning it into a weak (logarithmic) singularity. Historically, such a singularity (called the $\lambda$-point because of the characteristic shape of the $C_{V}(T)$ dependence) was the first noticed, though not immediately understood sign of the Bose-Einstein condensation, observed in 1931 by W. Keesom and K . Clusius in liquid ${ }^{4} \mathrm{He}$ at $T=T_{c} \approx 2.17 \mathrm{~K}$. Other milestones of the Bose-Einstein condensation studies include:

- the experimental discovery of superconductivity in metals, by H. Kamerlingh-Onnes in 1911;
- the development of the Bose-Einstein statistics implying the condensation, in 1924-1925;
- the discovery of superfluidity in liquid ${ }^{4} \mathrm{He}$ by P. Kapitza and (independently) by J. Allen and D. Misener in 1937, and its explanation as a result of the Bose-Einstein condensation by F. and H. Londons and L. Titza, with further elaborations by L. Landau (all in 1938);
- the explanation of superconductivity as the result of formation of Cooper pairs of electrons, with an integer total spin, with the simultaneous Bose-Einstein condensation of such effective bosons, by J. Bardeen, L. Cooper, and J. Schrieffer in 1957;
-the discovery of superfluidity of two different phases of ${ }^{3} \mathrm{He}$, due to the similar Bose-Einstein condensation of pairs of its fermion atoms, by D. Lee, D. Osheroff, and R. Richardson in 1972;
- the first observation of the Bose-Einstein condensation in dilute gases $\left({ }^{87} \mathrm{Ru}\right.$ by E. Cornell, C. Wieman et al. and ${ }^{23} \mathrm{Na}$ by W. Ketterle et al.) in 1995.

Fig. 3.5. Temperature dependences of the heat capacity of an ideal Bose-Einstein gas, calculated from Eqs. (52) and (40) for $T \geq T_{c}$, and from Eq. (80) for $T \leq T_{c}$.

The importance of the last achievement (and of the continuing intensive work in this direction ${ }^{32}$ ) stems from the fact that in contrast to other Bose-Einstein condensates, in dilute gases (with the typical density $n$ as low as $\sim 10^{14} \mathrm{~cm}^{-3}$ ) the particles interact very weakly, and hence many experimental results are very close to the simple theory described above and its straightforward elaborations - see, e.g., Fig. 4. On the other hand, the importance of prior implementations of the Bose-Einstein condensates, which involve more complex and challenging physics, should not be underestimated - as it sometimes is.

The most important feature of any Bose-Einstein condensate is that all $N_{0}$ condensed particles are in the same quantum state, and hence are described by exactly the same wavefunction. This wavefunction is substantially less "feeble" than that of a single particle - in the following sense. In the second quantization language, ${ }^{33}$ the well-known Heisenberg's uncertainty relation may be rewritten for the creation/annihilation operators; in particular, for bosons,

$$
\begin{equation*}
\left[\hat{a}, \hat{a}^{\dagger}\right]=1 \tag{3.82}
\end{equation*}
$$

[^862]Since $\hat{a}$ and $\hat{a}^{\dagger}$ are quantum-mechanical operators of the complex amplitude $a=A \exp \{i \varphi\}$ and its complex conjugate $a^{*}=A \exp \{-i \varphi\}$, where $A$ and $\varphi$ are real amplitude and phase of the wavefunction. Equation (82) yields the following approximate uncertainty relation (strict in the limit $\delta \varphi \ll 1$ ) between the number of particles $N=A A^{*}$ and phase $\varphi$

$$
\begin{equation*}
\delta N \delta \varphi \geq 1 / 2 \tag{3.83}
\end{equation*}
$$

This means that a condensate of $N \gg 1$ bosons may be in a state with both phase and amplitude of the wavefunction behaving virtually as $c$-numbers, with negligible relative uncertainties: $\delta N \ll N$, $\delta \varphi \ll 1$. Moreover, such states are much less susceptible to perturbations by experimental instruments. For example, the supercurrent $I_{S}$ carried along a superconducting wires by a coherent Bose-Einstein condensate of Cooper pairs may be as high as hundreds of amperes. As a result, the "strange" behaviors predicted by the quantum mechanics are not averaged out as in the usual particle ensembles (see, e.g., the discussion of the density matrix in Sec. 2.1), but may be directly revealed in macroscopic, measurable behaviors of the condensate.

For example, density $\mathbf{j}_{S}$ of the supercurrent may be described by the same formula as the usual probability current density of a single particle, ${ }^{34}$ multiplied by the Cooper pair density $n$ and the electric charge $q=-2 e$ of a single pair:

$$
\begin{equation*}
\mathbf{j}_{S}=q n \frac{\hbar}{m}\left(\nabla \varphi-\frac{q}{\hbar} \mathbf{A}\right), \tag{3.84}
\end{equation*}
$$

where $\mathbf{A}$ is the vector-potential of the (electro)magnetic field. If a superconducting wire is not extremely thin, current flow does not penetrate its interior, ${ }^{35}$ so that $\mathbf{j}_{S}$ may be taken for zero. As a result, the integral of Eq. (84), taken along a contour inside a closed wire loop yields

$$
\begin{equation*}
\frac{q}{\hbar} \oint_{C} \mathbf{A} \cdot d \mathbf{r}=\Delta \varphi=2 \pi m \tag{3.85}
\end{equation*}
$$

where $m$ is an integer. But, according to electrodynamics, the integral participating in this equation is nothing more than flux $\Phi$ of the magnetic field $\mathcal{B}$ piercing the wire loop area $A$. Thus we immediately arrive at the famous magnetic flux quantization effect

$$
\begin{equation*}
\Phi \equiv \int_{A} \mathcal{B}_{n} d^{2} r=m \Phi_{0}, \quad \Phi_{0} \equiv \frac{2 \pi \hbar}{|q|}=\frac{h}{2 e} \approx 2.07 \times 10^{-15} \mathrm{~Wb} \tag{3.86}
\end{equation*}
$$

which was theoretically predicted in 1950 and experimentally observed in 1961. Most fantastically, this effect holds true even in very large loops, sustained by the Bose-Einstein condensate of Cooper pairs, "coherent over miles of dirty lead wire", citing J. Bardeen's famous expression.

Other prominent examples of such macroscopic quantum effects in Bose-Einstein condensates include not only the superfluidity and superconductivity as such, but also the Josephson effect,

[^863]quantized Abrikosov vortices, etc. Some of these effects are briefly discussed in other parts of this series. ${ }^{36}$

### 3.5. Gases of weakly interacting particles

Now let us discuss the weak particle interaction effects on macroscopic properties of their gas. (Unfortunately, I will have time to do that only for a brief discussion of these effects in classical gases of indistinguishable particles. ${ }^{37}$ )

In most cases of interest, particle interaction may be described by certain potential energy $U$, so that the total energy is

$$
\begin{equation*}
E=\sum_{k=1}^{N} \frac{p_{k}^{2}}{2 m}+U\left(\mathbf{r}_{1}, . ., \mathbf{r}_{j}, \ldots, \mathbf{r}_{N}\right) \tag{3.87}
\end{equation*}
$$

where $\mathbf{r}_{k}$ is the position of $k^{\text {th }}$ particle's center. Let us see how far would the statistical physics allow us to proceed for an arbitrary potential $U$. For $N \gg 1$, at the calculation of the Gibbs statistical sum (2.59), we may perform the usual transfer from the summation over all quantum states of the system to integration over the 6 N -dimensional space, with the correct Boltzmann counting:

$$
\begin{align*}
Z & =\sum_{m} e^{-E_{m} / T} \rightarrow \frac{1}{N!} \frac{g^{N}}{(2 \pi \hbar)^{3 N}} \int \exp \left\{-\sum_{k=1}^{N} \frac{p_{j}^{2}}{2 m T}\right\} d^{3} p_{1} \ldots d^{3} p_{N} \int \exp \left\{-\frac{U\left(\mathbf{r}_{1}, \ldots \mathbf{r}_{N}\right)}{T}\right\} d^{3} r_{1} \ldots d^{3} r_{N} \\
& =\left(\frac{1}{N!} \frac{g^{N} V^{N}}{(2 \pi \hbar)^{3 N}} \int \exp \left\{-\sum_{k=1}^{N} \frac{p_{j}^{2}}{2 m T}\right\} d^{3} p_{1} \ldots d^{3} p_{N}\right) \times\left(\frac{1}{V^{N}} \int \exp \left\{-\frac{U\left(\mathbf{r}_{1}, \ldots \mathbf{r}_{N}\right)}{T}\right\} d^{3} r_{1} \ldots d^{3} r_{N}\right) \tag{3.88}
\end{align*}
$$

But according to Eq. (14), the first operand in the last product is the statistical sum of an ideal gas (with the same $g, N, V$, and $T$ ), so that we may use Eq. (2.63) to write

$$
\begin{equation*}
F=F_{\text {ideal }}-T \ln \left[\frac{1}{V^{N}} \int d^{3} r_{1} \ldots d^{3} r_{N} e^{-U / T}\right]=F_{\text {ideal }}-T \ln \left[1+\frac{1}{V^{N}} \int d^{3} r_{1} \ldots d^{3} r_{N}\left(e^{-U / T}-1\right)\right], \tag{3.89}
\end{equation*}
$$

where $F_{\text {ideal }}$ is the free energy of the ideal gas (i.e. the same gas but with $U=0$ ), given by Eq. (16).
I believe that Eq. (89) is a very convincing demonstration of the enormous power of the statistical physics. Instead of trying to solve an impossibly complex problem of classical dynamics of $N$ >> 1 (think of $N \sim 10^{23}$ ) interacting particles, and calculating appropriate ensemble averages later on, the Gibbs approach reduces finding the free energy (and then, from thermodynamic relations, all other thermodynamic variables) to the calculation of just one integral in its right-hand part of Eq. (89). Still, this integral is 3 N -dimensional and may be worked out analytically only if particle interaction is weak in some sense. Indeed, the last form of Eq. (89) makes its especially evident that if $U \rightarrow 0$ everywhere, the term in parentheses under the integral vanishes, and so does the integral itself, and hence the addition to $F_{\text {ideal }}$.

[^864]Now let us see what would this integral yield for the simplest, short-range interactions, in which potential $U$ is substantial only when the mutual distance $\mathbf{r}_{j j^{\prime}} \equiv \mathbf{r}_{j}-\mathbf{r}_{j^{\prime}}$, between particle centers is smaller than certain value $2 r_{0}$, where $r_{0}$ may be interpreted as the particle size scale. If the gas in sufficiently dilute, so that the particle radius $r_{0}$ is much smaller than the average distance $r_{\mathrm{A}}$ between the particles, the integral in Eq. (89) is of the order of $\left(2 r_{0}\right)^{3 N}$, i.e. much smaller than $r_{A}{ }^{3 N} \sim V^{N}$. Then we may expand the logarithm in Eq. (89) into the Taylor series with respect to the small second term in the square brackets, and keep just the first term of the series:

$$
\begin{equation*}
F \approx F_{\text {ideal }}-\frac{T}{V^{N}} \int d^{3} r_{1} \ldots d^{3} r_{N}\left(e^{-U / T}-1\right) \tag{3.90}
\end{equation*}
$$

Even more importantly, if the gas density is so low that the chances for 3 or more particles to come close to each other and interact (collide) are very small, pair collisions are the most important. In this case, we may recast the integral in Eq. (90) as a sum of $N(N-1) / 2 \approx N^{2} / 2$ similar terms describing such pair interactions, each of the type

$$
\begin{equation*}
V^{N-2} \int\left(e^{-U\left(\mathbf{r}_{k k^{\prime}}\right) / T}-1\right) d^{3} r_{k} d^{3} r_{k^{\prime}} \tag{3.91}
\end{equation*}
$$

It is convenient to think about $\mathbf{r}_{k k^{\prime}}$ as the radius-vector of particle $k$ in the reference frame with the origin placed at particle $k$ ' - see Fig. 6a.

Fig. 3.6. The definition of interparticle distance vectors at their (a) pair and (b) triple interactions.

Then it is clear that in Eq. (91), we may first calculate the integral over $\mathbf{r}_{k}$, while keeping the distance vector $\mathbf{r}_{k k^{\prime}}$, and hence $U\left(\mathbf{r}_{k k^{\prime}}\right)$, constant, getting one more factor $V$. Moreover, since all particle pairs are similar, in the remaining integral over $\mathbf{r}_{k k^{\prime}}$ we may drop the radius-vector index, so that Eq. (90) becomes

$$
\begin{equation*}
F=F_{\text {ideal }}-\frac{T}{V^{N}} \frac{N^{2}}{2} V^{N-1} \int\left(e^{-U(\mathbf{r}) / T}-1\right) d^{3} r=F_{\text {ideal }}+\frac{T}{V} N^{2} B(T), \tag{3.92}
\end{equation*}
$$

where $B(T)$, called the second virial coefficient, ${ }^{38}$ has an especially simple form for sphericallysymmetric interactions:

[^865]\[

$$
\begin{equation*}
B(T) \equiv \frac{1}{2} \int\left(1-e^{-U(\mathbf{r}) / T}\right) d^{3} r \rightarrow \frac{1}{2} \int_{0}^{\infty} 4 \pi r^{2} d r\left(1-e^{-U(r) / T}\right) . \tag{3.93}
\end{equation*}
$$

\]

From Eq. (92), and the second of the thermodynamic relations (1.35), we already can already tell something important about the equation of state:

$$
\begin{equation*}
P=-\left(\frac{\partial F}{\partial V}\right)_{T, N}=P_{\text {ideal }}+\frac{N^{2} T}{V^{2}} B(T)=T\left[\frac{N}{V}+B(T) \frac{N^{2}}{V^{2}}\right] \tag{3.94}
\end{equation*}
$$

We see that at a fixed gas density $n=N / V$, the pair interaction creates additional pressure, proportional to $(N / V)^{2}=n^{2}$ and a function of temperature, $B(T) T$.

Let us calculate $B(T)$ for a couple of simple models of particle interactions. Solid line in Fig. 7 shows (schematically) a typical form of the interaction potential between electrically neutral molecules with zero spontaneous electric dipole momentum.

Fig. 3.7. Pair interaction of particles. Solid line: a typical interaction potential; dashed line: its hardball model (95); dash-dotted line: the improved model (97) - schematically. The inset illustrates the idea of the hardball model.

At large distances the interaction of particles that do not their own permanent electrical dipole moment $\mathbf{p}$, is dominated by the attraction (the so-called London dispersion force) between correlated components of the spontaneously induced dipole moments, giving $U(r) \rightarrow r^{-6}$ at $r \rightarrow \infty$. ${ }^{39}$ At closer distances the potential is always repulsive $(U>0)$ and growing very fast at $r \rightarrow 0$, but its quantitative form is specific for each particular molecule. ${ }^{40}$ The crudest description of such repulsion is given by the so-called hardball model:

[^866]\[

U(r)= $$
\begin{cases}+\infty, & \text { for } 0<r<2 r_{0},  \tag{3.95}\\ 0, & \text { for } 2 r_{0}<r<\infty,\end{cases}
$$
\]

- see the dashed line and inset in Fig. 7. According to Eq. (93), in this model the second virial coefficient is temperature-independent:

$$
\begin{equation*}
B(T)=b \equiv \frac{1}{2} \int_{0}^{2 r_{0}} 4 \pi r^{2} d r=\frac{2 \pi}{3}\left(2 r_{0}\right)^{3}, \tag{3.96}
\end{equation*}
$$

(and is 4 times larger than the hardball volume $V_{0}=(4 \pi / 3) r_{0}{ }^{3}$ ), so that the equation of state (94) still gives a linear dependence of pressure on temperature.

A correction to this result may be obtained by the following approximate account of the longrange attraction (see the dash-dotted line in Fig. 7):41

$$
U(r)= \begin{cases}+\infty, & \text { for } 0<r<2 r_{0},  \tag{3.97}\\ U(r), & \text { with }|U| \ll T, \\ \text { for } 2 r_{0}<r<\infty,\end{cases}
$$

which is sometimes called the hard core model. Then Eq. (93) yields:

$$
\begin{equation*}
B(T)=b+\frac{1}{2} \int_{2 r_{0}}^{\infty} 4 \pi r^{2} d r \frac{U(r)}{T}=b-\frac{a}{T}, \quad \text { with } a \equiv 2 \pi \int_{2 r_{0}}^{\infty} r^{2} d r|U(r)| . \tag{3.98}
\end{equation*}
$$

In this model, the equation of state (94) acquires a temperature-independent term:

$$
\begin{equation*}
P=T\left[\frac{N}{V}+\left(\frac{N}{V}\right)^{2}\left(b-\frac{a}{T}\right)\right] . \tag{3.99}
\end{equation*}
$$

Still, the correction to the ideal-gas pressure is proportional to $(N / V)^{2}$, and has to be relatively small for Eq. (99) to be valid, so that the right-hand part of Eq. (99) may be considered as the sum of two leading terms in the general expansion of $P$ into the Taylor series in low density $n=N / V$ of the gas:

$$
\begin{equation*}
P=T\left[\frac{N}{V}+B(T)\left(\frac{N}{V}\right)^{2}+C(T)\left(\frac{N}{V}\right)^{3}+\ldots\right] \tag{3.100}
\end{equation*}
$$

where $C(T)$ is called the third virial coefficient. It is natural to ask how can we calculate $C(T)$ and the higher virial coefficients.

Generally, this may be done just by a careful analysis of Eq. (90), ${ }^{42}$ but I would like to use this occasion to demonstrate a different, very interesting approach, called the cluster expansion method, ${ }^{43}$

[^867]which allows to streamline such calculations. Let us apply to our system, with energy (87), the grand canonical distribution. (Just as in Sec. 2, we may argue that if the average number $\langle N\rangle$ of particles in a member of a grand canonical ensemble, with fixed $\mu$ and $T$, is much larger than 1 , the relative fluctuations of that number are small, so that all its thermodynamic properties should be similar to those when $N$ is exactly fixed - as it is assumed when applying the Gibbs distribution valid for the canonical ensemble.) For our case, the grand canonical distribution, Eq. (2.109), may be recast as
\[

$$
\begin{equation*}
\Omega=-T \ln \sum_{N=0}^{\infty} Z_{N}, \quad Z_{N} \equiv e^{\mu N / T} \sum_{m} e^{-E_{m, N} / T}, \quad E_{m, N}=\sum_{k=1}^{N} \frac{p_{k}^{2}}{2 m}+U\left(r_{1}, \ldots, r_{N}\right) \tag{3.101}
\end{equation*}
$$

\]

(Notice that here, as always in the grand canonical distribution, $N$ means a particular rather than average number of particles.) Now, let us try to forget for a second that in real systems of interest the number of particles is extremely large, and start to calculate, one by one, the first terms $Z_{N}$.

In the term with $N=0$, both contributions to $E_{m, N}$ vanish, and so does $\mu N / T$, so that $Z_{0}=1$. In the next term, with $N=1$, the interaction term vanishes, so that $E_{m, 1}$ is reduced to kinetic energy of one particle, giving

$$
\begin{equation*}
Z_{1}=e^{\mu / T} \sum_{k} \exp \left\{-\frac{p_{k}^{2}}{2 m T}\right\} \tag{3.102}
\end{equation*}
$$

Making the usual transition from summation to integration, we may write

$$
\begin{equation*}
Z_{1}=Z I_{1}, \quad \text { where } Z \equiv e^{\mu / T} \frac{g V}{(2 \pi \hbar)^{3}} \int \exp \left\{-\frac{p^{2}}{2 m T}\right\} d^{3} p, \quad \text { and } I_{1} \equiv 1 \tag{3.103}
\end{equation*}
$$

This is the same simple (Gaussian) integral as in Eq. (6), giving

$$
\begin{equation*}
Z=e^{\mu / T} \frac{g V}{(2 \pi \hbar)^{3}}(2 \pi m T)^{3 / 2}=e^{\mu / T} g V\left(\frac{m T}{2 \pi \hbar^{2}}\right)^{3 / 2} \tag{3.104}
\end{equation*}
$$

Now let us explore the next term, with $N=2$, which describes, in particular, pair interactions $U=$ $U(\mathbf{r})$, with $\mathbf{r}=\mathbf{r}-\mathbf{r}$ ". Due to the particle indistinguishability, this term needs the "correct Boltzmann counting" factor $1 / 2$ ! - cf. Eqs. (12) and (88):

$$
\begin{equation*}
Z_{2}=e^{2 \mu / T} \frac{1}{2!} \sum_{k, k^{\prime}}\left(\exp \left\{-\frac{p_{k}^{2}}{2 m T}-\frac{p_{k^{\prime}}^{2}}{2 m T}\right\} e^{-U(\mathbf{r}) / T}\right) \tag{3.105}
\end{equation*}
$$

Since $U$ is coordinate-dependent, here the transfer from summation to integration should be done more carefully than in the first term - cf. Eqs. (24) and (88):

$$
\begin{equation*}
Z_{2}=e^{2 \mu / T} \frac{1}{2!} \frac{(g V)^{2}}{(2 \pi \hbar)^{6}} \int \exp \left\{-\frac{p^{2}}{2 m T}\right\} d^{3} p \int \exp \left\{-\frac{p^{\prime 2}}{2 m T}\right\} d^{3} p^{\prime} \times \frac{1}{V} \int e^{-U(\mathbf{r}) / T} d^{3} r \tag{3.106}
\end{equation*}
$$

Comparing this expression with the definition of parameter $Z$ in Eq. (103), we get

[^868]\[

$$
\begin{equation*}
Z_{2}=\frac{Z^{2}}{2!} I_{2}, \quad \text { where } I_{2} \equiv \frac{1}{V} \int e^{-U(\mathbf{r}) / T} d^{3} r \tag{3.107}
\end{equation*}
$$

\]

Acting absolutely similarly, for the third term of the grand canonical sum we may get

$$
\begin{equation*}
Z_{3}=\frac{Z^{3}}{3!} I_{3}, \quad I_{3} \equiv \frac{1}{V^{2}} \int e^{-U\left(\mathbf{r}^{\prime}, \mathbf{r}^{\prime \prime}\right) / T} d^{3} r^{\prime} d^{3} r^{\prime \prime} \tag{3.108}
\end{equation*}
$$

where $\mathbf{r}$ ' and $\mathbf{r}$ " are the vectors characterizing the mutual positions of 3 particles - see Fig. 6b.
These result may be extended by induction to an arbitrary $N$. Plugging the expression for $Z_{N}$ into Eq. (101) and recalling that $\Omega=-P V$, we get the equation of state of the gas in the form

$$
\begin{equation*}
P=\frac{T}{V} \ln \left(1+Z I_{1}+\frac{Z^{2}}{2!} I_{2}+\frac{Z^{3}}{3!} I_{3}+\ldots\right) . \tag{3.109}
\end{equation*}
$$

As a sanity check, at $U=0$, all integrals $I_{N}$ are obviously equal to 1 , the expression under the logarithm in just the Taylor expansion of $e^{Z}$, giving $P=T Z / V$, and $\Omega=-P V=-T Z$. In this case, according to the last of Eqs. (1.62), the average number of particles of particles in the system is $\langle N\rangle=-$ $(\partial \Omega / \partial \mu)_{T, V}=Z$, because since $Z \propto \exp \{\mu / T\}, \partial Z / \partial \mu=Z / T$. Thus, we have happily recovered the equation of state of the ideal gas. ${ }^{44}$

Returning to the general case of nonvanishing interactions, let us assume that the logarithm in Eq. (109) may be also presented as a Taylor series in $Z$ :

$$
\begin{equation*}
P=\frac{T}{V} \sum_{l=1}^{\infty} \frac{J_{l}}{l!} Z^{l} \tag{3.110}
\end{equation*}
$$

(The lower limit of the sum reflects the fact that according to Eq. (109), at $Z=0, P=(T / V) \ln 1=0$.) According to Eq, (1.60), this expansion corresponds to the grand potential

$$
\begin{equation*}
\Omega=-P V=-T \sum_{l=1}^{\infty} \frac{J_{l}}{l!} Z^{l} . \tag{3.111}
\end{equation*}
$$

Again using the last of Eqs. (1.62), we get

Cluster expansion of $\langle N\rangle$

$$
\begin{equation*}
\langle N\rangle=\sum_{l=1}^{\infty} \frac{J_{l}}{(l-1)!} Z^{l} \tag{3.112}
\end{equation*}
$$

This equation, for given $\langle N\rangle$, may be used to find $Z$ and hence for the calculation of the equation of state from Eq. (110). The only remaining conceptual action item is to express coefficients $J_{l}$ via the integrals $I$ participating in expansion (109). This may be done using the well-known Taylor expansion of the logarithm function, ${ }^{45}$

[^869]\[

$$
\begin{equation*}
\ln (1+\xi)=\sum_{l=1}^{\infty}(-1)^{l+1} \frac{\xi^{l}}{n} . \tag{3.113}
\end{equation*}
$$

\]

Using it together with Eq. (109), we get a Taylor series in $Z$, starting as

$$
\begin{equation*}
P=\frac{T}{V}\left(Z+\frac{Z^{2}}{2!}\left(I_{2}-1\right)+\frac{Z^{3}}{3!}\left[\left(I_{3}-1\right)-3\left(I_{2}-1\right)\right]+\ldots\right) . \tag{3.114}
\end{equation*}
$$

Comparing this expression with Eq. (110), we see that

$$
\begin{align*}
J_{1} & =1, \\
J_{2} & =I_{2}-1=\frac{1}{V} \int\left(e^{-U(\mathbf{r}) / T}-1\right) d^{3} r  \tag{3.115}\\
J_{3} & =\left(I_{3}-1\right)-3\left(I_{2}-1\right) \\
& =\frac{1}{V^{2}} \int\left(e^{-U\left(\mathbf{r}^{\prime}, \mathbf{r}^{\prime \prime}\right) / T}-e^{-U\left(\mathbf{r}^{\prime}\right) / T}-e^{-U\left(\mathbf{r}^{\prime \prime}\right) / T}-e^{-U\left(\mathbf{r}^{\prime \prime \prime}\right) / T}+2\right) d^{3} r^{\prime} d^{3} r^{\prime \prime}
\end{align*}
$$

where $\mathbf{r}^{\prime \prime \prime} \equiv \mathbf{r}^{\prime}-\mathbf{r}^{\prime \prime}$ - see Fig. 6 b. The expression of $J_{2}$, describing the pair interactions of particles, is (within a numerical factor) equal to the second virial coefficient $B(T)$ - see Eq. (93). As a reminder, the subtraction of 1 from integral $I_{2}$ in the second of Eqs. (115) makes the contribution of each elementary 3D volume $d^{3} r$ into integral $J_{2}$ nonvanishing only if at this $\mathbf{r}$ two particles interact $(U \neq 0)$. Very similarly, in the last of Eqs. (115), the subtraction of three pair-interaction terms from ( $I_{3}-1$ ) makes the contribution from elementary 6D volume $d^{3} r^{\prime} d^{3} r$ '" into integral $J_{3}$ finite only if at that mutual location of particles all three of them interact simultaneously.

In order to illustrate the cluster expansion method at work, let us eliminate factor $Z$ from the system of equations (110) and (112), keeping (for the sake of simplicity) the terms up to $O\left(Z^{3}\right)$ only, as has been done in Eq. (114):

$$
\begin{align*}
& \frac{P V}{T}=J_{1} Z+\frac{J_{2}}{2} Z^{2}+\frac{J_{3}}{6} Z^{3}+\ldots,  \tag{3.116}\\
& \langle N\rangle=J_{1} Z+J_{2} Z^{2}+\frac{J_{3}}{2} Z^{3}+\ldots \tag{3.117}
\end{align*}
$$

Dividing these two expressions, we get a result,

$$
\begin{equation*}
\frac{P V}{\langle N\rangle T} \approx \frac{1+\left(J_{2} / 2 J_{1}\right) Z+\left(J_{3} / 6 J_{1}\right) Z^{2}}{1+\left(J_{2} / J_{1}\right) Z+\left(J_{3} / 2 J_{1}\right) Z^{2}}=1-\frac{J_{2}}{2 J_{1}} Z+\left(\frac{J_{2}^{2}}{2 J_{1}^{2}}-\frac{J_{3}}{3 J_{1}}\right) Z^{2}+\ldots . \tag{3.118}
\end{equation*}
$$

which is accurate with to terms $O\left(Z^{2}\right)$. In this approximation, we may use Eq. (117), solved for $Z$ with the same accuracy:

$$
\begin{equation*}
Z \approx\langle N\rangle-\frac{J_{2}}{J_{1}}\langle N\rangle^{2} . \tag{3.119}
\end{equation*}
$$

Plugging this expression into Eq. (118), we get expansion (100) with

$$
\begin{equation*}
B(T)=-\frac{J_{2}}{2 J_{1}} V, \quad C(T)=\left(\frac{J_{2}^{2}}{J_{1}^{2}}-\frac{J_{3}}{3 J_{1}}\right) V^{2} . \tag{3.120}
\end{equation*}
$$

The first of these relations, combined with the first two of Eqs. (115), yields, for the $2^{\text {nd }}$ virial coefficient, the same Eq. (93) that was obtained from the Gibbs distribution, while the second one allows us to calculate the $3^{\text {rd }}$ virial coefficient $C(T)$. (Let me leave the calculation of $J_{3}$ and $C(T)$, for the hardball model, for the reader's exercise.) Evidently, a more accurate expansion of Eqs. (110), (112), and (114) may be used to calculate an arbitrary virial coefficient, though starting from the $5^{\text {th }}$ coefficient, such calculations may be completed only numerically even in the simplest hardball model.

### 3.6. Exercise problems

3.1. Use the Maxwell distribution for an alternative (statistical) calculation of the mechanical work performed (per cycle) by the Maxwell-Demon heat engine discussed in Sec. 2.3.

Hint: You may assume the simplest geometry of the engine - see Fig. 2.4.
3.2.* Use the Maxwell distribution to find the damping coefficient $\eta_{P} \equiv-\partial P / \partial u$, where $P$ is pressure excerted by an ideal classical gas on a piston moving with very low velocity $u$, in the simplest geometry shown in Fig. on the right, assuming that collisions of gas
 particles with the piston are elastic.
3.3. An ideal gas of $N \gg 1$ classical particles of mass $m$ is confined in a container of volume $V$. At some moment, a very small hole, of area $A \ll V^{2 / 3}, l^{2}$ (where 1 is the mean free path of the particles) is open in its wall, allowing the particles to escape into the surrounding vacuum. Find the r.m.s. velocity of the escaped particles, assuming that the gas stays in a virtual thermal equilibrium at temperature $T$.
3.4.* For the system analyzed in the previous problem, calculate the law of reduction of the number of particles in time after opening the hole.
3.5. Derive the equation of state of the ideal classical gas from the grand canonical distribution.
3.6. ${ }^{*}$ A round cylinder of radius $R$ and length $L$, containing an ideal classical gas of $N \gg 1$ particles of mass $m$, is rotated about its symmetry axis with angular velocity $\omega$. Assuming that the gas rotates with the cylinder, and is in the thermodynamic equilibrium at temperature $T$,
(i) calculate the gas pressure distribution along its radius, and analyze it temperature dependence,
(ii) neglecting the internal degrees of freedom of the particles, calculate the total energy of the gas and its heat capacity in the high- and low-temperature limits, and
(iii) formulate the conditions of validity of your result in terms of strong inequalities between the following length scales: the quantum correlation length $r_{c} \equiv \hbar /(m T)^{1 / 2}$, the effective particle size $r_{0}$, the average distance $r_{A} \equiv\left(\pi R^{2} L / N\right)^{1 / 3}$ between the particles, and cylinder's radius $R$.

Hint: One of considerations in (iii) should be the role of particle's mean free path.
3.7. Prove that Eq. (22), derived for the change of entropy at mixing of two ideal classical gases of completely distinguishable particles (that had equal densities $N / V$ and temperatures $T$ before mixing) is also valid if particles in each of the initial volumes are identical to each other, but different from those in the counterpart sub-volume. Assume that masses of all the particles are equal.
3.8. $N$ classical, non-interacting, indistinguishable particles of mass $m$ are confined in a parabolic, spherically-symmetric 3D potential well $U(\mathbf{r})=\kappa r^{2} / 2$. Use two different approaches to calculate all major thermodynamic characteristics of the system, in thermal equilibrium at temperature $T$, including its heat capacity. What of the results should be changed if the particles are distinguishable, and how?

Hint: Suggest a reasonable replacement of the notions of volume and pressure for this system.
3.9. Calculate the basic thermodynamic characteristics, including all relevant thermodynamic potentials, specific heat, and the surface tension for an ideal, non-relativistic 2D electron gas with given areal density $n=N / A$ :
(i) at $T=0$, and
(ii) at low but nonvanishing temperatures (to the first substantial order in $T / \varepsilon_{\mathrm{F}} \ll 1$ ),
neglecting the Coulomb interaction effects.
3.10. How does the Fermi statistics of an ideal gas affect the barometric formula (28)?
3.11.* Calculate the free carrier density in a semiconductor with bandgap $\Delta \gg T$, assuming isotropic, parabolic dispersion laws of excitations in its conduction and valence bands.

Hint: In semiconductor physics, the names of conduction and valence bands are used for two adjacent allowed energy bands ${ }^{46}$ that at $T=0$, all states of the valence band are fully occupied by electrons, while the conduction band is completely empty - see Fig. on the right. Within the simple model mentioned in the assignment (which gives a good approximation for semiconductors of the $\mathrm{A}_{3} \mathrm{~B}_{5}$ group, e.g., GaAs) the energy of an electron-like excitation, with its energy in the conduction band, follows the isotropic, parabolic law (3.3), but with the origin at the band edge $\varepsilon_{C}$, and an effective mass $m_{C}$ usually smaller than the free electron mass $m_{e}$. Similarly, the parabolic dispersion law of a single "no-electron"
 excitation (called the hole) in the valence band is offset to the edge of that band, $\varepsilon_{V}$, and corresponds to a negative effective mass $\left(-m_{V}\right)$ - see Fig. on the right:

$$
\varepsilon=\left\{\begin{array}{ll}
\varepsilon_{C}+p^{2} / 2 m_{C}, & \text { for } \varepsilon \geq \varepsilon_{C}, \\
\varepsilon_{V}-p^{2} / 2 m_{V}, & \text { for } \varepsilon \leq \varepsilon_{V},
\end{array} \text { where } \varepsilon_{C}-\varepsilon_{V} \equiv \Delta\right.
$$

The excitations of both types follow the Fermi-Dirac statistics, and (within this simple model) do not interact directly.
3.12.* Using the same energy band model as in the previous problem, calculate the chemical potential and the equilibrium density of electrons and holes in an $n$-doped semiconductor, with $n_{D}$ dopants per unit volume.

[^870]Hint: $n$-doping means placing, into a semiconductor crystal, a relatively small density $n_{D}$ of different atoms, called dopants or donors, which may be easily single-ionized - in the case of donors, giving an additional electron to the semiconductor crystal, with the donor atom becoming a positive ion. As a result, the $n$-doping may be represented as a set of additional electrons with the ground state energy on an additional discrete level $\varepsilon_{D}$ slightly below the
 conduction band edge $\varepsilon_{C}-$ see Fig. on the right.
3.13. ${ }^{*}$ Generalize the solution of the previous problem to the case when the $n$-doping with dopant density $n_{D}$ is complemented with the simultaneous $p$ doping by acceptor atoms, whose energy of accepting an additional electron (and hence the negative ionization) is much less than the bandgap.

Hint: Similarly to the $n$-doping, the effect of $p$-doping may be described as an addition of a discrete electron energy level $\varepsilon_{A}$, slightly above
 the valence band edge $\varepsilon_{V}-$ see Fig. on the right.
3.14. Calculate the paramagnetic response (the Pauli paramagnetism) of a degenerate ideal gas of spin- $1 / 2$ particles to a weak external magnetic field, due to partial spin alignment with the field.
3.15.* Explore the Thomas-Fermi model ${ }^{47}$ of a heavy atom, with nuclear charge $Q=Z e \gg e$, in which the electrons are treated as a degenerate Fermi gas, interacting with each other only via their contribution to the common electrostatic potential $\phi(\mathbf{r})$. In particular, derive the ordinary differential equation obeyed by the radial distribution of the potential, and use it to estimate the effective radius of the atom.
3.16.* Use the Thomas-Fermi model, explored in the previous problem, to calculate the total binding energy of a heavy atom. Compare the result with that for the simpler model, in which the electron-electron interaction is completely ignored.
3.17. Derive the general expressions for the calculation of energy $E$ and chemical potential $\mu$ of a Fermi gas of $N$ non-interacting, indistinguishable, ultra-relativistic particles confined in volume $V .48$ Calculate $E$, and also gas pressure $P$ explicitly in the degenerate gas limit $T \rightarrow 0$. In particular, is Eq. (3.48) of the lecture notes, $P V=(2 / 3) E$, valid in this case?
3.18. Calculate the pressure of an ideal gas of ultra-relativistic, indistinguishable quantum particles, for an arbitrary temperature, as a function of the total energy $E$ of the gas, and its volume $V$. Compare the result with the corresponding relations for the electromagnetic blackbody radiation and an ideal gas of non-relativistic particles.
3.19.* Calculate the speed of sound in an ideal gas of ultra-relativistic fermions of density $n$ at negligible temperature.

[^871]3.20. Calculate the effective latent heat $\Lambda \equiv-N\left(\partial Q / \partial N_{0}\right)_{N, V}$, of the Bose-Einstein condensate evaporation, as a function of temperature $T$. Here $Q$ is the heat absorbed by the (condensate + gas) system as a whole, while $N_{0}$ is the number of particles in the condensate alone.
3.21. ${ }^{*}$ For an ideal Bose gas, calculate the law of the chemical potential disappearance at $T \rightarrow T_{c}$, and use the result to prove that the gas' specific heat $C_{V}$ is a continuous function of temperature at the critical point $T=T_{c}$.
3.22. In Chapter 1 of the lecture notes, several thermodynamic equations involving entropy have been discussed, including the first of Eqs. (1.39):
$$
S=-(\partial G / \partial T)_{P}
$$

If we combine this expression with the fundamental relation (1.56), $G=\mu N$, it looks like that for the Bose-Einstein condensate, whose chemical potential $\mu$ vanishes at temperatures below the critical value $T_{c}$, the entropy should vanish as well. On the other hand, dividing both parts of Eq. (1.19) by $d T$, and assuming that at this temperature change the volume is kept constant, we get

$$
C_{V}=T(\partial S / \partial T)_{V}
$$

If $C_{V}$ is known as a function of temperature, the last equation may be integrated to calculate $S$ :

$$
S=\int_{V=\text { const }} \frac{C_{V}(T)}{T} d T+\text { const. }
$$

For the Bose-Einstein condensate, we have calculated the specific heat to be proportional to $T^{3 / 2}$, so that the integration gives nonvanishing entropy $S \propto T^{3 / 2}$. Explain this paradox.
3.23. The standard approach to the Bose-Einstein condensation, outlined in Sec. 4, may seem to ignore the energy quantization of particles confined in volume $V$. Use the particular case of a cubic confining volume $V=a \times a \times a$ with rigid walls to analyze whether the main conclusions of the standard theory, in particular Eq. (71) for the critical temperature, are affected by such quantization.
3.24. ${ }^{*}$ An ideal 3D Bose gas of $N \gg 1$ non-interacting particles is confined at the bottom of a soft, spherically-symmetric potential well, whose potential may be approximated as $U(\mathbf{r})=m \omega^{2} r^{2} / 2$. Develop the theory of the Bose-Einstein condensation in this system; in particular, prove Eq. (3.74b) of the lecture notes, and calculate the critical temperature $T_{c}{ }^{*}$. Looking at the solution, what is the most straightforward way to detect the condensation?
3.25. Calculate the chemical potential of an ideal 2D gas of spin-0 Bose particles as a function of its areal density $n$ (the number of particles per unit area), and find out whether such a gas can condense at low temperatures.
3.26. ${ }^{*}$ Use Eqs. (115) and (120) to calculate the third virial coefficient $C(T)$ for the hardball model of particle interactions.

## Chapter 4. Phase Transitions

This chapter is a brief discussion of coexistence between different states ("phases") of collections of the same particles, and the laws of transitions between these phases. Due to the complexity of these phenomena, which involve interaction of the particles, quantitative results have been obtained only for a few very simple models, typically giving only a very approximate description of real systems.

### 4.1. First-order phase transitions

From everyday experience, say with ice, water, and water vapor, we know that one chemical substance (i.e. a set of many similar particles) may exist in several stable states - phases. A typical substance may have:
(i) a dense solid phase, in which interatomic forces keep all atoms in fixed relative positions, with just small thermal fluctuations about them;
(ii) a liquid phase, of comparable density, in which the relative distances between atoms or molecules are almost constant, but the particles are free to move about each other, and
(iii) the gas phase, typically of a much lower density, in which the molecules are virtually free to move all around the containing volume. ${ }^{1}$

Experience also tells us that at certain conditions, two phases may be in thermal and chemical equilibrium - say, ice floating on water, with temperature at the freezing point. Actually, in Sec. 3.4 we already discussed a qualitative theory of one such equilibrium, the Bose-Einstein condensate coexistence with the uncondensed "vapor" of similar particles. However, this is a rather rare case when the phase coexistence is due to the quantum nature of particles (bosons) that may not interact directly. Much more frequently, the formation of different phases, and transitions between them, is an essentially classical effect due to particle interactions.

Phase transitions are sometimes classified by their order. ${ }^{2}$ I will start my discussion with the first-order phase transitions that feature non-vanishing latent heat $\Lambda$ - the amount of heat that is necessary to give to one phase in order to turn it into another phase, even if temperature and pressure are kept constant. ${ }^{3}$ Let us discuss the most simple and popular phenomenological model of the first-order phase transition, suggested in 1873 by J. van der Waals.

In the last chapter, we have derived Eq. (3.99) for the classical gas of weakly interacting particles, which takes into account (albeit approximately) both interaction components necessary for a

[^872]realistic discussion of gas condensation - the long-range attraction of the particles and their short-range repulsion. Let us rewrite that result as follows:
\[

$$
\begin{equation*}
P+a \frac{N^{2}}{V^{2}}=\frac{N T}{V}\left(1+\frac{N b}{V}\right) \tag{4.1}
\end{equation*}
$$

\]

As we saw in Sec. 3.5, the physical meaning of constant $b$ is the effective volume of space taken by a particle pair collision. Equation (1) is quantitatively valid only if the second term in the parentheses is small, $N b \ll V$, i.e. if the total volume excluded from particles' free motion because of their collisions is much smaller than the whole volume $V$ of the system. In order to describe the condensed phase (which I will call "liquid"), ${ }^{4}$ we need to generalize this relation to the case $N b \sim V$. Since the effective volume left for particles' motion is $V-N b$, it is very natural to make the following replacement: $V \rightarrow V-N b$, in the ideal gas' equation of state. If we still keep the term $a N^{2} / V^{2}$, which describes the long-range attraction of particles, we get the van der Waals equation

$$
\begin{equation*}
P+a \frac{N^{2}}{V^{2}}=\frac{N T}{V-N b} \tag{4.2}
\end{equation*}
$$

Van der Waals equation

The advantage of this simple model is that in the rare gas limit, $N b \ll V$, it reduces back to Eq. (1). (To check this, it is sufficient to Taylor-expand the right-hand part of Eq. (2) in small parameter $N b / V \ll 1$, and retain only two leading terms corresponding to two first virial coefficients.) Let us explore properties of this model.

It is frequently convenient to discuss any equation of state in terms of its isotherms, i.e. $P(V)$ curves plotted at constant $T$. As Eq. (2) shows, in the van der Waals model such a plot depends on 4 parameters ( $a, b, N$, and $T$.) However, for its analysis it is convenient to introduce dimensionless variables: pressure $p \equiv P / P_{c}$, volume $v \equiv V / V_{c}$, and temperature $t \equiv T / T_{c}$, normalized to their so-called critical values,

$$
\begin{equation*}
P_{c} \equiv \frac{1}{27} \frac{a}{b^{2}}, \quad V_{c} \equiv 3 N b, \quad T_{c} \equiv \frac{8}{27} \frac{a}{b} . \tag{4.3}
\end{equation*}
$$

In these notations, Eq. (2) acquires the following form,

$$
\begin{equation*}
\left(p+\frac{3}{v^{2}}\right)=\frac{8 t}{(3 v-1)} \tag{4.4}
\end{equation*}
$$

so that the normalized isotherms $p(v)$ depend on only one parameter, the normalized temperature $t-$ see Fig. 1. The most important property of these plots is that the isotherms have qualitatively different shapes in two temperature regions. ${ }^{5}$ At $t>1$, i.e. $T>T_{c}$, pressure increases monotonically at gas compression (just like in an ideal gas, to which this system tends at $T \gg T_{c}$ ), i.e. $(\partial P / \partial V)_{T}<0$ at all points of the isotherm. However, below the critical temperature $T_{c}$, all isotherms feature segments with $(\partial P / \partial V)_{T}>0$. It is easy to understand that, as least in a constant pressure experiment (see, for example,

[^873]Fig. 1.5), ${ }^{6}$ these segments describe a mechanically unstable equilibrium. Indeed, if due to a random fluctuation, the volume deviated upward from the equilibrium value, the pressure would also increase, forcing the environment (say, the heavy piston in Fig. 1.5) to allow a further expansion of the system, leading to even higher pressure, etc. A similar deviation of volume downward would lead to a similar avalanche-like decrease of the volume. Such avalanche instability would develop further and further until the system has reached one of the stable branches with a negative slope $(\partial P / \partial V)_{T}$. In the range where the single-phase equilibrium state is unstable, the system as a whole may be stable only if it consists of the two phases (one with a smaller, and another with a higher density $n=N / V$ ) that are described by the two stable branches.

Fig. 4.1. The van der Waals equation plotted on the $[p, v]$ plane for several values of reduced temperature $t \equiv T / T_{c}$. Shading shows the single-phase instability range in which $(\partial P / \partial V)_{T}>0$. (The reader is invited to contemplate the physical sense and possibility of experimental observation of the negative values of pressure, predicted by the model.)

In order to understand the basic properties of this two-phase system, let us recall the general conditions of equilibrium of two thermodynamic systems, which have been discussed in Chapter 1:

$$
\begin{gather*}
T_{1}=T_{2} \text { (thermal equilibrium) },  \tag{4.5}\\
\mu_{1}=\mu_{2} \text { ("chemical" equilibrium) } \tag{4.6}
\end{gather*}
$$

the latter condition meaning that the average energy of a single ("probe") particle in both systems is the same. To those, we should add the evident condition of mechanical equilibrium,

$$
\begin{equation*}
P_{1}=P_{2}(\text { mechanical equilibrium }) \tag{4.7}
\end{equation*}
$$

that immediately follows from the balance of normal forces exerted on an inter-phase boundary.
If we discuss isotherms, Eq. (5) is fulfilled automatically, while Eq. (7) means that the effective isotherm $P(V)$ describing a two-phase system should be a horizontal line (Fig. 2): ${ }^{7}$

$$
\begin{equation*}
P=P_{0}(T) . \tag{4.8}
\end{equation*}
$$

[^874]

Fig. 4.2. Phase equilibrium at $T<T_{\mathrm{c}}$ (schematically).

Along this line, internal properties of each phase do not change; only the particle distribution is: it evolves gradually from all particles being in the liquid phase at point 1 to all particles being in the gas phase at point $2 .{ }^{8}$ In particular, according to Eq. (6), the chemical potentials $\mu$ of the phases should be equal at each point of the horizontal line (8). This fact enables us to find the line's position: it has to connect points 1 and 2 in which the chemical potentials of the phases are equal to each other.

Let us recast this condition as

$$
\begin{equation*}
\int_{1}^{2} d \mu=0, \quad \text { i.e. } \int_{1}^{2} d G=0 \tag{4.9}
\end{equation*}
$$

where the integral may be taken along the single-phase isotherm. (For this mathematical calculation, the mechanical instability of some states on this curve is not important.) Along that curve, $N=$ const and $T$ $=$ const, so that according to Eq. (1.53c), $d G=-S d T+V d P+\mu d N$, for a slow (reversible) change, $d G=$ $V d P$. Hence Eq. (9) yields

$$
\begin{equation*}
\int_{1}^{2} V d P=0 \tag{4.10}
\end{equation*}
$$

From Fig. 2, it is easy to see that geometrically this equality means that the shaded areas $A_{d}$ and $A_{u}$ should be equal, and hence Eq. (10) may be rewritten in the form of the so-called Maxwell's rule

$$
\begin{equation*}
\int_{1}^{2}\left[P-P_{0}(T)\right] d V=0 \tag{4.11}
\end{equation*}
$$

[^875]This relation is more convenient for calculations than Eq. (10) if the equation of state may be explicitly solved for $P$ - as it is the case for the van der Waals equation (2). Such calculation (left for

[^876]reader's exercise) shows that for that model, the temperature dependence of the saturated gas pressure at low $T$ is exponential,
\[

$$
\begin{equation*}
P_{0}(T)=27 P_{c} \exp \left\{-\frac{U_{0}}{T}\right\}, \quad \text { with } U_{0} \equiv \frac{a}{b}=\frac{27}{8} T_{c}, \quad \text { for } T \ll T_{c}, \tag{4.12}
\end{equation*}
$$

\]

corresponding very well to the physical picture of the rate of particle activation from the potential well of depth $U_{0 .}{ }^{9}$

The signature parameter of the first-order phase transition, the latent heat of evaporation

$$
\begin{equation*}
\Lambda \equiv \int_{1}^{2} d Q \tag{4.13}
\end{equation*}
$$

may be found by a similar integration along the single-phase isotherm. Indeed, using Eq. (1.19), $d Q=$ $T d S$, we get

$$
\begin{equation*}
\Lambda \equiv \int_{1}^{2} T d S=T\left(S_{2}-S_{1}\right) \tag{4.14}
\end{equation*}
$$

Instead of calculating entropy from the equation of state (as was done for the ideal gas in Sec. 1.4), it is easier to express the right-hand side of Eq. (14) directly via that equation. For that, let us take the full derivative of Eq. (6) over temperature, considering each value of $G=N \mu$ as a function of $P$ and $T$, and taking into account that according to Eq. (7), $P_{1}=P_{2}=P_{0}(T)$ :

$$
\begin{equation*}
\left(\frac{\partial G_{1}}{\partial T}\right)_{P}+\left(\frac{\partial G_{1}}{\partial P}\right)_{T} \frac{d P_{0}}{d T}=\left(\frac{\partial G_{2}}{\partial T}\right)_{P}+\left(\frac{\partial G_{2}}{\partial P}\right)_{T} \frac{d P_{0}}{d T} \tag{4.15}
\end{equation*}
$$

According to the first of Eqs. (1.39), the partial derivative $(\partial G / \partial T)_{P}$ is just minus entropy, while according to the second of those equations, $(\partial G / \partial P)_{T}$ is the volume. Thus Eq. (15) becomes

$$
\begin{equation*}
-S_{1}+V_{1} \frac{d P_{0}}{d T}=-S_{2}+V_{2} \frac{d P_{0}}{d T} \tag{4.16}
\end{equation*}
$$

Solving this equation for $\left(S_{2}-S_{1}\right)$, and plugging the result into Eq. (14), we get the Clapeyron-Clausius formula

ClapeyronClausius formula

$$
\begin{equation*}
\Lambda=T\left(V_{2}-V_{1}\right) \frac{d P_{0}}{d T} \tag{4.17}
\end{equation*}
$$

For the van der Waals model, this formula may be readily used for the analytical calculation of $\Lambda$ may in two limits: $T \ll T_{c}$ and $\left(T_{c}-T\right) \ll T_{c}-$ the exercise left for the reader. In the latter limit, $\Lambda \propto\left(T_{c}-\right.$ $T)^{1 / 2}$, naturally vanishing at the critical temperature.

Finally, some important properties of the van der Waals' model may be revealed more easily by looking at the set of its isochores $P=P(T)$ for $V=$ const, rather than at the isotherms. Indeed, as Eq. (2) shows, all single-phase isochores are straight lines. However, if we interrupt these lines at the points when the single phase becomes metastable, and complement them with the (very nonlinear!) dependence $P_{0}(T)$, we get the pattern (called the phase diagram) shown schematically in Fig. 3a.

[^877]

Fig. 4.3. (a) The van der Waals model's isochores, the saturated gas pressure diagram and the critical point, and (b) the phase diagram of a typical 3-phase system (schematically).

At this plot, one more meaning of the critical point $\left\{P_{c}, T_{c}\right\}$ becomes very clear. At fixed pressure $P<P_{c}$, the liquid and gaseous phases are clearly separated by the transition line $P_{0}(T)$, so if we achieve the transition just by changing temperature, and hence volume (shown with the red line in Fig. 3), we will pass through the phase coexistence stage. However, if we perform the same final transition by changing both the pressure and temperature, going around above the critical point (the blue line in Fig. 3), no definite point of transition may be observed: the substance stays in a single phase, and it is a subjective judgment of the observer in which region that phase should be called the liquid, and which region the gas. For water, the critical point corresponds to $647 \mathrm{~K}\left(374^{\circ} \mathrm{C}\right)$ and $P_{c} \approx 22.1 \mathrm{MPa}$ (i.e. $\sim 200$ bars), so that a lecture demonstration of its critical behavior would require substantial safety precautions. This is why such demonstrations are typically carried out with other fluids such as the diethyl ether, ${ }^{10}$ with much lower $T_{c}\left(194{ }^{\circ} \mathrm{C}\right)$ and $P_{c}(3.6 \mathrm{MPa})$. Though the ether is colorless and clear in both gas and liquid phases, their separation (due to gravity) is visible (due to a difference in an optical refraction coefficient) at $P<P_{c}$, but not above $P_{C} .{ }^{11}$

Thus, in the van der Waals model, two phases may coexist, though only at certain conditions ( $P$ $<P_{c}$ ). Now the natural question is whether the coexistence of more than two phases of the same substance is possible. For example, can the water ice, liquid water, and water vapor (steam) be in thermodynamic equilibrium? The answer is essentially given by Eq. (6). From thermodynamics, we know that for a uniform system (with $G=\mu N$ ), pressure and temperature completely define the chemical potential. Hence, dealing with two phases, we have to satisfy just one chemical equilibrium condition (6) for two common parameters $P$ and $T$. Evidently, this leaves us with one extra degree of freedom, so that the two-phase equilibrium is possible within a certain range of $P$ at fixed $T$ (or vice versa) - see Fig.

[^878]3a. Now, if we want three phases to be in equilibrium, we need to satisfy two equations for these variables:

$$
\begin{equation*}
\mu_{1}(P, T)=\mu_{2}(P, T)=\mu_{3}(P, T) . \tag{4.18}
\end{equation*}
$$

Typically, functions $\mu(P, T)$ are monotonic, so that Eqs. (18) have just one solution, the so-called triple point $\left\{P_{t}, T_{t}\right\}$. Of course, the triple point $\left\{P_{t}, T_{t}\right\}$ of equilibrium between three phases should not to be confused with the critical points $\left\{P_{c}, T_{c}\right\}$ of transitions between two phase pairs. Fig. 3b shows, very schematically, their relation for a typical three-phase system solid-liquid-gas. For example, water, ice, and water vapor are at equilibrium at a triple point corresponding to 0.612 KPa and (by definition, exactly) $273.16 \mathrm{~K} .{ }^{12}$ The particular importance of this particular temperature point is that by an international agreement it has been accepted for the Celsius scale definition, as $0.01^{\circ} \mathrm{C}$, so that the absolute temperature zero corresponds to exactly $-273.15^{\circ} \mathrm{C}$. More generally, triple points of pure substances (such as $\mathrm{H}_{2}, \mathrm{~N}_{2}, \mathrm{O}_{2}, \mathrm{Ar}, \mathrm{Hg}$, and $\mathrm{H}_{2} \mathrm{O}$ ) are broadly used for thermometer calibration, defining the so-called international temperature scales including the currently accepted scale ITS-90.

This result may be readily generalized to multi-component systems consisting of particles of several (say, $L$ ) sorts. ${ }^{13}$ If such a system is in a single phase, i.e. macroscopically uniform, its chemical potential may be defined by the natural generalization of Eq. (1.53c):

$$
\begin{equation*}
d G=-S d T+V d P+\sum_{l=1}^{L} \mu^{(l)} d N^{(l)} . \tag{4.19}
\end{equation*}
$$

Typically, a single phase is not a pure substance, but has certain concentrations of other components, so that $\mu^{(l)}$ may depend not only on $P$ and $T$, but also on concentrations $c^{(l)} \equiv N^{(l)} / N$ of particles of each sort. If the total number $N$ of particles is fixed, the number of independent concentrations is $(L-1)$. For the chemical equilibrium of $R$ phases, all $R$ values of $\mu_{r}^{(l)}(r=1,2, \ldots, R)$ have to be equal for particles of each sort: $\mu_{1}{ }^{(l)}=\mu_{2}{ }^{(l)}=\ldots=\mu_{R}{ }^{(l)}$, with each $\mu_{r}{ }^{(l)}$ depending on $(L-1)$ concentrations $c_{r}{ }^{(l)}$, and also on $P$ and $T$. This requirement gives $L(R-1)$ equations for $(L-1) R$ concentrations $c_{r}{ }^{(l)}$, plus two common arguments $P$ and $T$, i.e. for $[(L-1) R+2]$ independent variables. This means that the number of phases has to satisfy the limitation

Gibbs phase rule

$$
\begin{equation*}
L(R-1) \leq(L-1) R+2, \quad \text { i.e. } R \leq L+2 \tag{4.20}
\end{equation*}
$$

where the equality sign may be reached in just one point in the whole parameter space. This is the Gibbs phase rule. As a sanity check, for a single-component system, $L=1$, the rule yields $R \leq 3$ - exactly the result we have already discussed.

### 4.2. Continuous phase transitions

As Fig. 2 shows, if we fix pressure $P$ in a system with a first-order phase transition, and start changing its temperature, crossing the transition point, defined by equation $P_{0}(T)=P$, requires the insertion (or extraction) a non-vanishing latent heat $\Lambda$. Relations (14) and (17) show that the latent heat

[^879]is directly related to the a non-vanishing difference between entropies and volumes of the two phases (at the same pressure). As we know from Chapter 1, both $S$ and $V$ may be presented as first derivatives of appropriate thermodynamic potentials. This is why such transitions, involving a jump of potentials' first derivatives, are called first-order phase transitions.

On the other hand, there are phase transitions that have zero latent heat $(\Lambda=0)$ and no first derivative jumps at the transition temperature $T_{c}$, so that the temperature point is clearly marked, for example, by a jump of a second derivative of a thermodynamic potential - for example, the derivative $\partial C / \partial T$ which, according to Eq. (1.24), equals to $\partial^{2} E / \partial T^{2}$. In the initial classification by P. Ehrenfest, this was an example of a second-order phase transition. However, most features of such phase transitions are also pertinent to some systems in which the second derivatives of potentials are continuous as well. Due to this reason, I will use a more recent terminology (suggested by M. Fisher), in which all phase transitions with $\Lambda=0$ are called continuous.

Most continuous phase transitions result from particle interactions. Here are some examples:
(i) At temperatures above $\sim 120^{\circ} \mathrm{C}$, the crystal lattice of barium titanate $\left(\mathrm{BaTiO}_{3}\right)$ is cubic, with a Ba ion in the center of each Ti-cornered cube (or vice versa) - see Fig. 4a. However, as temperature is being lowered below that critical value, the sublattice of Ba ions starts moving along one of 6 sides of the $\mathrm{TiO}_{3}$ sublattice, leading to a small deformation of both lattices - which become tetragonal. This is a typical example of a structural transition, in this particular case combined with a ferroelectric transition, because (due to the positive electric charge of Ba ions) below the critical temperature the $\mathrm{BaTiO}_{3}$ crystal acquires a spontaneous electric polarization.

Fig. 4.4. Cubic lattices of
(a) $\mathrm{BaTiO}_{3}$ and (b) CuZn .
(ii) A different kind of phase transition happens, for example, in $\mathrm{Cu}_{x} \mathrm{Zn}_{1-x}$ alloys (brasses). Their crystal lattice is always cubic, but above certain critical temperature $T_{c}$ (which depends on $x$ ) any of its nodes is occupied by either a copper or a zinc atom, at random. At $T<T_{c}$, a trend towards atom alternation arises, and at low temperatures, the atoms are fully ordered, as shown in Fig. 4b for the stoichiometric case $x=0.5$. This is a good example of an order-disorder transition.
(iii) At ferromagnetic transitions (happening, e.g., in Fe at $1,388 \mathrm{~K}$ ) and antiferromagnetic transitions (e.g., in MnO at 116 K ), lowering of temperature below the critical value ${ }^{14}$ does not change atom positions substantially, but results in a partial ordering of atomic spins, eventually leading to their full ordering (Fig. 5).

[^880](iv) Finally, the Bose-Einstein condensation of atoms in liquid helium and electrons in superconducting metals and metal oxides may be also considered as continuous phase transitions. At the first glance, this contradicts to the nonvanishing latent heat given by the BEC theory outlined in Sec. 3.4. However, that theory shows that $\Lambda \rightarrow 0$ at $T \rightarrow 0$ and hence $P(T) \rightarrow 0-$ see Eq. (3.79). Hence, at zero pressure the Bose Einstein condensation of an ideal gas could may be considered a continuous phase transition. For a gas, this is just not a very interesting limit, because of the vanishing gas density. On the contrary, the Bose-Einstein condensation of strongly interacting particles in liquids or solids is not affected by pressure - at least on the ambient pressure scale, and taking $P=0$ is quite a legitimate assumption. ${ }^{15}$

Fig. 4.5. Classical images of completely ordered phases: (a) a ferromagnet, and (b) an antiferromagnet.

Besides these standard examples, some other threshold phenomena, such as formation of a coherent optical field in a laser, and even the self-excitation of oscillators with negative damping (see, e.g., CM Sec. 4.4), may be treated, at certain conditions, as continuous phase transitions. ${ }^{16}$

The general feature of all these transitions is the gradual formation, at $T<T_{\mathrm{c}}$, of certain ordering, which may be characterized by some order parameter $\eta \neq 0$. The simplest example of such order parameter is the magnetization at the ferromagnetic transitions, and this is why the continuous phase transitions are usually discussed on certain models of ferromagnetism. (I will follow this tradition, while mentioning in passing other important cases that require a substantial modification of theory.) Most of such models are defined on an infinite 3D cubic lattice (see, e.g., Fig. 5), with evident generalizations to lower dimensions. For example, the Heisenberg model of a ferromagnet is defined by the following Hamiltonian:

$$
\begin{equation*}
\hat{H}=-J \sum_{\left\{j, j^{\prime}\right\}} \hat{\boldsymbol{\sigma}}_{j} \cdot \hat{\boldsymbol{\sigma}}_{j^{\prime}}-\sum_{j} \mathbf{h} \cdot \hat{\boldsymbol{\sigma}}_{j}, \quad \text { with } \mathbf{h} \equiv \mu_{\mathrm{B}} \boldsymbol{B}, \tag{4.21}
\end{equation*}
$$

[^881]where $\hat{\boldsymbol{\sigma}}_{j}$ is the Pauli matrix operator ${ }^{17}$ acting on $j$-th spin, $\mathbf{n}_{\mathcal{B}}$ is the direction of magnetic field $\mathcal{B}$, and constant $\mu_{\mathrm{B}}$ is the Bohr magneton
\[

$$
\begin{equation*}
\mu_{\mathrm{B}}=\frac{e \hbar}{2 m_{e}} \approx 0.927 \times 10^{-23} \mathrm{~J} / \mathrm{T} \tag{4.22}
\end{equation*}
$$

\]

with ( $-e$ ) and $m_{e}$ being electron's charge and mass. The figure brackets $\{j, j ’\}$ in Eq. (21) denote the summation over the pairs of adjacent sites, so that the magnitude of constant $J$ may be interpreted as the maximum coupling energy per "bond" between two adjacent particles. At $J>0$, the coupling tries to keep spins aligned (thus minimizing the coupling energy), i.e. to implement the ferromagnetic ordering. ${ }^{18}$ The second term in Eq. (21) describes the effect of external magnetic field $\mathcal{B}$, which tries to turn all spins, with their magnetic moments, along its direction.

However, even the Heisenberg model, while being approximate, is still too complex for analysis. This is why most theoretical results have been obtained for its classical twin, the Ising model: ${ }^{19}$

$$
\begin{equation*}
E_{m}=-J \sum_{\left\{j, j^{\prime}\right\}} s_{j} s_{j^{\prime}}-h \sum_{j} s_{j} . \tag{4.23}
\end{equation*}
$$

Here $E_{m}$ are eigenvalues of energy in the magnetic field, constant $h$ mimics an external magnetic field, and $s_{j}$ are classical scalar variables that may take only two values, $s_{j}= \pm 1$. (Despite its classical character, variable $s_{j}$ modeling the real spin of an electron, is usually called "spin" for brevity, and I will follow this tradition.) Index $m$ numbers all possible combinations of variables $s_{j}$ - there are $2^{N}$ of them in a system of $N$ Ising "spins". Somewhat shockingly, even for this toy model, no analytical 3D solutions have been found, and the solution of its 2D version by L. Onsager in 1944 (see Sec. 5 below) is still considered one of the top intellectual achievements of the statistical physics. Still, Eq. (23) is very useful for the introduction of basic notions of continuous phase transitions, and methods of their analysis, and I will focus my brief discussion on this model. ${ }^{20}$

Evidently, if $T=0$ and $h=0$, the lowest value of internal energy,

$$
\begin{equation*}
E_{\min }=-J N d, \tag{4.24}
\end{equation*}
$$

where $d$ is the lattice dimensionality, is achieved in the "ferromagnetic" phase in which all spins $s_{j}$ are equal to either +1 or -1 simultaneously, so that the lattice average $\left\langle s_{j}\right\rangle= \pm 1$. On the other hand, at $J=0$ and $h=0$, the spins are independent, and in the absence of external field their signs are completely random, with the $50 \%$ probability to have either of values $\pm 1$, so that $\left\langle s_{j}\right\rangle=0$. Hence in the case of arbitrary parameters we may use the average

[^882]Ising
model's
order parameter

$$
\begin{equation*}
\eta \equiv\left\langle s_{j}\right\rangle \tag{4.25}
\end{equation*}
$$

as a good measure of spin ordering, i.e. as the order parameter. Since in a real ferromagnet, each spin carries a magnetic moment, the order parameter $\eta$ corresponds to the substance magnetization, at $\eta h>$ 0 , directed along the applied magnetic field. ${ }^{21}$

Due to the difficulty of calculating the order parameter for arbitrary temperatures, most theoretical discussions of continuous phase transitions are focused on its temperature dependence just below $T_{c}$. Both experiment and theory show that (in the absence of external field) this dependence is close to a certain power,

$$
\begin{equation*}
\eta \propto \tau^{\beta}, \text { for } \tau>0 \tag{4.26}
\end{equation*}
$$

of the small deviation from the critical temperature, which is conveniently normalized as

$$
\begin{equation*}
\tau \equiv \frac{T_{c}-T}{T_{c}} . \tag{4.27}
\end{equation*}
$$

Remarkably, most other key variables follow a similar temperature behavior, with the same critical exponent for both signs of $\tau$. In particular, the heat capacity at fixed magnetic field behaves as ${ }^{22}$

$$
\begin{equation*}
C_{h} \propto \frac{1}{|\tau|^{\alpha}} . \tag{4.28}
\end{equation*}
$$

Similarly, the (normalized) low-field susceptibility ${ }^{23}$

$$
\begin{equation*}
\left.\chi \equiv \frac{\partial \eta}{\partial h}\right|_{h=0} \propto \frac{1}{|\tau|^{\gamma}} . \tag{4.29}
\end{equation*}
$$

Two more important critical exponents, $\zeta$ and $v$, describe temperature behavior of the correlation function $\left\langle s_{j} s_{j}\right\rangle$, whose dependence on distance $r_{j j}$, between two spins may be well fitted by the following law,

$$
\begin{equation*}
\left\langle s_{j} s_{j^{\prime}}\right\rangle \propto \frac{1}{r_{i j j^{\prime}} d-2+\zeta} \exp \left\{-\frac{r_{j j^{\prime}}}{r_{c}}\right\}, \tag{4.30}
\end{equation*}
$$

with the correlation radius

$$
\begin{equation*}
r_{c} \propto \frac{1}{|\tau|^{v}} \tag{4.31}
\end{equation*}
$$

Finally, three more critical exponents, usually denoted $\varepsilon, \delta$, and $\mu$, describe the external field dependences of, respectively, $c, \eta$ and $r_{c}$ at $\tau=0$. For example, $\delta$ is defined as

[^883]\[

$$
\begin{equation*}
\eta \propto h^{1 / \delta} . \tag{4.32}
\end{equation*}
$$

\]

(Other field exponents are used less frequently, and for their discussion I have to refer the interested reader to the special literature listed above.)

The second column of Table 1 shows experimental values of the critical exponents for various 3D physical systems featuring continuous phase transitions. One can see that their values vary from system to system, leaving no hope for a universal theory that would describe them all. However, certain combination of the exponents are much more reproducible - see the bottom lines of the table.

Table 4.1. Major critical exponents of continuous phase transitions

| Exponents and <br> combinations | Experimental <br> range (3D) ${ }^{(\mathrm{a})}$ | Mean-field <br> theory | 2D Ising <br> model | 3D Ising <br> model | 3D Heisenberg <br> Model $^{(\mathrm{d})}$ |

${ }^{(a)}$ Experimental data are from the monograph by A. Patashinskii and V. Pokrovskii, cited above.
${ }^{(b)}$ Discontinuity at $\tau=0-$ see below.
${ }^{(c)}$ Instead of following Eq. (28), in this case $C_{h}$ diverges as $\ln |\tau|$.
${ }^{(d)}$ With the order parameter $\eta$ defined as $\left\langle\boldsymbol{\sigma}_{j} \cdot \mathbf{n}_{\mathcal{B}}\right\rangle$.
${ }^{(e)}$ I could not find any data on this.

Historically the first (and perhaps the most fundamental) of these universal relations was derived in 1963 by J. Essam and M. Fisher:

$$
\begin{equation*}
\alpha+2 \beta+\gamma=2 \tag{4.33}
\end{equation*}
$$

It may be proved, for example, by finding the temperature dependence such magnetic field value, $h_{\tau}$, which changes the order parameter by the amount similar to that already existing at $h=0$, due to a finite temperature deviation $\tau>0$. First, we may compare Eqs. (26) and (29), to get

$$
\begin{equation*}
h_{\tau} \propto \tau^{\beta+\gamma} . \tag{4.34}
\end{equation*}
$$

By the physical sense of $h_{\tau}$ we may expect that such field has to affect system's free energy ${ }^{24} F(T, h)$ by the amount comparable to the effect of a bare temperature change $\tau$. Ensemble-averaging the last term of Eq. (23) and using the definition (25) of the order parameter $\eta$, we see that the change of $F$ (per particle) due to the field equals $-h_{\tau} \eta$ and, according to Eq. (26), scales as $h_{\tau} \tau^{\beta} \propto \tau^{(2 \beta+\gamma)}$.

In order to estimate the thermal effect on $F$, let us first derive one more useful general thermodynamic formula. ${ }^{25}$ Dividing Eq. (1.19) by $d T$, we may present heat capacity of a system as

$$
\begin{equation*}
C_{X}=T\left(\frac{\partial S}{\partial T}\right)_{X} \tag{4.35}
\end{equation*}
$$

where $X$ is the variable maintained constant at the temperature variation. For example, in the standard " $P-V$ " thermodynamics, we may use the first of Eqs. (1.35) to recast Eq. (35) for $X=V$ as

$$
\begin{equation*}
C_{V}=T\left(\frac{\partial S}{\partial T}\right)_{V}=-T\left(\frac{\partial^{2} F}{\partial T^{2}}\right)_{V} \tag{4.36}
\end{equation*}
$$

while for $\mathrm{X}=\mathrm{P}$ it may be combined with Eq. (1.39) to get

$$
\begin{equation*}
C_{P}=T\left(\frac{\partial S}{\partial T}\right)_{P}=-T\left(\frac{\partial^{2} G}{\partial T^{2}}\right)_{P} \tag{4.37}
\end{equation*}
$$

As was just discussed, in the Ising model the role of pressure $P$ is played by the external magnetic field $h$, and of $G$ by $F$, so that the last form of Eq. (37) means that the thermal part of $F$ may be found by double integration of $\left(-C_{h} / T\right)$ over temperature. In the context of our current discussion, this means that near $T_{\mathrm{c}}$, the free energy scales as the double integral of $C_{h} \propto \tau^{-\alpha}$ over $\tau$. In the limit $\tau \ll 1$, factor $T$ may be treated as a constant; as a result, the change of $F$ due to $\tau>0$ alone scales as $\tau^{(2-\alpha)}$. Requiring this change to be proportional to the same power of $\tau$ as the field-induced part of energy, we get the Essam-Fisher relation (33).

Using similar reasoning, it is straightforward to derive a few other universal relations of critical exponents, including the Widom relation,

[^884]\[

$$
\begin{equation*}
\delta-\frac{\gamma}{\beta}=1, \tag{4.38}
\end{equation*}
$$

\]

very similar relations for other high-field exponents $\varepsilon$ and $\mu$ (which I do not have time to discuss), and the Fisher relation

$$
\begin{equation*}
v(2-\zeta)=\gamma . \tag{4.39}
\end{equation*}
$$

A slightly more complex reasoning, involving the so-called scaling hypothesis, yields the dimensionality-dependent Josephson relation

$$
\begin{equation*}
v d=2-\alpha . \tag{4.40}
\end{equation*}
$$

Table 1 shows that at least three of these relations are in a very reasonable agreement with experiment, so that we will use them as a testbed for various theoretical approaches to continuous phase transitions.

### 4.3. Landau's mean-field theory

The most general approach to analysis of the continuous phase transitions, formally not based on any particular model (though in fact implying the Ising model (23) or one of it siblings), is the meanfield theory developed in 1937 by L. Landau, on the basis of prior ideas by P.-E. Weiss - to be discussed in the next section. The main approximation of this phenomenological approach is to present the free energy change $\Delta F$ at the phase transition as an explicit function of the order parameter $\eta(25)$. Generally this function may be complicated and model-specific, but near $T_{c}, \eta$ has to tend to zero, so that the change of the relevant thermodynamic potential, the free energy,

$$
\begin{equation*}
\Delta F \equiv F(T)-F\left(T_{c}\right), \tag{4.41}
\end{equation*}
$$

may be expanded into the Taylor series in $\eta$, and only a few, most important first terms of that expansion retained. In order to keep the symmetry between two possible signs of the order parameter in the absence of external field, at $h=0$ this expansion should not include odd powers of $\eta$ :

$$
\begin{equation*}
\left.\frac{\Delta F}{V}\right|_{h=0}=A(T) \eta^{2}+\frac{1}{2} B(T) \eta^{4}+\ldots \tag{4.42}
\end{equation*}
$$

As we will see imminently, these two terms are sufficient to describe finite (non-vanishing but limited) stationary values of the order parameter; this is why Landau's theory ignores the higher terms of the Taylor expansion - which are much smaller at $\eta \rightarrow 0$.

Now let us discuss temperature dependences of coefficients $A$ and $B$. The equilibrium of the system should correspond to minimum of $F$. Equation (42) shows that, first of all, coefficient $B(T)$ has to be positive for any sign of $\tau$, to ensure the equilibrium at a finite value of $\eta^{2}$. Thus, it is reasonable to ignore the temperature dependence of $B$ near the critical temperature altogether and use approximation

$$
\begin{equation*}
B(T)=b>0 . \tag{4.43}
\end{equation*}
$$

On the other hand, as Fig. 6 shows, coefficient $A(T)$ has to change sign at $T=T_{c}$, being positive at $T>$ $T_{c}$ and negative at $T<T_{c}$, to ensure the transition from $\eta=0$ at $T>T_{c}$ to a certain non-vanishing value at $T<T_{\mathrm{c}}$. Since $A$ should be a smooth function of temperature, we may approximate it by the leading term in its Taylor expansion in $\tau$ :

$$
\begin{equation*}
A(T)=-a \tau, \quad \text { with } a>0, \tag{4.44}
\end{equation*}
$$

so that Eq. (42) becomes

$$
\begin{equation*}
\left.\frac{\Delta F}{V}\right|_{h=0}=-a \tau \eta^{2}+\frac{1}{2} b \eta^{4} . \tag{4.45}
\end{equation*}
$$

Fig. 4.6. Free energy (42) as a function of (a) $\eta$ and (b) $\eta^{2}$ in Landau's mean-field theory, for two different signs of coefficient $A(\tau)$.

The main strength of Landau's theory is the possibility of its straightforward extension to the effects of the external field and of spatial variations of the order parameter. First, averaging of the field term of Eq. (23) over all sites of the system, with the account of Eq. (25), gives an energy addition of $h \eta$ per particle, i.e. - $n h \eta$ per unit volume, where $n$ is the particle density. Second, since (according to Eq. (23) with $v>0$, see Table 1) the correlation radius diverges at $\tau \rightarrow 0$, spatial variations of the order parameter should be slow, $|\nabla \eta| \rightarrow 0$. Hence, the effects of the gradient on $\Delta F$ may be approximated by the first nonvanishing term of its expansion into the Taylor series in $(\nabla \eta)^{2}$. As a result, Eq. (45) may be generalized as

$$
\begin{equation*}
\Delta F=\int \Delta f d^{3} r, \quad \text { with } \quad \Delta f=-a \tau \eta^{2}+\frac{1}{2} b \eta^{4}-n h \eta+c(\nabla \eta)^{2} \tag{4.46}
\end{equation*}
$$

where $c$ is a factor independent of $\eta$. In order to avoid the unphysical effect of spontaneous formation of spatial variations of the order parameter, that factor has to be positive at all temperatures, and hence may be taken for constant in a small vicinity of $T_{c}$ - the only region where Eq. (46) may be expected to provide quantitatively correct results.

Relation (46) is the full version of the free energy in Landau's theory. ${ }^{26}$ Now let us find out what critical exponents are predicted by this phenomenological approach. First of all, we may find equilibrium values of the order parameter from the condition of $F$ having a minimum, $\partial F / \partial \eta=0$. At $h=$ 0 , it is easier to use the equivalent equation $\partial F / \partial\left(\eta^{2}\right)=0$, where $F$ is given by Eq. (45) - see Fig. 6b. This immediately yields

$$
\eta= \begin{cases}(a \tau / b)^{1 / 2}, & \text { for } \tau>0  \tag{4.47}\\ 0, & \text { for } \tau<0\end{cases}
$$

[^885]Comparing this result with Eq. (26), we see that in the Landau theory, $\beta=1 / 2$. Next, plugging result (47) back into Eq. (45), for the equilibrium (minimal) value of the free energy, we get

$$
\Delta f= \begin{cases}-a^{2} \tau^{2} / 2 b, & \text { for } \tau>0  \tag{4.48}\\ 0, & \text { for } \tau<0\end{cases}
$$

From here and Eq. (36), the specific heat,

$$
\frac{C_{h}}{V}= \begin{cases}a^{2} / b T_{c}, & \text { for } \tau>0  \tag{4.49}\\ 0, & \text { for } \tau<0\end{cases}
$$

has, at the critical point, a discontinuity rather than a singularity, i.e. the critical exponent $\alpha=0$.
In the presence of a uniform field, the equilibrium order parameter should be found from the condition $\partial f / \partial \eta=0$ applied to Eq. (46) with $\nabla \eta=0$, giving

$$
\begin{equation*}
\frac{\partial f}{\partial \eta} \equiv-2 a \tau \eta+2 b \eta^{3}-n h=0 . \tag{4.50}
\end{equation*}
$$

In the limit of small order parameter, $\eta \rightarrow 0$, term with $\eta^{3}$ is negligible, and Eq. (50) gives

$$
\begin{equation*}
\eta=-\frac{n h}{2 a \tau}, \tag{4.51}
\end{equation*}
$$

so that according to Eq. (29), $\gamma=1$. On the other hand, at $\tau=0$ (or at relatively high fields at other temperatures), the cubic term in Eq. (50) is much larger than the linear one, and this equation yields

$$
\begin{equation*}
\eta=\left(\frac{n h}{2 b}\right)^{1 / 3} \tag{4.52}
\end{equation*}
$$

so that comparison with Eq. (32) yields $\delta=3$.
Finally, according to Eq. (30), the last term in Eq. (46) scales as $c \eta^{2} / r_{c}{ }^{2}$. (If $r_{c} \neq \infty$, the effects of the pre-exponential factor in that equation are negligible.) As a result, the gradient term contribution is comparable ${ }^{27}$ with the two leading terms in $\Delta f$ (which, according to Eq. (47), are of the same order), if

$$
\begin{equation*}
r_{c} \approx\left(\frac{c}{a|\tau|}\right)^{1 / 2} \tag{4.53}
\end{equation*}
$$

so that according to definition (31) of the critical exponent $v$, it is equal to $1 / 2$.
The third column in Table 1 summarizes the critical exponents and their combinations in Landau's theory. It shows that these values are somewhat out of the experimental ranges, and while some of their universal relations are correct, some are not; for example, the Josephson relation would be only correct at $d=4$ (not the most realistic spatial dimensionality :-) The main reason for this

[^886]disappointing result is that describing the spin interaction with the field, the Landau mean-field theory neglects spin randomness, i.e. fluctuations. Though a quantitative theory of thermodynamic fluctuations will not be discussed until the next chapter, we can readily perform their crude estimate. Looking at Eq. (46), we see that its first term is a quadratic function of the effective "half-degree of freedom", $\eta$. Hence in accordance with the equipartition theorem (2.28) we may expect that the average square of its thermal fluctuations, within a $d$-dimensional volume with linear size $\sim r_{c}$, should be of the order of $T / 2$ (close to the critical temperature, $T_{c} / 2$ is a good approximation):
\[

$$
\begin{equation*}
a|\tau|\left\langle\widetilde{\eta}^{2}\right\rangle r_{c}^{d} \sim \frac{T_{c}}{2} . \tag{4.54}
\end{equation*}
$$

\]

In order to be negligible, the variance has to be negligible in comparison with the average $\eta^{2} \sim a \tau / b$. Plugging in the $\tau$-dependences of the operands of this relation, and values of the critical exponents in the Landau theory, for $\tau>0$ we get the so-called Levanyuk-Ginzburg criterion of its validity:

$$
\begin{equation*}
\frac{T_{c}}{2 a \tau}\left(\frac{a \tau}{c}\right)^{\frac{d}{2}} \ll \frac{a}{b} \tau \tag{4.55}
\end{equation*}
$$

We see that for any realistic dimensionality, $d<4$, at $\tau \rightarrow 0$ the order parameter fluctuations grow faster than the its average value, and hence the theory becomes invalid.

Thus the Landau mean-field theory is not a perfect approach to finding critical indices at continuous phase transitions in Ising-type systems with their next-neighbor interactions between the particles. Despite of that fact, this theory is very much valued because of the following reason. Any long-range interactions between particles increase the correlation radius $r_{c}$, and hence suppress the order parameter fluctuations. For an example, at laser self-excitation, the emerging coherent optical field couples all photon-emitting particles in the electromagnetic "cavity" (resonator). As another example, in superconductors the role of the correlation radius is played by the Cooper-pair size $\xi_{0}$, which is typically of the order of $10^{-6} \mathrm{~m}$, i.e. much larger than the average distance between the pairs ( $\sim 10^{-8} \mathrm{~m}$ ). As a result, the mean-field theory remains valid at all temperatures besides an extremely small temperature interval near $T_{c}$ - for bulk superconductors, of the order of $10^{-6} \mathrm{~K}$.

Another strength of Landau's classical mean-field theory is that it may be readily generalized for description of Bose-Einstein condensates, i.e. quantum fluids. Of those generalizations, the most famous is the Ginzburg-Landau theory of superconductivity developed in 1950, i.e. even before the "microscopic" explanation of this phenomenon by Bardeen, Cooper and Schrieffer in the 1956-57. In the Ginzburg-Landau theory, the real order parameter $\eta$ is replaced with the modulus of a complex function $\psi$, physically the wavefunction of the coherent Bose-Einstein condensate of Cooper pairs. Since each pair carry electric charge $q=-2 e,{ }^{28}$ and has zero spin, it interacts with magnetic field in a way different from that described by the Heisenberg or Ising models. Namely, as was already discussed in Sec. 3.4, the del operator $\nabla$ in Eq. (46) has to be complemented by term $-i(q / \hbar) \mathbf{A}$, where $\mathbf{A}$ is the vector-potential of the total magnetic field $\mathcal{B}=\nabla \times \mathbf{A}$, including not only the external magnetic field $\mathcal{H}$,

[^887]but also the field induced by the supercurrent itself. With the account for the well-known formula for the magnetic field energy in the external field, ${ }^{29}$ Eq. (46) is now replaced with
\[

$$
\begin{equation*}
\Delta f=-a \tau|\psi|^{2}+\frac{1}{2} b|\psi|^{4}-\frac{\hbar^{2}}{2 m}\left|\left(\nabla-i \frac{q}{\hbar} \mathbf{A}\right) \psi\right|^{2}+\frac{B^{2}}{2 \mu_{0}}-\boldsymbol{\mathcal { H }} \cdot \boldsymbol{B}, \tag{4.56}
\end{equation*}
$$

\]

where $m$ is a phenomenological coefficient rather than the actual particle mass. The variational minimization of the resulting $\Delta F$ over variables $\psi$ and $\mathbf{B}$ (which is suggested for reader's exercise ${ }^{30}$ ) yields two differential equations:

$$
\begin{align*}
& \frac{\nabla \times \boldsymbol{B}}{\mu_{0}}=q \frac{i \hbar}{2 m}\left[\psi\left(\nabla-i \frac{q}{\hbar} \mathbf{A}\right) \psi^{*}-\text { c.c. }\right],  \tag{4.57}\\
& a \tau \psi=b|\psi|^{2} \psi-\frac{\hbar^{2}}{2 m}\left(\nabla-i \frac{q}{\hbar} \mathbf{A}\right)^{2} \psi . \tag{4.58}
\end{align*}
$$

The first of these Ginzburg-Landau equations should be no big surprise for the reader, because according to the Maxwell equations, in magnetostatics the left-hand part of Eq. (57) has to be equal to the electric current density, while the right-hand part is the usual quantum-mechanical probability current density multiplied by $q$, i.e. the electric current (or rather supercurrent) density $\mathbf{j}_{s}$ of the Cooper pair condensate. (Indeed, after plugging $\psi=n^{1 / 2} \exp \{i \varphi\}$ into that expression, we come back to Eq. (3.84) which, as we already know, explains such macroscopic quantum phenomena as magnetic flux quantization and Meissner-Ochsenfeld effect.)

However, Eq. (58) is new - for this course. Since last term in its right-hand part is the standard wave-mechanics expression for the kinetic energy of a particle in the presence of magnetic field, ${ }^{31}$ if this term dominates that part of the equation, Eq. (58) is reduced to the stationary Schrödinger equation, $E \psi=\hat{H} \psi$, for the ground state of confinement-free Cooper pairs, with energy $E=a \tau$. However, in contrast to the usual (single-particle) Schrödinger equation, in which $|\psi|$ is determined by the normalization condition, the Cooper pair condensate density $n=|\psi|^{2}$ is determined by the thermodynamic balance of the condensate with the ensemble of "normal" (unpaired) electrons that play the role of the uncondensed part of Bose gas, discussed in Sec. 3.4. In Eq. (58), such balance is enforced by the first term $b|\psi|^{2} \psi$ of the right-hand part. ${ }^{32}$ As we have already seen, in the absence of magnetic field and spatial gradients, such term yields $|\psi| \propto\left(T_{c}-T\right)^{1 / 2}-$ see Eq. (47).

[^888]It is easy to see that as either the external magnetic field or the current density in a superconductor are increased, so is the last term in Eq. (58). This increase has to be matched by a corresponding decrease of $|\psi|^{2}$, i.e. of the condensate density $n$, until it is completely suppressed. This explains the well documented effect of superconductivity suppression by magnetic field and supercurrent. Moreover, together with the flux quantization discussed in Sec. 3.4, it explains the existence of the so-called Abrikosov vortices - thin tubes of magnetic field, each carrying one quantum $\Phi_{0}$ of magnetic flux - see Eq. (3.86). At the core part of the vortex, $|\psi|^{2}$ is suppressed (down to zero at its central line) by the persistent supercurrent, which circulates around the core and screens the rest of superconductor from the magnetic field carried by the vortex. The penetration of such vortices into the so-called type-II superconductors ${ }^{33}$ enables them to sustain vanishing electric resistance up to very high magnetic fields of the order of 20 T , and to be used in very compact magnets - including those used for beam bending in particle accelerators.

Moreover, generalizing Eq. (58) to the time-dependent case, just as it is done with the usual Schrödinger equation ( $E \rightarrow i \hbar \partial / \partial t$ ), one can describe other fascinating quantum macroscopic phenomena such as the Josephson effects, including the generation of oscillations with frequency $\omega_{\mathrm{J}}=(q / \hbar) \mathscr{V}$ by tunnel junctions between two superconductors, biased by dc voltage $V$. Unfortunately, time/space restrictions do not allow me to discuss these effects in any detail here, and I have to refer the reader to special literature. ${ }^{34}$ Let me only note that at $T \approx T_{c}$, and not extremely pure superconductors (in which the so-called non-local transport phenomena may be important), the Ginzburg-Landau equations are exact, and may be derived (and their parameters $T_{c}, a, b, q$, and $m$ determined) from the "microscopic" theory of superconductivity based on the initial work by Bardeen, Cooper and Schrieffer. ${ }^{35}$ Most importantly, such derivation proves that $q=-2 e$ - the electric charge of a singe Cooper pair.

### 4.4. Ising model: The Weiss' molecular-field theory

The Landau mean-field theory is phenomenological in the sense that even within the range of its validity, it tells us nothing about the value of the critical temperature $T_{c}$ and other parameters (in Eq. (46), $a, b$, and $c$ ), so that they have to be found from a particular "microscopic" model of the system under analysis. In this course, we would have time to discuss only the Ising model (23) for various dimensionalities $d$.

The most simplistic way to map the model on a mean-field theory is to assume that all spins are exactly equal, $s_{j}=\eta$, with an additional condition $\eta^{2} \leq 1$, forgetting for a minute that in the genuine Ising model, $s_{j}$ may equal only +1 or -1 . Plugging this relation into Eq. (23), we get ${ }^{36}$

[^889]\[

$$
\begin{equation*}
F=-(N J d) \eta^{2}-N h \eta \tag{4.59}
\end{equation*}
$$

\]

This energy is plotted in Fig. 7a as a function of $\eta$, for several values of $h$. The plots show that at $h=0$, the system may be in either of two stable states, with $\eta= \pm 1$, corresponding to two different directions of spins (magnetization), with equal energy. ${ }^{37}$ (Formally, the state with $\eta=0$ is also stationary, because at this point $\partial F / \partial \eta=0$, but it is unstable, because for the ferromagnetic interaction, $J$ $>0$, the second derivative $\partial^{2} F / \partial \eta^{2}$ is negative.)

Fig. 4.7. Field dependence of (a) the free energy profile and (b) order parameter (i.e. magnetization) in the crudest mean-field approach to the Ising model.

As the external field is increased, it tilts the potential profile, and finally at a critical field,

$$
\begin{equation*}
h_{c} \equiv 2 J d, \tag{4.60}
\end{equation*}
$$

the state with $\eta=-1$ becomes unstable, leading to system's jump into the only remaining state with opposite magnetization, $\eta=+1$. Application of the similar external field of the opposite polarity leads to the similar switching back to $\eta=-1$, so that the full field dependence of $\eta$ follows the hysteretic pattern shown in Fig. 7b. Such a pattern is the most visible experimental feature of actual ferromagnetic materials, with the coercive magnetic field $\mathbb{Z}_{c}$ (modeled with $h_{c}$ ) of the order of $10^{3} \mathrm{~A} / \mathrm{m}$, and the saturated magnetization (modeled with $\eta= \pm 1$ ) corresponding to much higher fields $B$ - of the order of a few tesla. The most important property of these materials, also called permanent magnets, is their stability, i.e. the ability to retain the history-determined direction of magnetization in the absence of external field, for a very long time. In particular, this property is the basis of all magnetic systems for data recording, including the ubiquitous hard disk drives with their incredible information density currently approaching 1 Terabit per square inch. ${ }^{38}$

So, this simplest mean-field theory gives a crude description of the ferromagnetic ordering, but grossly overestimates the stability of these states with respect to thermal fluctuations. Indeed, in this

[^890]theory, there is no thermally-induced randomness at all, until $T$ becomes comparable with the height of the energy barrier separating two stable states,
\[

$$
\begin{equation*}
\Delta F \equiv F(\eta=0)-F(\eta= \pm 1)=N J d \tag{4.61}
\end{equation*}
$$

\]

which is proportional to the number of particles. At $N \rightarrow \infty$, this value diverges, and in this sense the critical temperature is infinite, while numerical experiments and more refined theories of the Ising model show that actually the ferromagnetic phase is suppressed at $T_{c} \sim J d-$ see below. ${ }^{39}$

The mean-field approach may be dramatically improved by even an approximate account for thermally-induced randomness. In this approach, suggested in 1908 by P.-E. Weiss under the name of molecular-field theory, ${ }^{40}$ random deviations of individual spin values from the lattice average,

$$
\begin{equation*}
\widetilde{s}_{j} \equiv s_{j}-\eta, \quad \eta \equiv\left\langle s_{j}\right\rangle, \tag{4.62}
\end{equation*}
$$

are allowed, but considered small, $\left|\widetilde{s}_{j}\right| \ll \eta$. This assumption allows us, after plugging expression $s_{j}=\eta+\widetilde{s}_{j}$ into the first term of the right-hand part of Eq. (23),

$$
\begin{equation*}
E_{m}=-J \sum_{\left\{j, j^{\prime}\right\}}\left(\eta+\widetilde{s}_{j}\right)\left(\eta+\widetilde{s}_{j^{\prime}}\right)-h \sum_{j} s_{j}, \tag{4.63}
\end{equation*}
$$

ignore the term proportional to $\widetilde{s}_{j} \widetilde{s}_{j^{\prime}}$. Making replacement (62) in the terms proportional to $\widetilde{s}_{j}$, we get

$$
\begin{equation*}
E_{m} \rightarrow E_{m}^{\prime} \equiv(N J d) \eta^{2}-h_{\mathrm{ef}} \sum_{j} s_{j} \tag{4.64}
\end{equation*}
$$

where $h_{\text {ef }}$ is defined as the sum

$$
\begin{equation*}
h_{\mathrm{ef}} \equiv h+(2 J d) \eta . \tag{4.65}
\end{equation*}
$$

The physical interpretation of $h_{\text {ef }}$ is the effective external field, which (besides the real external field $h$ ) takes into account the effect that would be exerted on spin $s_{j}$ by its $2 d$ next neighbors, if they all had unperturbed (but possibly fractional) spins $s_{j^{\prime}}=\eta$. Such an addition to external field,

$$
\begin{equation*}
h_{\mathrm{mol}} \equiv h_{\mathrm{ef}}-h=(2 J d) \eta, \tag{4.66}
\end{equation*}
$$

is called the molecular field - giving its name to the theory.
From the point of view of statistical physics, at fixed parameters of the system (including the order parameter $\eta$ ), the first term in the right-hand part of Eq. (64) is merely a constant energy offset, and $h_{\text {ef }}$ is just another constant, so that

$$
E_{m}^{\prime}=\text { const }+\sum_{j} E_{j}, \quad E_{j}=-h_{\mathrm{ef}} s_{j}= \begin{cases}-h_{\mathrm{ef}}, & \text { for } s_{j}=+1,  \tag{4.67}\\ +h_{\mathrm{ef}}, & \text { for } s_{j}=-1 .\end{cases}
$$

[^891]Such separability of energies means that in the Weiss approximation the spin fluctuations are independent, and their statistics may be examined individually, using energy spectrum $E_{j}$. But this is exactly the two-level system which was the subject of three exercise problems in Chapter 2. Actually, its statistics is so simple that it is easier to redo this fundamental problem starting from scratch, rather than to use the results of those exercises (which would require changing notation). Indeed, according to the Gibbs distribution (2.58)-(2.59), the equilibrium probabilities of states $s_{j}= \pm 1$ may be found as

$$
\begin{equation*}
W_{ \pm}=\frac{1}{Z} e^{ \pm h_{\mathrm{ef}} / T}, \quad Z=\exp \left\{+\frac{h_{\mathrm{ef}}}{T}\right\}+\exp \left\{-\frac{h_{\mathrm{ef}}}{T}\right\}=2 \cosh \frac{h_{\mathrm{ef}}}{T} . \tag{4.68}
\end{equation*}
$$

From here, we may readily calculate $F=-T \ln Z$ and other thermodynamic variables, but let us immediately use Eq. (68) to calculate the statistical average of $s_{j}$, i.e. the order parameter:

$$
\begin{equation*}
\eta \equiv\left\langle s_{j}\right\rangle=(+1) W_{+}+(-1) W_{-}=\frac{e^{+h_{\mathrm{ef}} / T}-e^{-h_{\mathrm{ef}} / T}}{2 \cosh \left(h_{\mathrm{ef}} / T\right)}=\tanh \frac{h_{\mathrm{ef}}}{T} \tag{4.69}
\end{equation*}
$$

Now comes the main trick of the Weiss' approach: plugging this result back into Eq. (65), we may write the condition of self-consistency of the molecular field theory:

$$
\begin{equation*}
h_{\mathrm{ef}}-h=2 J d \tanh \frac{h_{\mathrm{ef}}}{T} . \tag{4.70}
\end{equation*}
$$

This is a transcendental equation that evades an explicit analytical solution, but its properties may be readily understood by plotting its both parts as functions of their argument, so that the stationary state(s) of the system corresponds to the intersection point(s) of these plots.

First of all, let us explore the field-free case $(h=0)$, when $h_{\text {ef }}=h_{\text {mol }} \equiv 2 d J \eta$, so that Eq. (70) is reduced to

$$
\begin{equation*}
\eta=\tanh \left(\frac{2 J d}{T} \eta\right) \tag{4.71}
\end{equation*}
$$

giving one of the patterns sketched in Fig. 8, depending on the dimensionless parameter 2Jd/T.

Fig. 4.8. Ferromagnetic phase transition in Weiss' molecular-field theory: two sides of Eq. (71) plotted as functions of $\eta$ for 3 temperatures: above $T_{c}$ (red), below $T_{c}$ (blue) and equal to $T_{c}$ (green).

If this parameter is small, the right-hand part of Eq. (71) grows slowly with $\eta$ (red line in Fig. 8), and there is only one intersection point with the left-hand part plot, at $\eta=0$. This means that the spin system features no spontaneous magnetization - the so-called paramagnetic phase. However, if parameter $2 J d / T$ exceeds 1 , i.e. $T$ is decreased below the following critical value,

$$
\begin{equation*}
T_{c}=2 J d \tag{4.72}
\end{equation*}
$$

the right-hand part grows, at small $\eta$, faster than the left-hand part, so that their plots intersect it in 3 points: $\eta=0$ and $\eta= \pm \eta_{0}$. It is almost evident that the former stationary point is unstable while two latter points are stable. ${ }^{41}$ Thus, below $T_{c}$ the system is in the ferromagnetic phase, with one of two possible directions of spontaneous magnetization, so that the critical (Curie) temperature, given by Eq. (72), marks the transition between the paramagnetic and ferromagnetic phases. (Since the stable minimum value of energy $G$ is a continuous function of temperature at $T=T_{c}$, this is the continuous phase transition.)

Now let us repeat the same graphics to examine how each of these phases responds to external magnetic field $h \neq 0$. According to Eq. (70), the effect of $h$ is just a shift of the straight line plot of its left-hand part - see Fig. 9.

(b)

Fig. 4.9 External field effect on:
(a) a paramagnet ( $T>T_{\mathrm{c}}$ ), and
(b) a ferromagnet ( $T<T_{\mathrm{c}}$ ).

In the paramagnetic case (Fig. 9a) the resulting dependence $h_{\text {ef }}(h)$ is evidently continuous, but the coupling effect $(J>0)$ makes it more steep than it would be without spin interaction. This effect may be characterized by the low-field susceptibility defined by Eq. (29). To calculate it, let us notice that for small $h$, and hence $h_{\text {ef }}$, function tanh in Eq. (70) is approximately equal to argument, so that Eq. (70) becomes

$$
\begin{equation*}
h_{\mathrm{ef}}-h=\frac{2 J d}{T} h_{\mathrm{ef}} . \tag{4.73}
\end{equation*}
$$

Solving this equation for $h_{\text {ef }}$, and then using Eq. (72), we get

$$
\begin{equation*}
h_{\mathrm{ef}}=\frac{h}{1-2 J d / T}=\frac{h}{1-T_{c} / T} . \tag{4.74}
\end{equation*}
$$

Recalling Eq. (66), we can rewrite this result for the order parameter,

$$
\begin{equation*}
\eta=\frac{h_{\mathrm{ef}}-h}{T_{c}}=\frac{h}{T-T_{c}}, \tag{4.75}
\end{equation*}
$$

meaning that the low-field susceptibility

[^892]\[

$$
\begin{equation*}
\left.\chi \equiv \frac{\partial \eta}{\partial h}\right|_{h=0}=\frac{1}{T-T_{c}}, \quad \text { for } T>T_{c} \tag{4.76}
\end{equation*}
$$

\]

## Curie- <br> Weiss <br> law

This is the famous Curie-Weiss law, which shows that the susceptibility diverges at the approach to the Curie temperature $T_{c}$.

In the ferromagnetic case, the graphic solution (Fig. 9b) of Eq. (70) gives a qualitatively different result. A field increase leads, depending on the spontaneous magnetization, either the further saturation of $h_{\text {mol }}$ (with the order parameter $\eta$ gradually approaching 1 ), or, if the initial $\eta$ was negative, a jump to positive $\eta$ at some critical (coercive) field $h_{c}$. In contrast with the crude mean-field approximation (59), at $T>0$ the coercive field is smaller than that given by Eq. (60), and the magnetization saturation is gradual, in a good (semi-qualitative) accordance with experiment.

To summarize, the Weiss' molecular-field theory gives a more realistic description of the ferromagnetic and paramagnetic phases in the Ising model, and a very simple prediction (72) of the temperature of the phase transition between them, for an arbitrary dimensionality $d$ of the cubic lattice. It also allows finding all other parameters of the mean-field theory for that model - an easy exercise left for the reader.

### 4.5. Ising model: Exact and numerical results

In order to evaluate the main prediction (72) of the Weiss theory, let us now discuss the exact (analytical) and quasi-exact (numerical) results obtained for the Ising model, going from the lowest dimensionality $d=0$ to its higher values.

Zero dimensionality means that a spin has no nearest neighbors at all, so that the first term of Eq. (23) vanishes. Hence Eq. (64), with $h_{\text {ef }}=h$, is exact, and so is its solution (69). Now we can repeat the calculations that have led us to Eq. (76), with $J=0$, i.e. $T_{c}=0$, and reduce this result to the so-called Curie law:

$$
\begin{equation*}
\chi=\frac{1}{T} . \tag{4.77}
\end{equation*}
$$

It shows that $T_{\mathrm{c}}=0$, i.e. the system is paramagnetic at any temperature. One may say that for this case the Weiss molecular-field theory is exact - or in some sense trivial, because it provides an exact, fully quantum-mechanical treatment of spin- $1 / 2$ particles at negligible interaction. Experimentally, the Curie law is approximately valid for many so-called paramagnetic materials, i.e. 3D systems with a weak interaction between particle spins.

The case $d=1$ is more complex, but has an exact analytical solution. Probably the simplest way to obtain it is to use the so-called transfer matrix approach. ${ }^{42}$ For this, first of all, we may argue that properties of a 1D system of $N \gg 1$ spins (say, put at equal distances on a straight line) should not change noticeably if we bend that line gently into a closed loop (Fig. 10), i.e. assume that spins $s_{1}$ and $s_{N}$ form one more pair of next neighbors, giving one more contribution, $-J s_{1} s_{\mathrm{N}}$, to energy (23):

$$
\begin{equation*}
E_{m}=-\left(J s_{1} s_{2}+J s_{2} s_{3}+\ldots+J s_{N} s_{1}\right)-\left(h s_{1}+h s_{2}+\ldots+h s_{N}\right) . \tag{4.78}
\end{equation*}
$$

[^893]Let us regroup terms of this sum in the following way:

$$
\begin{equation*}
E_{m}=-\left[\left(\frac{h}{2} s_{1}+J s_{1} s_{2}+\frac{h}{2} s_{2}\right)+\left(\frac{h}{2} s_{2}+J s_{2} s_{3}+\frac{h}{2} s_{3}\right)+\ldots+\left(\frac{h}{2} s_{N}+J s_{N} s_{1}+\frac{h}{2} s_{1}\right)\right], \tag{4.79}
\end{equation*}
$$

so that the group in each parentheses depends only on the state of two adjacent spins. The corresponding statistical sum,

$$
\begin{equation*}
Z=\sum_{\substack{s_{j}= \pm 1 \\ j=1,2 \ldots N}} \exp \left\{h \frac{s_{1}}{2 T}+J \frac{s_{1} s_{2}}{T}+h \frac{s_{2}}{2 T}\right\} \exp \left\{h \frac{s_{2}}{2 T}+J \frac{s_{2} s_{3}}{T}+h \frac{s_{3}}{2 T}\right\} \ldots \exp \left\{h \frac{s_{N}}{2 T}+J \frac{s_{N} s_{1}}{T}+h \frac{s_{1}}{2 T}\right\}, \tag{4.80}
\end{equation*}
$$

has $2^{N}$ terms, each corresponding to a certain combination of signs of $N$ spins. Each operand of the product under the sum may take 4 values for 4 different combinations of its two arguments:

$$
\exp \left\{h \frac{s_{j}}{2 T}+J \frac{s_{j} s_{j+1}}{T}+h \frac{s_{j+1}}{2 T}\right\}=\left\{\begin{align*}
\exp \{(J+h) / T\}, & \text { for } s_{j}=s_{j+1}=+1  \tag{4.81}\\
\exp \{(J-h) / T\}, & \text { for } s_{j}=s_{j+1}=-1 \\
\exp \{-J / T\}, & \text { for } s_{j}=-s_{j+1}
\end{align*}\right.
$$

Fig. 4.10. 1D Ising system on a circular loop.

These values do not depend on index $j,{ }^{43}$ and may be presented as elements of the so-called transfer matrix

$$
M=\left(\begin{array}{cc}
\exp \{(J+h) / T\} & \exp \{-J / T\}  \tag{4.82}\\
\exp \{-J / T\} & \exp \{(J-h) / T\}
\end{array}\right),
$$

and the whole statistical sum may be recast as a product:

$$
\begin{equation*}
Z=\sum_{\substack{s_{j} \pm \pm 1 \\ j=1, \ldots, \ldots N}} M_{S_{1} s_{2}} M_{S_{2} s_{3}} \ldots M_{S_{N} s_{1}} . \tag{4.83}
\end{equation*}
$$

According to the basic rule of matrix multiplication, this sum is just

[^894]\[

$$
\begin{equation*}
\mathrm{Z}=\operatorname{Tr}\left(\mathrm{M}^{N}\right) \tag{4.84}
\end{equation*}
$$

\]

Matrix algebra tells us that this trace may be presented just as

$$
\begin{equation*}
Z=\lambda_{+}^{N}+\lambda_{-}^{N} \tag{4.85}
\end{equation*}
$$

where $\lambda_{ \pm}$are the eigenvalues of the transfer matrix M , i.e. the roots of its characteristic equation,

$$
\left|\begin{array}{cc}
\exp \{(J+h) / T\}-\lambda & \exp \{-J / T\}  \tag{4.86}\\
\exp \{-J / T\} & \exp \{(J-h) / T\}-\lambda
\end{array}\right|=0 .
$$

A straightforward calculation yields

$$
\begin{equation*}
\lambda_{ \pm}=\exp \left\{\frac{J}{T}\right\}\left[\cosh \frac{h}{T} \pm\left(\sinh ^{2} \frac{h}{T}+\exp \left\{-\frac{4 J}{T}\right\}\right)^{1 / 2}\right] \tag{4.87}
\end{equation*}
$$

Now the last simplification comes from condition $N \gg 1$ - which we needed anyway, to make the loop model equivalent to an in infinite 1D system. In this limit, even a small difference of exponents, $\lambda_{+}>\lambda_{\text {-, makes the second term in Eq. (85) negligible, so that we finally get }}$

$$
\begin{equation*}
Z=\lambda_{+}^{N}=\exp \left\{\frac{N J}{T}\right\}\left[\cosh \frac{h}{T}+\left(\sinh ^{2} \frac{h}{T}+\exp \left\{-\frac{4 J}{T}\right\}\right)^{1 / 2}\right]^{N} . \tag{4.88}
\end{equation*}
$$

From here, we can find the free energy per particle

$$
\begin{equation*}
\frac{F}{N}=\frac{T}{N} \ln \frac{1}{Z}=-J-T \ln \left[\cosh \frac{h}{T}+\left(\sinh ^{2} \frac{h}{T}+\exp \left\{-\frac{4 J}{T}\right\}\right)^{1 / 2}\right] \tag{4.89}
\end{equation*}
$$

and hence can calculate all variables of interest from thermodynamic relations. In particular, the equilibrium value of the order parameter may be found from the last of Eqs. (1.39), with the replacements discussed above: $G \rightarrow F, P \rightarrow-h$, and hence $V=(\partial G / \partial P)_{T} \rightarrow-(\partial F / \partial h)_{T}=N \eta$. For low fields ( $h \ll T$ ), this formula yields

$$
\begin{equation*}
\eta=\frac{h}{T} \exp \left\{\frac{2 J}{T}\right\} \tag{4.90}
\end{equation*}
$$

This result describes linear magnetization with the following low-field susceptibility,

$$
\begin{equation*}
\left.\chi \equiv \frac{\partial \eta}{\partial h}\right|_{h=0}=\frac{1}{T} \exp \left\{\frac{2 J}{T}\right\} \tag{4.91}
\end{equation*}
$$

and means that the 1D Ising model does not exhibit a phase transition, i.e., $T_{c}=0$. However, its susceptibility grows, at $T \rightarrow 0$, much faster than the Curie law (77). This gives us a hint that at low temperatures the system is "virtually ferromagnetic", with has the ferromagnetic order with some rare violations. (In physics, such violations are called low-temperature excitations.) This perception may be confirmed by the following approximate calculation.

It is almost evident that the lowest-energy excitation of a 1 D ferromagnet at $h=0$ is the reversal of signs of all spins in one of its parts (Fig. 11). Indeed, since such excitation (called the Bloch wall)
involves the change of sign of just one product $s_{j} s_{j}$, according to Eq. (23), its energy $E_{W}$ (defined as the difference between values of $E_{m}$ with and without the excitation) equals $2 J$, regardless of the wall position. Since in a ferromagnet, parameter $J$ is positive, $E_{W}>0$. If the system tried to minimize its potential energy, having any wall in the system would be energy-disadvantageous. However, thermodynamics tells us that at finite $T$, system's equilibrium corresponds to the minimum of free energy rather than just energy. ${ }^{44}$ Hence, we have to calculate Bloch wall's contribution $F_{W}$ to the free energy. Since in a linear chain of $N \gg 1$ spins, the wall can take $(N-1) \approx N$ positions with the same energy $E_{W}$, we may claim that the entropy $S_{W}$ associated with an excitation of this type is $\ln N$, and its according to definition (1.33) of the free energy,

$$
\begin{equation*}
F_{W}=E_{W}-T S_{W} \approx 2 J-T \ln N . \tag{4.92}
\end{equation*}
$$

Fig. 4.11. A Bloch wall in a 1D Ising system.

This result tells us that in the limit $N \rightarrow \infty$, and at $T \neq 0$, walls are always free-energy-beneficial, thus explaining the absence of the perfect ferromagnetic order in the 1D Ising system. Note, however, that since the logarithm grows extremely slowly at large values of its argument, one may argue that a large but finite 1D system would still feature a quasi-critical temperature

$$
\begin{equation*}
" T_{c} "=\frac{2 J}{\ln N}, \tag{4.93}
\end{equation*}
$$

below which it would feature a virtually complete ferromagnetic order. (The exponentially large susceptibility (91) is a manifestation of this fact.)

Now let us apply a similar approach to estimate $T_{c}$ of a 2D Ising model. Here the Bloch wall is a line of certain length $L$ - see Fig. 12. (For this example, counting from the left to the right, $L=2+1+4$ $+2+3=12$ lattice periods.)

Fig. 4.12. A Bloch wall in a 2D Ising system.

Evidently, the additional energy associated with such wall is $E_{\mathrm{W}}=2 J L$, while wall's entropy may be estimated approximately using the following reasoning. Let the wall be formed by the path of a "Manhattan pedestrian" traveling through the lattice between its nodes. At each junction, the pedestrian

[^895]may select 3 choices of 4 directions (except the one that leads backward), so that there are approximately $3^{(L-1)}$ options for a walk starting from a certain point, i.e. approximately $M \sim 2(N-$ 1) ${ }^{1 / 2} \times 3^{L} \approx 2 N^{1 / 2} 3^{L}$ different walks starting from two sides of a square-shaped lattice (of linear size $N^{1 / 2}$ ). Again calculating $S_{W}$ as $\ln M$, we get
\[

$$
\begin{equation*}
F_{W}=E_{W}-T S_{W} \approx 2 J L-T \ln \left(2 N^{1 / 2} \times 3^{L}\right)=L(2 J-T \ln 3)-T \ln \left(2 N^{1 / 2}\right) . \tag{4.94}
\end{equation*}
$$

\]

Since $L$ scales as $N^{1 / 2}$ or higher, at $N \rightarrow \infty$ the last term is negligible, and we see that sign of $\partial F_{W} / \partial L$ depends on whether the temperature is higher or lower than the following critical value

$$
\begin{equation*}
T_{c}=\frac{2}{\ln 3} J \approx 1.82 \mathrm{~J} . \tag{4.95}
\end{equation*}
$$

At $T<T_{c}$, the Free energy minimum corresponds to $L \rightarrow 0$, i.e. Bloch walls are free-energy-beneficial, and the system is in the ferromagnetic phase.

So, for $d=2$ the estimates predict a finite critical temperature of the same order as the Weiss' theory $\left(T_{\mathrm{c}}=4 J\right)$. The major approximation in the calculation leading to Eq. (95) is disregarding possible self-crossing of the "Manhattan walk". An accurate counting of such self-crossings is rather difficult. It had been carried out in 1944 by L. Onsager; since then his calculations have been redone in several easier ways, but even they are rather cumbersome, and I will not have time to discuss then in detail. ${ }^{45}$ The final result, however, is surprisingly simple:

$$
\begin{equation*}
\tanh \frac{J}{T_{c}}=\sqrt{2}-1, \quad \text { giving } T_{c} \approx 2.269 \mathrm{~J} \tag{4.96}
\end{equation*}
$$

Onsager's result
i.e. showing that the simple estimate (95) is only $\sim 20 \%$ off the mark.

The Onsager solution, as well as all alternative solutions of the problem that were found later, are so "artificial" (2D-specific) that they do not give a clear clue to their generalization to other (higher) dimensions. As a result, the 3D Ising problem is still unsolved analytically. Nevertheless, we do know $T_{c}$ for that case with an extremely high precision - at least to the $6^{\text {th }}$ decimal place. This has been achieved by numerical methods; they deserve a thorough discussion, are applicable to other problems as well. Conceptually, this task is rather simple: just compute, to the desired precision, the statistical sum of system (23):

$$
\begin{equation*}
Z=\sum_{\substack{s_{j}= \pm 1 \\ j=1,2, \ldots, N}} \exp \left\{\frac{J}{T} \sum_{\left\{j, j^{\prime}\right\}} s_{j} s_{j^{\prime}}+\frac{h}{T} \sum_{j} s_{j}\right\} . \tag{4.97}
\end{equation*}
$$

As soon as this has been done for a sufficient number of values of dimensionless parameters $J / T$ and $h / T$, everything else is easy; in particular, we can compute the dimensionless function

$$
\begin{equation*}
F / T=-\ln Z \tag{4.98}
\end{equation*}
$$

and then find the ratio $J / T_{c}$ as the smallest value of parameter $J / T$, at that $F / T$ (as a function of ratio $h / T$ ) has a minimum at zero field. However, for any system of a reasonable size $N$, the "exact" computation of the statistical sum (97) is impossible, because it contains to many terms for any supercomputer to

[^896]handle. For example, let us take a relatively small 3D lattice with $N=10 \times 10 \times 10=10^{3}$ spins, which still feature substantial boundary effects even using the periodic boundary conditions (similar to the BornKarman conditions in the wave theory), so that its phase transition is smeared about $T_{c}$ by $\sim 1 \%$. Still, even for that crude model, $Z$ would include $2^{1,000}=\left(2^{10}\right)^{100} \approx\left(10^{3}\right)^{100}=10^{300}$ terms. Let us suppose we are using a prospective exaflops-scale computer performing $10^{18}$ floating-point operations per second, i.e. $\sim 10^{26}$ such operations per year. With those resources, the computation of just one statistical sum would require $\sim 10^{(300-26)}=10^{274}$ years. To call such number "astronomic" would be a strong understatement. (As a reminder, the age of our Universe is believed to be close to $1.3 \times 10^{10}$ years -a very humble number in comparison.)

This situation may be improved dramatically by noticing that any statistical sum,

$$
\begin{equation*}
Z=\sum_{m} \exp \left\{-\frac{E_{m}}{T}\right\} \tag{4.99}
\end{equation*}
$$

is dominated by terms with lower values of $E_{m}$. In order to find those lowest-energy states, we may use the following powerful approach (belonging to a broad class of Monte-Carlo techniques), which essentially mimics one (randomly selected) path of system's evolution in time. One could argue that for that we would need to know the exact laws of evolution of statistical systems, ${ }^{46}$ that may differ from one system to another, even if their energy spectra $E_{m}$ are the same. This is true, but since the equilibrium value of $Z$ should be independent of these details, it may be evaluated using any kinetic model, provided that it satisfies certain general rules. In order to reveal these rules, let us start from a system with just two states, $E_{m}$ and $E_{m}=E_{m}+\Delta$ - see Fig. 13.

Fig. 4.13. Deriving the detailed balance equation.

In the absence of quantum coherence between the states (see Sec. 2.1), equations for time evolution of the corresponding probabilities $W_{m}$ and $W_{m}$, should depend only on the probabilities (plus certain constant coefficients). Moreover, since equations of quantum mechanics are linear, the equations of probability evolution should be also linear. Hence, it is natural to expect them to have the following form,

$$
\begin{equation*}
\frac{d W_{m}}{d t}=W_{m^{\prime}} \Gamma_{\downarrow}-W_{m} \Gamma_{\uparrow}, \quad \frac{d W_{m^{\prime}}}{d t}=W_{m} \Gamma_{\uparrow}-W_{m^{\prime}} \Gamma_{\downarrow} \tag{4.100}
\end{equation*}
$$

where constant coefficients $\Gamma \uparrow$ and $\Gamma \downarrow$ have the physical sense of rates of the corresponding transitions see Fig. 13. According to the master equations (100) the rates have simple meaning: for example, $\Gamma \uparrow d t$ is the probability of the system's transition into state $m^{\prime}$ during an infinitesimal time interval $d t$, provided that in the beginning of that interval it was in state $m$ with full certainty: $W_{m}=1, W_{m^{\prime}}=0 .{ }^{47}$

[^897]Since for the system with just two energy levels, the time derivatives of the probabilities are equal and opposite, Eqs. (100) describe an (irreversible) redistribution of the probabilities while keeping their sum $W=W_{m}+W_{m}$, constant. At $t \rightarrow \infty, d / d t \rightarrow 0$, and the probabilities settle to their stationary values related as

$$
\begin{equation*}
\frac{W_{m^{\prime}}}{W_{m}}=\frac{\Gamma_{\uparrow}}{\Gamma_{\downarrow}} . \tag{4.101}
\end{equation*}
$$

Now let us require that these stationary values obey the Gibbs distribution (2.58); then

$$
\begin{equation*}
\frac{W_{m^{\prime}}}{W_{m}}=\exp \left\{\frac{E_{m}-E_{m^{\prime}}}{T}\right\}=\exp \left\{-\frac{\Delta}{T}\right\}<1 . \tag{4.102}
\end{equation*}
$$

Comparing these two expressions, we see that the rates have to satisfy the following detailed balance relation

$$
\begin{equation*}
\frac{\Gamma_{\uparrow}}{\Gamma_{\downarrow}}=\exp \left\{-\frac{\Delta}{T}\right\} . \tag{4.103}
\end{equation*}
$$

By the way, this relation may serve as an important sanity check: the rates calculated using any reasonable model of a quantum system have to satisfy it. ${ }^{48}$

Now comes the final argument: since the rates of transition between two particular states should not depend on other states and their occupation, Eq. (103) has to be valid for each pair of states of any multi-state system. The detailed balance yields only one equation for two rates $\Gamma_{\uparrow}$ and $\Gamma_{\downarrow}$; if our only goal is the calculation of $Z$, the choice of the other equation is not too important. Perhaps the simplest choice is

$$
\Gamma(\Delta) \propto \gamma(\Delta) \equiv\left\{\begin{array}{lc}
1, & \text { if } \Delta<0  \tag{4.104}\\
\exp \{-\Delta / T\}, & \text { otherwise }
\end{array}\right.
$$

where $\Delta$ is the energy change resulting from the transition. This model, which evidently satisfies the detailed balance relation (103), is the most popular for its simplicity, despite the uphysical cusp this function has at $\Delta=0$. The simplicity of Eq. (104) enables the following Metropolis algorithm (Fig. 14). The calculation starts from setting a certain initial state of the system. At relatively high temperatures, the state may be generated randomly; for example, for the Ising system, the initial state of each spin $s_{j}$ may be selected independently, with the $50 \%$ probability. At low temperatures, starting the calculations from the lowest-energy state (in particular, for the Ising model, from the ferromagnetic state $s_{j}=\operatorname{sgn}(h)$ $=$ const) may give the fastest convergence of the sum (97).

Now one spin is flipped at random, and the corresponding change of energy $(\Delta)$ is calculated, ${ }^{49}$ and plugged into Eq. (104) to calculate $\gamma(\Delta)$. Next, a pseudo-random number generator is used to generate a random number $\xi$, with the probability density uniformly distributed on segment $[0,1]$. (Such

[^898]functions, typically called RND, are available in virtually any numerical library.) If the resulting $\xi$ is less than $\gamma(\Delta)$, the transition is accepted, while if $\xi>\gamma(\Delta)$, it is rejected. In the view of Eq. (104), this means that any transition down the energy spectrum $(\Delta<0)$ are always accepted, while those up the energy profile $(\Delta>0)$ are accepted with the probability proportional to $\exp \{-\Delta / T\}$. The latter feature is necessary to avoid system trapping in local minima of its multidimensional energy profile $E_{m}\left(s_{1}, s_{2}, \ldots, s_{N}\right)$. Now the statistical sum may be calculated approximately as a partial sum over the states passed by the system. (It is better to discard the contributions from a few first steps to avoid an error due to the initial state choice.)

Fig. 4.14. Crude scheme of the Monte Carlo algorithm for the Ising model simulation.

This algorithm is extremely efficient. Even with modest computers available in the 1980s, it has allowed to simulate a 3D Ising system of $(128)^{3}$ spins to get the following result: $J / T_{c} \approx 0.221650 \pm$ 0.000005 . For all practical purposes, this result is exact (so that perhaps the largest benefit of the possible analytical solution for the infinite 3D Ising system would be a virtually certain Nobel Prize for the author :-). Table 2 summarizes values of $T_{c}$ for the Ising model. Very visible is the fast improvement of prediction accuracy of the molecular-field theory - which is asymptotically correct at $d \rightarrow \infty$.

Table 2. Critical temperature $T_{c}$ (in the units of $J$ ) of the Ising model of a ferromagnet $(J>0)$ for several values of dimensionality $d$

| $d$ | Molecular-field theory - Eq. (72) | Exact value | Exact value's source |
| :---: | :---: | :---: | :---: |
| 0 | 0 | 0 | Gibbs distribution |
| 1 | 2 | 0 | Transfer matrix theory |
| 2 | 4 | $2.269 \ldots$ | Onsager's solution |
| 3 | 6 | $4.513 \ldots$ | Numerical simulation |

Finally, I need to mention the renormalization-group ("RG") approach, ${ }^{50}$ despite its low efficiency for the Ising problem. The basic idea of this approach stems from the scaling law (30)-(31): at $T=T_{c}$ the correlation radius $r_{c}$ diverges. Hence, the critical temperature may be found from the requirement for the system to be spatially self-similar. Namely, let us form larger and larger groups ("blocks") of adjacent spins, and require that all properties of the resulting system of the blocks approach those of the initial system, as $T$ approaches $T_{c}$.

Let us see how does this idea work for the simplest nontrivial (1D) case, which is described by statistical sum (80). Assuming $N$ to be even (which does not matter at $N \rightarrow \infty$ ), and adding an inconsequential constant $C$ to each exponent (for the purpose that will be clear later on), we may rewrite this expression as

$$
\begin{equation*}
Z=\sum_{s_{j}= \pm 1} \prod_{j=1,2, \ldots N} \exp \left\{\frac{h}{2 T} s_{j}+\frac{J}{T} s_{j} s_{j+1}+\frac{h}{2 T} s_{j+1}+C\right\} \tag{4.105}
\end{equation*}
$$

Let us group each two adjacent exponents to recast this expression as a product over only even numbers j,

$$
\begin{equation*}
Z=\sum_{s_{j}= \pm 1} \prod_{j=2,4, \ldots N} \exp \left\{\frac{h}{2 T} s_{j-1}+s_{j}\left[\frac{J}{T}\left(s_{j-1}+s_{j+1}\right)+\frac{h}{T}\right]+\frac{h}{2 T} s_{j+1}+2 C\right\} \tag{4.106}
\end{equation*}
$$

and carry out the summation over two possible states of the internal spins $s_{j}$ explicitly:

$$
\begin{align*}
Z & =\sum_{\substack{\left.s_{j}= \pm 1 \\
\text { (for odd } j\right)}} \prod_{j=2,4, \ldots N}\left[\begin{array}{l}
\exp \left\{\frac{h}{2 T} s_{j-1}+\frac{J}{T}\left(s_{j-1}+s_{j+1}\right)+\frac{h}{T}+\frac{h}{2 T} s_{j+1}+2 C\right\} \\
+\exp \left\{\frac{h}{2 T} s_{j-1}-\frac{J}{T}\left(s_{j-1}+s_{j+1}\right)-\frac{h}{T}+\frac{h}{2 T} s_{j+1}+2 C\right\}
\end{array}\right]  \tag{4.107}\\
& =\sum_{\substack{\left.s_{j} \pm 11 \\
\text { (for odd } j\right)}} \prod_{j=2,4, \ldots N} 2 \cosh \left\{\frac{J}{T}\left(s_{j-1}+s_{j+1}\right)+\frac{h}{T}\right\} \exp \left\{\frac{h}{2 T}\left(s_{j-1}+s_{j+1}\right)+2 C\right\} .
\end{align*}
$$

Now let us require this statistical sum (and hence all statistical properties of the system of 2-spin blocks) to be identical to that of the Ising system of $N / 2$ spins, numbered by odd $j$ :

$$
\begin{equation*}
Z^{\prime}=\sum_{\substack{s_{j}= \pm 1 \\\left(\text { for odd } s_{j}\right)}} \prod_{j=2,4, \ldots, N} \exp \left\{\frac{J^{\prime}}{T} s_{j-1} s_{j+1}+\frac{h^{\prime}}{T} s_{j+1}+C^{\prime}\right\} \tag{4.108}
\end{equation*}
$$

with some different parameters $h^{\prime}, J^{\prime}$, and $C^{\prime}$, for all 4 possible values of $s_{j-1}= \pm 1$ and $s_{j+1}= \pm 1$. Since the right-hand part of Eq. (107) depends only on the sum $\left(s_{j-1}+s_{j+1}\right)$, this requirement yields only 3 (rather than 4) independent equations for finding $h^{\prime}, J^{\prime}$, and $C^{\prime}$. Of them, equations for $h$ ' and $J^{\prime}$ depend only on $h$ and $J$ (but not on $C$ ), ${ }^{51}$ and may be presented in an especially simple form,

[^899]equations for 1D Ising model
\[

$$
\begin{equation*}
x^{\prime}=\frac{x(1+y)^{2}}{(x+y)(1+x y)}, \quad y^{\prime}=\frac{y(x+y)}{1+x y} \tag{4.109}
\end{equation*}
$$

\]

using notation

$$
\begin{equation*}
x \equiv \exp \left\{-4 \frac{J}{T}\right\}, \quad y \equiv \exp \left\{-2 \frac{h}{T}\right\} . \tag{4.110}
\end{equation*}
$$

Now the grouping procedure may be repeated, with the same result (109)-(110). Hence these equations may be considered as recurrence relations describing repeated doubling of the spin block size. Figure 15 shows (schematically) the trajectories of this dynamic system on the phase plane $[x, y]$. (A trajectory is defined by the following property: for each of its points $\{x, y\}$, the point $\left\{x^{\prime}, y^{\prime}\right\}$ defined by the "mapping" Eq. (109) is also on the same trajectory.) For ferromagnetic coupling ( $J>0$ ) and $h>0$, we may limit the analysis to the unit square $0 \leq x, y \leq 1$. If this flow diagram had a stable fixed point with $x^{\prime}=x=x_{\infty} \neq 0$ (i.e. $T / J<\infty$ ) and $y^{\prime}=y=1$ (i.e. $h=0$ ), then the first of Eqs. (110) would immediately give us the critical temperature of the phase transition in the field-free system:

$$
\begin{equation*}
T_{c}=\frac{4 J}{\ln \left(1 / x_{\infty}\right)} . \tag{4.111}
\end{equation*}
$$

However, Fig. 15 shows that the only fixed point of the 1 D system is $x=y=0$, which (at finite coupling $J)$ should be interpreted as $T_{c}=0$. This is of course in agreement with the exact result of the transfermatrix analysis, but does not give any additional information.

$$
y=\exp \left\{-\frac{2 h}{T}\right\} \uparrow \text { Coment }
$$

Fig. 4.15. The RG flow diagram of the 1D Ising system (schematically).

Unfortunately, for higher dimensionalities the renormalization-group approach rapidly becomes rather cumbersome, and requires certain approximations, whose accuracy cannot be easily controlled. For 2D Ising system, such approximations lead to the prediction $T_{\mathrm{c}} / J \approx 2.55$, i.e. to a substantial difference from the exact (Onsager's) result.

### 4.6. Exercise problems

4.1. Compare the third virial coefficient $C(T)$ for the hardball model of particle interactions, that follows from the van der Waals equation, with the exact result (whose calculation was the subject of Problem 3.18).
4.2. Calculate the entropy and the internal energy of the van der Waals gas, and discuss the results.
4.3. Use two different approaches to calculate $(\partial E / \partial V)_{T}$ for the van der Waals gas, and the change of temperature of such a gas, with temperature-independent $C_{V}$, at its fast expansion into free space.
4.4.* Derive as many analytical results as you can for temperature dependence of the phaseequilibrium pressure $P_{0}(T)$ and the latent heat $\Lambda(T)$ within the van der Waals model. In particular, explore the low-temperature limit $\left(T \ll T_{C}\right)$, and the close vicinity of the critical point $T_{C}$.
4.5.* Calculate the critical values $P_{c}, V_{c}$, and $T_{c}$ for the so-called Redlich-Kwong model of the real gas, with the following phenomenological equation of state: ${ }^{52}$

$$
P+\frac{a}{V(V+N b) T^{1 / 2}}=\frac{N T}{V-N b} .
$$

Hint: Be prepared to solve a cubic equation with particular (numerical) coefficients.
4.6. Use the Clapeyron-Clausius formula (4.17) to calculate the latent heat $\Lambda$ of the BoseEinstein condensate, and compare the result with that obtained in Problem 3.18.
4.7. In the simplest model of the liquid-gas equilibrium, ${ }^{53}$ temperature and pressure do not affect molecule's condensation energy $\Delta$. Calculate the concentration and pressure of the gas over liquid's surface, assuming that its molecules are classical, non-interacting particles.
4.8. Assuming the hardball model, with volume $V_{0}$ per molecule, for the liquid phase, but still treating the gaseous phase an ideal gas, describe how do the results of the previous problem change if the liquid phase is in the form of spherical drops of radius $R \gg V_{0}{ }^{1 / 3}$. Briefly discuss the implications of the result for water cloud formation.
4.9. A classical ideal gas of $N \gg 1$ particles is placed into a container of volume $V$ and wall surface area $A$. The particles may condense on container walls, loosing potential energy $\Delta$ per particle, and forming an ideal 2D gas. Calculate the equilibrium number of condensed particles and gas pressure, and discuss their temperature dependences.
4.10. The inner surfaces of the walls of a closed container of volume $V$, filled with $N \gg 1$ indistinguishable particles, have $N_{S} \gg 1$ similar traps (small potential wells). Each trap can hold only one particle, at energy $-\Delta<0$. Assuming that the gas is ideal and classical, derive the equation for the chemical potential $\mu$ of the system in equilibrium, and use it to calculate the potential and the gas pressure in the limits of small and large values of the ratio $N / N_{S}$.

[^900]4.11. Superconductivity may be suppressed by a sufficiently strong magnetic field. In the simplest case of a bulk, long cylindrical sample of the type-I superconductor, placed into an external magnetic field $\mathcal{B}_{\text {ext }}$ parallel to its surface, this suppression takes a form of a simultaneous transition of the whole sample from the superconducting to the "normal" (non-superconducting) state at certain critical magnitude $B_{c}(T)$. The critical field gradually decreases with temperature from the maximum value $B_{c}(0)$ at $T \rightarrow 0$ to zero at the critical temperature $T_{c}$. Assuming that the function $B_{c}(T)$ is known, calculate the latent heat of transition as a function of temperature, and find its values at $T \rightarrow 0$ and $T=$ $T_{c}$.

Hint: In this context, "bulk" means a sample much larger than the intrinsic length scales of the superconductor (such as the London penetration depth $\delta_{\mathrm{L}}$ and the coherence length $\xi$ ). ${ }^{54}$ For such bulk samples, magnetic properties of the superconducting state may be well described just as a perfect diamagnetism, with zero magnetic permeability $\mu$.
4.12. In some textbooks, the discussion of thermodynamics of superconductivity is started with displaying, as self-evident, the following formula:

$$
F_{n}(T)-F_{s}(T)=\frac{B_{c}^{2}(T)}{2 \mu_{0}} V,
$$

where $F_{s}$ and $F_{n}$ are the free energy values in the superconducting and non-superconducting ("normal") phases, and $B_{c}(T)$ is the critical value of field. Is this formula correct, and if not, what modification is necessary to make it valid? Assume that all conditions of the simultaneous field-induced phase transition in the whole sample, spelled out in the previous problem, are satisfied.
4.13. In Sec. 4, we have discussed Weiss' molecular-field approach to the Ising model, in which the lattice average $\left\langle s_{j}\right\rangle$ plays the role of the order parameter $\eta$. Use the results of that analysis to find coefficients $a$ and $b$ in the corresponding Landau expansion (46) of the free energy. List the values of critical exponents $\alpha$ and $\beta$, defined by Eqs. (26) and (28), within this approach.
4.14. Calculate the average order parameter and the low-field susceptibility $\chi$ of a ring of three Ising-type "spins" $\left(s_{j}= \pm 1\right)$, with similar ferromagnetic coupling $J$ between all sites, in thermal equilibrium. From the result, can you predict the low-temperature behavior of $\chi$ in an $N$-spin ring?
4.15. Use Eq. (88) to calculate the average energy, free energy, entropy and heat capacity (all per lattice site), as functions of temperature $T$ and field $h$, for the 1D Ising model. Sketch the temperature dependence of the heat capacity for various values of ratio $h / J$, and give a physical interpretation of the result.
4.16. Use the molecular-field theory to calculate the critical temperature and low-field susceptibility of a d-dimensional cubic lattice of spins described by the so-called classical Heisenberg model: 55

[^901]$$
E_{m}=-J \sum_{\left.\left\{, j^{\prime}\right)^{\prime}\right\}} \mathbf{s}_{j} \cdot \mathbf{s}_{j^{\prime}}-\sum_{j} \mathbf{h} \cdot \mathbf{s}_{j} .
$$

Here, in contrast to the (otherwise, very similar) Ising model (23), the spin of each site is modeled by a classical 3D vector $\mathbf{s}_{j}=\left\{s_{x j}, s_{y j}, s_{z j}\right\}$ of unit length: $s_{j}^{2}=1$.

## Chapter 5. Fluctuations

This chapter discusses fluctuations of statistical variables, mostly at thermodynamic equilibrium. In particular, I will describe the intimate connection between fluctuations and dissipation (damping) in a dynamic system weakly coupled to a multi-particle environment, which culminates in the Einstein relation between the diffusion coefficient and mobility, the Nyquist formula, and their quantummechanical generalization - the fluctuation-dissipation theorem. An alternative approach to the same problem, based on the Smoluchowski and Fokker-Planck equations, is also discussed in brief.

### 5.1. Characterization of fluctuations

In the beginning of Chapter 2, we have discussed the notion of averaging, $\langle f\rangle$, of a variable $f$ over a statistical ensemble - see Eqs. (2.7) and (2.10). Now, the variable's fluctuation may be defined simply as its deviation from the average:

$$
\begin{equation*}
\widetilde{f} \equiv f-\langle f\rangle \tag{5.1}
\end{equation*}
$$

this deviation is, evidently, also a random variable. The most important property of any fluctuation is that its average (over the same statistical ensemble) equals zero:

$$
\begin{equation*}
\langle\tilde{f}\rangle=\langle f-\langle f\rangle\rangle=\langle f\rangle-\langle\langle f\rangle\rangle=\langle f\rangle-\langle f\rangle=0 \tag{5.2}
\end{equation*}
$$

As a result, such average cannot characterize fluctuations' intensity, whose simplest characteristic is the variance (also called "dispersion"):

Variance: definition

Th

$$
\begin{equation*}
\left\langle\widetilde{f}^{2}\right\rangle=\left\langle(f-\langle f\rangle)^{2}\right\rangle \tag{5.3}
\end{equation*}
$$

The following simple property of the variance is frequently convenient for its calculation:

$$
\begin{equation*}
\left\langle\widetilde{f}^{2}\right\rangle=\left\langle(f-\langle f\rangle)^{2}\right\rangle=\left\langle f^{2}-2 f\langle f\rangle+\langle f\rangle^{2}\right\rangle=\left\langle f^{2}\right\rangle-2\langle f\rangle^{2}+\langle f\rangle^{2} \tag{5.4a}
\end{equation*}
$$

so that, finally:
Variance via

As the simplest example of its application, consider a variable which can take only two values, $\pm 1$, with equal probabilities $W_{j}=1 / 2$. For such a variable,

$$
\begin{gather*}
\langle f\rangle=\sum_{j} W_{j} f_{j}=\frac{1}{2}(+1)+\frac{1}{2}(-1)=0, \quad \text { but }\left\langle f^{2}\right\rangle=\sum_{j} W_{j} f_{j}^{2}=\frac{1}{2}(+1)^{2}+\frac{1}{2}(-1)^{2}=1,  \tag{5.5}\\
\text { so that }\left\langle\tilde{f}^{2}\right\rangle=\left\langle f^{2}\right\rangle-\langle f\rangle^{2}=1 .
\end{gather*}
$$

The square root of variance,
R.m.s. fluctuation

$$
\begin{equation*}
\delta f \equiv\left\langle\widetilde{f}^{2}\right\rangle^{1 / 2} \tag{5.6}
\end{equation*}
$$

is called the root-mean-square (r.m.s.) fluctuation. An advantage of this measure is that it has the same dimensionality as the variable itself, so that ratio $\delta f /\langle f\rangle$ is dimensionless, and may be used to characterize the relative intensity of fluctuations. In particular, as has been mentioned in Chapter 1, all results of thermodynamics are valid only if the fluctuations of thermodynamic variables (internal energy $E$, entropy $S$, etc.) are relatively small. ${ }^{1}$ Let us make the simplest estimate of the relative intensity of fluctuations by considering a system of $N$ independent, similar particles, and an extensive variable

$$
\begin{equation*}
7 \equiv \sum_{j=1}^{N} f_{j} \tag{5.7}
\end{equation*}
$$

where $f_{j}$ depends on the state of just one $\left(j^{\text {th }}\right)$ particle. The statistical average of $\neq$ is evidently

$$
\begin{equation*}
\langle\boldsymbol{\chi}\rangle=\sum_{j=1}^{N}\langle f\rangle=N\langle f\rangle, \tag{5.8}
\end{equation*}
$$

while the variance is

$$
\begin{equation*}
\left\langle\widetilde{\boldsymbol{f}}^{2}\right\rangle=\left\langle\sum_{j=1}^{N} \widetilde{f}_{j} \sum_{j^{\prime}=1}^{N} \widetilde{f}_{j^{\prime}}\right\rangle=\left\langle\sum_{j, j^{\prime}=1}^{N} \widetilde{f}_{j} \widetilde{f}_{j^{\prime}}\right\rangle=\sum_{j, j^{\prime}=1}^{N}\left\langle\widetilde{f}_{j} \widetilde{f}_{j^{\prime}}\right\rangle . \tag{5.9}
\end{equation*}
$$

Now we may use the fact that for two independent variables

$$
\begin{equation*}
\left\langle\widetilde{f}_{j} \widetilde{f}_{j^{\prime}}\right\rangle=0 ; \tag{5.10}
\end{equation*}
$$

actually, this equation may be considered as the mathematical definition of the independence. Hence, in the sum (9), only the terms with $j^{\prime}=j$ survive, and

$$
\begin{equation*}
\left\langle\widetilde{f}^{2}\right\rangle=\sum_{j, j^{\prime}=1}^{N}\left\langle\widetilde{f}_{j}^{2}\right\rangle \delta_{j, j^{\prime}}=N\left\langle\widetilde{f}^{2}\right\rangle . \tag{5.11}
\end{equation*}
$$

Comparing Eqs. (8) and (11), we see that the relative intensity of fluctuations of variable $\mathcal{\neq}$,

$$
\begin{equation*}
\frac{\delta 7}{\langle 7\rangle}=\frac{1}{N^{1 / 2}} \frac{\delta f}{\langle f\rangle} \tag{5.12}
\end{equation*}
$$

Relative fluctuation estimate
tends to zero as the system size grows $(N \rightarrow \infty)$. It is this fact that justifies the thermodynamic approach to typical physical systems, with the number $N$ of particles of the order of the Avogadro number $N_{\mathrm{A}} \approx$ $10^{24}$. Nevertheless, in many situations even small fluctuations of thermodynamic variables are important, and in this chapter we will calculate their basic properties, starting from the variance.

It will be pleasant for the reader to notice that for some simple (but important) cases, such calculation has already been done in our course. For example, for any generalized coordinate $q_{j}$ and generalized momentum $p_{j}$ that give quadratic contributions to system's Hamiltonian (2.46), we have derived the equipartition theorem (2.48), valid in the classical limit. Since the average values of these

[^902]variables, in the thermodynamic equilibrium, equal zero, Eq. (6) immediately yields their r.m.s. fluctuations:
\[

$$
\begin{equation*}
\delta p_{j}=(m T)^{1 / 2}, \quad \delta q_{j}=\left(\frac{T}{m \omega^{2}}\right)^{1 / 2} . \tag{5.13}
\end{equation*}
$$

\]

The generalization of these classical relations to the quantum-mechanical case $(T \sim \hbar \omega)$ for a 1D harmonic oscillator is provided by Eqs. (2.78) and (2.81):

$$
\begin{equation*}
\delta p_{j}=\left[\frac{\hbar m \omega}{2} \operatorname{coth} \frac{\hbar \omega}{2 T}\right]^{1 / 2}, \quad \delta q_{j}=\left[\frac{\hbar}{2 m \omega} \operatorname{coth} \frac{\hbar \omega}{2 T}\right]^{1 / 2} . \tag{5.14}
\end{equation*}
$$

However, the intensity of fluctuations in other systems requires special calculations. Moreover, only a few cases allow for general, model-independent results. Let us review some of them.

### 5.2. Energy and the number of particles

First of all, note that fluctuations of macroscopic variables depend on particular conditions. ${ }^{2}$ For example, in a mechanically- and thermally-insulated system, e.g., a member of a microcanonical ensemble, there are no fluctuations of internal energy: $\delta E=0$.

However, if a system is in a thermal contact with environment, for example is a member of a canonical ensemble (Fig. 2.6), the Gibbs distribution (2.58)-(2.59) is valid. We already know that application of this distribution to energy itself,

$$
\begin{equation*}
\langle E\rangle=\sum_{m} W_{m} E_{m}, \quad W_{m}=\frac{1}{Z} \exp \left\{-\frac{E_{m}}{T}\right\}, \quad Z=\sum_{m} \exp \left\{-\frac{E_{m}}{T}\right\}, \tag{5.15}
\end{equation*}
$$

yields Eq. (2.61b), which may be rewritten in the form

$$
\begin{equation*}
\langle E\rangle=\frac{1}{Z} \frac{\partial Z}{\partial(-\beta)}, \quad \text { with } \beta \equiv \frac{1}{T}, \tag{5.16}
\end{equation*}
$$

more convenient for our current purposes. Now let us carry out a similar calculation for variable $E^{2}$ :

$$
\begin{equation*}
\left\langle E^{2}\right\rangle=\sum_{m} W_{m} E_{m}^{2}=\frac{1}{Z} \sum_{m} E_{m}^{2} \exp \left\{-\beta E_{m}\right\} . \tag{5.17}
\end{equation*}
$$

It is straightforward to check, by double differentiation, that this expression may be rewritten as

$$
\begin{equation*}
\left\langle E^{2}\right\rangle=\frac{1}{Z} \frac{\partial^{2}}{\partial(-\beta)^{2}} \sum_{m} \exp \left\{-\beta E_{m}\right\}=\frac{1}{Z} \frac{\partial^{2} Z}{\partial(-\beta)^{2}} . \tag{5.18}
\end{equation*}
$$

Now it is straightforward to use Eq. (4) to calculate the energy fluctuation variance:

$$
\begin{equation*}
\left\langle\widetilde{E}^{2}\right\rangle=\left\langle E^{2}\right\rangle-\langle E\rangle^{2}=\frac{1}{Z} \frac{\partial^{2} Z}{\partial(-\beta)^{2}}-\frac{1}{Z^{2}}\left(\frac{\partial Z}{\partial(-\beta)}\right)^{2}=\frac{\partial}{\partial(-\beta)}\left(\frac{1}{Z} \frac{\partial Z}{\partial(-\beta)}\right)=\frac{\partial\langle E\rangle}{\partial(-\beta)} . \tag{5.19}
\end{equation*}
$$

[^903]Since Eq. (15) is valid only if system's volume $V$ is fixed, it is customary to rewrite this extremely simple and important result as follows:

$$
\begin{equation*}
\left\langle\widetilde{E}^{2}\right\rangle=\frac{\partial\langle E\rangle}{\partial(-1 / T)}=T^{2}\left(\frac{\partial\langle E\rangle}{\partial T}\right)_{V}=C_{V} T^{2} \tag{5.20}
\end{equation*}
$$

This is a remarkably simple, fundamental result. As a sanity check, for a system of $N$ similar, independent particles, $\langle E\rangle$ and hence $C_{V}$ and are proportional to $N$, so that $\delta E \propto N^{1 / 2}$ and $\delta E /\langle E\rangle \propto N^{1 / 2}$, in agreement with Eq. (12). Let me emphasize that the classically-looking Eq. (20) is based on the general Gibbs distribution, and hence is valid for any system - either classical or quantum.

We will discuss the corollaries of this result in the next section, and now let me carry out a very similar calculation for a system whose number $N$ of particles in a system is not fixed, because they may go to, and come from the environment at will. If the chemical potential $\mu$ of the environment and its temperature $T$ are fixed, we are dealing with the grand canonical ensemble (Fig. 2.13), and may use the grand canonical distribution (2.106)-(2.107):

$$
\begin{equation*}
W_{m, N}=\frac{1}{Z_{G}} \exp \left\{\frac{\mu N-E_{m, N}}{T}\right\}, \quad Z_{G}=\sum_{N, m} \exp \left\{\frac{\mu N-E_{m, N}}{T}\right\} . \tag{5.21}
\end{equation*}
$$

Acting exactly as we did above for energy, we get

$$
\begin{align*}
\langle N\rangle & =\frac{1}{Z_{G}} \sum_{m, N} N \exp \left\{\frac{\mu N-E_{m, N}}{T}\right\}=\frac{T}{Z_{G}} \frac{\partial Z_{G}}{\partial \mu},  \tag{5.22}\\
\left\langle N^{2}\right\rangle & =\frac{1}{Z_{G}} \sum_{m, N} N^{2} \exp \left\{\frac{\mu N-E_{m, N}}{T}\right\}=\frac{T^{2}}{Z_{G}} \frac{\partial^{2} Z_{G}}{\partial \mu^{2}}, \tag{5.23}
\end{align*}
$$

so that the particle number variance is

$$
\begin{equation*}
\left\langle\tilde{N}^{2}\right\rangle=\left\langle N^{2}\right\rangle-\langle N\rangle^{2}=\frac{T^{2}}{Z_{G}} \frac{\partial Z_{G}}{\partial \mu}-\frac{T^{2}}{Z_{G}^{2}}\left(\frac{\partial Z_{G}}{\partial \mu}\right)^{2}=T \frac{\partial}{\partial \mu}\left(\frac{T}{Z_{G}} \frac{\partial Z_{G}}{\partial \mu}\right)=T \frac{\partial\langle N\rangle}{\partial \mu}, \tag{5.24}
\end{equation*}
$$

Fluctuations of $E$
we get from Eq. (24) a surprisingly simple result:

Fluctuations of $N$ in classical gas

$$
\begin{equation*}
\left\langle\widetilde{N}^{2}\right\rangle=\langle N\rangle, \quad \text { i.e. } \delta N=\langle N\rangle^{1 / 2} \tag{5.27}
\end{equation*}
$$

This relation is so simple and important that I will now show how it may be derived in a different way, in order to prove that this result is valid for systems with an arbitrary (say, small) $N$, and also get more detailed information about the statistics of fluctuations of that number. Let us consider an ideal classical gas of $N_{0}$ particles in a volume $V_{0}$, and calculate the probability $W_{N}$ to have exactly $N \leq N_{0}$ of these particles in a part $V \leq V_{0}$ of this volume - see Fig. 1.

Fig. 5.1. Deriving the binomial and Poissonian distributions.

For one particle such probability is of course $W=V / V_{0} \leq 1$, while the probability of one particle being in the remaining part of the volume is $W^{\prime}=1-W=1-V / V_{0}$. If all particles were distinguishable, the probability of having $N \leq N_{0}$ specific particles in volume $V$, and $\left(N-N_{0}\right)$ specific particles in volume ( $V-V_{0}$ ), would be $W^{N} W^{,\left(N_{0}-N\right)}$. However, if we do not distinguish the particles, we should multiply the probability by the number of possible particle combinations keeping numbers $N$ and $N_{0}$ constant, i.e. by the binomial coefficient $N_{0}!/ N!\left(N_{0}-N\right)!.^{3}$ As the result, the required probability is

$$
\begin{equation*}
W_{N}=W^{N} W^{\left(N_{0}-N\right)} \frac{N_{0}!}{N!\left(N_{0}-N\right)!}=\left(\frac{\langle N\rangle}{N_{0}}\right)^{N}\left(1-\frac{\langle N\rangle}{N_{0}}\right)^{N_{0}-N} \frac{N_{0}!}{N!\left(N_{0}-N\right)!} \tag{5.28}
\end{equation*}
$$

where in the second instance I have used the evident expression $\langle N\rangle=W N_{0}=\left(V / V_{0}\right) N_{0}$ for the average number of particles in volume $V$. Relation (28) is the so-called binomial probability distribution, valid for any $\langle N\rangle$ and $N_{0}$.

If we are interested in keeping $\langle N\rangle$ arbitrary, but do not care how large the additional volume ( $V_{0}$ $-V$ ) is, we can simplify the binomial distribution by assuming that the external part, and hence $N_{0}$, are very large:

$$
\begin{equation*}
N_{0} \gg N, \tag{5.29}
\end{equation*}
$$

where $N$ means all values of interest, including $\langle N\rangle$. In this limit we can neglect $N$ in comparison with $N_{0}$ in the second exponent of Eq. (28), and also approximate the fraction $N_{0}!/\left(N_{0}-N\right)$ !, i.e. the product of $N$ terms, $\left(N_{0}-N+1\right)\left(N_{0}-N+2\right) \ldots\left(N_{0}-1\right) N_{0}$, as just $N_{0}{ }^{N}$. As a result, we get

$$
\begin{equation*}
W_{N} \approx\left(\frac{\langle N\rangle}{N_{0}}\right)^{N}\left(1-\frac{\langle N\rangle}{N_{0}}\right)^{N_{0}} \frac{N_{0}^{N}}{N!}=\frac{\langle N\rangle^{N}}{N!}\left(1-\frac{\langle N\rangle}{N_{0}}\right)^{N_{0}}=\frac{\langle N\rangle^{N}}{N!}\left[(1-W)^{\frac{1}{W}}\right]^{\langle N\rangle} . \tag{5.30}
\end{equation*}
$$

[^904]In the limit (29), $W \rightarrow 0$, and factor inside the square brackets tends to $1 / e$, the reciprocal of the natural logarithm base. ${ }^{4}$ Thus, we finally get an expression independent of $N_{0}$ :

$$
\begin{equation*}
W_{N}=\frac{\langle N\rangle^{N}}{N!} e^{-\langle N\rangle} \tag{5.31}
\end{equation*}
$$

Poisson distribution

This is the much celebrated Poisson distribution, which describes a very broad family of random phenomena. Figure 2 shows this distribution for several values of $\langle N\rangle$ - which, in contrast to $N$, are not necessarily integer.

Fig. 5.2. The Poisson distribution for several values of $\langle N\rangle$. In contrast to that average, argument $N$ may take only integer values, so that lines are only guides for the eye.

At very small $\langle N\rangle$, function $W_{N}(N)$ distribution is close to an exponential one, $W_{N} \approx W^{N} \propto\langle N\rangle^{N}$, while in the opposite limit, $\langle N\rangle \gg 1$, it rapidly approaches the Gaussian (alternatively called "normal") distribution

$$
\begin{equation*}
W_{N}=\frac{1}{(2 \pi)^{1 / 2} \delta N} \exp \left\{-\frac{(N-\langle N\rangle)^{2}}{2(\delta N)^{2}}\right\}, \quad \text { with } \delta N=\langle N\rangle^{1 / 2} \tag{5.32}
\end{equation*}
$$

Gaussian distribution
(Note that the Gaussian distribution is also valid if both $N$ and $N_{0}$ are large, regardless of relation (29) between them - see Fig. 3.)

Fig. 5.3. Hierarchy of three major probability distributions.

[^905]The key property of the Poisson (and hence of the Gaussian) distribution is that it has the same variance as given by Eq. (27):

$$
\begin{equation*}
\left\langle\widetilde{N}^{2}\right\rangle \equiv\left\langle(N-\langle N\rangle)^{2}\right\rangle=\langle N\rangle . \tag{5.33}
\end{equation*}
$$

(This is not true for the general binomial distribution.) For our current purposes, this means that for the ideal classical gas, Eq. (27) is valid for any number of particles.

### 5.3. Volume and temperature

What are the r.m.s. fluctuations of other thermodynamic variables - like $V, T$, etc.? Again, the answer depends on conditions. For example, if the volume $V$ occupied by a gas is externally fixed (say, by rigid walls), it evidently does not fluctuate at all: $\delta V=0$. On the other hand, the volume may fluctuate in the situation when average pressure is fixed - see, e.g., Fig. 1.5. A formal calculation of these fluctuations, using the approach applied in the last section, is hampered by the fact that it is physically impracticable to fix its conjugate variable, $P$, i.e. suppress its fluctuations. For example, the force $\mathcal{F}(t)$ exerted by an ideal classical gas on vessel's wall (whose measure the pressure is) is the result of individual, independent hits of the wall by particles (Fig. 4), with time scale $\tau_{c} \sim r_{\mathrm{B}} /(T / m)^{1 / 2} \sim 10^{-16} \mathrm{~s}$, so that its frequency spectrum extends to very high frequencies, virtually impossible to control.

Fig. 5.4. Force exerted by gas particles on container's wall, as a function of time (schematically).

However, we can use the following trick, very typical for the theory of fluctuations. It is almost evident that r.m.s. fluctuations of volume are independent of the shape of the container. Let us consider the particular situation similar to that shown in Fig. 1.5, with the container of a cylindrical shape, with the base area $A .{ }^{5}$ Then the coordinate of the piston is just $q=V / A$, while the average force exerted by the gas on the cylinder is $\nexists=P A$ - see Fig. 5. Now if the piston is sufficiently massive, its free oscillation frequency $\omega$ near the equilibrium position is small enough to satisfy the following three conditions.

First, besides balancing the average force $\langle\mathcal{\not}\rangle$, and thus sustaining average pressure $\langle P\rangle=\langle\mathcal{F}\rangle / A$ of the gas, the interaction between the heavy piston and light molecules of the gas is weak because of a relatively short duration of the wall hits (Fig. 4). Because of that, the full energy of the system may be presented as a sum of those of the gas and the piston, with a quadratic contribution to piston's potential energy from small deviations of equilibrium:

$$
\begin{equation*}
U_{P}=\frac{\kappa}{2} \widetilde{q}^{2}, \quad \widetilde{q} \equiv q-\langle q\rangle=\frac{\widetilde{V}}{A}, \tag{5.34}
\end{equation*}
$$

[^906]where $\kappa$ is the effective spring constant arising from gas' compressibility.

Fig. 5.5. Deriving Eq. (37).

Second, at $\omega \rightarrow 0$, that spring constant may be calculated just as for constant variations of volume, with the gas remaining in quasi-equilibrium at all times:

$$
\begin{equation*}
\kappa=-\frac{\partial\langle\nmid\rangle}{\partial q}=A^{2}\left(-\frac{\partial\langle P\rangle}{\partial\langle V\rangle}\right) . \tag{5.35}
\end{equation*}
$$

This partial derivative ${ }^{6}$ should be taken at whatever the given thermal conditions are, e.g., with $S=$ const for adiabatic conditions (i.e., thermally insulated gas), or with $T=$ const for isothermic conditions (gas in a good thermal contact with a heat bath), etc. With that constant denoted as $X$, Eqs. (34)-(35) give

$$
\begin{equation*}
U_{P}=\frac{1}{2}\left(-A^{2} \frac{\partial\langle P\rangle}{\partial\langle V\rangle}\right)_{X}\left(\frac{\widetilde{V}}{A}\right)^{2}=\frac{1}{2}\left(-\frac{\partial\langle P\rangle}{\partial\langle V\rangle}\right)_{X} \widetilde{V}^{2} . \tag{5.36}
\end{equation*}
$$

Finally, making $\omega$ sufficiently small (namely, $\hbar \omega \ll T$ ) by a sufficiently large piston mass, we can apply, to the piston's fluctuations, the classical equipartition theorem: $\left\langle U_{P}\right\rangle=T / 2$, giving

$$
\begin{equation*}
\left\langle\widetilde{V}^{2}\right\rangle_{X}=T\left(-\frac{\partial\langle V\rangle}{\partial\langle P\rangle}\right)_{X} \tag{5.37a}
\end{equation*}
$$

Fluctuations of volume

Since this result is valid for any $A$ and $\omega$, it should not depend on system's geometry and piston mass, provided that it is large in comparison with the effective mass of a single system component (say, a gas molecule) - the condition that is naturally fulfilled in most experiments. ${ }^{7}$ For the particular case of fluctuations at constant temperature ( $X=T$ ), we may use the second of Eqs. (1.39) to rewrite Eq. (37a) as

[^907]\[

$$
\begin{equation*}
\left\langle\widetilde{V}^{2}\right\rangle_{T}=-T\left(\frac{\partial^{2} G}{\partial\langle P\rangle^{2}}\right)_{T} \tag{5.37b}
\end{equation*}
$$

\]

In the specific case of an ideal classical gas of $N$ particles, with the equation of state $\langle V\rangle=N T /\langle P\rangle$, it is easier to use directly Eq. (37a), with $X=T$, to get

$$
\begin{equation*}
\left\langle\widetilde{V}^{2}\right\rangle_{T}=-T\left(-\frac{N T}{\langle P\rangle^{2}}\right) \equiv \frac{\langle V\rangle^{2}}{N}, \quad \text { i.e. } \frac{\delta V_{T}}{\langle V\rangle}=\frac{1}{N^{1 / 2}}, \tag{5.38}
\end{equation*}
$$

in agreement with the trend given by Eq. (12).
Now let us proceed to fluctuations of temperature, for simplicity focusing on the case $V=$ const. Let us again assume that the system we are considering is weakly coupled to a heat bath of temperature $T_{0}$, in the sense that the time $\tau$ of temperature equilibration between the two is much larger than the internal temperature relaxation (thermalization) time. Then we may assume that $T$ changes in the whole system virtually simultaneously, and consider it a function of time alone:

$$
\begin{equation*}
T=\langle T\rangle+\widetilde{T}(t) \tag{5.39}
\end{equation*}
$$

Moreover, due to the (relatively) large $\tau$, we may use the stationary relation between small fluctuations of temperature and the internal energy of the system:

$$
\begin{equation*}
\widetilde{T}(t)=\frac{\widetilde{E}(t)}{C_{V}}, \quad \text { so that } \delta T=\frac{\delta E}{C_{V}} \tag{5.40}
\end{equation*}
$$

With those assumptions, Eq. (20) immediately yields the famous expression for the so-called thermodynamic fluctuations of temperature:

$$
\begin{equation*}
\delta T=\frac{\delta E}{C_{V}}=\frac{\langle T\rangle}{C_{V}^{1 / 2}} \tag{5.41}
\end{equation*}
$$

The most straightforward application of this result is to analysis of so-called bolometers broadband detectors of electromagnetic radiation in microwave and infrared frequency bands. In such a detector (Fig. 6), the incoming radiation it focused on a small sensor (e.g., either a small piece of a Ge crystal, or a superconductor thin film at temperature $T \approx T_{c}$, etc.) that is well isolated thermally from the environment.

Fig. 5.6. Conceptual scheme of a bolometer.
to electronics
As a result, the absorption of even small radiation power $\mathcal{P}$ leads to a noticeable change $\Delta T$ of sensor's average temperature $\langle T\rangle$ and hence of its electric resistance $R$, which is probed up by low-noise
external electronics. ${ }^{8}$ If power does not change in time too fast, $\Delta T$ is a certain function of $\mathcal{P}$, turning into 0 at $\mathcal{P}=0$. Hence, if $\Delta T$ is much lower than the environment temperature $T_{0}$, we may keep only the main, linear term in it Taylor expansion in $P$.

$$
\begin{equation*}
\Delta T \equiv\langle T\rangle-T_{0}=\frac{P}{g}, \tag{5.42}
\end{equation*}
$$

where coefficient $g \equiv \partial \nexists \partial T$ is called the thermal conductance of the unavoidable thermal coupling between the sensor and the heat bath - see Fig. 6. The power may be detected if the electric signal from the sensor, which results from change $\Delta T$, is not drowned in spontaneous fluctuations. In practical systems, these fluctuations are is contributed by several sources including electronic amplifiers, sensor, etc. However, in modern systems these "technical" contributions to noise are successfully suppressed, and the dominating noise source are the fundamental fluctuations of sensor temperature, described by Eq. (41). In this case the so-called noise-equivalent power ("NEP"), defined as the level of $\mathcal{P}$ that produces signal equal to r.m.s. value of noise, may be calculated by equating Eqs. (41) (with $\langle T\rangle \approx T_{0}$ ) and (42):

$$
\begin{equation*}
\mathrm{NEP}=\frac{T_{0} g}{C_{V}^{1 / 2}} . \tag{5.43}
\end{equation*}
$$

This expression shows that in order to decrease $N E P$, i.e. improve the device sensitivity, both the environment temperature $T_{0}$ and thermal conductance $g$ should be reduced. In modern receivers of radiation, their typical values (in SI units) are of the order of 0.1 K and $10^{-10} \mathrm{~W} / \mathrm{K}$, respectively.

On the other hand, Eq. (43) implies that in order to increase bolometer sensitivity, i.e. reduce NEP, the $C_{V}$ of the sensor, and hence its mass, should be increased. This conclusion is valid only to a certain extent, because due to technical reasons (parameter drift and the so-called $1 / f$ noise of the sensor and external electronics), incoming power has to be modulated with as high frequency $\omega$ as possible (in most cases, the cyclic frequency $v=\omega / 2 \pi$ of the modulation is between 10 to $1,000 \mathrm{~Hz}$ ), so that the electrical signal may be picked up from the sensor at that frequency. As a result, $C_{V}$ may be increased only until the thermal constant of the sensor,

$$
\begin{equation*}
\tau=\frac{C_{V}}{g}, \tag{5.44}
\end{equation*}
$$

becomes close to $1 / \omega$, because at $\omega \tau \gg 1$ the useful signal drops faster than noise. As a result, the lowest (i.e. the best) value of NEP,

$$
\begin{equation*}
\frac{(\mathrm{NEP})_{\min }}{v^{1 / 2}}=\alpha T_{0} g^{1 / 2}, \quad \alpha \sim 1 \tag{5.45}
\end{equation*}
$$

is reached at $v \tau \approx 1$. (The exact values of the optimal product $\omega \tau$, and the numerical constant $\alpha \sim 1$ in Eq. (45), depend on the exact law of power modulation in time, and the output signal processing procedure.) With the parameters cited above, this estimate yields (NEP) $\min / v^{1 / 2} \sim 3 \times 10^{-17} \mathrm{~W} / \mathrm{Hz}^{1 / 2}-\mathrm{a}$ very low power indeed.

[^908]However, surprisingly enough, the power modulation allows bolometric (and other broadband) receivers to register radiation with power much lower than this NEP! Indeed, picking up the sensor signal at the modulation frequency $\omega$, we can use the following electronics stages to filter out all the noise besides its components within a very narrow band, of width $\Delta v \ll v$, around the modulation frequency (Fig. 7). This is the idea of a microwave radiometer, ${ }^{9}$ currently used in all sensitive broadband receivers.

Fig. 5.7. Basic idea of the Dicke radiometer.

In order to analyze this opportunity, we need to develop theoretical tools for a quantitative description of the spectral distribution of fluctuations. Another motivation for that description is the need in analysis of variables dominated by fast (high-frequency) components, such as pressure - please have one more look at Fig. 4. Finally, during the analysis, we will run into the fundamental relation between fluctuations and dissipation, which is one of the main results of statistical physics as a whole.

### 5.4. Fluctuations as functions of time

There are two mathematically-equivalent approaches to time-dependent functions of time, called time-domain and frequency-domain pictures, with their relative convenience depending on the particular problem to be solved.

In the time domain, we cannot characterize a random fluctuation $\tilde{f}(t)$ of a classical variable by its statistical average, because it equals zero - see Eq. (2). Of course, variance (3) does not vanish, but if fluctuations are stationary, it does not depend on time either. Because of that, let us consider the following average: ${ }^{10}$

$$
\begin{equation*}
\left\langle\tilde{f}(t) \widetilde{f}\left(t^{\prime}\right)\right\rangle \tag{5.46}
\end{equation*}
$$

Generally, this is a function of two arguments. Moreover, in the systems that are stationary (whose macroscopic parameters and hence the variable expectation values do not change with time), averages like (46) may depend only on the difference,

$$
\begin{equation*}
\tau \equiv t^{\prime}-t \tag{5.47}
\end{equation*}
$$

[^909]between the two observation times. In this case, average (46) is called the correlation function of variable $f$ :
\[

$$
\begin{equation*}
K_{f}(\tau) \equiv\langle\widetilde{f}(t) \widetilde{f}(t+\tau)\rangle \tag{5.48}
\end{equation*}
$$

\]

Correlation function

This name ${ }^{11}$ catches the idea of this notion very well: $K_{\mathcal{f}}(\tau)$ tells us about the average mutual relation between the fluctuations at two times separated by interval $\tau$. Let us list the basic properties of this function.

First of all, $K_{f}(\tau)$ has to be an even function of the time delay $\tau$. Indeed, we may write

$$
\begin{equation*}
K_{f}(-\tau)=\langle\widetilde{f}(t) \widetilde{f}(t-\tau)\rangle=\langle\widetilde{f}(t-\tau) \widetilde{f}(t)\rangle=\left\langle\tilde{f}\left(t^{\prime}\right) \widetilde{f}\left(t^{\prime}+\tau\right)\right\rangle, \tag{5.49}
\end{equation*}
$$

with $t^{\prime} \equiv t-\tau$. For stationary processes, this average cannot depend on the common shift $t^{\prime}$ of the two observation times, so that averages (48) and (49) have to be equal:

$$
\begin{equation*}
K_{f}(-\tau)=K_{f}(\tau) \tag{5.50}
\end{equation*}
$$

Second, at $\tau \rightarrow 0$ the correlation function tends to the variance:

$$
\begin{equation*}
K_{f}(0)=\langle\widetilde{f}(t) \widetilde{f}(t)\rangle=\left\langle\widetilde{f}^{2}\right\rangle \tag{5.51}
\end{equation*}
$$

In the opposite limit, when $\tau$ is much larger than some characteristic correlation time $\tau_{c}$ of the system, ${ }^{12}$ the correlation function tends to zero, because fluctuations separated by such large time interval are virtually independent (uncorrelated). As a result, the correlation function typically looks like one of the plots sketched in Fig. 8. Note that on a time scale much longer than $\tau_{c}$, any physically-realistic correlation function may be well approximated with a delta-function of $\tau .{ }^{13}$

Fig. 5.8. Correlation function of fluctuations: two typical examples.

In the reciprocal, frequency domain, process $\tilde{f}(t)$ is presented as a Fourier integral,

$$
\begin{equation*}
\tilde{f}(t)=\int_{-\infty}^{+\infty} f_{\omega} e^{-i \omega t} d \omega \tag{5.52}
\end{equation*}
$$

with the reciprocal transform being
${ }^{11}$ Another term, the autocorrelation function, is sometimes used for average (48) to distinguish it from the mutual correlation function, $\langle f(t) g(t+\tau)\rangle$, of two stationary processes.
${ }^{12}$ Correlation time $\tau_{c}$ is the direct temporal analog of the correlation radius $r_{c}$ which was discussed in Sec. 4.2.
${ }^{13}$ For example, for a process which is a sum of independent very short pulses, e.g., the gas pressure force exerted on the container wall (Fig. 4), such approximation is legitimate on time scales longer than the single pulse duration, e.g., the time of particle's impact on the wall.

$$
\begin{equation*}
f_{\omega}=\frac{1}{2 \pi} \int_{-\infty}^{+\infty} \widetilde{f}(t) e^{i \omega t} d t \tag{5.53}
\end{equation*}
$$

If the initial function $\tilde{f}(t)$ is random (as it is in the case of fluctuations), with zero average, its Fourier transform $f_{\omega}$ is a random function (now of frequency) as well, also with a vanishing statistical average:

$$
\begin{equation*}
\left\langle f_{\omega}\right\rangle=\left\langle\frac{1}{2 \pi} \int_{-\infty}^{+\infty} \widetilde{f}(t) e^{i \omega t} d t\right\rangle=\frac{1}{2 \pi} \int_{-\infty}^{+\infty}\langle\widetilde{f}(t)\rangle e^{i \omega t} d t=0 \tag{5.54}
\end{equation*}
$$

The simplest nonvanishing average may be formed similarly to Eq. (46), but with due respect to the complex-variable character of the Fourier images:

$$
\begin{equation*}
\left\langle f_{\omega} f_{\omega^{\prime}}^{*}\right\rangle=\frac{1}{(2 \pi)^{2}} \int_{-\infty}^{+\infty} d t^{\prime} \int_{-\infty}^{+\infty} d t\left\langle\tilde{f}(t) \tilde{f}\left(t^{\prime}\right)\right\rangle e^{i\left(\omega^{\prime} t^{\prime}-\omega t\right)} \tag{5.55}
\end{equation*}
$$

It turns out that for a stationary process, averages (46) and (55) are directly related. Indeed, since the integration over $t^{\prime}$ in Eq. (55) is in infinite limits, we may replace it with integration over $\tau \equiv t^{\prime}-t$ (at fixed $t$ ), also in infinite limits. Replacing $t^{\prime}$ by $t+\tau$ in expressions under the integral, we see that the average is just the correlation function $K_{\mathcal{A}}(\tau)$, while the time exponent is equal to $\exp \left\{i\left(\omega^{\prime}-\right.\right.$ $\omega) t\} \exp \left\{i \omega^{\prime} \tau\right\}$. As a result, changing the order of integration, we get

$$
\begin{equation*}
\left\langle f_{\omega} f_{\omega^{\prime}}^{*}\right\rangle=\frac{1}{(2 \pi)^{2}} \int_{-\infty}^{+\infty} d t \int_{-\infty}^{+\infty} d \tau K_{f}(\tau) e^{i\left(\omega-\omega^{\prime}\right) t} e^{i \omega^{\prime} \tau}=\frac{1}{(2 \pi)^{2}} \int_{-\infty}^{+\infty} K_{f}(\tau) e^{i \omega^{\prime} \tau} d \tau \int_{-\infty}^{+\infty} e^{i\left(\omega-\omega^{\prime}\right) t} d t \tag{5.56}
\end{equation*}
$$

But the last integral is just $2 \pi \delta\left(\omega-\omega^{\prime}\right),{ }^{14}$ so that we finally get

Spectral density of fluctuations

$$
\begin{equation*}
\left\langle f_{\omega} f_{\omega^{\prime}}^{*}\right\rangle=S_{f}(\omega) \delta\left(\omega-\omega^{\prime}\right) \tag{5.57}
\end{equation*}
$$

where the real function of frequency,

$$
\begin{equation*}
S_{f}(\omega) \equiv \frac{1}{2 \pi} \int_{-\infty}^{+\infty} K_{f}(\tau) e^{i \omega \tau} d \tau=\frac{1}{\pi} \int_{0}^{\infty} K_{f}(\tau) \cos \omega \tau d \tau \tag{5.58}
\end{equation*}
$$

WienerKhinchin theorem
is called the spectral density of fluctuations at frequency $\omega$. According to Eq. (58), the spectral density is a Fourier image of the correlation function, and hence the reciprocal Fourier transform is: ${ }^{15,16}$

$$
\begin{equation*}
K_{f}(\tau)=\int_{-\infty}^{+\infty} S_{f}(\omega) e^{-i \omega \tau} d \omega=2 \int_{0}^{\infty} S_{f}(\omega) \cos \omega \tau d \omega \tag{5.59}
\end{equation*}
$$

In particular, for the variance, Eq. (59) yields

[^910]\[

$$
\begin{equation*}
\left\langle\tilde{f}^{2}\right\rangle=K_{f}(0)=\int_{-\infty}^{+\infty} S_{f}(\omega) d \omega=2 \int_{0}^{\infty} S_{f}(\omega) d \omega \tag{5.60}
\end{equation*}
$$

\]

This relation shows that term "spectral density" describes the physical sense of function $S_{f}(\omega)$ very well. Indeed, if a random signal $f(t)$ had been passed through a frequency filter with a small bandwidth $\Delta v \ll v$ of positive cyclic frequencies, the integral in Eq. (60) had to be limited to interval $\Delta \omega=2 \pi \Delta v$, i.e. that the variance of the output signal would become ${ }^{17}$

$$
\begin{equation*}
\left\langle\tilde{f}^{2}\right\rangle_{\Delta v}=2 S_{f}(\omega) \Delta \omega=4 \pi S_{f}(\omega) \Delta v \tag{5.61}
\end{equation*}
$$

To complete this introductory section, let me note an important particular case. If the spectral density of some process, is nearly constant within the frequency range of interest, $S_{f}(\omega)=$ const $=S_{f}(0),{ }^{18}$ Eq. (59) shows that its correlation function may be well approximated by a delta-function:

$$
\begin{equation*}
K_{f}(\tau)=S_{f}(0) \int_{-\infty}^{+\infty} e^{-i \omega \tau} d \omega=2 \pi S_{f}(0) \delta(\tau) \tag{5.62}
\end{equation*}
$$

From this relation stems another popular name of the white noise, the delta-correlated process. We have already seen that this is a very reasonable approximation, for example, for the gas pressure force fluctuations (Fig. 4). Of course, for spectral density of a realistic, limited physical variable the approximation of constant spectral density cannot be true for all frequencies (otherwise, for example, integral (60) would diverge, giving an unphysical, infinite value of variance), and is valid only at frequencies much lower than $1 / \tau_{c}$.

### 5.5. Fluctuations and dissipation

Now we are mathematically equipped to address one of the most important topics of statistical physics, the relation between fluctuations and dissipation This relation is especially simple for the following hierarchical situation: a relatively "heavy", slowly moving system interacting with an environment consisting of rapidly moving, "light" components. A popular theoretical term for such a system is the Brownian particle, named after botanist R. Brown who first noticed in 1827 the random motion of pollen grains, caused by their random hits by fluid molecules, under a microscope. However, the family of such systems is much broader than that of mechanical particles. ${ }^{19}$

One more important assumption of this theory is that the system's motion does not violate the thermal equilibrium of the environment - well fulfilled in many cases. (Think, for example, about a usual mechanical pendulum whose motion does not overheat the air around it.) In this case, the statistical averaging over the thermally-equilibrium environment may be performed for any (slow)

[^911]motion of the system of interest, considering the motion fixed. ${ }^{20}$ I will denote such a "primary" averaging by angular brackets $\langle\ldots\rangle$. At a later stage we may carry out another, "secondary" averaging, over an ensemble of many similar systems of interest, coupled to similar environments. If we do, it will be denoted by double angle brackets $\langle\langle\ldots\rangle\rangle$.

Let me start from a simple classical system, a 1D harmonic oscillator whose equation of evolution may be presented as

$$
\begin{equation*}
m \ddot{q}+\kappa q=\mathcal{7}_{\mathrm{det}}(t)+\gamma_{\mathrm{env}}(t)=\mathcal{\gamma}_{\mathrm{det}}(t)+\langle\boldsymbol{7}\rangle+\tilde{7}(t) \tag{5.63}
\end{equation*}
$$

where $q$ is the (generalized) coordinate of the oscillator, $\not_{\text {det }}(t)$ is the deterministic (generalized) external force, while both components of the random force $\mathcal{Z}(t)$ present the impact of the environment on oscillator's motion. Again, from the point of view of the fast-moving environmental components, the oscillator's motion is slow. The average of the force exerted by environment on such a slowly moving object may have a part depending on not only $q$, but on the velocity $\dot{q}$ as well. For most systems, the Taylor expansion of the force in small velocity would have a finite leading, linear term, so that we may take

$$
\begin{equation*}
\langle\boldsymbol{\eta}\rangle=-\eta \dot{q} \tag{5.64}
\end{equation*}
$$

so that Eq. (63) may be rewritten as

$$
\begin{equation*}
m \ddot{q}+\eta \dot{q}+\kappa q={\neq \mathrm{det}^{2}}(t)+\tilde{\gamma}(t) \tag{5.65}
\end{equation*}
$$

This way of describing the effects of environment on an otherwise Hamiltonian system is called the Langevin equation. ${ }^{21}$ Due to the linearity of the differential equation (65), its general solution may be presented as a sum of two parts: the deterministic motion of the linear oscillator due to the external force $7_{\mathrm{det}}(t)$, and random fluctuations due to the random force exerted by the environment. The former effects are well known from classical dynamics, ${ }^{22}$ so let us focus on the latter part by taking $\chi_{\operatorname{det}}(t)=0$. The remaining term in the right-hand part describes the fluctuating part of the environmental force; in contrast to the average component (64), its intensity (read: its spectral density at relevant frequencies $\omega$ $\sim \omega_{0} \equiv(\kappa / m)^{1 / 2}$ ) does not vanish at $q(t)=0$, and hence may be evaluated ignoring system's motion.

Plugging into Eq. (65) the presentation of both variables in the form similar to Eq. (52), for their Fourier images we get the following relation:

$$
\begin{equation*}
-m \omega^{2} q_{\omega}-i \omega \eta q_{\omega}+\kappa q_{\omega}=7_{\omega} \tag{5.66}
\end{equation*}
$$

which immediately gives us $q_{\omega}$ :

[^912]\[

$$
\begin{equation*}
q_{\omega}=\frac{7_{\omega}}{\left(\kappa-m \omega^{2}\right)-i \eta \omega} . \tag{5.67}
\end{equation*}
$$

\]

Now multiplying Eq. (67) by its complex conjugate, averaging both parts of the resulting equation, and using for each of them Eq. (57), ${ }^{23}$ we get the following relation between spectral densities of the oscillations and force:

$$
\begin{equation*}
S_{q}(\omega)=\frac{1}{\left(\kappa-m \omega^{2}\right)^{2}+(\eta \omega)^{2}} S_{\neq}(\omega) \tag{5.68}
\end{equation*}
$$

As the reader should know well from classical dynamics, at small damping ( $\eta \ll m \omega_{0}$ ) the first factor in the right-hand part of Eq. (68) describes the resonance, i.e. has a sharp peak near oscillator's eigenfrequency $\omega_{0}$, and may be presented in that vicinity as

$$
\begin{equation*}
\frac{1}{\left(\kappa-m \omega^{2}\right)^{2}+(\eta \omega)^{2}} \approx \frac{1}{4 m \kappa\left(\xi^{2}+\delta^{2}\right)}, \quad \text { at }|\xi| \ll \omega_{0} \quad \text { with } \xi \equiv \omega-\omega_{0}, \quad \delta \equiv \eta / 2 m \tag{5.69}
\end{equation*}
$$

In contrast, spectral density $S_{\neq}(\omega)$ of fluctuations of a typical environment is changing slowly near that frequency, so that for the purpose of integration over frequencies near $\omega_{0}$ we may replace $S_{\neq}(\omega)$ with $S_{\neq}$ $\left(\omega_{0}\right)$. As a result, the variance of the environment-imposed random oscillations may be calculated as

$$
\begin{equation*}
\left\langle\left\langle\widetilde{q}^{2}\right\rangle\right\rangle=2 \int_{0}^{\infty} S_{q}(\omega) d \omega \approx 2 \int_{\omega \approx \omega_{0}} S_{q}(\omega) d \omega \approx 2 S_{\neq}\left(\omega_{0}\right) \frac{1}{4 m \kappa} \int_{-\infty}^{+\infty} \frac{d \xi}{\xi^{2}+\delta^{2}} . \tag{5.70}
\end{equation*}
$$

The last expression includes a well-known table integral, ${ }^{24}$ equal to $\pi / \delta=2 \pi m / \eta$, so that finally

$$
\begin{equation*}
\left\langle\left\langle\widetilde{q}^{2}\right\rangle\right\rangle=2 S_{\neq}\left(\omega_{0}\right) \frac{1}{4 m \kappa} \frac{2 \pi m}{\eta}=\frac{\pi}{\kappa \eta} S_{\neq}\left(\omega_{0}\right) . \tag{5.71}
\end{equation*}
$$

But on the other hand, the weak interaction with environment should keep the oscillator in thermodynamic equilibrium at the same temperature $T$. Since our analysis has been based on the classical Langevin equation (65), we may only use it in the classical limit $\hbar \omega_{0} \ll T$, in which we may use the equipartition theorem (2.48). In our current notation, it yields

$$
\begin{equation*}
\frac{\kappa}{2}\left\langle\left\langle\widetilde{q}^{2}\right\rangle\right\rangle=\frac{T}{2} . \tag{5.72}
\end{equation*}
$$

Comparing Eqs. (71) and (72), we see that the spectral density of the random force exerted by environment is fundamentally related to the damping it provides:

$$
\begin{equation*}
S_{\neq}\left(\omega_{0}\right)=\frac{\eta}{\pi} T . \tag{5.73a}
\end{equation*}
$$

Now we may argue (rather convincingly :-) that since this relation does not depend on oscillator's parameters $m$ and $\kappa$, and hence its eigenfrequency $\omega_{0}=(\kappa / m)^{1 / 2}$, it should be valid at any (but

[^913]sufficiently low, $\omega \tau_{c} \ll 1$ ) frequency. Using Eq. (58) with $\omega \rightarrow 0$, it may be rewritten as a formula for the effective low-frequency drag (friction) coefficient:
\[

$$
\begin{equation*}
\eta=\frac{1}{T} \int_{0}^{\infty} K_{\not{\not}}(\tau) d \tau \equiv \frac{1}{T} \int_{0}^{\infty}\langle\tilde{\mathcal{F}}(0) \widetilde{\mathcal{F}}(\tau)\rangle d \tau \tag{5.73b}
\end{equation*}
$$

\]

Relation (73) reveals an intimate, fundamental connection between fluctuations and dissipation provided by a thermally-equilibrium environment. Verbally, "there is no dissipation without fluctuations" - and vice versa. ${ }^{25}$ Historically, this fact was first recognized in 1905 by A. Einstein, ${ }^{26}$ in the following form. Let us apply our result (73) to the particular case of a free 1D Brownian particle, by taking $\kappa=0$. In this case both equations (71) and (72) give infinities. In order to understand the reason for that divergence, let us go back to the Langevin equation (65) with not only $\kappa=0$, but also, just for the sake of simplicity, $m \rightarrow 0$ as well. (The latter approximation, frequently called the overdamping limit, is quite appropriate for the motion of a small particle in a viscous fluid, when $m \ll \eta \Delta t$ even for smallest time intervals $\Delta t$ between the successive observations of particle's positions.) In this approximation, Eq. (65) is reduced to a simple equation,

$$
\begin{equation*}
\eta \dot{q}=f_{\mathrm{det}}(t)+\tilde{f}(t), \tag{5.74}
\end{equation*}
$$

with a ready solution for particle displacement during a finite time interval $t$ :

$$
\begin{equation*}
\Delta q(t) \equiv q(t)-q(0)=\langle\langle\Delta q(t)\rangle\rangle+\widetilde{q}(t), \quad\langle\langle\Delta q(t)\rangle\rangle=\frac{1}{\eta} \int_{0}^{t} \gamma_{\operatorname{det}}\left(t^{\prime}\right) d t^{\prime}, \quad \Delta \widetilde{q}(t)=\frac{1}{\eta} \int_{0}^{t} \widetilde{\gamma}\left(t^{\prime}\right) d t^{\prime} . \tag{5.75}
\end{equation*}
$$

Evidently, in the statistical average of the displacement, the fluctuation effects vanish, but this does not mean that the particle does not deviate from the deterministic trajectory $\langle\langle q(t)\rangle\rangle$ - just that is has equal probabilities to be shifted either of two possible directions from that trajectory. To see that, let us calculate the variance of the displacement:

$$
\begin{equation*}
\left\langle\left\langle\Delta \widetilde{q}^{2}(t)\right\rangle\right\rangle=\frac{1}{\eta^{2}} \int_{0}^{t} d t^{\prime} \int_{0}^{t} d t^{\prime \prime}\left\langle\widetilde{\mathcal{F}}\left(t^{\prime}\right) \widetilde{7}\left(t^{\prime \prime}\right)\right\rangle=\frac{1}{\eta^{2}} \int_{0}^{t} d t^{\prime} \int_{0}^{t} d t^{\prime \prime} K_{\mathcal{F}}\left(t^{\prime}-t^{\prime \prime}\right) . \tag{5.76}
\end{equation*}
$$

As we already know, at times $\tau \gg \tau_{c}$ (this correlation time, for typical molecular impacts, is of the order of a picosecond), correlation function may be well approximated by the delta-function - see Eq. (62). In this approximation, with $S_{\neq}(0)$ expressed by Eq. (73), and Eq. (76) yields

$$
\begin{equation*}
\left\langle\left\langle\Delta \widetilde{q}^{2}(t)\right\rangle\right\rangle=\frac{2 \pi}{\eta^{2}} S_{\neq}(0) \int_{0}^{t} d t^{\prime} \int_{0}^{t} d t^{\prime \prime} \delta\left(t^{\prime}-t^{\prime \prime}\right)=\frac{2 \pi}{\eta^{2}} \frac{\eta T}{\pi} \int_{0}^{t} d t^{\prime}=2 D t \tag{5.77}
\end{equation*}
$$

with

[^914]\[

$$
\begin{equation*}
D=\frac{T}{\eta} \tag{5.78}
\end{equation*}
$$

\]

## Einstein's relation

The final form of Eq. (77) describes the well-known law of diffusion ("random walk") of a 1D system, with the r.m.s. deviation from the point of origin growing as $(2 D t)^{1 / 2}$. Coefficient $D$ is this relation is called the coefficient of diffusion, and Eq. (78) describes the extremely simple Einstein relation between that coefficient and particle's damping. Often this relation is rewritten in SI units of temperature as $D=\mu_{m} k_{\mathrm{B}} T_{\mathrm{K}}$, where $\mu_{m} \equiv 1 / \eta$ is the mobility of the particle. The physical sense of $\mu_{m}$ becomes clear from rewriting the expression for the deterministic viscous motion $\langle\langle q(t)\rangle\rangle$ (particle's "drift") in the form:

$$
\begin{equation*}
v_{\mathrm{drift}} \equiv \frac{d\langle\langle q(t)\rangle\rangle}{d t}=\frac{1}{\eta} \not_{\mathrm{det}}(t)=\mu_{m} \not_{\mathrm{det}}(t), \tag{5.79}
\end{equation*}
$$

so that mobility is just velocity given to the particle by unit force. ${ }^{27}$
Another famous example of application of Eq. (73) is to the thermal (or "Johnson", or "JohnsonNyquist", or just "Nyquist") noise in resistive electron devices. Let us consider a two-terminal "probe" circuit, playing the role of the harmonic oscillator in our analysis above, connected to a resistor $R$ (Fig. 9), playing the role of noisy environment. (The noise is generated by the thermal motion of numerous electrons, randomly moving inside the resistor.) For this system, one convenient choice of conjugate variables (the generalized coordinate and generalized force) is, respectively, the electric charge $Q \equiv$ $\int I(t) d t$ that has passed through the "probe" circuit by time $t$, and voltage $V$ across its terminals, with the polarity shown in Fig. 9. (Indeed, the product $V d Q$ is the elementary work $d w$ done by the environment on the probe circuit.)

Fig. 5.9. Resistor $R$ of temperature $T$ as a noisy environment of a two-terminal probe circuit.

Making the corresponding replacements, $q \rightarrow Q$ and $\nrightarrow \vee$ in Eq. (64), we see that it becomes

$$
\begin{equation*}
\langle v\rangle=-\eta \dot{Q} \equiv-\eta I . \tag{5.80}
\end{equation*}
$$

Comparing this relation with Ohm's law, $R(-I)=\mathcal{R}_{2}^{8}$ we see that in this case, coefficient $\eta$ has the physical sense of the usual Ohmic resistance $R,{ }^{29}$ so that Eq. (73) becomes

[^915]\[

$$
\begin{equation*}
S_{v}(\omega)=\frac{R}{\pi} T . \tag{5.81a}
\end{equation*}
$$

\]

Using Eq. (61), and transferring to the SI units of temperature ( $T \rightarrow k_{\mathrm{B}} T_{\mathrm{K}}$ ), we can bring this famous Nyquist formula ${ }^{30}$ to its most popular form

Nyquist formula

$$
\begin{equation*}
\left\langle\tilde{V}^{2}\right\rangle_{\Delta v}=4 k_{\mathrm{B}} T_{\mathrm{K}} R \Delta v \tag{5.81b}
\end{equation*}
$$

Note that according to Eq. (65), this result is only valid at a negligible speed of change of the generalized coordinate $q$ (in this case, negligible current $I$ ), i.e. Eq. (81) expresses the voltage fluctuations as would be measured by an ideal voltmeter, with an input resistance much higher that $R$.

On the other hand, applying a different choice of generalized coordinate and force, $q \rightarrow \Phi, \nrightarrow I$ (where $\left.\Phi \equiv \int \mathscr{\varkappa} t\right) d t$ is the generalized magnetic flux, so that $d w=I d \Phi$ ), we get $\eta \rightarrow 1 / R$, and Eq. (73) yields the thermal fluctuations of the current through the resistor (as measured by an ideal ammeter, i.e. at $V \rightarrow 0)$ :

$$
\begin{equation*}
S_{I}(\omega)=\frac{1}{\pi R} T \text {, i.e. }\left\langle\widetilde{I}^{2}\right\rangle_{\Delta v}=\frac{4 k_{\mathrm{B}} T_{\mathrm{K}}}{R} \Delta v . \tag{5.81c}
\end{equation*}
$$

Note that Eqs. (81) as valid for noise in thermal equilibrium only. In electric circuits, which may be readily driven out of equilibrium by applied voltage $\langle V\rangle$, other types of noise are frequently important, notably the shot noise, which arises in short conductors, e.g., tunnel junctions, at applied voltages $\langle V\rangle \gg T / q$, due to the discreteness of charge carriers. ${ }^{31} \mathrm{~A}$ straightforward analysis using a simple model, described in the assignment of Exercise Problem 9, shows that this noise may be characterized by current fluctuations with low-frequency spectral density

$$
\begin{equation*}
S_{I}(\omega)=\frac{|q \bar{I}|}{2 \pi}, \quad \text { i.e. }\left\langle\widetilde{I}^{2}\right\rangle_{\Delta v}=2|q \bar{I}| \Delta v \tag{5.82}
\end{equation*}
$$

where $q$ is the electric charge of a single current carrier. This is the Schottky formula, valid for any relation between $I$ and $V$. Comparison of Eqs. (81c) and (82) for a device that obeys the Ohm law shows that the shot noise has the same intensity as the thermal noise with effective temperature

$$
\begin{equation*}
T_{\mathrm{ef}}=\frac{|q \bar{V}|}{2} \gg T \tag{5.83}
\end{equation*}
$$

This relation may be interpreted as a result of charge carrier overheating by the applied electric field, and explains why the Schottky formula (82) is only valid in conductors much shorter than the energy

[^916]relaxation length $l_{e}$ of the charge carriers. ${ }^{32}$ Another mechanism of the shot noise suppression, that becomes noticeable if system's transparency is high, is the Fermi-Dirac statistics of electrons. ${ }^{33}$

Returning to the bolometric Dicke radiometer (see Figs. 6-7 and their discussion), we may now use the Langevin equation formalism to finalize its analysis. For this system, the Langevin equation is just the usual equation of heat balance:

$$
\begin{equation*}
C_{V} \frac{d T}{d t}+g\left(T-T_{0}\right)=\mathcal{P}_{\operatorname{det}}(t)+\widetilde{\mathcal{P}}(t) \tag{5.84}
\end{equation*}
$$

where $\mathcal{P}_{\text {det }}=\langle\mathcal{P}\rangle$ describes the (deterministic) power of absorbed radiation, and $\widetilde{\mathcal{P}}$ presents the effective source of temperature fluctuations. Now we can use Eq. (84) to carry out a calculation of the spectral density $S_{T}(\omega)$ of temperature fluctuations absolutely similar to how this was done with Eq. (65), assuming that the frequency spectrum of the fluctuation source is much broader than the intrinsic bandwidth $1 / \tau=g / C_{V}$ of the bolometer, so that its spectral density at frequencies $\omega \tau \sim 1$ may be well approximated by its low-frequency value $S_{\mathcal{A}}(0)$ :

$$
\begin{equation*}
S_{T}(\omega)=\left|\frac{1}{-i \omega C_{V}+g}\right|^{2} S_{\mathcal{P}}(0) \tag{5.85}
\end{equation*}
$$

Then, requiring the variance of temperature fluctuations,

$$
\begin{equation*}
(\delta T)^{2} \equiv\left\langle\widetilde{T}^{2}\right\rangle=2 \int_{0}^{\infty} S_{T}(\omega) d \omega=2 S_{\mathcal{P}}(0) \int_{0}^{\infty}\left|\frac{1}{-i \omega C_{V}+g}\right|^{2} d \omega=2 S_{\mathcal{P}}(0) \frac{1}{C_{V}^{2}} \int_{0}^{\infty} \frac{d \omega}{\omega^{2}+\left(g / C_{V}\right)^{2}}=\frac{\pi S_{\mathcal{P}}(0)}{g C_{V}}, \tag{5.86}
\end{equation*}
$$

to coincide with our earlier "thermodynamic fluctuation" result (41), we get

$$
\begin{equation*}
S_{\mathcal{P}}(0)=\frac{g}{\pi} T_{0}^{2} . \tag{5.87}
\end{equation*}
$$

The r.m.s. value of the "power noise" $\widetilde{P}$ within bandwidth $\Delta v \ll 1 / \tau$ (Fig. 7) becomes equal to the deterministic signal power $\mathcal{P}_{\text {det }}$ (or more exactly, the main harmonic of its modulation law) at

$$
\begin{equation*}
\mathcal{P}_{\min }=\left(\left\langle\widetilde{\mathcal{P}}^{2}\right\rangle_{\Delta v}\right)^{1 / 2}=\left(2 S_{\mathcal{P}}(0) \Delta \omega\right)^{1 / 2}=2(g \Delta v)^{1 / 2} T_{0} . \tag{5.88}
\end{equation*}
$$

This result shows that our earlier prediction (45) may be improved by a substantial factor of the order of $(\Delta v / v)^{1 / 2}$, where the reduction of the output bandwidth is limited only by the signal accumulation time $\Delta t \sim 1 / \Delta v$, while the increase of $v$ is limited by the speed of (typically, mechanical) devices performing the power modulation. In practical systems this factor may improve the sensitivity by a couple orders of magnitude, enabling observation of extremely weak radiation. Maybe the most spectacular example are the recent measurements of the CMB radiation (discussed in Sec. 2.6), which corresponds to blackbody temperature $T_{\mathrm{K}} \approx 2.725 \mathrm{~K}$, with accuracy $\delta T_{\mathrm{K}} \sim 10^{-6} \mathrm{~K}$, using microwave

[^917]receivers with physical temperature of all their components much higher than $\delta T$. The observed weak $\left(\sim 10^{-5} \mathrm{~K}\right)$ anisotropy of the CMB radiation is a major experimental basis of all modern cosmology.

Let me also note that Eq. (73) may be readily generalized to the case when environment's response is different from the Ohmic model (64). This generalization is virtually evident from Eq. (66). Indeed, the second term in its left-hand part is just the Fourier component of the average response of the environment:

$$
\begin{equation*}
\left\langle\boldsymbol{\eta}_{\omega}\right\rangle=i \omega \eta q_{\omega} . \tag{5.89}
\end{equation*}
$$

Let the environment's response be still linear, but have an arbitrary dispersion,

$$
\begin{equation*}
\left\langle 7_{\omega}\right\rangle=\chi(\omega) q_{\omega}, \tag{5.90}
\end{equation*}
$$

where the function $\chi(\omega)$, called the generalized susceptibility of the environment, may be complex, i.e. have both the imaginary and real parts:

$$
\begin{equation*}
\chi(\omega)=\chi^{\prime}(\omega)+i \chi^{\prime \prime}(\omega) . \tag{5.91}
\end{equation*}
$$

Then Eq. (73) remains valid ${ }^{34}$ with the replacement $\eta \rightarrow \chi$ " $(\omega) / \omega$ :

$$
\begin{equation*}
S_{\mathcal{7}}(\omega)=\frac{\chi^{\prime \prime}(\omega)}{\pi \omega} T \tag{5.92}
\end{equation*}
$$

This fundamental relation ${ }^{35}$ is used not only to calculate the fluctuation intensity from the known generalized responsibility (i.e. the deterministic response of a complex system to a small perturbation), but sometimes in the opposite direction - to calculate the linear response from the known fluctuations. (The latter use is especially attractive at numerical simulations, such as molecular dynamics approaches, because it allows to avoid filtering a weak response from the noisy background.)

Now let us discuss what generalization of Eq. (92) is necessary to make that fundamental result suitable for arbitrary temperatures, $T \sim \hbar \omega$. The calculations we had performed started from the apparently classical equation of motion, Eq. (63). However, quantum mechanics shows ${ }^{36}$ that a similar equation is valid for the corresponding Heisenberg-picture operators, so that repeating all arguments leading to the Langevin equation (65), we may write its quantum-mechanical version

$$
\begin{equation*}
m \ddot{\hat{q}}+\eta \dot{\hat{q}}+\kappa \hat{q}=\hat{F}_{\mathrm{det}}+\hat{\tilde{\gamma}} \tag{5.93}
\end{equation*}
$$

[^918]This is the so-called the Heisenberg-Langevin (or "quantum Langevin") equation - in this particular case, for a harmonic oscillator.

The further operations, however, require certain caution, because the right-hand part of the equation is now an operator, and has some nontrivial properties. For example, the "values" of the Heisenberg operator, representing the same variable $f(t)$ at different times, do not necessarily commute:

$$
\begin{equation*}
\left[\hat{\tilde{f}}(t), \hat{\tilde{f}}\left(t^{\prime}\right)\right] \neq 0, \quad \text { if } t^{\prime} \neq t \tag{5.94}
\end{equation*}
$$

As a result, the function defined by Eq. (46) may not be an even function of time delay $\tau \equiv t^{\prime}-t$ even for a stationary process, making it inadequate for representation of the real correlation function - which has to obey Eq. (51). This technical difficulty may be circumvented by the introduction of the following symmetrized correlation function

$$
\begin{equation*}
K_{f}(\tau) \equiv \frac{1}{2}\langle\hat{\tilde{f}}(t) \hat{\tilde{f}}(t+\tau)+\hat{\tilde{f}}(t+\tau) \hat{\tilde{f}}(t)\rangle \equiv \frac{1}{2}\langle\{\hat{\tilde{f}}(t), \hat{\tilde{f}}(t+\tau)\}\rangle, \tag{5.95}
\end{equation*}
$$

(where $\{\ldots, \ldots\}$ denotes the anticommutator of the two operators), and, similarly, the symmetrical spectral density $S_{f}(\omega)$, defined by relation

$$
\begin{equation*}
S_{f}(\omega) \delta\left(\omega-\omega^{\prime}\right) \equiv \frac{1}{2}\left\langle\hat{f}_{\omega} \hat{f}_{\omega^{\prime}}^{*}+\hat{f}_{\omega^{\prime}}^{*} \hat{f}_{\omega}\right\rangle \equiv \frac{1}{2}\left\langle\left\{\hat{f}_{\omega}, \hat{f}_{\omega^{\prime}}^{*}\right\}\right\rangle, \tag{5.96}
\end{equation*}
$$

with $K_{f}(\tau)$ and $S_{f}(\omega)$ still related by the Fourier transform (59). ${ }^{37}$
Now we may repeat all the analysis that was carried out for the classical case, and get Eq. (71) again, but this expression has to be compared not with the equipartition theorem (72), but with its quantum-mechanical generalization (2.78), which, in our current notation, reads

$$
\begin{equation*}
\left\langle\left\langle\widetilde{q}^{2}\right\rangle\right\rangle=\frac{\hbar \omega_{0}}{2 \kappa} \operatorname{coth} \frac{\hbar \omega_{0}}{2 T} . \tag{5.97}
\end{equation*}
$$

As a result, we get the following quantum-mechanical generalization of Eq. (92):

$$
\begin{equation*}
S_{\neq}(\omega)=\frac{\hbar \chi^{\prime \prime}(\omega)}{2 \pi} \operatorname{coth} \frac{\hbar \omega}{2 T} \tag{5.98}
\end{equation*}
$$

Fluctuationdissipation theorem

This is the much-celebrated fluctuation-dissipation theorem, frequently referred to just as FDT. 38
As natural as it seems, this generalization poses a very interesting conceptual dilemma. Let, for the sake of clarity, temperature be relatively low, $T \ll \hbar \omega$; then Eq. (98) gives a temperatureindependent result

$$
\begin{equation*}
S_{\neq}(\omega)=\frac{\hbar \chi^{\prime \prime}(\omega)}{2 \pi} \tag{5.99}
\end{equation*}
$$

[^919]which is frequently called the quantum noise. According to the quantum Langevin equation (93), nothing but these fluctuations of the force exerted by the environment, with spectral density proportional to the imaginary part of susceptibility (i.e. damping), are the source of the ground-state "fluctuations" of the coordinate and momentum of a quantum harmonic oscillator, with r.m.s. values
\[

$$
\begin{equation*}
\delta q \equiv\left\langle\left\langle\widetilde{q}^{2}\right\rangle\right\rangle^{1 / 2}=\left(\frac{\hbar}{2 m \omega_{0}}\right)^{1 / 2}, \quad \delta p \equiv\left\langle\left\langle\widetilde{p}^{2}\right\rangle\right\rangle^{1 / 2}=m \omega_{0} \delta q=\left(\frac{\hbar m \omega_{0}}{2}\right)^{1 / 2}, \quad \text { i.e. } \delta q \cdot \delta p=\frac{\hbar}{2}, \tag{5.100}
\end{equation*}
$$

\]

and average energy $\hbar \omega_{0} / 2$. On the other hand, the basic quantum mechanics tells us that exactly these formulas describe the ground state of a dissipation-free oscillator, not coupled to any environment, and are a direct corollary of the Heisenberg uncertainty relation

$$
\begin{equation*}
\delta q \cdot \delta p \geq \frac{\hbar}{2} \tag{5.101}
\end{equation*}
$$

(The Gaussian wave packets, pertinent to a harmonic oscillator' ground state, turn the sign in Eq. (101) into pure equality.) So, what is the genuine source of Eqs. (100)?

The resolution of this paradox is that either interpretation of Eqs. (100) is legitimate, with their relative convenience depending on the particular application. (One can say that since the right-hand part of the quantum Langevin equation (93) is a quantum-mechanical operator, rather than a classical force, it "carries the uncertainty relation within itself".) However, this opportunistic resolution leaves the following question open: is the quantum noise (99) of the environment observable directly, without any probe oscillator subjected to it? An experimental resolution of this dilemma is not quite simple, because usual scientific instruments have their own zero-point fluctuations, which may be readily confused with those of the system under study. Fortunately, this difficulty may be overcome, for example, using unique frequency-mixing ("down-conversion") properties of Josephson junctions. ${ }^{39}$ Special low-temperature experiments using such down-conversion ${ }^{40}$ have confirmed that noise (99) is real and measurable. This has been one of the most convincing direct demonstrations of the reality of the zero-point energy $\hbar \omega / 2 .{ }^{41}$

Finally, let me mention briefly an alternative derivation ${ }^{42}$ of the fluctuation-theorem from the general quantum mechanics of open systems. This derivation is substantially longer, but gives an interesting sub-product,

$$
\begin{equation*}
\langle[\hat{\tilde{\gamma}}(t), \hat{\tilde{\gamma}}(t+\tau)]\rangle=i \hbar g(\tau) \tag{5.102}
\end{equation*}
$$

where $\mathfrak{g} \tau$ ) is the temporal Green's function of the environment (as "seen" by the system subjected to the generalized force $\mathcal{F}$ ), defined by equation

$$
\begin{equation*}
\langle\mathcal{\chi}(t)\rangle=\int_{0}^{\infty} g(\tau) q(t-\tau) d \tau=\int_{-\infty}^{t} g\left(t-t^{\prime}\right) q\left(t^{\prime}\right) d t^{\prime} . \tag{5.103}
\end{equation*}
$$

[^920]Plugging the Fourier transforms of all three functions participating in Eq. (103) into that relation, it is straightforward to check ${ }^{43}$ that the Green's function is just the Fourier image of the complex susceptibility $\chi(\omega)$, defined by Eq. (90):

$$
\begin{equation*}
\int_{0}^{\infty} g(\tau) e^{i \omega \tau} d \tau=\chi(\omega) \tag{5.104}
\end{equation*}
$$

here 0 is used as a lower limit instead of $(-\infty)$ just to emphasize that due to the causality principle, the Green's function has to be equal zero for $\tau<0$.

In order to reveal the real beauty of Eq. (102), we may use the Wiener-Khinchin theorem (59) to rewrite the fluctuation-dissipation theorem (98) in a form similar to Eq. (102):

$$
\begin{equation*}
\langle\{\hat{\tilde{\gamma}}(t), \hat{\tilde{\gamma}}(t+\tau)\}\rangle=2 K_{\neq 7}(\tau) \tag{5.105}
\end{equation*}
$$

where the correlation function $K_{\neq}(\tau)$ is most simply described by its Fourier transform, equal to $\pi S_{\neq}(\omega)$ :

$$
\begin{equation*}
\int_{0}^{\infty} K_{\ngtr}(\tau) \cos \omega \tau d \tau=\frac{\hbar \chi^{\prime \prime}(\omega)}{2} \operatorname{coth} \frac{\hbar \omega}{2 T} . \tag{5.106}
\end{equation*}
$$

The comparison of Eqs. (102) and (104), on one hand, and Eqs (105)-(106), on the other hand, shows that both the commutation and anticommutation properties of the Heisenberg-Langevin force operator at different moments of time are determined by the same generalized susceptibility $\chi(\omega)$, but the average anticommutator also depends on temperature, while the average commutator does not. ${ }^{44}$

### 5.6. The Kramers problem and the Smoluchowski equation

Returning to the classical case, it is evident that the Langevin equation (65) provides the means not only for the analysis of stationary fluctuations, but also for the description of an arbitrary time evolution of (classical) dynamic systems coupled to their environment - which, again, provides both dissipation and fluctuations. However, this approach suffers from two major handicaps.

First, this equation does enable us to find the statistical average of variable $q$, and the variance of its fluctuations (i.e., in the common mathematical terminology, the first and second moments of the probability distribution) as functions of time, but not the distribution $w(q, t)$ as such. This may not look like a big problem, because in most cases (in particular, in linear systems such as the harmonic oscillator) the distribution is Gaussian - see, e.g., Eq. (2.77).

The second, more painful, drawback of the Langevin approach is that it is instrumental only for the already mentioned "linear" systems - i.e., the systems whose dynamics is described by linear differential equations, such as Eq. (65). However, as we know from classical dynamics, many important problems (for example, the Kepler problem of planetary motion ${ }^{45}$ ) are reduced to 1 D motion in substantially anharmonic potentials $U_{\text {ef }}(q)$, leading to nonlinear equations of motion. If the energy of interaction between the system and its random environment is bilinear - i.e. is a product of variables

[^921]belonging to these sub-systems (as it is very frequently the case), we may repeat all arguments of the last section to derive the following generalized version of the Langevin equation
\[

$$
\begin{equation*}
m \ddot{q}+\eta \dot{q}+\frac{\partial U(q, t)}{\partial q}=\tilde{\not}(t), \tag{5.107}
\end{equation*}
$$

\]

valid for an arbitrary, possibly time-dependent potential $U(q, t){ }^{46}$ Unfortunately, the solution of this equation may be very hard. Indeed, the Fourier analysis carried out in the last section was essentially based on the linear superposition principle that is invalid for nonlinear equations.

If the fluctuation intensity is low, $|\delta q| \ll\langle q\rangle$, where $\langle q\rangle(t)$ is the deterministic solution of Eq. (107) in the absence of fluctuations, this equation may be linearized ${ }^{47}$ with respect to small fluctuations $\widetilde{q} \equiv q-\langle q\rangle$ to get a linear equation,

$$
\begin{equation*}
m \ddot{\tilde{q}}+\eta \dot{\widetilde{q}}+\kappa(t) \widetilde{q}=\tilde{\boldsymbol{q}}(t), \quad \text { with } \kappa(t) \equiv \frac{\partial^{2}}{\partial q^{2}} U(\langle q\rangle(t), t) \tag{5.108}
\end{equation*}
$$

This equation differs from Eq. (65) only by the time dependence of the effective spring constant $\kappa(t)$, and may be solved by the Fourier expansion of both fluctuations and function $\kappa(t)$. Such calculations are somewhat more cumbersome than have been performed above, but may be doable (especially if the unperturbed motion $\langle q\rangle(t)$ is periodic), and sometimes give useful analytical results. ${ }^{48}$

However, some important problems cannot be solved by the linearization. Perhaps, the most apparent example is the so-called Kramers problem ${ }^{49}$ of finding the lifetime of a metastable state of a 1D classical system in a potential well separated from the continuum motion region with a potential barrier (Fig. 10).

Fig. 5.10. The Kramers problem.

In the absence of fluctuations, the system, placed close to well's bottom ( $q=q_{1}$ ), would stay there forever. Fluctuations result not only in a finite spread of the probability density $w(q, t)$ around that point, but also in the gradual decrease of the total probability

$$
\begin{equation*}
W(t)=\int_{\substack{\text { wells } \\ \text { bottom }}} w(q, t) d q \tag{5.109}
\end{equation*}
$$

[^922]to find the system in the well, because of the growing probability of escape from the well, over the potential barrier, due to thermal activation. If the barrier height,
\[

$$
\begin{equation*}
U_{0} \equiv U\left(q_{2}\right)-U\left(q_{1}\right), \tag{5.110}
\end{equation*}
$$

\]

is much larger than temperature $T,{ }^{50}$ the Boltzmann distribution $w \propto \exp \{-U(q) / T\}$ should be approximately valid in most of the well, so that the probability for the system to overcome the barrier should scale as $\exp \left\{-U_{0} / T\right\}$. From these handwaving arguments, one may reasonably expect that if probability $W(t)$ that the system is still in the well by time $t$ should obey the usual "decay law"

$$
\begin{equation*}
\dot{W}=-\frac{W}{\tau}, \tag{5.111}
\end{equation*}
$$

then lifetime $\tau$ has to obey the general Arrhenius law, $\tau=\tau_{A} \exp \left\{U_{0} / T\right\}$. However, that relation needs to be proved, and the pre-exponential coefficient $\tau_{A}$ (frequently called the attempt time) needs to be calculated. This cannot be done by the linearization of Eq. (107), because the linearization is equivalent to a quadratic approximation of the potential $U(q)$, which evidently cannot describe the potential well and the potential barrier simultaneously - see Fig. 10.

This and other essentially nonlinear problems may be addressed using an alternative approach to fluctuation analysis, dealing directly with the time evolution of the probability density $w(q, t)$. Due to the shortage of time, I will review this approach a bit superficially, using mostly handwaving arguments, and refer the interested reader to special literature ${ }^{51}$ for strict mathematical proofs. Let us start from the effect of diffusion of a free 1D particle in the high damping limit, described by the Langevin equation (74), and assume that at all times the probability distribution stays Gaussian:

$$
\begin{equation*}
w(q, t)=\frac{1}{(2 \pi)^{1 / 2} \delta q(t)} \exp \left\{-\frac{\left(q-q_{0}\right)^{2}}{2 \delta q^{2}(t)}\right\} \tag{5.112}
\end{equation*}
$$

where $q_{0}$ is the initial position of the particle, and $\delta q(t)$ is the time-dependent distribution width, which grows in time in accordance with Eq. (77):

$$
\begin{equation*}
\delta q(t)=(2 D t)^{1 / 2} \tag{5.113}
\end{equation*}
$$

It is straightforward to check, by substitution, that this solution satisfies the following simple partial differential equation, ${ }^{52}$

$$
\begin{equation*}
\frac{\partial w}{\partial t}=D \frac{\partial^{2} w}{\partial q^{2}} \tag{5.114}
\end{equation*}
$$

with the delta-functional initial condition

$$
\begin{equation*}
w(q, 0)=\delta\left(q-q_{0}\right) \tag{5.115}
\end{equation*}
$$

[^923]The simple and important equation of diffusion (114) may be naturally generalized to the 3D motion: ${ }^{53}$

Equation
of $3 D$
of 3D

$$
\begin{equation*}
\frac{\partial w}{\partial t}=D \nabla^{2} w \tag{5.116}
\end{equation*}
$$

Now let us compare this equation with the probability conservation law, ${ }^{54}$

$$
\begin{equation*}
\frac{\partial w}{\partial t}+\nabla \cdot \mathbf{j}_{w}=0 \tag{5.117a}
\end{equation*}
$$

where vector $\mathbf{j}_{w}$ has the physical sense of the probability current density. (The validity of this relation is evident from its integral form,

$$
\begin{equation*}
\frac{d}{d t} \int_{V} w d^{3} r+\oint_{S} \mathbf{j}_{w} \cdot d^{2} \mathbf{r}=0 \tag{5.117b}
\end{equation*}
$$

that results from integration of Eq. (117a) over an arbitrary time-independent volume $V$ limited by surface $S$, and applying the divergence theorem ${ }^{55}$ to the second term.) The continuity relation (117a) coincides with Eq. (116), with $D$ given by Eq. (78), only if we take

$$
\begin{equation*}
\mathbf{j}_{w}=-D \nabla w=-\frac{T}{\eta} \nabla w . \tag{5.118}
\end{equation*}
$$

The first form of this relation allows a simple interpretation: the probability flow is proportional to the spatial gradient of probability density (i.e., in application to many ( $N$ ) similar and independent particles, just to the gradient of their concentration $n=N w$ ), with the sign corresponding to the flow from the higher to lower concentration. This flow is the very essence of the effect of diffusion.

The fundamental Eq. (117) has to be satisfied also for a force-driven particle at negligible diffusion $(D \rightarrow 0)$; in this case

$$
\begin{equation*}
\mathbf{j}_{w}=w \mathbf{v}, \tag{5.119}
\end{equation*}
$$

where $\mathbf{v}$ is the deterministic velocity of the particle. In the high-damping limit we are considering right now, $\mathbf{v}$ is just the drift velocity:

$$
\begin{equation*}
\mathbf{v}=\frac{1}{\eta} \boldsymbol{\gamma}_{\mathrm{det}}=-\frac{1}{\eta} \nabla U(\mathbf{r}) \tag{5.120}
\end{equation*}
$$

where $\boldsymbol{F}_{\text {det }}$ is the deterministic force described by potential energy $U(\mathbf{r})$. Now, as we have descriptions of $\mathbf{j}_{w}$ due to both drift and diffusion separately, we may rationally assume that in the general case when both effects are present, the corresponding components of the probability current just add up, so that

$$
\begin{equation*}
\mathbf{j}_{w}=\frac{1}{\eta}[w(-\nabla U)-T \nabla w], \tag{5.121}
\end{equation*}
$$

[^924]and Eq. (117a) takes the form
\[

$$
\begin{equation*}
\eta \frac{\partial w}{\partial t}=\nabla(w \nabla U)+T \nabla^{2} w \tag{5.122}
\end{equation*}
$$

\]

This is the Smoluchowski equation, ${ }^{56}$ which is closely related to the Boltzmann equation in multiparticle kinetics - to be discussed in the next chapter.

As a sanity check, let us see what does the Smoluchowski equation give in the stationary limit, $\partial w / \partial t \rightarrow 0$ (which evidently may be achieved only if the deterministic potential $U$ is time-independent.) Then Eq. (117a) yields $\mathbf{j}_{w}=$ const, where the constant describes the motion of the system as the whole. If such motion is absent, $\mathbf{j}_{w}=0$, then according to Eq. (121),

$$
\begin{equation*}
w \nabla U+T \nabla w=0, \quad \text { i.e. } \frac{\nabla w}{w}=-\frac{\nabla U}{T} . \tag{5.123}
\end{equation*}
$$

Since the left-hand part of the last form of the last relation is just $\nabla(\ln w)$, Eq. (123) may be immediately integrated, giving

$$
\begin{equation*}
\ln w=-\frac{U}{T}+\ln C, \quad \text { i.e. } w(\mathbf{r})=C \exp \left\{-\frac{U(\mathbf{r})}{T}\right\}, \tag{5.124}
\end{equation*}
$$

Multiplied by the number $N$ of similar, independent systems, with spatial density $n(\mathbf{r})=N w(\mathbf{r})$, this is just the Boltzmann distribution (3.26).

Now, as a less trivial example of the Smoluchowski equation's applications, let us use it to solve the 1 D Kramers problem (Fig. 10) in the corresponding high-damping limit, $m \ll \eta \tau_{A}$. It is straightforward to check that the 1D version of Eq. (121),

$$
\begin{equation*}
I_{w}=\frac{1}{\eta}\left[w\left(-\frac{\partial U}{\partial q}\right)-T \frac{\partial w}{\partial q}\right] \tag{5.125a}
\end{equation*}
$$

is equivalent to

$$
\begin{equation*}
I_{w}=-\frac{T}{\eta} \exp \left\{-\frac{U(q)}{T}\right\} \frac{\partial}{\partial q}\left(w \exp \left\{\frac{U(q)}{T}\right\}\right) \tag{5.125b}
\end{equation*}
$$

(where $I_{w}$ is the probability current at a certain location $q$, rather than its density), so that we can write

$$
\begin{equation*}
I_{w} \exp \left\{\frac{U(q)}{T}\right\}=-\frac{T}{\eta} \frac{\partial}{\partial q}\left(w \exp \left\{\frac{U(q)}{T}\right\}\right) \tag{5.126}
\end{equation*}
$$

As was discussed above, the notion of metastable state's lifetime is well defined only for sufficiently low temperatures

$$
\begin{equation*}
T \ll U_{0} . \tag{5.127}
\end{equation*}
$$

[^925]when the lifetime is relatively long, $\tau \gg \tau_{A}$, where $\tau_{A}$ has to be of the order of the time of the system relaxation inside the well. Since the first term of the continuity equation (117b) is of the order of $W / \tau$, in this limit the term, and hence the gradient of $I_{w}$, are negligibly small, so the probability current does not depend on $q$ in the potential barrier region. Let us integrate both sides of Eq. (126) over that region, using that fact:
\[

$$
\begin{equation*}
I_{w} \int_{q^{\prime}}^{q^{\prime \prime}} \exp \left\{\frac{U(q)}{T}\right\} d q=-\frac{T}{\eta}\left(w \exp \left\{\frac{U(q)}{T}\right\}\right)_{q^{\prime}}^{q^{\prime \prime}} \tag{5.128}
\end{equation*}
$$

\]

where the integration limits $q^{\prime}$ and $q^{\prime \prime}$ (Fig. 10) are selected so that so that

$$
\begin{equation*}
T \ll U\left(q^{\prime}\right)-U\left(q_{1}\right), U\left(q_{2}\right)-U\left(q^{\prime \prime}\right) \ll U_{0} . \tag{5.129}
\end{equation*}
$$

(Evidently, such selection is only possible if condition (127) is satisfied.) In this limit the contribution to the right-hand part from point $q^{\prime \prime}$ is negligible because the probability density behind the barrier is exponentially small. On the other hand, the probability at point $q$ ' is close to its stationary, Boltzmann value (124), so that

$$
\begin{equation*}
w\left(q^{\prime}\right) \exp \left\{\frac{U\left(q^{\prime}\right)}{T}\right\}=w\left(q_{1}\right) \exp \left\{\frac{U\left(q_{1}\right)}{T}\right\}, \tag{5.130}
\end{equation*}
$$

and Eq. (128) yields

$$
\begin{equation*}
I_{w}=\frac{T}{\eta} w\left(q_{1}\right) / \int_{q^{\prime}}^{q^{\prime \prime}} \exp \left\{\frac{U(q)-U\left(q_{1}\right)}{T}\right\} d q . \tag{5.131}
\end{equation*}
$$

We are almost done. The probability density $w\left(q_{1}\right)$ at the well's bottom may be expressed in terms of the total probability $W$ of the particle being in the well by using the normalization condition

$$
\begin{equation*}
W=\int_{\substack{\text { wells } \\ \text { bottom }}} w\left(q_{1}\right) \exp \left\{\frac{U\left(q_{1}\right)-U(q)}{T}\right\} d q \tag{5.132}
\end{equation*}
$$

the integration here may be limited by the region where the difference $U(q)-U\left(q_{1}\right)$ is larger then $T$ but still much smaller than $U_{0}-$ cf. Eq. (129). According to the Taylor expansion, the shape of any smooth potential well near its bottom may be well approximated by a quadratic parabola:

$$
\begin{equation*}
U\left(q \approx q_{1}\right)-U\left(q_{1}\right) \approx \frac{\kappa_{1}}{2}\left(q-q_{1}\right)^{2}, \quad \text { where }\left.\kappa_{1} \equiv \frac{d^{2} U}{d q^{2}}\right|_{q=q_{1}}>0 . \tag{5.133}
\end{equation*}
$$

With this approximation, Eq. (132) is reduced to the standard Gaussian integral: ${ }^{57}$

$$
\begin{equation*}
W=w\left(q_{1}\right) \int_{\substack{\text { wells } \\ \text { bottom }}} \exp \left\{-\frac{\kappa_{1}\left(q-q_{1}\right)^{2}}{2 T}\right\} d q \approx w\left(q_{1}\right) \int_{-\infty}^{+\infty} \exp \left\{\frac{\kappa_{1} \widetilde{q}^{2}}{2 T}\right\} d \widetilde{q}=w\left(q_{1}\right)\left(\frac{2 \pi T}{\kappa_{1}}\right)^{1 / 2} . \tag{5.134}
\end{equation*}
$$

To complete the calculation, we may use the similar approximation,

[^926]\[

$$
\begin{align*}
U\left(q \approx q_{2}\right)-U\left(q_{1}\right) & \approx\left[U\left(q_{2}\right)-\frac{\kappa_{2}}{2}\left(q-q_{2}\right)^{2}\right]-U\left(q_{1}\right)=U_{0}-\frac{\kappa_{2}}{2}\left(q-q_{2}\right)^{2}  \tag{5.135}\\
& \text { where } \kappa_{2} \equiv-\left.\frac{d^{2} U}{d q^{2}}\right|_{q=q_{2}}>0
\end{align*}
$$
\]

to work out the remaining integral in Eq. (131), because in the limit (129) this integral is dominated by the contribution from a region very close to the barrier top, where approximation (135) is asymptotically exact. As a result, we get

$$
\begin{equation*}
\int_{q^{\prime}}^{q^{\prime \prime}} \exp \left\{\frac{U(q)-U\left(q_{1}\right)}{T}\right\} d q \approx \exp \left\{\frac{U_{0}}{T}\right\}\left(\frac{2 \pi T}{\kappa_{2}}\right)^{1 / 2} \tag{5.136}
\end{equation*}
$$

Plugging Eqs. (136), and $w\left(q_{1}\right)$ expressed from Eq. (134), into Eq. (131), we finally get

$$
\begin{equation*}
I_{w}=W \frac{\left(\kappa_{1} \kappa_{2}\right)^{1 / 2}}{2 \pi \eta} \exp \left\{-\frac{U_{0}}{T}\right\} \tag{5.137}
\end{equation*}
$$

This expression should be compared with the 1D version of Eq. (117b) for the segment $\left[-\infty, q^{\prime}\right]$. Since this interval covers the region near $q_{1}$ where most of the probability density resides, and $I_{q}(-\infty)=$ 0 , the result is merely

$$
\begin{equation*}
\frac{d W}{d t}+I_{w}\left(q^{\prime}\right)=0 \tag{5.138}
\end{equation*}
$$

In our approximation, $I_{w}\left(q^{\prime}\right)$ does not depend on the exact position of point $q^{\prime}$, and is given by Eq. (137), so that plugging it into Eq. (138), we recover the exponential decay law (111), with lifetime

$$
\begin{equation*}
\tau=\frac{2 \pi \eta}{\left(\kappa_{1} \kappa_{2}\right)^{1 / 2}} \exp \left\{\frac{U_{0}}{T}\right\}=2 \pi\left(\tau_{1} \tau_{2}\right)^{1 / 2} \exp \left\{\frac{U_{0}}{T}\right\}, \quad \text { where } \tau_{1,2} \equiv \frac{\eta}{\kappa_{1,2}} \tag{5.139}
\end{equation*}
$$

Thus the metastable state lifetime is indeed described by the Arrhenius law, with the attempt time scaling as the geometric mean of system's "relaxation times" near the potential well bottom $\left(\tau_{1}\right)$ and the potential barrier top $\left(\tau_{2}\right) .{ }^{58}$ Let me leave for reader's exercise to prove that if the potential profile near well's bottom and/or top is sharp, the pre-exponential factor in Eq. (139) should be modified, but the Arrhenius exponent is not affected.

### 5.7. The Fokker-Planck equation

Expression (139) is just a particular, high-damping limit of a more general result obtained by Kramers. In order to recover all of it, we need to generalize the Smoluchowski equation to arbitrary values of damping $\eta$. In this case, the probability density $w$ is a function of not only the particle's position $\mathbf{q}$ (and time $t$ ), but also its momentum $\mathbf{p}$ - see Eq. (2.11). Thus the continuity equation (117a) needs to be generalized to 6D phase space. Such generalization is natural:

[^927]\[

$$
\begin{equation*}
\frac{\partial w}{\partial t}+\nabla_{q} \cdot \mathbf{j}_{q}+\nabla_{p} \cdot \mathbf{j}_{p}=0 \tag{5.140}
\end{equation*}
$$

\]

where $\mathbf{j}_{q}$ (which was called $\mathbf{j}_{w}$ in the last section) is the probability current density in the coordinate space, while $\mathbf{j}_{p}$ is the current density in the momentum space, and $\nabla_{p}$ is the gradient operator in that space,

$$
\begin{equation*}
\nabla_{p} \equiv \sum_{j=1}^{3} \mathbf{n}_{j} \frac{\partial}{\partial p_{j}} \tag{5.141}
\end{equation*}
$$

while $\nabla_{q}$ is the usual gradient operator in the coordinate space, that was denoted as $\nabla$ in the previous section - with index $q$ added here just for additional clarity. At negligible fluctuations ( $T \rightarrow 0$ ), $\mathbf{j}_{p}$ in the momentum space may be evaluated using the natural analogy with $\mathbf{j}_{q}$ - see Eq. (119). In our new notation, that relation takes the following form,

$$
\begin{equation*}
\mathbf{j}_{q}=w \mathbf{v}=w \dot{\mathbf{q}}=w \frac{\mathbf{p}}{m}, \tag{5.142}
\end{equation*}
$$

so it is naturally to take

$$
\begin{equation*}
\mathbf{j}_{p}=w \dot{\mathbf{p}}=w\langle\boldsymbol{\gamma}\rangle=w\left(-\nabla_{q} U-\eta \mathbf{v}\right)=w\left(-\nabla_{q} U-\eta \frac{\mathbf{p}}{m}\right) . \tag{5.143}
\end{equation*}
$$

As a sanity check, it is straightforward to verify that the diffusion-free equation resulting from the combination of Eqs. (140), (142) and (143),

$$
\begin{equation*}
\left.\frac{\partial w}{\partial t}\right|_{\mathrm{drift}}=-\nabla_{q} \cdot\left(w \frac{\mathbf{p}}{m}\right)+\nabla_{p} \cdot\left[w\left(\nabla_{q} U+\eta \frac{\mathbf{p}}{m}\right)\right] \tag{5.144}
\end{equation*}
$$

allows the following particular solution

$$
\begin{equation*}
w(\mathbf{q}, \mathbf{p}, t)=\delta(\mathbf{q}-\langle\mathbf{q}\rangle(t)) \delta(\mathbf{p}-\langle\mathbf{p}\rangle(t)) \tag{5.145}
\end{equation*}
$$

where the statistical-average coordinate and momentum satisfy the deterministic equations of motion,

$$
\begin{equation*}
\langle\dot{\mathbf{q}}\rangle=\frac{\langle\mathbf{p}\rangle}{m}, \quad\langle\dot{\mathbf{p}}\rangle=-\nabla_{q} U-\eta \frac{\langle\mathbf{p}\rangle}{m}, \tag{5.146}
\end{equation*}
$$

describing particle's drift, with the appropriate deterministic initial conditions.
In order to understand how the diffusion may be accounted for, let us consider a statistical ensemble of free $\left(\nabla_{q} U=0, \eta \rightarrow 0\right)$ particles that are uniformly distributed in direct space (so that $\nabla_{q} w=$ 0 ), but possibly localized in the momentum space. For this case, the right-hand part of Eq. (144) vanishes, i.e. the time evolution of the probability density $w$ may be only due to diffusion. In the corresponding limit $\langle\boldsymbol{\eta}\rangle \rightarrow 0$, the Langevin equation (107) for each Cartesian coordinate is reduced to

$$
\begin{equation*}
m \ddot{q}_{j}=\widetilde{\mathcal{F}}_{j}(t), \text { i.e. } \dot{p}_{j}=\widetilde{\mathcal{F}}_{j}(t) \tag{5.147}
\end{equation*}
$$

This equation is similar to the high-damping 1D equation (74) (with $\not_{\mathrm{det}}=0$ ), with replacement $q \rightarrow$ $p_{j} / \eta$, and hence the corresponding contribution to $\partial w / \partial t$ may be described by the second term of Eq. (122) with that replacement:

$$
\begin{equation*}
\left.\frac{\partial w}{\partial t}\right|_{\text {diffusion }}=D \nabla_{p / \eta}^{2} w=\frac{T}{\eta} \eta^{2} \nabla_{p}^{2} w=\eta T \nabla_{p}^{2} w . \tag{5.148}
\end{equation*}
$$

Now the reasonable assumption that in the arbitrary case the drift and diffusion contributions to $\partial w / \partial t$ just add up, immediately leads us to the full Fokker-Planck equation: ${ }^{59}$

$$
\begin{equation*}
\frac{\partial w}{\partial t}=-\nabla_{q} \cdot\left(w \frac{\mathbf{p}}{m}\right)+\nabla_{p} \cdot\left[w\left(\nabla_{q} U+\eta \frac{\mathbf{p}}{m}\right)\right]+\eta T \nabla_{p}^{2} w . \tag{5.149}
\end{equation*}
$$

As a sanity check, let us use this equation to find the stationary probability distribution of momentum of free particles, at arbitrary damping $\eta$, in the momentum space, assuming their uniform distribution in the direct space, $\nabla_{q}=0$. In the stationary case $\partial w / \partial t=0$, so that Eq. (149) is reduced to

$$
\begin{equation*}
\nabla_{p} \cdot\left[w\left(\eta \frac{\mathbf{p}}{m}\right)\right]+\eta T \nabla_{p}^{2} w=0 . \tag{5.150}
\end{equation*}
$$

The damping coefficient $\eta$ cancels, and the first integration over momentum yields

$$
\begin{equation*}
\frac{\mathbf{p}}{m} w+T \nabla_{p} w=\mathbf{j} \tag{5.152}
\end{equation*}
$$

where $\mathbf{j}$ is a vector constant describing a possible motion of the system as the whole. In the absence of such motion, $\mathbf{j}=0$, the second integration over momentum gives

$$
\begin{equation*}
w=\text { const } \times \exp \left\{-\frac{p^{2}}{2 m T}\right\}, \tag{5.153}
\end{equation*}
$$

i.e. the Maxwell distribution (3.5). However, result (153) is more general than that obtained in Sec. 3.1, because it shows that the distribution stays the same even at nonvanishing damping.

It is also easy to show that if the damping is large (in the sense assumed in the last section), the solution of the Fokker-Planck equation tends to the following product

$$
\begin{equation*}
w(\mathbf{q}, \mathbf{p}, t) \rightarrow \text { const } \times \exp \left\{-\frac{p^{2}}{2 m T}\right\} \times w(\mathbf{q}, t) \tag{5.154}
\end{equation*}
$$

where the direct-space distribution $\mathrm{w}(\mathbf{q}, t)$ obeys the Smoluchowski equation (122). However, in the general case, solutions of Eq. (149) may be rather complex, ${ }^{60}$ so I would mention (rather than derive) only one of them, that of the Kramers problem (Fig. 10). Acting virtually exactly as in Sec. 6, one can show at arbitrary damping (but still in the limit (127), $T \ll U_{0}$, with the additional restriction $\tau \gg m / \gamma$ ), the metastable state's lifetime is again given by the Arrhenius formula (139), with the same exponent $\exp \left\{U_{0} / T\right\}$, but with the reciprocal time constants $1 / \tau_{1,2}$ replaced with

$$
\omega_{1,2}^{\prime} \equiv\left[\omega_{1,2}^{2}+\left(\frac{\eta}{2 m}\right)^{2}\right]^{1 / 2}-\frac{\eta}{2 m} \rightarrow \begin{cases}\omega_{1,2}, & \text { for } \eta \ll m \omega_{1,2}  \tag{5.155}\\ 1 / \tau_{1,2}, & \text { for } m \omega_{1,2} \ll \eta\end{cases}
$$

[^928]where $\omega_{1,2} \equiv\left(\kappa_{1,2} / m\right)^{1 / 2}$, while $\kappa_{1,2}$ are the effective spring constants defined by Eqs. (133) and (135). Thus, in the most important particular limit of low damping, Eq. (139) is replaced with the famous formula

Kramers
formula for low damping

$$
\begin{equation*}
\tau=\frac{2 \pi}{\left(\omega_{1} \omega_{2}\right)^{1 / 2}} \exp \left\{\frac{U_{0}}{T}\right\} \tag{5.156}
\end{equation*}
$$

This Kramers' result for the classical thermal activation of the virtually-Hamiltonian system over the potential barrier may be compared with that for its quantum-mechanical tunneling through the barrier. ${ }^{61}$ Even the simplest, WKB approximation for the latter time,

$$
\begin{equation*}
\tau_{Q}=\tau_{A} \exp \left\{-2 \int_{\kappa^{2}(q)>0} \kappa(q) d q\right\}, \quad \text { with } \frac{\hbar^{2} \kappa^{2}(q)}{2 m} \equiv U(q)-E \text {, } \tag{5.157}
\end{equation*}
$$

shows that generally those two lifetimes have different dependences on the barrier shape. For example, for a nearly-rectangular potential barrier, the exponent that determines the classical lifetime (156) depends (linearly) only on the barrier height $U_{0}$, while that defining the quantum lifetime is proportional to the barrier width, while scaling as a square root of $U_{0}$. However, in the important case of "soft" potential profiles, which are typical for the case of barely emerging (or nearly disappearing) quantum wells (Fig. 11) the classical and quantum results may be simply related.

Fig. 5.11. Cubic-parabolic potential profile and its parameters.

Indeed, such potential profile $U(q)$ may be well approximated by 4 leading terms of its Taylor expansion, with the highest term proportional to $\left(q-q_{0}\right)^{3}$, near some point $q_{0}$ in the vicinity of the well. In this approximation, the second derivative $d^{2} U / d q^{2}$ vanishes at the point $q_{0}=\left(q_{1}+q_{2}\right) / 2$, exactly between the well's bottom and the barrier's top (in Fig. 11, $q_{1}$ and $q_{2}$ ). Selecting the origin at this point, we may reduce the approximation to just two terms: ${ }^{62}$

$$
\begin{equation*}
U(q)=a q-\frac{b}{3} q^{3}, \tag{5.158}
\end{equation*}
$$

with $a b>0$. Using a straightforward calculus, we can find all important parameters of this cubicparabola: the positions of its minimum and maximum:

$$
\begin{equation*}
q_{2}=-q_{1}=(a / b)^{1 / 2} \tag{5.159}
\end{equation*}
$$

the barrier height over the well's bottom:

[^929]\[

$$
\begin{equation*}
U_{0} \equiv U\left(q_{2}\right)-U\left(q_{1}\right)=\frac{4}{3}\left(\frac{a^{3}}{b}\right)^{1 / 2}, \tag{5.160}
\end{equation*}
$$

\]

and the effective spring constants:

$$
\begin{equation*}
\kappa_{1}=\kappa_{2} \equiv\left|\frac{d^{2} U}{d q^{2}}\right|_{q_{1,2}}=2(a b)^{1 / 2} \tag{5.161}
\end{equation*}
$$

The last expression shows that for this potential profile, frequencies $\omega_{1,2}$ participating in Eq. (161) are equal to each other, so that this result may be rewritten as

$$
\begin{equation*}
\tau=\frac{2 \pi}{\omega_{0}} \exp \left\{\frac{U_{0}}{T}\right\}, \quad \text { with } \omega_{0}^{2} \equiv \frac{2(a b)^{1 / 2}}{m} \tag{5.162}
\end{equation*}
$$

On the other hand, for the same profile, the WKB approximation (157) (which is accurate when the height of the metastable state energy over the well's bottom, $E-U\left(q_{1}\right) \approx \hbar \omega_{0} / 2$, is much less than the barrier height $U_{0}$ ) yields ${ }^{63}$

Comparison of the dominating, exponential factors in these two results shows that the thermal activation yields lower lifetime (i.e., dominates the metastable state decay) if temperature is above the crossover value

$$
\begin{equation*}
T_{c}=\frac{36}{5} \hbar \omega_{0}=7.2 \hbar \omega_{0} \tag{5.164}
\end{equation*}
$$

This expression for the cubic-parabolic barrier may be compared with the similar crossover for a quadratic-parabolic barrier, ${ }^{64}$ for which $T_{c}=2 \pi \hbar \omega_{0} \approx 6.28 \hbar \omega_{0}$. We see that the numerical factors for these two different soft potential profiles are very substantial, but rather close.

### 5.8. Back to the correlation function

Unfortunately I will not have time to review solutions of other problems using the Smoluchowski and Fokker-Planck equations, but have to mention one conceptual issue. Since it is intuitively clear that these equations provide the complete statistical information about the system under analysis, one may wonder whether they may be used to find the temporal characteristics of the system, which were discussed in Secs. $4-5$ using the Langevin formalism. For any statistical average of a function taken at the same time instant, the answer is evidently yes - cf. Eq. (2.11):

$$
\begin{equation*}
\langle f(\mathbf{q}(t), \mathbf{p}(t))\rangle=\int f(\mathbf{q}, \mathbf{p}) w(\mathbf{q}, \mathbf{p}, t) d^{3} q d^{3} p, \tag{5.165}
\end{equation*}
$$

[^930]but what if the function depends on variables taken at different times, for example the components of the correlation function $K_{f}(\tau)$ defined by Eq. (49)?

To answer this question, let us start from the discrete variable case when Eq. (165) takes form (2.7), which, for our current purposes, may be rewritten as

$$
\begin{equation*}
\langle f(t)\rangle=\sum_{m} f_{m} W_{m}(t) . \tag{5.166}
\end{equation*}
$$

In plain English, this is a sum of all possible values of the function, each multiplied by its probability as a function of time. But this means that average $\left\langle f(t) f\left(t^{\prime}\right)\right\rangle$ may be calculated as the sum of all possible products $f_{m} f_{m}$, multiplied by the joint probability for measurement outcome $m$ at moment $t$, and outcome $m^{\prime}$ at moment $t$ '. The joint probability may be presented as a product of $W_{m}(t)$ by the conditional probability $W\left(m^{\prime}, t^{\prime} \mid m, t\right)$. Since the correlation function is well defined only for stationary systems, in the last expression we can take $t=0$, i.e. find the conditional probability as the result, $W_{m} \cdot(\tau)$, of solution of the equation describing system's probability evolution, at time $\tau=t^{\prime}-t$ (rather than $t^{\prime}$ ), with the special initial condition

$$
\begin{equation*}
W_{m^{\prime}}(0)=\delta_{m^{\prime}, m} \tag{5.167}
\end{equation*}
$$

On the other hand, since the average $\langle f(t) f(t+\tau)\rangle$ of a stationary process should not depend on $t$, instead of $W_{m}(t)$ we may take the stationary probability distribution $W_{m}(\infty)$, independent of the initial conditions, and may be found as the same special solution, but at time $\tau \rightarrow \infty$. As a result, we may write

$$
\begin{equation*}
\langle f(t) f(t+\tau)\rangle=\sum_{m, m^{\prime}} f_{m} W_{m}(\infty) f_{m^{\prime}} W_{m^{\prime}}(\tau) \tag{5.168}
\end{equation*}
$$

This expression looks simple, but note that this recipe requires to solve the time evolution equations for each $W_{m} \cdot(\tau)$ for all possible initial conditions (167). To see how this recipe works in practice, let us revisit the simplest two-level system (see, e.g., Fig. 4.13 reproduced in Fig. 12 below in a notation more convenient for our current purposes), and calculate the correlation function of its energy fluctuations.

Fig. 5.12. Dynamics of a two-level system.

The stationary probabilities for this system (i.e. the probabilities for $\tau \rightarrow \infty$ ) have been calculated in Chapter 2, and then again in Sec. 4.4. In our current notation (Fig. 12),

$$
\begin{equation*}
W_{0}(\infty)=\frac{1}{1+e^{-\Delta / T}}, \quad W_{1}(\infty)=\frac{1}{e^{\Delta / T}+1}, \quad\langle E\rangle=W_{0}(\infty) \times 0+W_{1}(\infty) \times \Delta=\frac{\Delta}{e^{\Delta / T}+1} . \tag{5.169}
\end{equation*}
$$

In order to calculate the conditional probabilities $W_{m} \cdot(\tau)$ with initial conditions (167) (according to Eq. (168), we need all 4 of them, for $m, m^{\prime}=0,1$ ), we may use master equations (4.100), in our current notation reading

$$
\begin{equation*}
\frac{d W_{1}}{d \tau}=-\frac{d W_{0}}{d \tau}=\Gamma_{\uparrow} W_{0}-\Gamma_{\downarrow} W_{1} . \tag{5.170}
\end{equation*}
$$

Since Eq. (170) conserves the total probability, $W_{0}+W_{1}=1$, only one probability (say, $W_{1}$ ) is an independent variable, and for it, Eq. (170) gives a simple, linear differential equation,

$$
\begin{equation*}
\frac{d W_{1}}{d \tau}=\Gamma_{\uparrow}-\Gamma_{\Sigma} W_{1}, \quad \text { where } \Gamma_{\Sigma} \equiv \Gamma_{\uparrow}+\Gamma_{\downarrow} \tag{5.171}
\end{equation*}
$$

This equation may be readily integrated for an arbitrary initial condition:

$$
\begin{equation*}
W_{1}(\tau)=W_{1}(0) e^{-\Gamma_{\Sigma} \tau}+W_{1}(\infty)\left(1-e^{-\Gamma_{\Sigma} \tau}\right), \tag{5.172}
\end{equation*}
$$

where $W_{1}(\infty)$ is given by the second of Eqs. (169). (It is straightforward to check that the solution for $W_{0}(\tau)$ may be presented in the similar form, with the corresponding change of the state index.) Now everything is ready to calculate average $\langle E(t) E(t+\tau)\rangle$ using Eq. (168), with $f_{m, m^{\prime}}=E_{0,1}$. Thanks to our (smart :-) choice of energy origin, of 4 terms in the double sum (168), all 3 terms that include at least one factor $E_{0}=0$ vanish, and we have only one term left:

$$
\begin{align*}
\langle E(t) E(t+\tau)\rangle & =\left.E_{1} W_{1}(\infty) E_{1} W_{1}(\tau)\right|_{W_{1}(0)=1}=E_{1}^{2} W_{1}(\infty)\left[W_{1}(0) e^{-\Gamma_{\Sigma} \tau}+W_{1}(\infty)\left(1-e^{-\Gamma_{\Sigma} \tau}\right)\right] W_{W_{1}}(0)=1 \\
& =\frac{\Delta^{2}}{e^{\Delta / T}+1}\left[e^{-\Gamma_{\Sigma} \tau}+\frac{1}{e^{\Delta / T}+1}\left(1-e^{-\Gamma_{\Sigma} \tau}\right)\right]=\frac{\Delta^{2}}{\left(e^{\Delta / T}+1\right)^{2}}\left(1+e^{\Delta / T} e^{-\Gamma_{\Sigma} \tau}\right) . \tag{5.173}
\end{align*}
$$

From here and the last of Eqs. (169), the correlation function of energy fluctuations is ${ }^{65}$

$$
\begin{align*}
K_{E}(\tau) & \equiv\langle\widetilde{E}(t) \widetilde{E}(t+\tau)\rangle=\langle(E(t)-\langle E(t)\rangle)(E(t+\tau)-\langle E(t)\rangle)\rangle=\langle E(t) E(t+\tau)\rangle-\langle E(t)\rangle\langle E(t+\tau)\rangle \\
& =\langle E(t) E(t+\tau)\rangle-\langle E\rangle^{2}=\Delta^{2} \frac{e^{\Delta / T}}{\left(e^{\Delta / T}+1\right)^{2}} e^{-\Gamma_{\Sigma} \tau} \tag{5.174}
\end{align*}
$$

Since transition rates $\Gamma \uparrow$ and $\Gamma \downarrow$ have to obey the detailed balance relation (4.103), $\Gamma \downarrow / \Gamma \uparrow=\exp \{\Delta / T\}$, and hence

$$
\begin{equation*}
\frac{e^{\Delta / T}}{\left(e^{\Delta / T}+1\right)^{2}}=\frac{\Gamma_{\downarrow} / \Gamma_{\uparrow}}{\left(\Gamma_{\downarrow} / \Gamma_{\uparrow}+1\right)^{2}}=\frac{\Gamma_{\uparrow} \Gamma_{\downarrow}}{\left(\Gamma_{\uparrow}+\Gamma_{\downarrow}\right)^{2}}=\frac{\Gamma_{\uparrow} \Gamma_{\downarrow}}{\Gamma_{\Sigma}^{2}}, \tag{5.175}
\end{equation*}
$$

expression (174) may be presented also in a simpler form:

$$
\begin{equation*}
K_{E}(\tau)=\Delta^{2} \frac{\Gamma_{\uparrow} \Gamma_{\downarrow}}{\Gamma_{\Sigma}^{2}} e^{-\Gamma_{\Sigma} \tau} \tag{5.176}
\end{equation*}
$$

We see that the correlation function of energy decays exponentially with time, with the net rate $\Gamma_{\Sigma}$, while its variance, equal to $K_{E}(0)$, does not depend on the transition rates. Now using the WienerKhinchin theorem (58) to calculate its spectral density, we get

[^931]\[

$$
\begin{equation*}
S_{E}(\omega)=\frac{1}{\pi} \int_{0}^{\infty} \Delta^{2} \frac{\Gamma_{\uparrow} \Gamma_{\downarrow}}{\Gamma_{\Sigma}^{2}} e^{-\Gamma_{\Sigma} \tau} \cos \omega \tau d \tau=\frac{\Delta^{2}}{\pi \Gamma_{\Sigma}} \frac{\Gamma_{\uparrow} \Gamma_{\downarrow}}{\Gamma_{\Sigma}^{2}+\omega^{2}} \tag{5.177}
\end{equation*}
$$

\]

Such dependence on frequency ${ }^{66}$ is very typical for discrete-state systems described by master equations. It is interesting that the most widely accepted explanation of the $1 / f$ noise (also called the "flicker" or "excess" noise), which was mentioned in Sec. 5, is that it is a result of thermally-activated jumps between metastable states of a statistical ensemble of such two-level systems, with an exponentially-broad statistical distribution of transition rates $\Gamma_{\uparrow, \downarrow}$. Such a broad distribution follows from the Kramers formula (156), which is approximately valid for lifetimes of states of systems with double-well potential profiles (Fig. 13), for a statistical ensemble with a smooth statistical distribution of energy gaps $\Delta$. Such profiles are typical, in particular, for electrons in disordered (amorphous) solidstate materials that, indeed, feature high $1 / f$ noise.

Fig. 5.13. Typical doublewell potential profile.

Returning to the Fokker-Planck equation, we may use the evident generalization of Eq. (168) to the continuous-variable case:

Correlation function of continuousstate system

$$
\begin{equation*}
\langle f(t) f(t+\tau)\rangle=\int d^{3} q d^{3} p \int d^{3} q^{\prime} d^{3} p^{\prime} f(\mathbf{q}, \mathbf{p}) w(\mathbf{q}, \mathbf{p}, \infty) f\left(\mathbf{q}^{\prime}, \mathbf{p}^{\prime}\right) w\left(\mathbf{q}^{\prime}, \mathbf{p}^{\prime}, \tau\right) \tag{5.178}
\end{equation*}
$$

were both probability density distributions are solutions of the equation with the delta-functional initial condition

$$
\begin{equation*}
w\left(\mathbf{q}^{\prime}, \mathbf{p}^{\prime}, 0\right)=\delta\left(\mathbf{q}^{\prime}-\mathbf{q}\right) \delta\left(\mathbf{p}^{\prime}-\mathbf{p}\right) \tag{5.179}
\end{equation*}
$$

For the Smoluchowski equation, valid in the high-damping limit, the expressions are similar, albeit with a lower dimensionality:

$$
\begin{gather*}
\langle f(t) f(t+\tau)\rangle=\int d^{3} q \int d^{3} q^{\prime} f(\mathbf{q}) w(\mathbf{q}, \infty) f\left(\mathbf{q}^{\prime}\right) w\left(\mathbf{q}^{\prime}, \tau\right)  \tag{5.180}\\
w\left(\mathbf{q}^{\prime}, 0\right)=\delta\left(\mathbf{q}^{\prime}-\mathbf{q}\right) \tag{5.181}
\end{gather*}
$$

To see this formalism in action, let us use it to find the correlation function $K_{q}(\tau)$ of a linear relaxator, i.e. an overdamped 1D harmonic oscillator with $m \omega_{0} \ll \eta$. In this limit, the coordinate averaged over the heat baths obeys a linear equation,

$$
\begin{equation*}
\eta\langle\dot{q}\rangle+\kappa\langle q\rangle=0, \tag{5.182}
\end{equation*}
$$

which describes its exponential relaxation from a certain initial condition $q_{0}$ to the equilibrium position $q=0$, with the reciprocal time constant $\Gamma=\kappa / \eta$ :

[^932]\[

$$
\begin{equation*}
\langle q\rangle(t)=q_{0} e^{-\Gamma t} . \tag{5.183}
\end{equation*}
$$

\]

The deterministic equation (182) corresponds to the quadratic potential energy $U(q)=\kappa q^{2} / 2$, so that the 1D version of the Smoluchowski equation (122) takes the following form:

$$
\begin{equation*}
\eta \frac{\partial w}{\partial t}=\kappa \frac{\partial}{\partial q}(w q)+T \frac{\partial^{2} w}{\partial q^{2}} . \tag{5.184}
\end{equation*}
$$

It is straightforward to check, by substitution, that this equation, rewritten for function $w\left(q^{\prime}, \tau\right)$, with the delta-functional initial condition (181), $w\left(q^{\prime}, 0\right)=\delta\left(q^{\prime}-q\right)$, is satisfied by a Gaussian function,

$$
\begin{equation*}
w\left(q^{\prime}, \tau\right)=\frac{1}{(2 \pi)^{1 / 2} \delta q(\tau)} \exp \left\{-\frac{\left(q^{\prime}-\langle q\rangle(\tau)\right)^{2}}{2 \delta q^{2}(\tau)}\right\} \tag{5.185}
\end{equation*}
$$

with its center, $\langle q\rangle(\tau)$, moving in accordance with Eq. (183), and the time-dependent variance

$$
\begin{equation*}
\delta q^{2}(\tau)=\delta q^{2}(\infty)\left(1-e^{-2 \Gamma \tau}\right), \quad \text { where } \delta q^{2}(\infty)=\left\langle q^{2}\right\rangle=\frac{T}{\kappa} \tag{5.186}
\end{equation*}
$$

(As a sanity check, the last equality coincides with the equipartition theorem's result.) Finally, the first probability under the integral in Eq. (180) may be found from Eq. (185) in the limit $\tau \rightarrow \infty$ (in which $\langle q\rangle(\tau) \rightarrow 0)$, by replacing $q^{\prime}$ for $q$ :

$$
\begin{equation*}
w(q, \infty)=\frac{1}{(2 \pi)^{1 / 2} \delta q(\infty)} \exp \left\{-\frac{q^{2}}{2 \delta q^{2}(\infty)}\right\} . \tag{5.187}
\end{equation*}
$$

Now, all components of recipe (180) are ready, and we can write it, for $f(q)=q$, as

$$
\begin{equation*}
\langle q(t) q(t+\tau)\rangle=\frac{1}{2 \pi \delta q(\tau) \delta q(\infty)} \int_{-\infty}^{+\infty} d q \int_{-\infty}^{+\infty} d q^{\prime} q \exp \left\{-\frac{q^{2}}{2 \delta q^{2}(\infty)}\right\} q^{\prime} \exp \left\{-\frac{\left(q^{\prime}-q e^{-\Gamma \tau}\right)^{2}}{2 \delta q^{2}(\tau)}\right\} \tag{5.188}
\end{equation*}
$$

The integral over $q^{\prime}$ may be worked our first, by the replacing that integration variable with ( $q^{\prime \prime}+q e^{-\Gamma \tau}$ ) and hence $d q$ ' with $d q$ ":

$$
\begin{equation*}
\langle q(t) q(t+\tau)\rangle=\frac{1}{2 \pi \delta q(\tau) \delta q(\infty)} \int_{-\infty}^{+\infty} q \exp \left\{-\frac{q^{2}}{2 \delta q^{2}(\infty)}\right\} d q \int_{-\infty}^{+\infty}\left(q^{\prime \prime}+q e^{-\Gamma \tau}\right) \exp \left\{-\frac{q^{\prime \prime 2}}{2 \delta q^{2}(\tau)}\right\} d q^{\prime \prime} \tag{5.189}
\end{equation*}
$$

The integral of the first term in parentheses $\left(q^{\prime \prime}+q e^{-\Gamma \tau}\right)$ equals zero (as that of an odd function in symmetric integration limits), while that with the second term is the standard Gaussian integral, giving

$$
\begin{equation*}
\langle q(t) q(t+\tau)\rangle=\frac{1}{(2 \pi)^{1 / 2} \delta q(\infty)} e^{-\Gamma \tau} \int_{-\infty}^{+\infty} q^{2} \exp \left\{-\frac{q^{2}}{2 \delta q^{2}(\infty)}\right\} d q=\frac{2 T}{\pi^{1 / 2} \kappa} e^{-\Gamma \tau} \int_{-\infty}^{+\infty} \xi^{2} \exp \left\{-\xi^{2}\right\} d \xi \tag{5.190}
\end{equation*}
$$

The last integral ${ }^{67}$ is just $\pi^{1 / 2} / 2$, so that taking into account that for this stationary system centered at the coordinate origin, the ensemble average $\langle q\rangle=0,{ }^{68}$ we finally get a very simple result,

[^933]Correlation function of linear relaxator

$$
\begin{equation*}
K_{q}(\tau) \equiv\langle\widetilde{q}(t) \widetilde{q}(t+\tau)\rangle=\langle q(t) q(t+\tau)\rangle-\langle q\rangle^{2}=\langle q(t) q(t+\tau)\rangle=\frac{T}{\kappa} e^{-\Gamma \tau} \tag{5.191}
\end{equation*}
$$

As a sanity check, for $\tau=0$ it yields $K_{q}(0) \equiv\left\langle q^{2}\right\rangle=T / \kappa$, in accordance with Eq. (186). As $\tau$ is increased the correlation function decreases monotonically - see the solid-line sketch in Fig. 8.

So, the solution of this very simple problem has required straightforward but somewhat bulky calculations. On the other hand, the same result may be obtained literally in one line, using the Langevin formalism - namely, as the Fourier transform (59) of the spectral density (68) in the corresponding limit $m \omega \ll \eta$, with $S_{\neq}(\omega)$ given by Eq. (73):69

$$
\begin{equation*}
K_{q}(\tau)=2 \int_{0}^{\infty} S_{q}(\omega) \cos \omega \tau d \omega=2 \int_{0}^{\infty} \frac{\eta T}{\pi} \frac{1}{\kappa^{2}+(\eta \omega)^{2}} \cos \omega \tau d \omega=2 \frac{T \Gamma}{\pi} \int_{0}^{\infty} \frac{\cos \xi}{(\Gamma \tau)^{2}+\xi^{2}} d \xi=\frac{T}{\kappa} e^{-\Gamma \tau} \tag{5.192}
\end{equation*}
$$

This example illustrates well that for linear systems (and small fluctuations in nonlinear systems) the Langevin approach is usually much simpler that the one based on the Fokker-Planck or Smoluchowski equations. However, again, the latter approach is indispensable for the analysis of fluctuations of arbitrary intensity in nonlinear systems.

To conclude this chapter, I have to emphasize again that the Fokker-Planck and Smoluchowski equations give a quantitative description of time evolution of nonlinear Brownian systems with finite dissipation in the classical limit. The description of quantum properties of such dissipative ("open") and nonlinear quantum systems is more complex, ${ }^{70}$ and only a few simple problems of such theory have been solved so far, ${ }^{71}$ typically using a particular model of the environment, e.g., as a large set of harmonic oscillators with different statistical distributions of their parameters, leading to different frequency dependence of susceptibility $\chi(\omega)$.

### 5.10. Exercise problems

5.1. Considering the first 30 digits of number $\pi=3.1415 \ldots$ as a statistical ensemble of integers $k$ (equal to $3,1,4,1,5, \ldots$ ), calculate
(i) average $\langle k\rangle$, and
(ii) the r.m.s. fluctuation $\delta k$.

Compare the results with those for an ensemble of completely random integers $0,1, ., 9$, and comment.
5.2. For a set of $N$ non-interacting Ising "spins" $s_{j}= \pm 1$, placed into magnetic field $h$, calculate the relative fluctuation of system's magnetization.

Hint: The total magnetic moment of an Ising system is assumed to be proportional to the sum

[^934]$$
\mathcal{S} \equiv \sum_{j=1}^{N} s_{j},
$$
so that the requested relative fluctuation may be calculated just as $\delta S \ll S T$.
5.3. For a field-free, two-site Ising system with energy values $E_{m}=-J s_{1} s_{2}$, in the thermal equilibrium at temperature $T$, find the variance of energy fluctuations. Explore the low-temperature and high-temperature limits of the result.
5.4. For the 1 D , three-site Ising ring with ferromagnetic coupling (and no external field), calculate the correlation coefficient $\left\langle s_{\left.j^{\prime} j_{j}\right\rangle}\right\rangle$ for both $j=j^{\prime}$ and $j \neq j^{\prime}$.
5.5. Within the framework of Weiss' molecular-field theory, calculate the variance of spin fluctuations in the $d$-dimensional Ising model. Use the result to derive the conditions of quantitative validity of the theory.
5.6. Calculate the variance of fluctuations of the energy of a quantum harmonic oscillator of frequency $\omega$, in thermal equilibrium at temperature $T$, and express it via the average value of the energy.
5.7. Express the r.m.s. fluctuation of the occupancy $N_{k}$ of a certain energy level $\varepsilon_{k}$ by:
(i) a classical particle,
(ii) a fermion, and
(iii) a boson,
in the thermodynamic equilibrium, via the average occupancy $\left\langle N_{k}\right\rangle$, and compare the results.
5.8.* Starting from the Maxwell distribution of velocities, calculate constant $C$ in the (approximate) expression $K_{P}(\tau)=C \delta(\tau)$, for the correlation function of fluctuations of pressure $P(t)$ of an ideal gas of $N$ classical particles. Compare the result with that of Problem 3.2, and estimate the pressure fluctuation variance.

Hint: You may like to consider a cylindrically-shaped container of volume $V=L A$ (see Fig. on the right) to calculate fluctuations of force acting on its plane lid of area $A$, and then recalculate them into fluctuations of pressure $P$.

5.9. Perhaps the simplest model of diffusion is the 1D discrete random walk: each time interval $\tau$, a particle leaps, with equal probability, to any of two neighboring sites of a 1D lattice with the spatial period $a$. Prove that particle's displacement during time interval $t \gg$ $\tau$, obeys Eq. (77), and calculate the corresponding diffusion coefficient $D$.
5.10.* Calculate the low-frequency spectral density of current $I(t)$ due to random passage of charged particles between two conducting electrodes - see Fig. on the right. Assume that the particles are emitted by one of the electrodes at random times, and are fully absorbed by the counterpart electrode.

5.11.* Within the rotating-wave approximation (RWA), ${ }^{72}$ calculate major statistical properties of fluctuations of the phase of classical self-oscillations, at:
(i) the free run of the oscillator, and
(ii) its phase locking by an external sinusoidal force, assuming that the fluctuations are caused by a weak, broadband noise with spectral density $S_{f}(\omega)$.
5.12. Calculate the correlation function of the coordinate of a 1 D harmonic oscillator with small Ohmic damping at thermal equilibrium.
5.13. Consider a very long, uniform, two-wire transmission line (see Fig. on the right), that allows the propagation of TEM waves with negligible attenuation, in thermal equilibrium with the environment at temperature $T$. Find variance $\left\langle V^{2}\right\rangle_{\Delta v}$ of electromagnetic fluctuations of voltage $V$ between the wires
 within a small frequency interval $\Delta v$.

Hint: As an E\&M reminder, ${ }^{73}$ TEM waves propagate with a frequency-independent velocity (equal to $c$ if the wires are in vacuum), with voltage $V$ and current $I$ (see Fig. above) related as $\mathcal{Z}(x, t) / I(x, t)= \pm \mathcal{Z}$, where $\mathcal{Z}$ is a frequency-independent constant ("wave impedance").
5.14. Now consider a similar line terminated, at one end, with an impedance-matching resistor $R$ $=\boldsymbol{Z}$. Find variance $\left\langle\boldsymbol{V}^{2}\right\rangle_{\Delta v}$ of the voltage across the resistor, and discuss the relation between the result and the Nyquist theorem (81).

Hint: Take into account that resistor with $R=\boldsymbol{Z}$ absorbs incident TEM waves without reflection.
5.15. An overdamped classical 1D particle escapes from a potential well with a smooth bottom, but a sharp edge - see Fig. on the right. Find the appropriate modification of the Kramers formula (139).

5.16. A particle may occupy any of $N$ similar sites. Particle's interaction with environment induces its random, incoherent jumps from the occupied site to any other one with the same rate $\Gamma$. Find the correlation function and the spectral density of fluctuations of the instant occupancy $n(t)$ (equal to either 1 or 0 ) of any particular site.

[^935]

## Chapter 6. Elements of Kinetics

This chapter gives a brief introduction to the basic notions of physical kinetics. Its main focus is on the Boltzmann equation, especially within the relaxation-time approximation, which allows, in particular, an approximate but reasonable and simple description of transport phenomena (such as the electric current and thermoelectric effects) in gases, including electron gases in metals and semiconductors.

### 6.1. The Liouville theorem

Physical kinetics is the branch of statistical physics that deals with systems out of thermodynamic equilibrium. Major tasks of kinetics include:
(i) for autonomous systems (those out of external fields): transient processes (relaxation) leading from an arbitrary initial state of a system to the thermodynamic equilibrium;
(ii) for systems in time-dependent external fields (say, in a sinusoidal "ac" field): the periodic oscillations of system's parameters; and
(iii) for systems in time-independent ("dc") external fields: dc transport effects.

In the last case, we are dealing with stationary $(\partial / \partial t=0$ everywhere $)$, but non-equilibrium situations, in which the effect of an external field, continuously driving the system out of the equilibrium, is balanced by the simultaneous relaxation - the trend toward the equilibrium. Perhaps the most important effect of this class is the dc current in conductors, which alone justifies the inclusion of the basic notions of kinetics into any set of core physics courses.

Actually, the reader who has reached this point of the notes, already has a good taste of physical kinetics, because the subject of the last part of Chapter 5 was the kinetics of a "Brownian particle", i.e. of a "heavy" system interacting with environment consisting of many "lighter" components. Indeed, the equations discussed in that part - whether the Smoluchowski equation (5.122) or the Fokker-Planck equation (5.149) - are valid if the environment is in thermodynamic equilibrium, but the system of our interest is not necessarily so. As a result, we could use those equations to discuss such non-equilibrium phenomena as the Kramers problem for the metastable state lifetime.

This chapter is devoted to the more traditional subject of kinetics: a system of very many similar particles - generally, interacting with each other, but not too strongly, so that the energy of the system still may be partitioned into a sum of the components, with the component interactions considered as a weak perturbation. Actually, we have already started the job of describing such a system in Sec. 5.8, in the course of deriving the Fokker-Planck equation for a single classical particle. Indeed, in the absence of particle interactions (i.e. when it is unimportant whether the particle is light or heavy), the probability current densities in the coordinate and momentum spaces are given, respectively, by Eqs. (5.142) and (5.143), so that the continuity equation (5.140) takes the form

$$
\begin{equation*}
\frac{\partial w}{\partial t}+\nabla_{q} \cdot(w \dot{\mathbf{q}})+\nabla_{p} \cdot(w \dot{\mathbf{p}})=0 . \tag{6.1}
\end{equation*}
$$

If similar particles do not interact, this equation for single-particle probability density $w(\mathbf{q}, \mathbf{p}, t)$ is valid for each of them, and the result of its solution may be used to calculate any average of the system as a whole.

Let us rewrite Eq. (1) in the Cartesian component form,

$$
\begin{equation*}
\frac{\partial w}{\partial t}+\sum_{j}\left[\frac{\partial}{\partial q_{j}}\left(w \dot{q}_{j}\right)+\frac{\partial}{\partial p_{j}}\left(w \dot{p}_{j}\right)\right]=0 \tag{6.2}
\end{equation*}
$$

where index $j$ lists all degrees of freedom of the particle, and assume that its motion in an external field may be described by a Hamiltonian function $\not \forall\left(q_{j}, p_{j}, t\right)$. Plugging into Eq. (2) the Hamiltonian equations of motion: ${ }^{1}$

$$
\begin{equation*}
\dot{q}_{j}=\frac{\partial \mathcal{H}}{\partial p_{j}}, \quad \dot{p}_{j}=-\frac{\partial \mathcal{H}}{\partial q_{j}}, \tag{6.3}
\end{equation*}
$$

we get

$$
\begin{equation*}
\frac{\partial w}{\partial t}+\sum_{j}\left[\frac{\partial}{\partial q_{j}}\left(w \frac{\partial \mathcal{H}}{\partial p_{j}}\right)-\frac{\partial}{\partial p_{j}}\left(w \frac{\partial \mathcal{H}}{\partial q_{j}}\right)\right]=0 . \tag{6.4}
\end{equation*}
$$

At the parentheses' differentiation, the mixed terms $w \partial^{2} \nexists \partial \partial q_{j} \partial p_{j}$ and $w \partial^{2} \nexists \partial \partial p_{j} \partial q_{j}$ cancel, and using Eq. (3) again, we get the so-called Liouville theorem ${ }^{2}$

$$
\begin{equation*}
\frac{\partial w}{\partial t}+\sum_{j}\left(\frac{\partial w}{\partial q_{j}} \dot{q}_{j}+\frac{\partial w}{\partial p_{j}} \dot{p}_{j}\right)=0 \tag{6.5}
\end{equation*}
$$

Liouville theorem

Since the left-hand part of this equation is just the full derivative of the probability density considered as a function of the generalized coordinates $q_{j}(t)$ of a particle, its generalized momenta components $p_{j}(t)$, and (possibly) time $t$, the Liouville theorem (5) may be presented in a surprisingly simple form:

$$
\begin{equation*}
\frac{d w(\mathbf{q}, \mathbf{p}, t)}{d t}=0 \tag{6.6}
\end{equation*}
$$

Physically it means that the probability $d W=w d^{3} q d^{3} p$ to find a Hamiltonian particle in a small volume of the coordinate-momentum space $[\mathbf{q}, \mathbf{p}]$, with the center moving in accordance to the deterministic law (3), does not change with time - see Fig. 1.

Fig. 6.1. Cartoon representation of the Liouville theorem in the 6 D space $[\mathbf{q}, \mathbf{p}]$.

[^936]At the first glance, this may not look surprising, because according to the fundamental Einstein relation (5.78), one needs non-Hamiltonian forces (such as kinematic friction, i.e. drag) to have diffusion. On the other hand, it is striking that the Liouville theorem is valid even for (Hamiltonian) systems with deterministic chaos, ${ }^{3}$ in which the deterministic trajectories corresponding to slightly different initial conditions become increasingly mixed with time.

For an ideal gas of 3D particles, we may select the usual Cartesian coordinates $r_{j}$ (with $j=1,2$, 3) for the generalized coordinates $q_{j}$, so that $p_{j}$ become the Cartesian components $m v_{j}$ of the usual (linear) momentum, and the elementary volume is just $d^{3} r d^{3} p-$ see Fig. 1. In this case Eqs. (3) are just

$$
\begin{equation*}
\dot{r}_{j}=\frac{p_{j}}{m} \equiv v_{j}, \quad \dot{p}_{j}=7_{j}, \tag{6.7}
\end{equation*}
$$

so that the Liouville theorem may be rewritten as

$$
\begin{equation*}
\frac{\partial w}{\partial t}+\sum_{j=1}^{3}\left(v_{j} \frac{\partial w}{\partial r_{j}}+7_{j} \frac{\partial w}{\partial p_{j}}\right)=0 \tag{6.8}
\end{equation*}
$$

and conveniently presented in the vector form ${ }^{4}$

$$
\begin{equation*}
\frac{\partial w}{\partial t}+\mathbf{v} \cdot \nabla w+\boldsymbol{7} \cdot \nabla_{p} w=0 \tag{6.9}
\end{equation*}
$$

where I have returned to using unindexed symbol $\nabla$ for the vector differentiation in the coordinate space.

### 6.2. The Boltzmann equation

The situation becomes much more complex if particles interact. Generally, a system of $N$ similar particles in 3D space has to be described by probability density $w$ being a function of $6 N+1$ arguments ( $3 N$ Cartesian coordinates, plus $3 N$ momentum components, plus time). Analytical or numerical solution of any equation describing time evolution of such a function for a typical ensemble of $N \sim 10^{23}$ particles is evidently a hopeless task. Hence, kinetics of realistic ensembles has to rely on making reasonable approximations that would simplify the situation.

One of the most useful approximation (sometimes called Stosszahlansatz, German for the "collision number assumption") was suggested by L. Boltzmann for a gas of particles that move freely most of the time, but interact during short time intervals, when a particle comes close to either an immobile scattering center (say, an impurity in a conductor) or to another particle of the gas. Such a brief scattering event changes particle's momentum, and may be approximately described by the addition of a special term (called the scattering integral) to the right-hand part of Eq. (9):

Boltzmann equation

$$
\begin{equation*}
\frac{\partial w}{\partial t}+\mathbf{v} \cdot \nabla w+\boldsymbol{\mathcal { F }} \cdot \nabla_{p} w=\left.\frac{\partial w}{\partial t}\right|_{\text {scattering }} \tag{6.10}
\end{equation*}
$$

while still keeping $w$ a function of only 7 arguments: 3 coordinate components of vector $\mathbf{r}$ and 3 components of momentum $\mathbf{p}$ (all of just one particle), plus time $t$. This is the Boltzmann transport equation.

[^937]The concrete form of the scattering integral depends on the scattering object. If scattering centers do not belong to the ensemble under consideration (again, for example, an impurity atom in a conductor - see Fig. 2), then the scattering integral may be obtained by an evident generalization of the master equation (4.100): ${ }^{5}$

$$
\begin{equation*}
\left.\frac{\partial w}{\partial t}\right|_{\text {scattering }}=\int d^{3} p^{\prime}\left[\Gamma_{\mathbf{p}^{\prime} \rightarrow \mathbf{p}} w\left(\mathbf{r}, \mathbf{p}^{\prime}, t\right)-\Gamma_{\mathbf{p} \rightarrow \mathbf{p}^{\prime}} w(\mathbf{r}, \mathbf{p}, t)\right] \tag{6.11}
\end{equation*}
$$

where the physical sense of $\Gamma_{\mathbf{p} \rightarrow \mathbf{p}}$, is the rate (i.e. the probability per unit time) for the particle to be scattered from the state with momentum $\mathbf{p}$ into the state with momentum $\mathbf{p}$ '.

Fig. 6.2. Particle scattering event.

Most elastic interactions are reciprocal, i.e. obey the following relation (closely related to the reversibility of time in Hamiltonian systems): $\Gamma_{\mathbf{p} \rightarrow \mathbf{p}^{\prime}}=\Gamma_{\mathbf{p}^{\prime} \rightarrow \mathbf{p}}$, so that Eq. (11) may be rewritten as ${ }^{6}$

$$
\begin{equation*}
\left.\frac{\partial w}{\partial t}\right|_{\text {scatteering }}=\int d^{3} p^{\prime} \Gamma_{\mathbf{p} \rightarrow \mathbf{p}^{\prime}}\left[w\left(\mathbf{r}, \mathbf{p}^{\prime}, t\right)-w(\mathbf{r}, \mathbf{p}, t)\right] . \tag{6.12}
\end{equation*}
$$

With such scattering integral, Eq. (10) stays linear in $w$, but becomes an integro-differential equation, typically harder to solve than differential equations.

The equation becomes even more complex if the scattering is due to mutual interaction of the particle members of the system (Fig. 3).

Fig. 6.3. Particle-particle scattering event.

[^938]In this case, the probability of the scattering event scales as a product of two single-particle probabilities, and the simplest form of the scattering integral is ${ }^{7}$

$$
\begin{equation*}
\left.\frac{\partial w}{\partial t}\right|_{\text {scatteering }}=\int d^{3} p^{\prime} \int d^{3} p \cdot\left[\Gamma_{\mathbf{p}^{\prime} \rightarrow \mathbf{p}, \mathbf{p}^{\prime} \rightarrow \mathbf{p}}, w\left(\mathbf{r}, \mathbf{p}^{\prime}, t\right) w\left(\mathbf{r}, \mathbf{p}^{\prime}, t\right)-\Gamma_{\mathbf{p} \rightarrow \mathbf{p}^{\prime}, \mathbf{p}, \rightarrow \mathbf{p},{ }^{\prime}} w(\mathbf{r}, \mathbf{p}, t) w(\mathbf{r}, \mathbf{p}, t)\right] . \tag{6.13}
\end{equation*}
$$

The integration dimensionality in Eq. (13) takes into account the fact that due to the conservation of the total momentum at scattering,

$$
\begin{equation*}
\mathbf{p}+\mathbf{p}=\mathbf{p}^{\prime}+\mathbf{p}^{\prime}, \tag{6.14}
\end{equation*}
$$

one of the momenta is not an independent argument, so that the integration in Eq. (13) may be restricted to a $6 \mathrm{D} p$-space rather than the 9 D one. For the reciprocal interaction, Eq. (13) may also be a bit simplified, but it still keeps Eq. (10) a nonlinear integro-differential transport equation, excluding such powerful solution methods as the Fourier expansion (which hinges on the linear superposition principle).

This is why most useful results based on the Boltzmann transport equation hinge on its further simplifications, most notably the relaxation-time approximation - RTA for short. ${ }^{8}$ This approximation is based on noticing that in the absence of spatial gradients $(\nabla=0)$, and external forces ( $\boldsymbol{7}=0)$, Eq. (10) yields

$$
\begin{equation*}
\frac{\partial w}{\partial t}=\left.\frac{\partial w}{\partial t}\right|_{\text {scattering }} \tag{6.15}
\end{equation*}
$$

so that the thermally-equilibrium probability distribution $w_{0}(\mathbf{r}, \mathbf{p}, t)$ has to turn any scattering integral into zero. Hence at small deviations from the equilibrium,

$$
\begin{equation*}
\widetilde{w}(\mathbf{r}, \mathbf{p}, t) \equiv w(\mathbf{r}, \mathbf{p}, t)-w_{0}(\mathbf{r}, \mathbf{p}, t) \rightarrow 0, \tag{6.16}
\end{equation*}
$$

the scattering integral should be proportional to the deviation $\widetilde{w}$, and its simplest reasonable model is
 approximation (RTA)
$\left.\frac{\partial w}{\partial t}\right|_{\text {scatteering }}=-\frac{\widetilde{w}}{\tau}$
where $\tau$ is a phenomenological constant (which, according to Eq. (15), has to be positive for system's stability) called the relaxation time. Its physical meaning will be more clear in the next section.

The relaxation-time approximation is quite reasonable if the angular distribution of the scattering rate is dominated by small angles between vectors $\mathbf{p}$ and $\mathbf{p}^{\prime}$ - as it is, for example, for the Rutherford scattering by a Coulomb center. ${ }^{9}$ Indeed, in this case the two functions $w$, participating in Eq. (12) are close to each other, so that the loss of the second momentum argument ( $\mathbf{p}$ ') is not too essential. However, while using the Boltzmann-RTA equation, which results from combining Eqs. (10) and (17),

$$
\begin{equation*}
\frac{\partial w}{\partial t}+\mathbf{v} \cdot \nabla w+\boldsymbol{7} \cdot \nabla_{p} w=-\frac{\widetilde{w}}{\tau} \tag{6.18}
\end{equation*}
$$

[^939]the reader should always remember this is just an approximation, sometimes giving completely wrong results. For example, it prescribes the same time scale, $\tau$, to the relaxation of the net momentum of the system, and to its energy relaxation, while in many real systems the latter process (that requires inelastic interactions) may be substantially longer. Naturally, in the following sections I will describe only those applications of the RTA approximation that give a reasonable description of reality.

### 6.3. The Ohm law and the Drude formula

Despite its shortcomings, Eq. (18) is adequate for quite a few applications. Perhaps the most important of them is deriving the Ohm law for dc current is a gas of charged particles, whose only important deviation from ideality is the scattering in the form of Eq. (17), and hence described, in equilibrium, by the equilibrium probability $w_{0}$ of an ideal gas (see Sec. 3.1):

$$
\begin{equation*}
w_{0}(\mathbf{r}, \mathbf{p}, t)=\frac{g}{(2 \pi \hbar)^{3}}\langle N(\varepsilon)\rangle, \tag{6.19}
\end{equation*}
$$

where $g$ is the degeneracy factor (say, $g=2$ for electrons due to their spin), and $\langle N(\varepsilon)\rangle$ is the average occupancy of a quantum state with momentum $\mathbf{p}$, that obeys either the Fermi-Dirac or the Bose-Einstein distribution:

$$
\begin{equation*}
\langle N(\varepsilon)\rangle=\frac{1}{e^{(\varepsilon-\mu) / T} \pm 1}, \quad \varepsilon=\varepsilon(\mathbf{p}) \tag{6.20}
\end{equation*}
$$

(Up to a point, our calculations will be valid for both statistics, and hence, in the limit $\mu / T \rightarrow-\infty$, for a classical gas as well.)

Now let a uniform, dc electric field $\boldsymbol{\varepsilon}$ be applied to the gas, exerting force $\boldsymbol{\mathcal { F }}=q \boldsymbol{\mathcal { E }}$ on each particle with electric charge $q$. Then the stationary solution to Eq. (18), with $\partial / \partial t=0$, should also be stationary and spatially-uniform $(\nabla=0)$, so that this equation is reduced to

$$
\begin{equation*}
q \varepsilon \cdot \nabla_{p} w=-\frac{\widetilde{w}}{\tau} . \tag{6.21}
\end{equation*}
$$

Let us assume the electric field to be relatively low as well, so that the perturbation $\widetilde{w}$ it produces is relatively small. (I will quantify this condition later on.) Then in the left-hand side of Eq. (21) we can neglect that perturbation, by replacing $w$ with $w_{0}$, because that side already has a small factor (乎). As a result, this equation yields

$$
\begin{equation*}
\widetilde{w}=-\tau q \varepsilon \cdot \nabla_{p} w_{0}=-\tau q \varepsilon \cdot\left(\nabla_{p} \varepsilon\right) \frac{\partial w_{0}}{\partial \varepsilon}, \tag{6.22}
\end{equation*}
$$

where the partial derivative sign marks the implied local constancy of parameters $\mu$ and $T$, i.e. their independence of momentum $\mathbf{p}$. But gradient $\nabla_{p} \varepsilon$ is nothing else than particle's velocity $\mathbf{v}$ - for a quantum particle, its group velocity. ${ }^{10}$ (This fact is easy to verify for the isotropic and parabolic dispersion law, pertinent to classical particles moving in free space,

[^940]\[

$$
\begin{equation*}
\varepsilon(\mathbf{p})=\frac{p^{2}}{2 m}=\frac{p_{1}^{2}+p_{2}^{2}+p_{3}^{2}}{2 m} . \tag{6.23}
\end{equation*}
$$

\]

Indeed, in this case the Cartesian components of vector $\nabla_{p} \varepsilon$ are

$$
\begin{equation*}
\left(\nabla_{p} \varepsilon\right)_{j} \equiv \frac{\partial \varepsilon}{\partial p_{j}}=\frac{p_{j}}{m}=v_{j} \tag{6.24}
\end{equation*}
$$

so that $\nabla_{p} \varepsilon=\mathbf{v}$.) Hence, Eq. (22) may be rewritten as

$$
\begin{equation*}
\widetilde{w}=-\tau q \varepsilon \cdot \mathbf{v} \frac{\partial w_{0}}{\partial \varepsilon} . \tag{6.25}
\end{equation*}
$$

Let us use this result to calculate the electric current density $\mathbf{j}$. The contribution of each quantum state to the current density is $q \mathbf{v} w$, so that the total density is

$$
\begin{equation*}
\mathbf{j}=\int q \mathbf{v} w d^{3} p=q \int \mathbf{v}\left(w_{0}+\widetilde{w}\right) d^{3} p . \tag{6.26}
\end{equation*}
$$

Since in the equilibrium state (with $w=w_{0}$ ), the current has to be zero, integral of the first term in the parentheses has to vanish. For the integral of the second term, plugging in Eq. (25), and also using Eq. (19), we get

$$
\begin{equation*}
\mathbf{j}=q^{2} \tau \int \mathbf{v}(\boldsymbol{\varepsilon} \cdot \mathbf{v})\left(-\frac{\partial w_{0}}{\partial \varepsilon}\right) d^{3} p=\frac{g q^{2} \tau}{(2 \pi \hbar)^{3}} \int \mathbf{v}(\varepsilon \cdot \mathbf{v})\left(-\frac{\partial\langle N(\varepsilon)\rangle}{\partial \varepsilon}\right) d^{2} p_{\perp} d p_{| |} \tag{6.27}
\end{equation*}
$$

where $d^{2} p_{\perp}$ is the elementary area of the constant energy surface in the momentum space, while $d p \|$ is the momentum differential's component normal to that surface. This result ${ }^{11}$ is valid even for particles with an arbitrary dispersion law $\varepsilon(\mathbf{p})$ (that may be rather complicated, for example, for particles moving in space-periodic potentials ${ }^{12}$ ), and may give, in particular, a fair description of conductivity's anisotropy in crystals.

For classical particles whose dispersion law is isotropic and parabolic, as in Eq. (23), the constant energy surface is a sphere of radius $p$, so that $d^{2} p_{\perp}=p^{2} d \Omega=p^{2} \sin \theta d \theta d \varphi$, while $d p \|=d p$. In spherical coordinates with the polar axis direction along vector $\mathcal{\varepsilon}$, we get $(\boldsymbol{\varepsilon} \cdot \mathbf{v})=\mathcal{E} v \cos \theta$. Now separating vector $\mathbf{v}$ outside the parentheses into a component $v \cos \theta$ directed along vector $\varepsilon$, and two perpendicular components, $v \sin \theta \cos \varphi$ and $v \sin \theta \sin \varphi$, we see that the integrals of the last two components over angle $\varphi$ give zero. Hence, as we could expect, in the isotropic case the net current is directed along the electric field and obeys the linear Ohm law, ${ }^{13}$

$$
\begin{equation*}
\mathbf{j}=\sigma \mathcal{\varepsilon} \tag{6.28}
\end{equation*}
$$

with a field-independent electric conductivity

[^941]\[

$$
\begin{equation*}
\sigma=\frac{g q^{2} \tau}{(2 \pi \hbar)^{3}} \int_{0}^{2 \pi} d \varphi \int_{0}^{\pi} \sin \theta d \theta \cos ^{2} \theta \int_{0}^{\infty} p^{2} d p v^{2}\left(-\frac{\partial\langle N(\varepsilon)\rangle}{\partial \varepsilon}\right) \tag{6.29}
\end{equation*}
$$

\]

Since $\sin \theta d \theta$ is just $-d(\cos \theta)$, the integral over $\theta$ equals $(2 / 3)$. The integral over $d \varphi$ is of course just $2 \pi$, while that over $p$ may be readily transformed to one over particle's energy $\varepsilon(\mathbf{p})=p^{2} / 2 m$ : $v d p=p d p / m=$ $d \varepsilon$, so that $p^{2} d p v^{2}=p^{2} v d \varepsilon=(2 m \varepsilon)(2 \varepsilon / m)^{1 / 2} d \varepsilon=\left(8 m \varepsilon^{3}\right)^{1 / 2} d \varepsilon$. As a result, the conductivity equals

$$
\begin{equation*}
\sigma=\frac{g q^{2} \tau}{(2 \pi \hbar)^{3}} \frac{4 \pi}{3} \int_{0}^{\infty}\left(8 m \varepsilon^{3}\right)^{1 / 2}\left(-\frac{\partial\langle N(\varepsilon)\rangle}{\partial \varepsilon}\right) d \varepsilon . \tag{6.30}
\end{equation*}
$$

Note that $\sigma$ is proportional to $q^{2}$ and hence does not depend on the particle charge sign; this is why the Hall effect in external magnetic field, which lacks this ambivalence, is typically used to determine the charge of current carriers (electrons or holes) in semiconductors.

So far, the calculations have been valid for any gas (Bose, Fermi, or classical), an arbitrary temperature. Let us work out the remaining integral over energy for the most important case of a degenerate Fermi (say, electron) gas, with $T \ll \varepsilon_{F} .{ }^{14}$ As was discussed in Sec. 3.3, in this limit, factor ($\partial\langle N(\varepsilon))\rangle / \partial \varepsilon)$ is essentially Dirac's delta-function $\delta\left(\varepsilon-\varepsilon_{\mathrm{F}}\right)$, so that the conductivity does not depend on temperature: ${ }^{15}$

$$
\begin{equation*}
\sigma=\frac{g q^{2} \tau}{(2 \pi \hbar)^{3}} \frac{4 \pi}{3}\left(8 m \varepsilon_{F}^{3}\right)^{1 / 2}=\frac{q^{2} \tau}{m} \frac{g}{(2 \pi \hbar)^{3}} \frac{4 \pi}{3}\left(2 m \varepsilon_{F}\right)^{3 / 2}=\frac{q^{2} \tau}{m} \frac{g}{(2 \pi \hbar)^{3}} \frac{4 \pi p_{\mathrm{F}}^{3}}{3} . \tag{6.31}
\end{equation*}
$$

But the last fraction in this product is just the volume of the Fermi sphere in the momentum space, so that the product of the last two fractions is the total number of quantum states filled at $T=0$ (per unit volume), i.e. the total density $n \equiv N / V$ of electrons in the gas. Hence, Sommerfeld's result is reduced to the Drude formula, ${ }^{16}$

$$
\begin{equation*}
\sigma=\frac{q^{2} \tau}{m} n \tag{6.32}
\end{equation*}
$$

[^942]which should be well familiar to the reader from an undergraduate physics course, with $\tau$ being a scale of time intervals between scattering events.

This calculation poses with an important conceptual question. The very structure of Eq. (30) implies that the only quantum states contributing to electric conductance are those where the derivative $(-\partial\langle N(\varepsilon)\rangle / \partial \varepsilon)$ is significant. At $T \ll \varepsilon_{\mathrm{F}}$, these are the states at the very surface of the Fermi sphere. On

[^943]the other hand, the classical derivation of Eq. (32) involves all electrons. ${ }^{17}$ So, what exactly electrons are responsible for conductance: all of them, or only those on the Fermi surface?

For the resolution of this paradox, let us return to Eq. (22) and analyze the physical meaning of that result. For that, let us compare it with the following model distribution:

$$
\begin{equation*}
w_{\text {model }} \equiv w_{0}(\mathbf{r}, \mathbf{p}-\widetilde{\mathbf{p}}, t), \tag{6.33}
\end{equation*}
$$

where $\widetilde{\mathbf{p}}$ is some constant, small vector, which describes a small shift of the unperturbed distribution $w_{0}$ in the momentum space as a whole. Performing the Taylor expansion of Eq. (33) in this small parameter, and keeping only two leading terms, we get

$$
\begin{equation*}
w_{\text {model }} \approx w_{0}(\mathbf{r}, \mathbf{p}, t)+\widetilde{w}_{\text {model }}, \quad \widetilde{w}_{\text {model }}=-\widetilde{\mathbf{p}} \cdot \nabla_{p} w_{0}(\mathbf{r}, \mathbf{p}, t) . \tag{6.34}
\end{equation*}
$$

Comparing the model perturbation with the first form of Eq. (22), we see that they coincide, provided that

$$
\begin{equation*}
\widetilde{\mathbf{p}}=q \boldsymbol{\varepsilon} \tau=\boldsymbol{\tau} \tau \tag{6.35}
\end{equation*}
$$

This means that Eq. (22) describes a small shift of the equilibrium distribution of electrons by $q \mathcal{E} \tau$ (in $p$ space) along the direction of electric field, ${ }^{18}$ and gives the picture of the electron transport in a degenerate gas, shown in Fig. 4.

Fig. 6.4. Filling of momentum states in a degenerate electron gas: (a) in the absence and (b) in the presence of external electric field $\boldsymbol{\varepsilon}$. Arrows show representative scattering events.

At $\boldsymbol{\varepsilon}=0$, the system is in equilibrium, so that the quantum states inside the Fermi sphere ( $\mathbf{p}<$ $\mathbf{p}_{\mathrm{F}}$ ), are occupied, while those outside of it are empty (Fig. 4a). Electron scattering events happen only between states within a very thin layer $\left(\left|p^{2} / 2 m-\varepsilon_{\mathrm{F}}\right| \sim T\right)$ at the Fermi surface, because only in this layer

[^944]the states are partially occupied, so that both components of the product $w(\mathbf{r}, \mathbf{p}, t)[1-w(\mathbf{r}, \mathbf{p}, t)]$, mentioned in Sec. 1, do not vanish. These scattering events, on the average, do not change the equilibrium probability distribution, because they are uniformly spread over the Fermi surface.

In the instant the electric field has been turned on, it starts to accelerate all electrons in its direction, i.e. the whole Fermi sphere starts moving in the momentum space, along the field's direction in the real space. For elastic scattering events (with $\left|p^{\prime}\right|=|p|$ ), this creates an addition of occupied states at the leading front of the accelerating sphere, and an addition of free states on its trailing edge (Fig. 4b). As a result, now there are more scattering events bringing electrons from the leading edge to the trailing edge of the sphere than in the opposite direction. This creates the average backflow of states occupancy in the momentum space. These two trends eventually cancel each other, and the Fermi sphere approaches a stationary (though not equilibrium!) state, with the shift (35) relatively to its thermalequilibrium position.

Thus Fig. 4b presents a clear answer to the question which of the two different interpretations of the Drude formula is correct, and due to electrons' indistinguishability, the answer is: either. On one hand, we can look at the electric current at a result of shift (35) of all electrons in the momentum space. On the other hand, each filled quantum state deep inside the sphere gives exactly the same contribution into the net current density as it did without the field. All these internal contributions to the net current cancel each other, so that the applied field changes the situation only at the Fermi surface. Thus it is equally legitimate to say that only the surface states are responsible for the nonvanishing net current. ${ }^{19}$

Let me also mention the second paradox related to the Drude formula, which is often misunderstood (not only by students :-). As was emphasized above, $\tau$ is finite even at elastic scattering that by itself does not change the total energy of the electron gas. The question is how can such scattering may be responsible for Ohmic resistivity $\rho \equiv 1 / \sigma$, and hence for the Joule heat production, with power density $\mathcal{P} V=\mathbf{j} \cdot \varepsilon=\rho j^{2}$ ? The answer is that the Drude and Sommerfeld formulas describe just the "bottleneck" of the Joule heat formation. In the scattering picture (Fig. 4b) the elastically scattered electron states are predominantly located above the (shifted) Fermi surface, and eventually need to relax onto it via some inelastic process that releases their additional energy in the form of heat (in solid state materials, described by phonons - see Sec. 2.6). The rate and other features of these inelastic phenomena do not participate in the Drude formula directly, but for keeping the theory valid (in particular, keeping the probability distribution $w$ close to its equilibrium value $w_{0}$ ), their intensity has to be sufficient to avoid gas overheating by the applied field. This gives an additional restriction on the simple theory described above. In some semiconductors, the charge carrier overheating effects, resulting in deviations from the Ohm law, i.e. from the linear relation (28) between $\mathbf{j}$ and $\boldsymbol{\varepsilon}$, may be readily observed already at rather modest applied electric fields.

### 6.4. Electrochemical potential and the drift-diffusion equation

Now let us generalize our calculation to the case when transport takes place in the presence of a time-independent spatial gradient of the probability distribution, $\nabla w \neq 0$, caused for example by that of the particle concentration $n=N / V$ (and hence, according to Eq. (3.40), of the chemical potential $\mu$ ),

[^945]while still considering temperature $T$ constant. For this generalization, we should just keep the second term in the left-hand part of Eq. (18). If the gradient of $w$ is sufficiently small, we can repeat arguments of the last section and replace $w$ with $w_{0}$ in this term as well. With the applied electric field $\boldsymbol{\varepsilon}$ presented as $(-\nabla \phi)$, where $\phi$ is the electrostatic potential, Eq. (25) now becomes
\[

$$
\begin{equation*}
\widetilde{w}=\tau \mathbf{v} \cdot\left(\frac{\partial w_{0}}{\partial \varepsilon} q \nabla \phi-\nabla w_{0}\right) . \tag{6.36}
\end{equation*}
$$

\]

Since in any of distributions (20), $\langle N(\varepsilon)\rangle$ is a function of $\varepsilon$ and $\mu$ only in combination $(\varepsilon-\mu)$, it obeys the following relation,

$$
\begin{equation*}
\frac{\partial\langle N(\varepsilon)\rangle}{\partial \mu}=-\frac{\partial\langle N(\varepsilon)\rangle}{\partial \varepsilon} \tag{6.37}
\end{equation*}
$$

Using this relation, the gradient of $w_{0} \propto\langle N(\varepsilon)\rangle$ may be presented as ${ }^{20}$

$$
\begin{equation*}
\nabla w_{0}=-\frac{\partial w_{0}}{\partial \varepsilon} \nabla \mu, \quad \text { for } T=\mathrm{const} \tag{6.38}
\end{equation*}
$$

so that Eq. (36) becomes

$$
\begin{equation*}
\widetilde{w}=\tau \frac{\partial w_{0}}{\partial \varepsilon} \mathbf{v} \cdot(q \nabla \phi+\nabla \mu)=\tau \frac{\partial w_{0}}{\partial \varepsilon} \mathbf{v} \cdot q \nabla \Phi \tag{6.39}
\end{equation*}
$$

where the following sum,

chemical potential

$$
\begin{equation*}
\Phi \equiv \phi+\frac{\mu}{q} \tag{6.40}
\end{equation*}
$$

is called the electrochemical potential. ${ }^{21}$ Now repeating the calculation of the electric current, carried out in the last section, we get the following generalization of the Ohm law (28):

$$
\begin{equation*}
\mathbf{j}=\sigma(-\nabla \Phi)=\sigma \mathcal{E} \tag{6.41}
\end{equation*}
$$

where the effective electric field $\mathcal{E}$ is the (minus) gradient of the electrochemical potential, rather of the electrostatic potential:

Effective electric field

$$
\begin{equation*}
\mathcal{E} \equiv-\nabla \Phi=\varepsilon-\frac{\nabla \mu}{q} \tag{6.42}
\end{equation*}
$$

The physics of this extremely important result ${ }^{22}$ may be explained in two ways. First, let us have a look at the energy spectrum of a uniform, degenerate Fermi gas confined in a volume of finite size. In order to ensure such a confinement, we need a piecewise-constant potential $U(\mathbf{r})$ - a "hard-wall, flat-

[^946]bottom potential well" - see Fig. 5a. (In a solid conductor, such profile is readily provided by the crystal lattice of positively charged ions of the crystal lattice.) The well should be of a sufficient depth $U_{0}>\varepsilon_{\text {F }}$ $\equiv \mu_{T=0}$ in order to provide the confinement of the overwhelming majority of the particles, with energies below or slightly above the Fermi level $\varepsilon_{\mathrm{F}}$. This means that there should be a substantial energy gap,
\[

$$
\begin{equation*}
\psi \equiv U_{0}-\mu \gg T \tag{6.43}
\end{equation*}
$$

\]

between the Fermi energy of a particle inside the well, and its potential energy outside the well. (The latter value is usually called the vacuum level.) The difference defined by Eq. (43) is called the workfunction; ${ }^{23}$ for most metals, its is between 4 and 5 eV , so that relation $\psi \gg T$ is well fulfilled for the room temperatures ( $T \sim 0.025 \mathrm{eV}$ ) - and actually for all temperatures up to material's evaporation point.

Fig. 6.5. Potential profiles of (a) a single conductor and (b,c) a system of two closely located conductors, for two different biasing conditions: (b) zero electrostatic field ("flat-band"), and (c) zero voltage $V \equiv \Delta \Phi$.

Now let us consider two conductors, with different values of $\psi$, separated by a small gap $d$ - see Fig. 5b,c. Panel (b) shows the case when the electric field $\mathcal{E}=-\nabla \phi$ in the free-space gap between the conductors equals zero, i.e. their electrostatic potentials $\phi$ are equal. ${ }^{24}$ If there is an opportunity for particles to cross the gap (e.g., by either the thermally-activated hopping over the potential barrier, discussed in Secs. 5.6-5.7, or quantum-mechanical tunneling through it), there will be an average flux of particles from the conductor with the higher Fermi level to that with the lower Fermi level, ${ }^{25}$ because the chemical equilibrium requires their equality - see Secs. 1.5 and 2.7. If the particles have an electric charge (as electrons do), the equilibrium will be automatically achieved by them recharging the effective capacitor formed by the conductors, until the electrostatic energy difference $q \Delta \phi$ reaches the value reproducing that of the workfunctions (Fig. 5c). According to Eq. (43), at the recharging, sum ( $\psi+\mu$ ) of each conductor has to stay constant, so that for the equilibrium potential difference ${ }^{26}$ we may write

$$
\begin{equation*}
q \Delta \phi=\Delta \psi=-\Delta \mu \tag{6.44}
\end{equation*}
$$

[^947]At this equilibrium, the electric field in the gap between the conductors is

$$
\begin{equation*}
\varepsilon \equiv-\frac{\Delta \phi}{d} \mathbf{n}=\frac{\Delta \mu}{q d} \mathbf{n}=\frac{\nabla \mu}{q} ; \tag{6.45}
\end{equation*}
$$

in Fig. 5c the field is clearly visible as the tilt of the electric potential profile. Comparing Eq. (45) with definition (42) of the effective electric field $\mathcal{E}$, we see that the transport equilibrium, i.e. the absence of current, is achieved exactly when $\mathcal{E}=0$, in accordance with Eq. (41).

Another interpretation of Eq. (41) may be achieved by modifying Eq. (38) for the particular case of a classical gas. Indeed, the gas' local density $n \equiv N / V$ obeys Eq. (3.32), which may be presented as

$$
\begin{equation*}
n(\mathbf{r})=\text { const } \times \exp \left\{\frac{\mu(\mathbf{r})}{T}\right\} \tag{6.46}
\end{equation*}
$$

Taking the spatial gradient of the both parts of this relation (at constant $T$ ), we get

$$
\begin{equation*}
\nabla n=\operatorname{const} \times \frac{1}{T} \exp \left\{\frac{\mu}{T}\right\} \nabla \mu=\frac{n}{T} \nabla \mu, \tag{6.47}
\end{equation*}
$$

so that $\nabla \mu=(T / n) \nabla n$, and Eq. (41), with $\sigma$ given by Eq. (32), may be recast as

$$
\begin{equation*}
\mathbf{j}=\sigma(-\nabla \Phi)=\frac{q^{2} \tau}{m} n\left(-\nabla \phi-\frac{1}{q} \nabla \mu\right)=q \frac{\tau}{m}(n q \varepsilon-T \nabla n) . \tag{6.48}
\end{equation*}
$$

Hence the current may be viewed as consisting of two independent parts: one due to the "usual" electric field $\varepsilon=-\nabla \phi$, and another due to the particle diffusion - see Eq. (5.118) and its discussion. This is exactly the physics of the "mysterious" term $\nabla \mu$ in Eq. (42), though it may be presented in the simple form (48) only in the classical limit.

Besides being very useful for practice, ${ }^{27}$ Eq. (48) gives us a pleasant surprise. Namely, plugging it into the continuity equation for electric charge,

$$
\begin{equation*}
\frac{\partial(q n)}{\partial t}+\nabla \cdot \mathbf{j}=0 \tag{6.49}
\end{equation*}
$$

we get (after the division of all terms by $q \tau / m$ ) the so-called drift-diffusion equation:28

Drift-
diffusion
equation

$$
\begin{equation*}
\frac{m}{\tau} \frac{\partial n}{\partial t}=\nabla(n \nabla U)+T \nabla^{2} n, \quad \text { with } U \equiv q \phi \tag{6.50}
\end{equation*}
$$

Comparing it with Eq. (5.122), we see that the drift-diffusion equation is identical to the Smoluchowski equation, ${ }^{29}$ if we identify ratio $\tau / m$ with mobility $\mu_{m}=1 / \eta$ :

$$
\begin{equation*}
\frac{\tau}{m} \leftrightarrow \mu_{\mathrm{m}} \equiv \frac{1}{\eta}, \tag{6.51}
\end{equation*}
$$

[^948]and hence the following combination, $\tau T / m$, with the diffusion constant $D$ - see (5.78). As a result, Eq. (48) is frequently rewritten as an expression for the particle flow density $\mathbf{j}_{n} \equiv n \mathbf{j}_{w}=\mathbf{j} /$ q:
\[

$$
\begin{equation*}
\mathbf{j}_{n}=n \mu_{m} q \boldsymbol{\varepsilon}-D \nabla n . \tag{6.52}
\end{equation*}
$$

\]

This similarity may look surprising. Indeed, our (or rather Einstein's :-) treatment of the Brownian motion in Chapter 5 was based on a strong hierarchy of the total system, consisting of a large "Brownian particle" in an environment of many smaller particles - "molecules". On the other hand, in this chapter we are considering a gas of similar particles. Nevertheless, the equations describing the dynamics of their probability distribution, are the same - at least within the framework of the Boltzmann transport equation with the relaxation-time approximation (17) of the scattering integral.

The origin of this similarity is that Eq. (12) is applicable to Brownian particles as well, with each "scattering" event being the particle's hit by a random molecule. Since, due to the mass hierarchy, the particle momentum change at each such event is small, the scattering integral has to be local, i.e. depend only on $w$ at the same momentum $\mathbf{p}$ as the left-hand part of the Boltzmann equation, so that the relaxation time approximation (17) is absolutely natural. But the same is true for collisions of similar particles, if they are dominated by small-angle scattering, as true, for example, for Coulomb scattering. ${ }^{30}$

Returning to the electric field duality ( $\mathcal{E} \leftrightarrow \mathcal{\mathcal { E }}$ ), recovered in our analysis, it raises a natural question: which of these fields we are speaking about in the everyday and laboratory practice? Upon some contemplation, the reader should agree that most of our electric field measurements are done indirectly, by measuring corresponding voltages - with voltmeters. A vast majority of these instruments belong to the electrodynamic variety that is based on the measurement of a small current flowing through the voltmeter. As Eq. (41) shows, electrodynamic voltmeters measure the electrochemical potential difference $\Delta \Phi$. However, there exist a rare breed of electrostatic voltmeters (also called "electrometers") that measure the electrostatic potential difference $\Delta \phi$ between two conductors. One way to implement such an instrument is to use a usual, electrodynamic voltmeter, but with the reference point set at the flat-band condition (Fig. 5b) between the conductors. This condition may be detected by vanishing electric charge on the adjacent surfaces of the conductors, and hence by the absence of its modulation in time, caused by a specially arranged periodic variation of the distance between the surfaces. Another (less sensitive but also less invasive) way to detect the flat-band condition is to measure the voltage at which the force of electrostatic interaction between two conductors, which is proportional to $\varepsilon^{2} \propto(\Delta \phi)^{2}$, vanishes.

### 6.5. Thermoelectric effects

Now let us extend our analysis even further, to the effects of a finite (though small) temperature gradient. Again, since for any of statistics (20), the average occupancy $\langle N(\varepsilon)\rangle$ is a function of just one combination of all its arguments, $\xi \equiv(\varepsilon-\mu) / T$, its partial derivatives obey not only Eq. (37), but also the following relation:

$$
\begin{equation*}
\frac{\partial\langle N(\varepsilon)\rangle}{\partial T}=-\frac{\varepsilon-\mu}{T^{2}} \frac{\partial\langle N(\varepsilon)\rangle}{\partial \xi}=\frac{\varepsilon-\mu}{T} \frac{\partial\langle N(\varepsilon)\rangle}{\partial \mu} . \tag{6.53}
\end{equation*}
$$

[^949]As a result, Eq. (38) is generalized as

$$
\begin{equation*}
\nabla w_{0}=-\frac{\partial w_{0}}{\partial \varepsilon}\left(\nabla \mu+\frac{\varepsilon-\mu}{T} \nabla T\right) \tag{6.54}
\end{equation*}
$$

giving the following generalization of Eq. (39):

$$
\begin{equation*}
\widetilde{w}=\tau \frac{\partial w_{0}}{\partial \varepsilon} \mathbf{v} \cdot\left(q \nabla \Phi+\frac{\varepsilon-\mu}{T} \nabla T\right) . \tag{6.55}
\end{equation*}
$$

Now, repeating the current density calculation, we get a result which is traditionally presented as

$$
\begin{equation*}
\mathbf{j}=\sigma(-\nabla \Phi)+\sigma S(-\nabla T) \tag{6.56}
\end{equation*}
$$

where constant $S$, called the Seebeck coefficient ${ }^{31}$ (or the "thermoelectric power", or just "thermopower") is defined by the following relation:

$$
\begin{equation*}
\sigma S=\frac{g q \tau}{(2 \pi \hbar)^{3}} \frac{4 \pi}{3} \int_{0}^{\infty}\left(8 m \varepsilon^{3}\right)^{1 / 2} \frac{(\varepsilon-\mu)}{T}\left(-\frac{\partial\langle N(\varepsilon)\rangle}{\partial \varepsilon}\right) d \varepsilon \tag{6.57}
\end{equation*}
$$

Working out this integral for the most important case of a degenerate Fermi gas, with $T \ll \varepsilon_{\mathrm{F}}$, we have to be careful, because the center of the sharp peak of the last factor under the integral coincides with the zero point of the previous factor, $(\varepsilon-\mu) / T$. This uncertainty may be resolved using the Sommerfeld expansion formula (3.59). Indeed, for a smooth function $f(\varepsilon)$ defined by Eq. (3.60), so that $f(0)=0$, we may use (3.61) to rewrite the formula as

$$
\begin{equation*}
\int_{0}^{\infty} f(\varepsilon)\left(-\frac{\partial\langle N(\varepsilon)\rangle}{\partial \varepsilon}\right) d \varepsilon=f(\mu)+\left.\frac{\pi^{2}}{6} T^{2} \frac{d^{2} f(\varepsilon)}{d \varepsilon^{2}}\right|_{\varepsilon=\mu} . \tag{6.58}
\end{equation*}
$$

In particular, for integral (57), we may take $f(\varepsilon) \equiv\left(8 m \varepsilon^{3}\right)^{1 / 2}(\varepsilon-\mu) / T$. (Evidently, for this function, condition $f(0)=0$ is satisfied.) Then $f(\mu)=0, d^{2} f /\left.d \varepsilon^{2}\right|_{\varepsilon=\mu}=3(8 m \mu)^{1 / 2} / T \approx 3\left(8 m \varepsilon_{\mathrm{F}}\right)^{1 / 2} / T$, and Eq. (57) yields

$$
\begin{equation*}
\sigma S=\frac{g q \tau}{(2 \pi \hbar)^{3}} \frac{4 \pi}{3} \frac{\pi^{2}}{6} T^{2} \frac{3\left(8 m \varepsilon_{F}\right)^{1 / 2}}{T} \tag{6.59}
\end{equation*}
$$

Comparing the result with Eq. (31), for constant $S$ we get a simple expression independent of $\tau$. ${ }^{32}$

$$
\begin{equation*}
\mathcal{S}=\frac{\pi^{2}}{2 q} \frac{T}{\varepsilon_{F}}=\frac{c_{V}}{q}, \tag{6.60}
\end{equation*}
$$

where $c_{v} \equiv C_{V} / N$ is the heat capacity of the gas per unit particle, given by Eq. (3.70).

[^950]In order to understand the physical meaning of the Seebeck coefficient, it is sufficient to consider a conductor carrying no current. For this case, Eq. (56) yields

$$
\begin{equation*}
\nabla(\Phi+S T)=0 \tag{6.61}
\end{equation*}
$$

Thus, the temperature gradient creates the oppositely directed gradient of the effective electric potential $\Phi$, i.e. the effective field $\mathcal{E}$ defined by Eq. (42). This is the Seebeck effect. Figure 6 shows the standard way of its measurement, using a usual (electrodynamic) voltmeter that measures the difference of potentials $\Phi$, and a connection (in this context, called thermocouple) of two different materials, with different coefficients $S$. Integrating Eq. (61) around the loop from point $A$ to point $B$, and neglecting the temperature drop across the voltmeter, we get the following simple expression for the thermally-induced difference of the electrochemical potential, frequently also called the either the thermoelectric power or "thermo e.m.f.":

$$
\begin{align*}
V & \equiv \Phi_{\mathrm{B}}-\Phi_{\mathrm{A}}=\int_{\mathrm{A}}^{\mathrm{B}} \nabla \Phi \cdot d \mathbf{r}=-\int_{\mathrm{A}}^{\mathrm{B}} \Omega \nabla T \cdot d \mathbf{r}=-\varsigma_{1} \int_{\mathrm{A}^{\prime}}^{\mathrm{A}^{\prime \prime}} \nabla T \cdot d \mathbf{r}-\varsigma_{2}\left(\int_{\mathrm{A}^{\prime \prime}}^{\mathrm{B}} \nabla T \cdot d \mathbf{r}+\int_{\mathrm{A}}^{\mathrm{A}^{\prime}} \nabla T \cdot d \mathbf{r}\right)  \tag{6.62}\\
& =-\varsigma_{1}\left(T^{\prime \prime}-T^{\prime}\right)-\varsigma_{2}\left(T^{\prime}-T^{\prime \prime}\right)=\left(\varsigma_{1}-\varsigma_{2}\right)\left(T^{\prime}-T^{\prime \prime}\right) .
\end{align*}
$$

(Note that according to Eq. (62), any attempt to measure such voltage across any two points of a uniform conductor would give results depending on the voltmeter lead materials, due to the unintentional gradient of temperature in them.)

Using thermocouples is a popular, inexpensive method of temperature measurement - especially in the few-hundred- ${ }^{\circ} \mathrm{C}$ range (where gas- and fluid-based thermometers are not too practicable), if a $1^{\circ} \mathrm{C}$-scale accuracy is sufficient. The "responsivity" $\left(S_{1}-S_{2}\right)$ of a typical popular thermocouple, chromel-constantan, ${ }^{33}$ is about $70 \mu \mathrm{~V} /{ }^{\circ} \mathrm{C}$. In order to understand why typical values of $S$ are so small, let us discuss Seebeck effect's physics. Superficially, it is very simple: particles, heated by an external source, diffuse from it toward the colder parts of the conductor, carrying electrical current with them if they are charged. However, this naïve argument neglects the fact that at $\mathbf{j}=0$, there should be no total flow of particles. For a more accurate interpretation, note that the Seebeck effect is described by the factor $(\varepsilon-\mu) / T$ in integral (57), which changes sign at the Fermi surface, i.e. at the same energy where the term $(-\partial\langle N(\varepsilon)\rangle / \partial \varepsilon)$, describing the state availability for transport (due to their intermediate occupancy

[^951]$0<\langle N(\varepsilon)\rangle<1$ ), reaches its peak. The only reason why that integral does not vanish completely, and hence $S \neq 0$, is the growth of first factor under the integral (which describes the number of available quantum states) with $\varepsilon$, so the hotter particles (with $\varepsilon>\mu$ ) are more numerous and carry more heat then the colder ones.

The Seebeck effect is of course not the only result of temperature gradient; the same diffusion of hotter particles also causes a flow of heat from the region of higher $T$ to those with lower $T$, i.e. the effect of thermal conductivity, well known from our everyday practice. The heat (i.e. thermal energy) flow density may be calculated similarly to that of the electric current - see Eq. (26), with the natural replacement of the electric charge $q$ of each particle with the thermal energy $(\varepsilon-\mu)$ of its state: ${ }^{34}$

$$
\begin{equation*}
\mathbf{j}_{h}=\int(\varepsilon-\mu) \mathbf{v} w d^{3} p \tag{6.63}
\end{equation*}
$$

Again, at equilibrium $\left(w=w_{0}\right)$ the heat flow vanishes, so that $w$ may be replaced with its perturbation $\widetilde{w}$, which already has been calculated - see Eq. (55). The substitution of that expression into Eq. (63), and its transformation exactly similar to the one perform above for the electric current $\mathbf{j}$, yields ${ }^{35}$

$$
\begin{equation*}
\mathbf{j}_{h}=\sigma \Pi(-\nabla \Phi)+\kappa(-\nabla T), \tag{6.64}
\end{equation*}
$$

with coefficients $\Pi$ and $\kappa$ defined by equalities

Peltier coefficient and thermal conductivity

$$
\begin{align*}
& \sigma \Pi=\frac{g q \tau}{(2 \pi \hbar)^{3}} \frac{4 \pi}{3} \int_{0}^{\infty}\left(8 m \varepsilon^{3}\right)^{1 / 2}(\varepsilon-\mu)\left(-\frac{\partial\langle N(\varepsilon)\rangle}{\partial \varepsilon}\right) d \varepsilon  \tag{6.65}\\
& \kappa=\frac{g \tau}{(2 \pi \hbar)^{3}} \frac{4 \pi}{3} \int_{0}^{\infty}\left(8 m \varepsilon^{3}\right)^{1 / 2} \frac{(\varepsilon-\mu)^{2}}{T}\left(-\frac{\partial\langle N(\varepsilon)\rangle}{\partial \varepsilon}\right) d \varepsilon \tag{6.66}
\end{align*}
$$

Besides the missing factor $T$ in the denominator, integral in Eq. (65) is the same as in Eq. (57), so that constant $\Pi$ (called the Peltier coefficient), is simply and fundamentally related to the Seebeck coefficient: ${ }^{36}$
$\Pi$ vs. $s$

$$
\begin{equation*}
\Pi=S T . \tag{6.67}
\end{equation*}
$$

[^952]On the other hand, integral (66) may be readily calculated, for the most important case of a degenerate Fermi gas, using the Sommerfeld expansion (58) with $f(\varepsilon) \equiv\left(8 m \varepsilon^{3}\right)^{1 / 2}(\varepsilon-\mu)^{2} / T$, for which $f(\mu)=0$ and $d^{2} f /\left.d \varepsilon^{2}\right|_{\varepsilon=\mu}=2\left(8 m \mu^{3}\right)^{1 / 2} / T \approx 2\left(8 m \varepsilon_{F}^{3}\right)^{1 / 2} / T$, so that

$$
\begin{equation*}
\kappa=\frac{g \tau}{(2 \pi \hbar)^{3}} \frac{4 \pi}{3} \frac{\pi^{2}}{6} T^{2} \frac{2\left(8 m \varepsilon_{F}^{3}\right)^{1 / 2}}{T} . \tag{6.68}
\end{equation*}
$$

Comparing the result with the first form of Eq. (31), we get the so called Wiedemann-Franz law ${ }^{37}$

$$
\begin{equation*}
\kappa=\frac{\pi^{2}}{3} \frac{T}{q^{2}} \sigma \tag{6.69}
\end{equation*}
$$

This relation between the electric conductivity $\sigma$ and thermal conductivity $\kappa$ is more general than our formal derivation might imply. Indeed, it is straightforward to show that the Wiedemann-Franz law is also valid for an arbitrary dispersion law anisotropy (i.e. arbitrary Fermi surface shape) and, moreover, well beyond the relaxation-time approximation. (For example, it is also valid for scattering integral (12) with an arbitrary angular dependence of rate $\Gamma$, provided that scattering is elastic.) Experiments show that the law is well obeyed by most metals, but only at relatively low temperatures $T$ $\ll T_{\mathrm{D}}$, when the thermal conductance due to electrons is well above the one due to lattice vibrations, i.e. phonons - see Sec. 2.6. (Note also that Eq. (69) is not valid for classical gases - see Problem 2.)

Now let us discuss the less evident, first term of Eq. (64). It describes the so-called Peltier effect, which may be measured in the geometry similar to that shown in Fig. 6, but driven by an external voltage source - see Fig. 7.

Fig. 7. The Peltier effect.

The voltage drives certain dc current $I=j A$ (where $A$ is conductor's cross-section area), necessarily the same in the whole loop. However, according to Eq. (64), if materials 1 and 2 are

[^953]different, power $\mathcal{P}=j_{\mathrm{H}} A$ of the heat flow is different in two parts of the loop. Indeed, if the whole system is kept at the same temperature $(\nabla T=0)$, integration of the equation over the cross-section yields
\[

$$
\begin{equation*}
\frac{(\mathcal{P})_{1,2}}{I}=\frac{\left(j_{h}\right)_{1,2}}{j}=\frac{(\sigma \Pi)_{1,2}}{\sigma_{1,2}}=\Pi_{1,2} . \tag{6.70}
\end{equation*}
$$

\]

This means that in order to sustain the constant temperature, the following power difference,

Peltier effect

$$
\begin{equation*}
\Delta \mathcal{P}=\left(\Pi_{1}-\Pi_{2}\right) I \tag{6.71}
\end{equation*}
$$

has to be extracted from one junction of the two materials, and inserted into another junction. If a constant temperature is not maintained, the former junction is heated, while the latter one is cooled (on the top of the bulk, Joule heating), thus implementing a thermoelectric heat pump / refrigerator. Such refrigerators, with no moving parts and gas/fluid materials, are very convenient for modest (by a few tens ${ }^{\circ} \mathrm{C}$ ) cooling of relatively small components of various systems - from sensitive radiation detectors in spacecraft, all the way to cold drinks in vending machines. It is straightforward to use above formulas to show that the efficiency of active materials used in such thermoelectric refrigerators may be characterized by the following dimensionless figure-of-merit,

$$
\begin{equation*}
Z T \equiv \frac{\sigma S^{2}}{\kappa} T \tag{6.72}
\end{equation*}
$$

For the best thermoelectric materials found so far, $Z T$ is in the range from 2 to 3 , providing the coefficient of performance, defined by Eq. (1.69), of the order of 0.5 - a few times lower than that of traditional, mechanical refrigerators. The search for composite materials (including those with nanoparticles) with higher values of $Z T$ is one of very active fields of applied solid state physics. ${ }^{38}$

Let me finish this chapter (and this course, and this series :-) by emphasizing again that due to time/space restrictions I was able to barely scratch the surface of physical kinetics. ${ }^{39}$

### 6.6. Exercise problems

6.1. Use the relaxation-time approximation of the Boltzmann equation to prove the Drude formula for the complex conductivity at frequency $\omega$,

$$
\sigma(\omega)=\frac{\sigma(0)}{1-i \omega \tau}
$$

where $\sigma(0)$ is the dc conductivity given by Eq. (6.30) of the lecture notes, and give a physical interpretation of the formula.

[^954]6.2. Use the variable separation method to calculate the time evolution of the particle density distribution in space, provided that at $t=0$, the particles are released from their uniform distribution in a wide box of thickness $2 a$ :
\[

n= $$
\begin{cases}n_{0}, & \text { for }-a \leq x \leq+a, \\ 0, & \text { otherwise }\end{cases}
$$
\]

6.3. For the 1 D version of the diffusion equation (i.e. of the drift-diffusion equation (6.50) with $\tau T / m \equiv D$, and without the drift-inducing field, $\nabla U=0$ ),

$$
\frac{\partial n}{\partial t}=D \frac{\partial^{2} n}{\partial x^{2}}, \quad \text { for }-\infty<x<+\infty
$$

find an appropriate spatial-temporal Green's function, and use it to solve the previous problem.
6.4.* Calculate the electric conductance of a narrow, uniform conducting channel between two bulk conductors, in the low-voltage and low-temperature limit, neglecting the electron interaction and scattering inside the channel.
6.5. Calculate the electric conductivity $\sigma$, the thermal conductivity $\kappa$, as well as the thermoelectric coefficients $\mathcal{S}$ and $\Pi$, for a classical, ideal gas of electrically charged particles. Compare the results with those for the degenerate Fermi gas, derived in the lecture notes.
6.6. Derive a partial differential equation describing the time evolution of temperature distribution in a medium with negligible thermal expansion and with temperature-independent specific heat $c_{V}$ and thermal conductivity $\kappa$, given by the Fourier law

$$
\mathbf{j}_{h}=-\kappa \nabla T .
$$

6.7. Use the equation derived in the previous problem to calculate the time evolution of temperature in the center of a uniform solid sphere of radius $R$, initially heated to temperature $T_{i}$, and at $t$ $=0$ placed into a heat bath that keeps its surface at temperature $T_{0}$.
6.8. Suggest a reasonable definition of the entropy production rate (per unit volume), and calculate this rate for a stationary thermal conduction, assuming that it obeys the Fourier law, in a material with negligible thermal expansion. Give a physical interpretation of the result. Does the stationary temperature distribution in a sample correspond to the minimum of the total entropy production in it?

## Selected Mathematical Formulas

that are used in this lecture course series, but not always remembered by students (and some instructors :-)

## 1. Constants

- Euclidean circle’s length-to-diameter ratio:

$$
\begin{equation*}
\pi=3.141592653 \ldots ; \quad \pi^{1 / 2} \approx 1.77 \tag{1.1}
\end{equation*}
$$

- Natural logarithm base:

$$
\begin{equation*}
e \equiv \lim _{n \rightarrow \infty}\left(1+\frac{1}{n}\right)^{n}=2.718281828 \ldots ; \tag{1.2a}
\end{equation*}
$$

from that value, the logarithm base conversion factors are as follows ( $\xi>0$ ):

$$
\begin{equation*}
\frac{\ln \xi}{\log _{10} \xi}=\ln 10 \approx 2.303, \quad \frac{\log _{10} \xi}{\ln \xi}=\frac{1}{\ln 10} \approx 0.434 \tag{1.2b}
\end{equation*}
$$

- The Euler (or "Euler-Mascheroni") constant:

$$
\begin{equation*}
\gamma \equiv \lim _{n \rightarrow \infty}\left(1+\frac{1}{2}+\frac{1}{3}+\ldots+\frac{1}{n}-\ln n\right)=0.5771566490 \ldots ; \quad e^{\gamma} \approx 1.781 \tag{1.3}
\end{equation*}
$$

## 2. Combinatorics, sums, and series

(i) Combinatorics

- The number of different permutations, i.e. ordered sequences of $k$ elements selected from a set of $n$ distinct elements ( $n \geq k$ ), is

$$
\begin{equation*}
{ }^{n} P_{k} \equiv n \cdot(n-1) \cdot \ldots \cdot(n-k+1)=\frac{n!}{(n-k)!} \tag{2.1a}
\end{equation*}
$$

in particular, the number of different permutations of all elements of the set $(n=k)$ is

$$
\begin{equation*}
{ }^{k} P_{k}=k \cdot(k-1) \cdot \ldots \cdot 2 \cdot 1=k! \tag{2.1b}
\end{equation*}
$$

- The number of different combinations, i.e. unordered sequences of $k$ elements from a set of $n \geq$ $k$ distinct elements, is equal to the binomial coefficient

$$
\begin{equation*}
{ }^{n} C_{k} \equiv\binom{n}{k} \equiv \frac{{ }^{n} P_{k}}{{ }^{k} P_{k}}=\frac{n!}{k!(n-k)!} \tag{2.2}
\end{equation*}
$$

In an alternative, very popular "ball/box language", ${ }^{n} C_{k}$ is the number of different ways to put in a box, in an arbitrary order, $k$ balls selected from $n$ distinct balls.

- A generalization of the binomial coefficient notion is the multinomial coefficient,

$$
\begin{equation*}
{ }^{n} C_{k_{1}, k_{2}, \ldots k_{l}} \equiv \frac{n!}{k_{1}!k_{2}!\ldots k_{l}!}, \quad \text { with } n=\sum_{j=1}^{l} k_{j} \tag{2.3}
\end{equation*}
$$

which, in the standard mathematical language, is a number of different permutations in a multiset of $l$ distinct element types from an $n$-element set which contains $k_{j}(j=1,2, \ldots l)$ elements of each type. In the "ball/box language", the coefficient (2.3) is the number of different ways to distribute $n$ balls between $l$ distinct boxes, each time keeping the number ( $k_{j}$ ) of balls in the $j$-th box fixed, but ignoring their order inside the box. The binomial coefficient ${ }^{n} C_{k}$ (2.2), is a particular case of the multinomial coefficient (2.3) for $l=2$ - counting the explicit box for the first one, and the remaining space for the second box, so that if $k_{1} \equiv k$, then $k_{2}=n-k$.

- One more important combinatorial quantity is the number $M_{n}{ }^{(k)}$ of ways to place $n$ indistinguishable balls into $k$ distinct boxes. It may be readily calculated from Eq. (2.2) as the number of different ways to select $(k-1)$ partitions between the boxes in an imagined linear row of $(k-1+n)$ "objects" (balls in the boxes and partitions between them):

$$
\begin{equation*}
M_{n}^{(k)}={ }^{n-1+k} C_{k-1} \equiv \frac{(k-1+n)!}{(k-1)!n!} . \tag{2.4}
\end{equation*}
$$

(ii) Sums and series

- Arithmetic progression:

$$
\begin{equation*}
r+2 r+\ldots+n r \equiv \sum_{k=1}^{n} k r=\frac{n(r+n r)}{2} ; \tag{2.5a}
\end{equation*}
$$

in particular, at $r=1$ it is reduced to the sum of $n$ first natural numbers:

$$
\begin{equation*}
1+2+\ldots+n \equiv \sum_{k=1}^{n} k=\frac{n(n+1)}{2} \tag{2.5b}
\end{equation*}
$$

- Sums of squares and cubes of $n$ first natural numbers:

$$
\begin{gather*}
1^{2}+2^{2}+\ldots+n^{2} \equiv \sum_{k=1}^{n} k^{2}=\frac{n(n+1)(2 n+1)}{6} ;  \tag{2.6a}\\
1^{3}+2^{3}+\ldots+n^{3} \equiv \sum_{k=1}^{n} k^{3}=\frac{n^{2}(n+1)^{2}}{4}, \tag{2.6b}
\end{gather*}
$$

- The Riemann zeta function:

$$
\begin{equation*}
\zeta(s) \equiv 1+\frac{1}{2^{s}}+\frac{1}{3^{s}}+\ldots=\sum_{k=1}^{\infty} \frac{1}{k^{s}} \tag{2.7a}
\end{equation*}
$$

the particular values frequently met in applications are

$$
\begin{equation*}
\zeta\left(\frac{3}{2}\right) \approx 2.612, \quad \zeta(2)=\frac{\pi^{2}}{6}, \quad \zeta\left(\frac{5}{2}\right) \approx 1.341, \quad \zeta(3) \approx 1.202, \quad \zeta(4)=\frac{\pi^{4}}{90}, \quad \zeta(5) \approx 1.037 \tag{2.7b}
\end{equation*}
$$

- Finite geometric progression (for real $\lambda \neq 1$ ):

$$
\begin{equation*}
1+\lambda+\lambda^{2}+\ldots+\lambda^{n-1} \equiv \sum_{k=0}^{n-1} \lambda^{k}=\frac{1-\lambda^{n}}{1-\lambda} ; \tag{2.8a}
\end{equation*}
$$

in particular, if $\lambda^{2}<1$, the progression has a finite limit at $n \rightarrow \infty$ (called the geometric series):

$$
\begin{equation*}
\lim _{n \rightarrow \infty} \sum_{k=0}^{n-1} \lambda^{k}=\sum_{k=0}^{\infty} \lambda^{k}=\frac{1}{1-\lambda} . \tag{2.8b}
\end{equation*}
$$

- Binomial sum (or the "binomial theorem"):

$$
\begin{equation*}
(1+a)^{n}=\sum_{k=0}^{n}{ }^{n} C_{k} a^{k}, \tag{2.9}
\end{equation*}
$$

where ${ }^{n} C_{k}$ are the binomial coefficients defined by Eq. (2.2).

- The Stirling formula:

$$
\begin{equation*}
\lim _{n \rightarrow \infty} \ln (n!)=n(\ln n-1)+\frac{1}{2} \ln (2 \pi n)+\frac{1}{12 n}-\frac{1}{360 n^{3}}+\ldots \tag{2.10}
\end{equation*}
$$

for most applications in physics, the first term ${ }^{1}$ is sufficient.

- The Taylor (or "Taylor-Maclaurin") series: for any infinitely differentiable function $f(\xi)$ :

$$
\begin{equation*}
\lim _{\tilde{x} \rightarrow 0} f(\xi+\tilde{\xi})=f(\xi)+\frac{d f}{d \xi}(\xi) \tilde{\xi}+\frac{1}{2!} \frac{d^{2} f}{d \xi^{2}}(\xi) \tilde{\xi}^{2}+\ldots=\sum_{k=0}^{\infty} \frac{1}{k!} \frac{d^{k} f}{d \xi^{k}}(\xi) \tilde{\xi}^{k} \tag{2.11a}
\end{equation*}
$$

note that for many functions this series converges only within a limited, sometimes small range of deviations $\tilde{x}$. For a function of several arguments, $f\left(\xi_{1}, \xi_{2}, \ldots, \xi_{N}\right)$, the first terms of the Taylor series are

$$
\begin{equation*}
\lim _{\tilde{\xi}_{k} \rightarrow 0} f\left(\xi_{1}+\tilde{\xi}_{1}, \xi_{2}+\tilde{\xi}_{2}, \ldots\right)=f\left(\xi_{1}, \xi_{2}, \ldots\right)+\sum_{k=1}^{N} \frac{\partial f}{\partial \xi_{k}}\left(\xi_{1}, \xi_{2}, \ldots\right) \tilde{\xi}_{k}+\frac{1}{2!} \sum_{k, k^{\prime}=1}^{N} \frac{\partial^{2} f}{\partial_{k} \xi \partial \xi_{k^{\prime}}} \widetilde{\xi}_{k} \tilde{\xi}_{k^{\prime}}+\ldots \tag{2.11b}
\end{equation*}
$$

- The Euler-Maclaurin formula, valid for any infinitely differentiable function $f(\xi)$ :

$$
\begin{align*}
\sum_{k=1}^{n} f(k)= & \int_{0}^{n} f(\xi) d \xi+\frac{1}{2}[f(n)-f(0)]+\frac{1}{6} \cdot \frac{1}{2!}\left[\frac{d f}{d \xi}(n)-\frac{d f}{d \xi}(0)\right] \\
& -\frac{1}{30} \cdot \frac{1}{4!}\left[\frac{d^{3} f}{d \xi^{3}}(n)-\frac{d^{3} f}{d \xi^{3}}(0)\right]+\frac{1}{42} \cdot \frac{1}{6!}\left[\frac{d^{5} f}{d \xi^{5}}(n)-\frac{d^{5} f}{d \xi^{5}}(0)\right]+\ldots \tag{2.12a}
\end{align*}
$$

[^955]the coefficients participating in this formula are the so-called Bernoulli numbers: ${ }^{2}$
\[

$$
\begin{equation*}
B_{1}=\frac{1}{2}, \quad B_{2}=\frac{1}{6}, \quad B_{3}=0, \quad B_{4}=\frac{1}{30}, \quad B_{5}=0, \quad B_{6}=\frac{1}{42}, \quad B_{7}=0, \quad B_{8}=\frac{1}{30}, \ldots . \tag{2.12b}
\end{equation*}
$$

\]

## 3. Basic trigonometric functions

- Trigonometric functions of the sum and the difference of two arguments: ${ }^{3}$

$$
\begin{align*}
\cos (a \pm b) & =\cos a \cos b \mp \sin a \sin b  \tag{3.1a}\\
\sin (a \pm b) & =\sin a \cos b \pm \cos a \sin b . \tag{3.1b}
\end{align*}
$$

- Sums of two functions of arbitrary arguments:

$$
\begin{align*}
& \cos a+\cos b=2 \cos \frac{a+b}{2} \cos \frac{b-a}{2}  \tag{3.2a}\\
& \cos a-\cos b=2 \sin \frac{a+b}{2} \sin \frac{b-a}{2},  \tag{3.2b}\\
& \sin a \pm \sin b=2 \sin \frac{a \pm b}{2} \cos \frac{ \pm b-a}{2} \tag{3.2c}
\end{align*}
$$

- Trigonometric function products:

$$
\begin{align*}
& 2 \cos a \cos b=\cos (a+b)+\cos (a-b)  \tag{3.3a}\\
& 2 \sin a \cos b=\sin (a+b)+\sin (a-b)  \tag{3.3b}\\
& 2 \sin a \sin b=\cos (a-b)-\cos (a+b) \tag{3.3c}
\end{align*}
$$

For the particular case of equal arguments, $b=a$, these three formulas yield the following expressions for the squares of trigonometric functions, and their product:

$$
\begin{equation*}
\cos ^{2} a=\frac{1}{2}(1+\cos 2 a), \quad \sin a \cos a=\frac{1}{2} \sin 2 a, \quad \sin ^{2} a=\frac{1}{2}(1-\cos 2 a) . \tag{3.3d}
\end{equation*}
$$

- Cubes of trigonometric functions:

$$
\begin{equation*}
\cos ^{3} a=\frac{3}{4} \cos a+\frac{1}{4} \cos 3 a, \quad \sin ^{3} a=\frac{3}{4} \sin a-\frac{1}{4} \sin 3 a . \tag{3.4}
\end{equation*}
$$

- Trigonometric functions of a complex argument:

$$
\begin{align*}
& \sin (a+i b)=\sin a \cosh b+i \cos a \sinh b, \\
& \cos (a+i b)=\cos a \cosh b-i \sin a \sinh b . \tag{3.5}
\end{align*}
$$

[^956]- Sums of trigonometric functions of $n$ equidistant arguments:

$$
\sum_{k=1}^{n}\left\{\begin{array}{c}
\sin  \tag{3.6}\\
\cos
\end{array}\right\} k \xi=\left\{\begin{array}{l}
\sin \\
\cos
\end{array}\right\}\left(\frac{n+1}{2} \xi\right) \sin \left(\frac{n}{2} \xi\right) / \sin \left(\frac{\xi}{2}\right) .
$$

## 4. General differentiation

- Full differential of a product of two functions:

$$
\begin{equation*}
d(f g)=(d f) g+f(d g) \tag{4.1}
\end{equation*}
$$

- Full differential of a function of several independent arguments, $f\left(\xi_{1}, \xi_{2}, \ldots, \xi_{n}\right)$ :

$$
\begin{equation*}
d f=\sum_{k=1}^{n} \frac{\partial f}{\partial \xi_{k}} d \xi_{k} . \tag{4.2}
\end{equation*}
$$

- Curvature of the Cartesian plot of a 1D function $f(\xi)$ :

$$
\begin{equation*}
\kappa \equiv \frac{1}{R}=\frac{\left|d^{2} f / d \xi^{2}\right|}{\left[1+(d f / d \xi)^{2}\right]^{3 / 2}} \tag{4.3}
\end{equation*}
$$

## 5. General integration

- Integration by parts - immediately follows from Eq. (4.1):

$$
\begin{equation*}
\int_{g(A)}^{g(B)} f d g=\left.f g\right|_{A} ^{B}-\int_{f(A)}^{f(B)} g d f . \tag{5.1}
\end{equation*}
$$

- Numerical (approximate) integration of 1D functions: the simplest trapezoidal rule,

$$
\begin{equation*}
\int_{a}^{b} f(\xi) d \xi \approx h\left[f\left(a+\frac{h}{2}\right)+f\left(a+\frac{3 h}{2}\right)+\ldots+f\left(b-\frac{h}{2}\right)\right]=h \sum_{n=1}^{N} f\left(a-\frac{h}{2}+n h\right), \quad h \equiv \frac{b-a}{N} . \tag{5.2}
\end{equation*}
$$

has relatively low accuracy (error of the order of $\left(h^{3} / 12\right) d^{2} f / d \xi^{2}$ per step), so that the following Simpson formula,

$$
\begin{equation*}
\int_{a}^{b} f(\xi) d \xi \approx \frac{h}{3}[f(a)+4 f(a+h)+2 f(a+2 h)+\ldots+4 f(b-h)+f(b)], \quad h \equiv \frac{b-a}{2 N}, \tag{5.3}
\end{equation*}
$$

whose error per step scales as $\left(h^{5} / 180\right) d^{4} f / d \xi^{4}$, is used much more frequently. ${ }^{4}$

[^957]
## 6. A few 1D integrals ${ }^{5}$

(i) Indefinite integrals

- Integrals with $\left(1+\xi^{2}\right)^{1 / 2}$ :

$$
\begin{gather*}
\int\left(1+\xi^{2}\right)^{1 / 2} d \xi=\frac{\xi}{2}\left(1+\xi^{2}\right)^{1 / 2}+\frac{1}{2} \ln \left|\xi+\left(1+\xi^{2}\right)^{1 / 2}\right|  \tag{6.1}\\
\int \frac{d \xi}{\left(1+\xi^{2}\right)^{1 / 2}}=\ln \left|\xi+\left(1+\xi^{2}\right)^{1 / 2}\right|  \tag{6.2a}\\
\int \frac{d \xi}{\left(1+\xi^{2}\right)^{3 / 2}}=\frac{\xi}{\left(1+\xi^{2}\right)^{1 / 2}} . \tag{6.2b}
\end{gather*}
$$

- Miscellaneous indefinite integrals:

$$
\begin{gather*}
\int \frac{d \xi}{\xi\left(\xi^{2}+2 a \xi-1\right)^{1 / 2}}=\cos ^{-1} \frac{a \xi-1}{|\xi|\left(a^{2}+1\right)^{1 / 2}}  \tag{6.3a}\\
\int \frac{(\sin \xi-\xi \cos \xi)^{2}}{\xi^{5}} d \xi=\frac{2 \xi \sin 2 \xi+\cos 2 \xi-2 \xi^{2}-1}{8 \xi^{4}},  \tag{6.3b}\\
\int \frac{d \xi}{a+b \cos \xi}=\frac{2}{\left(a^{2}-b^{2}\right)^{1 / 2}} \tan ^{-1}\left[\frac{(a-b)}{\left(a^{2}-b^{2}\right)^{1 / 2}} \tan \frac{\xi}{2}\right], \quad \text { for } a^{2}>b^{2}  \tag{6.3c}\\
\int \frac{d \xi}{1+\xi^{2}}=\tan ^{-1} \xi \tag{6.3d}
\end{gather*}
$$

(ii) Semi-definite integrals:

- Integrals with $1 /\left(e^{\xi} \pm 1\right)$ :

$$
\begin{align*}
& \int_{a}^{\infty} \frac{d \xi}{e^{\xi}+1}=\ln \left(1+e^{-a}\right)  \tag{6.4a}\\
& \int_{a>0}^{\infty} \frac{d \xi}{e^{\xi}-1}=\ln \frac{1}{1-e^{-a}} \tag{6.4b}
\end{align*}
$$

(iii) Definite integrals

- Integrals with $1 /\left(1+\xi^{2}\right):{ }^{6}$

$$
\begin{equation*}
\int_{0}^{\infty} \frac{d \xi}{1+\xi^{2}}=\frac{\pi}{2} \tag{6.5a}
\end{equation*}
$$

[^958]\[

$$
\begin{equation*}
\int_{0}^{\infty} \frac{d \xi}{\left(1+\xi^{2}\right)^{3 / 2}}=1 ; \tag{6.5b}
\end{equation*}
$$

\]

more generally,

$$
\begin{equation*}
\int_{0}^{\infty} \frac{d \xi}{\left(1+\xi^{2}\right)^{n}}=\frac{\pi}{2} \frac{(2 n-3)!!}{(2 n-2)!!} \equiv \frac{\pi}{2} \frac{1 \cdot 3 \cdot 5 \ldots(2 n-3)}{2 \cdot 4 \cdot 6 \ldots(2 n-2)}, \quad \text { for } n=2,3, \ldots \tag{6.5c}
\end{equation*}
$$

- Integrals with $\left(1-\xi^{2 n}\right)^{1 / 2}$ :

$$
\begin{align*}
& \int_{0}^{1} \frac{d \xi}{\left(1-\xi^{2 n}\right)^{1 / 2}}=\frac{\pi^{1 / 2}}{2 n} \Gamma\left(\frac{1}{2 n}\right) / \Gamma\left(\frac{n+1}{2 n}\right),  \tag{6.6a}\\
& \int_{0}^{1}\left(1-\xi^{2 n}\right)^{1 / 2} d \xi=\frac{\pi^{1 / 2}}{4 n} \Gamma\left(\frac{1}{2 n}\right) / \Gamma\left(\frac{3 n+1}{2 n}\right), \tag{6.6b}
\end{align*}
$$

where $\Gamma(s)$ is the gamma-function, which is most often defined (for $\operatorname{Re} s>0$ ) by the following integral:

$$
\begin{equation*}
\int_{0}^{\infty} \xi^{s-1} e^{-\xi} d \xi=\Gamma(s) \tag{6.7a}
\end{equation*}
$$

The key property of this function is the recurrence relation, valid for any $s \neq 0,-1,-2, \ldots$, is

$$
\begin{equation*}
\Gamma(s+1)=s \Gamma(s) . \tag{6.7b}
\end{equation*}
$$

Since, according to Eq. (6.7a), $\Gamma(1)=1$, Eq. (6.7b) for non-negative integers takes the form

$$
\begin{equation*}
\Gamma(n+1)=n!, \text { for } n=0,1,2, \ldots \tag{6.7c}
\end{equation*}
$$

(where $0!\equiv 1$ ). Because of this, for integer $s=n+1 \geq 1$, Eq. (6.7a) is reduced to

$$
\begin{equation*}
\int_{0}^{\infty} \xi^{n} e^{-\xi} d \xi=n! \tag{6.7d}
\end{equation*}
$$

Other frequently met values of the gamma-function are those for positive semi-integer arguments:

$$
\begin{equation*}
\Gamma\left(\frac{1}{2}\right)=\pi^{1 / 2}, \quad \Gamma\left(\frac{3}{2}\right)=\frac{1}{2} \pi^{1 / 2}, \quad \Gamma\left(\frac{5}{2}\right)=\frac{1}{2} \cdot \frac{3}{2} \pi^{1 / 2}, \quad \Gamma\left(\frac{7}{2}\right)=\frac{1}{2} \cdot \frac{3}{2} \cdot \frac{5}{2} \pi^{1 / 2}, \ldots . \tag{6.7e}
\end{equation*}
$$

- Integrals with $1 /\left(e^{\xi} \pm 1\right)$ :

$$
\begin{gather*}
\int_{0}^{\infty} \frac{\xi^{s-1} d \xi}{e^{\xi}+1}=\left(1-2^{1-s}\right) \Gamma(s) \zeta(s), \quad \text { for } s>0,  \tag{6.8a}\\
\int_{0}^{\infty} \frac{\xi^{s-1} d \xi}{e^{\xi}-1}=\Gamma(s) \zeta(s), \quad \text { for } s>1, \tag{6.8b}
\end{gather*}
$$

where $\zeta(s)$ is the Riemann zeta-function - see Eq. (2.6). Particular cases: for $s=2 n$,

$$
\begin{equation*}
\int_{0}^{\infty} \frac{\xi^{2 n-1} d \xi}{e^{\xi}+1}=\frac{2^{2 n-1}-1}{2 n} \pi^{2 n} B_{2 n} \tag{6.8c}
\end{equation*}
$$

$$
\begin{equation*}
\int_{0}^{\infty} \frac{\xi^{2 n-1} d \xi}{e^{\xi}-1}=\frac{(2 \pi)^{2 n}}{4 n} B_{2 n} \tag{6.8d}
\end{equation*}
$$

where $B_{n}$ are the Bernoulli numbers - see Eq. (2.12). For the particular case $s=1$ (when Eq. (6.8a) yields uncertainty),

$$
\begin{equation*}
\int_{0}^{\infty} \frac{d \xi}{e^{\xi}+1}=\ln 2 . \tag{6.8e}
\end{equation*}
$$

- Integrals with $\exp \left\{-\xi^{2}\right\}$ :

$$
\begin{equation*}
\int_{0}^{\infty} \xi^{s} e^{-\xi^{2}} d \xi=\frac{1}{2} \Gamma\left(\frac{s+1}{2}\right), \text { for } s>-1 \text {; } \tag{6.9a}
\end{equation*}
$$

for applications the most important particular values of $s$ are 0 and 2:

$$
\begin{align*}
& \int_{0}^{\infty} e^{-\xi^{2}} d \xi=\frac{1}{2} \Gamma\left(\frac{1}{2}\right)=\frac{\pi^{1 / 2}}{2}  \tag{6.9b}\\
& \int_{0}^{\infty} \xi^{2} e^{-\xi^{2}} d \xi=\frac{1}{2} \Gamma\left(\frac{3}{2}\right)=\frac{\pi^{1 / 2}}{4} \tag{6.9c}
\end{align*}
$$

though we will also run into the cases $s=4$ and $s=6$ :

$$
\begin{equation*}
\int_{0}^{\infty} \xi^{4} e^{-\xi^{2}} d \xi=\frac{1}{2} \Gamma\left(\frac{5}{2}\right)=\frac{3 \pi^{1 / 2}}{8}, \quad \int_{0}^{\infty} \xi^{6} e^{-\xi^{2}} d \xi=\frac{1}{2} \Gamma\left(\frac{7}{2}\right)=\frac{15 \pi^{1 / 2}}{16} ; \tag{6.9d}
\end{equation*}
$$

for odd integer values $s=2 n+1$ (with $n=0,1,2, \ldots$ ), Eq. (6.9a) takes a simpler form:

$$
\begin{equation*}
\int_{0}^{\infty} \xi^{2 n+1} e^{-\xi^{2}} d \xi=\frac{1}{2} \Gamma(n+1)=\frac{n!}{2} . \tag{6.9e}
\end{equation*}
$$

- Integrals with cosine and sine functions:

$$
\begin{gather*}
\int_{0}^{\infty} \cos \left(\xi^{2}\right) d \xi=\int_{0}^{\infty} \sin \left(\xi^{2}\right) d \xi=\left(\frac{\pi}{8}\right)^{1 / 2} .  \tag{6.10}\\
\int_{0}^{\infty} \frac{\cos \xi}{a^{2}+\xi^{2}} d \xi=\frac{\pi}{2 a} e^{-a} .  \tag{6.11}\\
\int_{0}^{\infty}\left(\frac{\sin \xi}{\xi}\right)^{2} d \xi=\frac{\pi}{2} \tag{6.12}
\end{gather*}
$$

- Integrals with logarithms:

$$
\begin{gather*}
\int_{0}^{1} \ln \frac{a+\left(1-\xi^{2}\right)^{1 / 2}}{a-\left(1-\xi^{2}\right)^{1 / 2}} d \xi=\pi\left[a-\left(a^{2}-1\right)^{1 / 2}\right], \quad \text { for } a \geq 1  \tag{6.13}\\
\int_{0}^{1} \ln \frac{1+(1-\xi)^{1 / 2}}{\xi^{1 / 2}} d \xi=1 \tag{6.14}
\end{gather*}
$$

- Integral representations of the Bessel functions of integer order:

$$
\begin{gather*}
J_{n}(\alpha)=\frac{1}{2 \pi} \int_{-\pi}^{+\pi} e^{i(\alpha \sin \xi-n \xi)} d \xi, \quad \text { so that } e^{i \alpha \sin \xi}=\sum_{k=-\infty}^{\infty} J_{k}(\alpha) e^{i k \xi} ;  \tag{6.15a}\\
I_{n}(\alpha)=\frac{1}{\pi} \int_{0}^{\pi} e^{\alpha \cos \xi} \cos n \xi d \xi \tag{6.15b}
\end{gather*}
$$

## 7. 3D vector products

(i) Definitions:

- Scalar ("dot-") product:

$$
\begin{equation*}
\mathbf{a} \cdot \mathbf{b}=\sum_{j=1}^{3} a_{j} b_{j}, \tag{7.1}
\end{equation*}
$$

where $a_{j}$ and $b_{j}$ are vector components in any orthogonal coordinate system. In particular, the vector squared (the same as its norm squared) is:

$$
\begin{equation*}
a^{2} \equiv \mathbf{a} \cdot \mathbf{a}=\sum_{j=1}^{3} a_{j}^{2} \equiv\|\mathbf{a}\|^{2} \tag{7.2}
\end{equation*}
$$

- Vector ("cross-") product:

$$
\mathbf{a} \times \mathbf{b} \equiv \mathbf{n}_{1}\left(a_{2} b_{3}-a_{3} b_{2}\right)+\mathbf{n}_{2}\left(a_{3} b_{1}-a_{1} b_{3}\right)+\mathbf{n}_{3}\left(a_{1} b_{2}-a_{2} b_{1}\right)=\left|\begin{array}{lll}
\mathbf{n}_{1} & \mathbf{n}_{2} & \mathbf{n}_{3}  \tag{7.3}\\
a_{1} & a_{2} & a_{3} \\
b_{1} & b_{2} & b_{3}
\end{array}\right|,
$$

where $\left\{\mathbf{n}_{j}\right\}$ is the set of mutually perpendicular unit vectors ${ }^{7}$ along the corresponding coordinate system axes. ${ }^{8}$ In particular, Eq. (7.3) yields

$$
\begin{equation*}
\mathbf{a} \times \mathbf{a}=0 . \tag{7.4}
\end{equation*}
$$

(ii) Corollaries (readily verified by Cartesian components):

- Double vector product (the so-called bac minus cab rule):

$$
\begin{equation*}
\mathbf{a} \times(\mathbf{b} \times \mathbf{c})=\mathbf{b}(\mathbf{a} \cdot \mathbf{c})-\mathbf{c}(\mathbf{a} \cdot \mathbf{b}) . \tag{7.5}
\end{equation*}
$$

- Mixed scalar-vector product (called the operand rotation rule):

$$
\begin{equation*}
\mathbf{a} \cdot(\mathbf{b} \times \mathbf{c})=\mathbf{b} \cdot(\mathbf{c} \times \mathbf{a})=\mathbf{c} \cdot(\mathbf{a} \times \mathbf{b}) . \tag{7.6}
\end{equation*}
$$

- Scalar product of vector products:

$$
\begin{equation*}
(\mathbf{a} \times \mathbf{b}) \cdot(\mathbf{c} \times \mathbf{d})=(\mathbf{a} \cdot \mathbf{c})(\mathbf{b} \cdot \mathbf{d})-(\mathbf{a} \cdot \mathbf{d})(\mathbf{b} \cdot \mathbf{c}) ; \tag{7.7a}
\end{equation*}
$$

in the particular case of two similar operands (say, $\mathbf{a}=\mathbf{c}$ and $\mathbf{b}=\mathbf{d}$ ), the last formula is reduced to

[^959]\[

$$
\begin{equation*}
(\mathbf{a} \times \mathbf{b})^{2}=(a b)^{2}-(\mathbf{a} \cdot \mathbf{b})^{2} . \tag{7.7b}
\end{equation*}
$$

\]

## 8. Differentiation in 3D Cartesian coordinates

- Definition of the del (or "nabla") vector-operator $\nabla$ : ${ }^{9}$

$$
\begin{equation*}
\nabla \equiv \sum_{j=1}^{3} \mathbf{n}_{j} \frac{\partial}{\partial r_{j}} \tag{8.1}
\end{equation*}
$$

where $r_{j}$ is a set of linear and orthogonal (called Cartesian) coordinates along directions $\mathbf{n}_{j}$. In accordance with this definition, the operator $\nabla$ acting on a scalar function of coordinates, $f(\mathbf{r}),{ }^{10}$ gives its gradient, i.e. a new vector:

$$
\begin{equation*}
\nabla f \equiv \sum_{j=1}^{3} \mathbf{n}_{j} \frac{\partial f}{\partial r_{j}} \equiv \operatorname{grad} f \tag{8.2}
\end{equation*}
$$

- The scalar product of del by a vector function of coordinates (a vector field),

$$
\begin{equation*}
\mathbf{f}(\mathbf{r}) \equiv \sum_{j=1}^{3} \mathbf{n}_{j} f_{j}(\mathbf{r}), \tag{8.3}
\end{equation*}
$$

compiled formally following Eq. (7.1), is a scalar function - the divergence of the initial function:

$$
\begin{equation*}
\nabla \cdot \mathbf{f} \equiv \sum_{j=1}^{3} \frac{\partial f_{j}}{\partial r_{j}} \equiv \operatorname{div} \mathbf{f}, \tag{8.4}
\end{equation*}
$$

while the vector product of $\nabla$ and $\mathbf{f}$, formed in a formal accordance with Eq. (7.3), is a new vector - the curl (in European tradition, called rotor and denoted rot) of $\mathbf{f}$ :

$$
\nabla \times \mathbf{f} \equiv\left|\begin{array}{ccc}
\mathbf{n}_{1} & \mathbf{n}_{2} & \mathbf{n}_{3}  \tag{8.5}\\
\frac{\partial}{\partial r_{1}} & \frac{\partial}{\partial r_{2}} & \frac{\partial}{\partial r_{3}} \\
f_{1} & f_{2} & f_{3}
\end{array}\right|=\mathbf{n}_{1}\left(\frac{\partial f_{3}}{\partial r_{2}}-\frac{\partial f_{2}}{\partial r_{3}}\right)+\mathbf{n}_{2}\left(\frac{\partial f_{1}}{\partial r_{3}}-\frac{\partial f_{3}}{\partial r_{1}}\right)+\mathbf{n}_{3}\left(\frac{\partial f_{2}}{\partial r_{1}}-\frac{\partial f_{1}}{\partial r_{2}}\right) \equiv \text { curl f. }
$$

- One more frequently met "product" is $(\mathbf{f} \cdot \nabla) \mathbf{g}$, where $\mathbf{f}$ and $\mathbf{g}$ are two arbitrary vector functions of $\mathbf{r}$. This product should be also understood in the sense implied by Eq. (7.1), i.e. as a vector whose $j$-th Cartesian component is

$$
\begin{equation*}
[(\mathbf{f} \cdot \nabla) \mathbf{g}]_{j}=\sum_{j^{\prime}=1}^{3} f_{j^{\prime}} \frac{\partial g_{j}}{\partial r_{j^{\prime}}} \tag{8.5}
\end{equation*}
$$

## 9. The Laplace operator $\nabla^{2} \equiv \nabla \cdot \nabla$

- Expression in Cartesian coordinates - in the formal accordance with Eq. (7.2):

[^960]\[

$$
\begin{equation*}
\nabla^{2}=\sum_{j=1}^{3} \frac{\partial^{2}}{\partial r_{j}^{2}} \tag{9.1}
\end{equation*}
$$

\]

- According to its definition, the Laplace operator acting on a scalar function of coordinates gives a new scalar function:

$$
\begin{equation*}
\nabla^{2} f \equiv \nabla \cdot(\nabla f)=\operatorname{div}(\operatorname{grad} f)=\sum_{j=1}^{3} \frac{\partial^{2} f}{\partial r_{j}^{2}} \tag{9.2}
\end{equation*}
$$

- On the other hand, acting on a vector function (8.3), operator $\nabla^{2}$ returns another vector:

$$
\begin{equation*}
\nabla^{2} \mathbf{f}=\sum_{j=1}^{3} \mathbf{n}_{j} \nabla^{2} f_{j} \tag{9.3}
\end{equation*}
$$

Note that Eqs. (9.1)-(9.3) are only valid in Cartesian (i.e. orthogonal and linear) coordinates, but generally not in other (even orthogonal) coordinates - see, e.g., Eqs. (10.3), (10.6), (10.9), and (10.12) below.

## 10. Operators $\nabla$ and $\nabla^{2}$ in the most important systems of orthogonal coordinates ${ }^{11}$

(i) Cylindrical ${ }^{12}$ coordinates $\{\rho, \varphi, z\}$ (see Fig. below) may be defined by their relations with the Cartesian coordinates:

- Gradient of a scalar function:

$$
\begin{equation*}
\nabla f=\mathbf{n}_{\rho} \frac{\partial f}{\partial \rho}+\mathbf{n}_{\varphi} \frac{1}{\rho} \frac{\partial f}{\partial \varphi}+\mathbf{n}_{z} \frac{\partial f}{\partial z} \tag{10.2}
\end{equation*}
$$

- The Laplace operator of a scalar function:

$$
\begin{equation*}
\nabla^{2} f=\frac{1}{\rho} \frac{\partial}{\partial \rho}\left(\rho \frac{\partial f}{\partial \rho}\right)+\frac{1}{\rho^{2}} \frac{\partial^{2} f}{\partial \varphi^{2}}+\frac{\partial^{2} f}{\partial z^{2}}, \tag{10.3}
\end{equation*}
$$

- Divergence of a vector function of coordinates ( $\mathbf{f}=\mathbf{n}_{\rho} f_{\rho}+\mathbf{n}_{\varphi} f_{\varphi}+\mathbf{n}_{z} f_{z}$ ):

$$
\begin{equation*}
\nabla \cdot \mathbf{f}=\frac{1}{\rho} \frac{\partial\left(\rho f_{\rho}\right)}{\partial \rho}+\frac{1}{\rho} \frac{\partial f_{\varphi}}{\partial \varphi}+\frac{\partial f_{z}}{\partial z} . \tag{10.4}
\end{equation*}
$$

[^961]- Curl of a vector function:

$$
\begin{equation*}
\nabla \times \mathbf{f}=\mathbf{n}_{\rho}\left(\frac{1}{\rho} \frac{\partial f_{z}}{\partial \varphi}-\frac{\partial f_{\varphi}}{\partial z}\right)+\mathbf{n}_{\varphi}\left(\frac{\partial f_{\rho}}{\partial z}-\frac{\partial f_{z}}{\partial \rho}\right)+\mathbf{n}_{z} \frac{1}{\rho}\left(\frac{\partial\left(\rho f_{\varphi}\right)}{\partial \rho}-\frac{\partial f_{\rho}}{\partial \varphi}\right) \tag{10.5}
\end{equation*}
$$

- The Laplace operator of a vector function:

$$
\begin{equation*}
\nabla^{2} \mathbf{f}=\mathbf{n}_{\rho}\left(\nabla^{2} f_{\rho}-\frac{1}{\rho^{2}} f_{\rho}-\frac{2}{\rho^{2}} \frac{\partial f_{\varphi}}{\partial \varphi}\right)+\mathbf{n}_{\varphi}\left(\nabla^{2} f_{\varphi}-\frac{1}{\rho^{2}} f_{\varphi}+\frac{2}{\rho^{2}} \frac{\partial f_{\rho}}{\partial \varphi}\right)+\mathbf{n}_{z} \nabla^{2} f_{z} \tag{10.6}
\end{equation*}
$$

(ii) Spherical coordinates $\{r, \theta, \varphi\}$ (see Fig. below) may be defined as:

- Gradient of a scalar function:

$$
\begin{equation*}
\nabla f=\mathbf{n}_{r} \frac{\partial f}{\partial r}+\mathbf{n}_{\theta} \frac{1}{r} \frac{\partial f}{\partial \theta}+\mathbf{n}_{\varphi} \frac{1}{r \sin \theta} \frac{\partial f}{\partial \varphi} . \tag{10.8}
\end{equation*}
$$

- The Laplace operator of a scalar function:

$$
\begin{equation*}
\nabla^{2} f=\frac{1}{r^{2}} \frac{\partial}{\partial r}\left(r^{2} \frac{\partial f}{\partial r}\right)+\frac{1}{r^{2} \sin \theta} \frac{\partial}{\partial \theta}\left(\sin \theta \frac{\partial f}{\partial \theta}\right)+\frac{1}{(r \sin \theta)^{2}} \frac{\partial^{2} f}{\partial \varphi^{2}} \tag{10.9}
\end{equation*}
$$

- Divergence of a vector function $\mathbf{f}=\mathbf{n}_{r} f_{r}+\mathbf{n}_{\theta} f_{\theta}+\mathbf{n}_{\varphi} f_{\varphi}$ :

$$
\begin{equation*}
\nabla \cdot \mathbf{f}=\frac{1}{r^{2}} \frac{\partial\left(r^{2} f_{r}\right)}{\partial r}+\frac{1}{r \sin \theta} \frac{\partial\left(f_{\theta} \sin \theta\right)}{\partial \theta}+\frac{1}{r \sin \theta} \frac{\partial f_{\varphi}}{\partial \varphi} . \tag{10.10}
\end{equation*}
$$

- Curl of a similar vector function:

$$
\begin{equation*}
\nabla \times \mathbf{f}=\mathbf{n}_{r} \frac{1}{r \sin \theta}\left(\frac{\partial\left(f_{\varphi} \sin \theta\right)}{\partial \theta}-\frac{\partial f_{\theta}}{\partial \varphi}\right)+\mathbf{n}_{\theta} \frac{1}{r}\left(\frac{1}{\sin \theta} \frac{\partial f_{r}}{\partial \varphi}-\frac{\partial\left(r f_{\varphi}\right)}{\partial r}\right)+\mathbf{n}_{\varphi} \frac{1}{r}\left(\frac{\partial\left(r f_{\theta}\right)}{\partial r}-\frac{\partial f_{r}}{\partial \theta}\right) \tag{10.11}
\end{equation*}
$$

- The Laplace operator of a vector function:

$$
\begin{align*}
\nabla^{2} \mathbf{f} & =\mathbf{n}_{r}\left(\nabla^{2} f_{r}-\frac{2}{r^{2}} f_{r}-\frac{2}{r^{2} \sin \theta} \frac{\partial}{\partial \theta}\left(f_{\theta} \sin \theta\right)-\frac{2}{r^{2} \sin \theta} \frac{\partial f_{\varphi}}{\partial \varphi}\right) \\
& +\mathbf{n}_{\theta}\left(\nabla^{2} f_{\theta}-\frac{1}{r^{2} \sin ^{2} \theta} f_{\theta}+\frac{2}{r^{2}} \frac{\partial f_{r}}{\partial \theta}-\frac{2 \cos \theta}{r^{2} \sin ^{2} \theta} \frac{\partial f_{\varphi}}{\partial \varphi}\right)  \tag{10.12}\\
& +\mathbf{n}_{\varphi}\left(\nabla^{2} f_{\varphi}-\frac{1}{r^{2} \sin ^{2} \theta} f_{\varphi}+\frac{2}{r^{2} \sin \theta} \frac{\partial f_{r}}{\partial \varphi}+\frac{2 \cos \theta}{r^{2} \sin ^{2} \theta} \frac{\partial f_{\theta}}{\partial \varphi}\right) .
\end{align*}
$$

## 11. Products involving $\nabla$

(i) Useful zeros:

- For any scalar function $f(\mathbf{r})$,

$$
\begin{equation*}
\nabla \times(\nabla f) \equiv \operatorname{curl}(\operatorname{grad} f)=0 \tag{11.1}
\end{equation*}
$$

- For any vector function $\mathbf{f}(\mathbf{r})$,

$$
\begin{equation*}
\nabla \cdot(\nabla \times \mathbf{f}) \equiv \operatorname{div}(\text { curl } \mathbf{f})=0 . \tag{11.2}
\end{equation*}
$$

(ii) Laplace operator expressed via the curl of a curl:

$$
\begin{equation*}
\nabla^{2} \mathbf{f}=\nabla(\nabla \cdot \mathbf{f})-\nabla \times(\nabla \times \mathbf{f}) \tag{11.3}
\end{equation*}
$$

(iii) Spatial differentiation of a product of a scalar function by a vector function:

- The scalar 3D generalization of Eq. (4.1) is

$$
\begin{equation*}
\nabla \cdot(f \mathbf{g})=(\nabla f) \cdot \mathbf{g}+f(\nabla \cdot \mathbf{g}) . \tag{11.4a}
\end{equation*}
$$

- Its vector generalization is similar:

$$
\begin{equation*}
\nabla \times(f \mathbf{g})=(\nabla f) \times \mathbf{g}+f(\nabla \times \mathbf{g}) . \tag{11.4b}
\end{equation*}
$$

(iv) 3 D spatial differentiation of products of two vector functions:

$$
\begin{gather*}
\nabla \times(\mathbf{f} \times \mathbf{g})=\mathbf{f}(\nabla \cdot \mathbf{g})-(\mathbf{f} \cdot \nabla) \mathbf{g}-(\nabla \cdot \mathbf{f}) \mathbf{g}+(\mathbf{g} \cdot \nabla) \mathbf{f},  \tag{11.5}\\
\nabla(\mathbf{f} \cdot \mathbf{g})=(\mathbf{f} \cdot \nabla) \mathbf{g}+(\mathbf{g} \cdot \nabla) \mathbf{f}+\mathbf{f} \times(\nabla \times \mathbf{g})+\mathbf{g} \times(\nabla \times \mathbf{f}),  \tag{11.6}\\
\nabla \cdot(\mathbf{f} \times \mathbf{g})=\mathbf{g} \cdot(\nabla \times \mathbf{f})-\mathbf{f} \cdot(\nabla \times \mathbf{g}) . \tag{11.7}
\end{gather*}
$$

## 12. Integro-differential relations

(i) For an arbitrary surface $S$ limited by closed contour $C$ :

- The Stokes theorem, valid for any differentiable vector field $\mathbf{f}(\mathbf{r})$ :

$$
\begin{equation*}
\int_{S}(\nabla \times \mathbf{f}) \cdot d^{2} \mathbf{r} \equiv \int_{S}(\nabla \times \mathbf{f})_{n} d^{2} r=\oint_{C} \mathbf{f} \cdot d \mathbf{r} \equiv \oint_{C} f_{\tau} d r, \tag{12.1}
\end{equation*}
$$

where $d^{2} \mathbf{r} \equiv \mathbf{n} d^{2} r$ is the elementary area vector (normal to the surface), and $d \mathbf{r}$ is the elementary contour length vector (tangential to the contour line).
(ii) For an arbitrary volume $V$ limited by closed surface $S$ :

- Divergence (or "Gauss") theorem, valid for any differentiable vector field $\mathbf{f}(\mathbf{r})$ :

$$
\begin{equation*}
\int_{V}(\nabla \cdot \mathbf{f}) d^{3} r=\oint_{S} \mathbf{f} \cdot d^{2} \mathbf{r} \equiv \oint_{S} f_{n} d^{2} r . \tag{12.2}
\end{equation*}
$$

- Green's theorem, valid for two differentiable scalar functions $f(\mathbf{r})$ and $g(\mathbf{r})$ :

$$
\begin{equation*}
\int_{V}\left(f \nabla^{2} g-g \nabla^{2} f\right) d^{3} r=\oint_{S}(f \nabla g-g \nabla f)_{n} d^{2} r \tag{12.3}
\end{equation*}
$$

- An identity valid for any two scalar functions $f$ and $g$, and a vector field $\mathbf{j}$ with $\nabla \cdot \mathbf{j}=0$ (all differentiable):

$$
\begin{equation*}
\int_{V}[f(\mathbf{j} \cdot \nabla g)+g(\mathbf{j} \cdot \nabla f)] d^{3} r=\oint_{S} f g j_{n} d^{2} r \tag{12.3}
\end{equation*}
$$

## 13. The Kronecker delta and Levi-Civita permutation symbols

- The Kronecker delta symbol (defined for integer indices):

$$
\delta_{i j^{\prime}} \equiv\left\{\begin{array}{lc}
1, & \text { if } j^{\prime}=j  \tag{13.1}\\
0, & \text { otherwise } .
\end{array}\right.
$$

- The Levi-Civita permutation symbol (most frequently used for 3 integer indices, each taking one of values 1 , 2 , or 3 ):

$$
\varepsilon_{i j^{\prime} j "} \equiv\left\{\begin{array}{lc}
+1, & \text { if the indices follow in the "correct"("even") order : } 1 \rightarrow 2 \rightarrow 3 \rightarrow 1 \rightarrow 2 \ldots,  \tag{13.2}\\
-1, & \text { if the indices follow in the "incorrect"("odd") order }: 1 \rightarrow 3 \rightarrow 2 \rightarrow 1 \rightarrow 3 \ldots, \\
0, & \text { if any two indices coincide. }
\end{array}\right.
$$

- Relation between the Levi-Civita and the Kronecker delta products:

$$
\varepsilon_{i j j^{\prime \prime}} \varepsilon_{k k^{\prime} k^{\prime \prime}}=\sum_{l, l^{\prime}, l^{\prime \prime}=1}^{3}\left|\begin{array}{lll}
\delta_{j l} & \delta_{j l^{\prime}} & \delta_{j l^{\prime \prime}}  \tag{13.3a}\\
\delta_{j^{\prime} l} & \delta_{j^{\prime} l^{\prime}} & \delta_{j^{\prime \prime \prime} l^{\prime \prime}} \\
\delta_{j^{\prime \prime} l} & \delta_{j^{\prime \prime \prime} l^{\prime}} & \delta_{j^{\prime \prime} l^{\prime \prime}}
\end{array}\right| ;
$$

summation of this relation, written for 3 different values of $j=k$, over these values yields the so-called contracted epsilon identity:

$$
\begin{equation*}
\sum_{j=1}^{3} \varepsilon_{j j j^{\prime} \xi^{\prime}} \varepsilon_{j k^{\prime} k^{\prime \prime}}=\delta_{j^{\prime} k^{\prime}} \delta_{j^{\prime \prime} k^{\prime \prime}}-\delta_{j^{\prime} k^{\prime \prime}} \delta_{j^{\prime \prime} k^{\prime}} \tag{13.3b}
\end{equation*}
$$

## 14. Dirac's delta-function, sign function, and theta-function

- Definition of 1D delta-function (for real $a<b$ ):

$$
\int_{a}^{b} f(\xi) \delta(\xi) d \xi=\left\{\begin{array}{c}
f(0), \quad \text { if } a<0<b  \tag{14.1}\\
0, \\
\text { otherwise }
\end{array}\right.
$$

where $f(\xi$ ) is any function continuous near $\xi=0$. In particular (if $f(\xi)=1$ near $\xi=0$ ), the definition yields

$$
\int_{a}^{b} \delta(\xi) d \xi=\left\{\begin{array}{cc}
1, & \text { if } a<0<b  \tag{14.2}\\
0, & \text { otherwise }
\end{array}\right.
$$

- Relation to the theta-function $\theta(\xi)$ and sign function $\operatorname{sgn}(\xi)$

$$
\begin{equation*}
\delta(\xi)=\frac{d}{d \xi} \theta(\zeta)=\frac{1}{2} \frac{d}{d \xi} \operatorname{sgn}(\xi), \tag{14.3a}
\end{equation*}
$$

where

$$
\theta(\xi) \equiv \frac{\operatorname{sgn}(\xi)+1}{2}=\left\{\begin{array}{ll}
0, & \text { if } \xi<0,  \tag{14.3b}\\
1, & \text { if } \xi>1,
\end{array} \quad \operatorname{sgn}(\xi) \equiv \frac{\xi}{|\xi|}= \begin{cases}-1, & \text { if } \xi<0 \\
+1, & \text { if } \xi>1\end{cases}\right.
$$

- An important integral: ${ }^{13}$

$$
\begin{equation*}
\int_{-\infty}^{+\infty} e^{i s \xi} d s=2 \pi \delta(\xi) \tag{14.4}
\end{equation*}
$$

- 3D generalization of the delta-function of the radius-vector (the 2D generalization is similar):

$$
\int_{V} f(\mathbf{r}) \delta(\mathbf{r}) d^{3} r=\left\{\begin{array}{c}
f(0), \quad \text { if } 0 \in V  \tag{14.5}\\
0, \quad \text { otherwise }
\end{array}\right.
$$

it may be presented as a product of 1D delta-functions of Cartesian coordinates:

$$
\begin{equation*}
\delta(\mathbf{r})=\delta\left(r_{1}\right) \delta\left(r_{2}\right) \delta\left(r_{3}\right) \tag{14.6}
\end{equation*}
$$

## 15. The Cauchy theorem and integral

Let a complex function $\boldsymbol{f}(\boldsymbol{z})$ be analytic within a part of the complex plane $\boldsymbol{z}$, that is limited by a closed contour $C$ and includes point $\boldsymbol{z}^{\prime}$. Then

$$
\begin{gather*}
\oint_{C} \boldsymbol{f}(\boldsymbol{z}) d \boldsymbol{z}=0,  \tag{15.1}\\
\oint_{C} \boldsymbol{f}(\boldsymbol{z}) \frac{d \boldsymbol{z}}{\boldsymbol{z}-\boldsymbol{z}^{\prime}}=2 \pi i \boldsymbol{f}\left(\boldsymbol{z}^{\prime}\right) . \tag{15.2}
\end{gather*}
$$

The first of these relations is usually called the Cauchy integral theorem (or the "CauchyGoursat theorem"), and the second one - the Cauchy integral (or the "Cauchy integral formula").

## 16. References

(i) Properties of some special functions are briefly discussed at the relevant points of the lecture notes; in the alphabetical order:

- Airy functions: QM Sec. 2.4;
- Bessel functions: EM Sec. 2.5;
- Fresnel integrals: EM Sec. 8.6;

[^962]- Hermite polynomials: QM Sec. 2.10;
- Laguerre polynomials (both simple and associated): QM Sec. 3.6;
- Legendre polynomials, associated Legendre functions: EM Sec. 2.5 and QM Sec. 3.6;
- Spherical harmonics: QM Sec. 3.6;
- Spherical Bessel functions: QM Secs. 3.6.
(ii) For more formulas, and their discussions, I can recommend the following handbooks (in the alphabetical order): ${ }^{14}$
- M. Abramowitz and I. Stegun (eds.), Handbook of Mathematical Formulas, Dover, 1965 (and numerous later printings); ${ }^{15}$
- I. Gradshteyn and I. Ryzhik, Tables of Integrals, Series, and Products, $5^{\text {th }}$ ed., Acad. Press, 1980;
- G. Korn and T. Korn, Mathematical Handbook for Scientists and Engineers, $2^{\text {nd }}$ ed., Dover, 2000;
- A. Prudnikov et al., Integrals and Series, vols. 1 and 2, CRC Press, 1986.

A popular textbook,

- G. Arfken et al., Mathematical Methods for Physicists, $7^{\text {th }}$ ed., Acad. Press, 2012, may be also used as a formula manual.

Many formulas are also available from the symbolic calculation parts of commercially available software packages listed in Sec. (iv) below.
(iii) Probably the most popular collection of numerical calculation codes are the twin manuals

- W. Press et al., Numerical Recipes in Fortran 77, $2^{\text {nd }}$ ed., Cambridge U. Press, 1992;
- W. Press et al., Numerical Recipes [in C++ - KKL], $3^{\text {rd }}$ ed., Cambridge U. Press, 2007.

My lecture notes include very brief introductions into numerical methods of differential equation solution:

- ordinary differential equations: CM Sec. 3.9, and
- partial differential equations: CM Sec. 8.5 and EM Sec. 2.8,
which include references to literature for further reading.
(iv) The most popular software packages for numerical and symbolic calculations, all with plotting capabilities (in the alphabetical order):
- Maple (http://www.maplesoft.com/);
- MathCAD (http://www.ptc.com/products/mathcad/);
- Mathematica (http://www.wolfram.com/products/mathematica/index.html);
- MATLAB (http://www.mathworks.com/products/matlab/).

[^964]
## Comments:

1. The fixed value of $c$ was defined by an international convention in 1983, in order to extend the official definition of a second (as "the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom") to that of a meter. The values are back-compatible with the legacy definitions of the meter (initially, as the $1 / 40,000,000$-th part of the Earth meridian length) and the second (for a long time, as the $1 /(24 \times 60 \times 60)$ $=1 / 86,400-$ th part of the Earth rotation period), within the experimental errors of those measures.
2. $\varepsilon_{0}$ and $\mu_{0}$ are not really the fundamental constants; in the SI system of units one of them (say, $\left.\mu_{0}\right)$ is selected arbitrarily, ${ }^{2}$ while the other one is defined via relation $\varepsilon_{0} \mu_{0}=1 / \mathrm{c}^{2}$.
3. The Boltzmann constant $k_{\mathrm{B}}$ is also not quite fundamental, because its only role is to comply with the independent definition of the kelvin $(\mathrm{K})$, as the temperature unit in which the triple point of water is exactly 273.16 K . If temperature is expressed in energy units $k_{\mathrm{B}} T$ (as is done, for example, in the SM part of this lecture note series), this constant disappears altogether.
4. The dimensionless fine structure ("Sommerfeld' s") constant $\alpha$ is numerically the same in any system of units:

$$
\alpha \equiv\left\{\begin{array}{c}
e^{2} / 4 \pi \varepsilon_{0} \hbar c \quad \text { in SI units } \\
e^{2} / \hbar c \quad \text { in Gaussian units }
\end{array}\right\} \approx 7.297352566 \times 10^{-3} \approx \frac{1}{137.03599914},
$$

and is known with a much smaller r.m.s. uncertainty $\left(\sim 3 \times 10^{-10}\right)$ than that of the component constants.

[^0]:    ${ }^{1}$ To the best of author's knowledge, the fair use clause of the U.S. copyright law (see, e.g., http://www.copyright.gov/fls/fl102.html) allows viewing, browsing and/or downloading copyrighted materials for temporary, non-commercial, personal purposes, without requesting copyright holder's permission.

[^1]:    ${ }^{2}$ The texts are saved as separate .pdf files of each chapter, optimized for two-page viewing and double-side printing; merged files for each part and the series as a whole, convenient for search purposes, are also provided.
    ${ }^{3}$ To list just a few: statics and dynamics of elastic and fluid continua, basic notions of physical kinetics, turbulence and deterministic chaos, physics of reversible and quantum computation, relaxation and dephasing of open quantum systems, the van der Pol method, a.k.a. the Rotating-Wave Approximation (RWA), in classical and quantum mechanics, physics of electrons and holes in semiconductors, weak-potential and tight-binding approximations in the energy band theory, optical fiber electrodynamics, macroscopic quantum effects in Bose-

[^2]:    Einstein condensates, Bloch oscillations and Landau-Zener tunneling, cavity QED, and the Density Functional Theory (DFT). All these topics are discussed, if only concisely, in these notes.
    ${ }^{4}$ Recently several high-quality, graduate-level teaching materials became freely available online, including R. Fitzpatrick's text on Classical Electromagnetism (farside.ph.utexas.edu/teaching/jk1/Electromagnetism.pdf), B. Simons' "lecture shrunks" on Advanced Quantum Mechanics (www.tcm.phy.cam.ac.uk/~bds10/aqp.html), and D. Tong's lecture notes on several topics (www.damtp.cam.ac.uk/user/tong/teaching.html).
    ${ }^{5}$ The problems that require either more bulky calculations, or more creative approaches (or both :-), are marked by asterisks.
    ${ }^{6}$ For an introduction to the subject, I can recommend either a review by S. Carroll, Spacetime and Geometry, Addison-Wesley, 2003, or a longer text by A. Zee, Einstein Gravity in a Nutshell, Princeton U. Press, 2013.
    ${ }^{7}$ Note added in June 2019: Revised versions of these lecture notes, and of model solutions of the exercise problems, are now published by the IOP - see the references on the title page of each part. However, in the view of possible future editions, the kind request formulated above remains very much valid.

[^3]:    ${ }^{8}$ Yes Virginia, these notes represent only my personal opinions, not necessarily those of the Department of Physics and Astronomy of Stony Brook University, the SBU at large, the SUNY system, the Empire State of New York, the federal agencies and private companies that funded my group's research, etc. No dear, I cannot be hold responsible for any harm, either bodily or mental, their reading may (?) cause.

[^4]:    ${ }^{9}$ I am very much sorry that I have not kept proper records from the beginning of my lectures at Stony Brook, so I cannot list all the numerous students and TAs who had kindly attracted my attention to typos in earlier versions of these notes. Needless to say, I am very grateful to them all as well.

[^5]:    ${ }^{10}$ The same letter, typeset in different fonts, typically denotes different variables.

[^6]:    ${ }^{1}$ The reader is advised to perform a self-check by solving a few problems of the dozen listed in Sec. 1.7. If the results are not satisfactory, it may make sense to start from some remedial reading. For that, I could recommend, for example (in the alphabetical order): G. R. Fowles and G. L. Cassiday, Analytical Mechanics, $7^{\text {th }}$ ed., Brooks Cole, 2004; K. R. Symon, Mechanics, $3^{\text {rd }}$ ed., Addison-Wesley, 1971; or J. B. Marion and S. T. Thornton, Classical Dynamics of Particles and Systems, $4^{\text {th }}$ ed., Saunders, 1995.
    ${ }^{2}$ This series assumes reader's familiarity with the basic calculus and vector algebra. The formulas most important for this series are listed in the Selected Mathematical Formulas appendix, referred below as MA. In particular, a reminder of the definition and the basic properties of the Laplace operator may be found in MA Sec. 9 .

[^7]:    ${ }^{7}$ Following tradition, an introduction to special relativity is included into the Classical Electrodynamics ("EM") part of these notes. The relativistic effects are small if all particles velocities are much lower than the speed of light, $c \approx 3.00 \times 10^{8} \mathrm{~m} / \mathrm{s}$, and all distances are much larger then the system's Schwarzschild radius $r_{s} \equiv 2 \mathrm{Gm} / \mathrm{c}^{2}$, where $G \approx 6.67 \times 10^{-11}$ SI units ( $\mathrm{m}^{3} / \mathrm{kg} \cdot \mathrm{s}$ ) is the Newtonian gravity constant, and $m$ is system's mass. (More exact values of $c, G$, and some other physical constants may be found in appendix CA: Selected Physical Constants.)

[^8]:    ${ }^{8}$ This approximation is legitimate, crudely, when the product of the coordinate and momentum scales of the particle motion is much larger than the Planck's constant $\hbar \approx 1.054 \times 10^{-34} \mathrm{~J}$ •s. A more exact formulation may be found, e.g., in the Quantum Mechanics ("QM") part of these note series.
    ${ }^{9}$ Due to the genius of Sir Isaac Newton, these laws were formulated as early as in 1687, far ahead of the science of that time.
    ${ }^{10}$ Some laws of Nature (including the Newton laws) may be derived from certain more general postulates, such as the Hamilton (or "least action") principle - see Sec. 10.2 below. Note, however, that such derivations are only acceptable because all known corollaries of the postulates comply with all known experimental results.

[^9]:    ${ }^{11}$ Of course, for composite bodies of varying mass (e.g., rockets emitting jets, see Problem 11), momentum's derivative may differ from ma.

[^10]:    12 Note that the fact that the masses participating in Eqs. (14) and (16) are equal, the so-called weak equivalence principle, is highly nontrivial, but has been verified experimentally to the relative accuracy of at least $10^{-13}$. Due to its conceptual significance of the principle, new space experiments, such as MISCROSCOPE (http://smsc.cnes.fr/MICROSCOPE/), are being planned for a substantial, nearly 100 -fold accuracy improvement.
    ${ }^{13}$ Of course, the most important particular case of Eq. (1.16b) is the motion of objects near Earth's surface. In this case, using the fact that (1.16a) remains valid for the gravity field created by a heavy sphere, we get $g=G M_{\mathrm{E}} / R_{\mathrm{E}}^{2}$, where $M_{\mathrm{E}}$ and $R_{\mathrm{E}}$ are the Earth mass and radius. Plugging in their values, $M_{\mathrm{E}} \approx 5.97 \times 10^{24} \mathrm{~kg}, R_{\mathrm{E}} \approx 6.37 \times 10^{6} \mathrm{~m}$, we get $g \approx 9.82 \mathrm{~m} / \mathrm{s}^{2}$. The effective value of $g$ varies from 9.78 to $9.83 \mathrm{~m} / \mathrm{s}^{2}$ at various locations on Earth's surface (due to the deviations of Earth's shape from a sphere, and the location-dependent effect of the centrifugal "inertial force" - see Sec. 6.5 below), with an average value of $g \approx 9.807 \mathrm{~m} / \mathrm{s}^{2}$.

[^11]:    ${ }^{14}$ Symbol a.b denotes the scalar (or "dot-") product of vectors a and b-see, e.g., MA Eq. (7.1).
    ${ }^{15}$ Note that because of its definition via the gradient, the potential energy is only defined to an arbitrary additive constant.
    ${ }^{16}$ Its basic properties are listed in MA Sec. 8.

[^12]:    Total mechanical energy

    Mechanical energy conservation

[^13]:    ${ }^{18}$ Here we imply that the internal motions of the particle, including its rotation about its own axis, are negligible. (Otherwise it could not be represented by a geometrical point, as was postulated in Sec. 1.) For a body with substantial rotation (see Chapter 6 below), vector $\mathbf{L}$ retains its definition (32), but is only a part of the total angular momentum and is called the orbital momentum - even if the particle does not move along a closed orbit. ${ }^{19}$ See, e.g., MA Eq. (7.3).

[^14]:    ${ }^{20}$ Assuming that the additional, non-conservative forces (such as viscosity) responsible for the mechanical energy drain, vanish at equilibrium - as they typically do. (Static friction is one counter-example.)

[^15]:    ${ }^{21}$ Physically, the difference $U_{\mathrm{G}}-U$ specified by Eq. (39) may be considered the r-dependent part of the potential energy $U^{\text {(ext) }}$ of the external system responsible for the force $\mathbf{F}^{(\text {ext })}$, so that $U_{\mathrm{G}}$ is just the total potential energy $U+$ $U^{\text {(ext) }}$, besides the part of $U^{(\text {ext })}$ which does not depend on $\mathbf{r}$ and hence is irrelevant for the fixed point analysis. According to the $3^{\text {rd }}$ Newton law, the force exerted by the particle on the external system equals ( $-\mathbf{F}^{(\mathrm{ext})}$ ), so that its work (and hence the change of $U^{(\text {ext })}$ due to the change of $\mathbf{r}$ ) is given by the second term in the right-hand part of Eq. (39). Thus the condition of equilibrium, $-\nabla U_{\mathrm{G}}=0$, is just the condition of an extremum of the total potential energy, $U+U^{(e x t)}$, of the two interacting systems.
    ${ }^{22}$ Unfortunately, in most physics teaching plans the introduction of $U_{\mathrm{G}}$ is postponed until a course of statistical mechanics and/or thermodynamics - where it is a part of the Gibbs free energy, in contrast to $U$, which is a part of the Helmholtz free energy - see, e.g., Sec. 1.4 of the Statistical Mechanics ("SM") part of my notes. However, the reader should agree that the difference between $U_{\mathrm{G}}$ and $U$, and hence that between the Gibbs and Helmholtz free energies, has nothing to do with statistics or thermal motion, and belongs to the basic mechanics.
    ${ }^{23}$ This is essentially a simplified model of the famous mechanical control device called the centrifugal (or "flyball, or "centrifugal flyball") governor - see, e.g., http://en.wikipedia.org/wiki/Centrifugal governor.

[^16]:    24 It was first stated by R. Clausius in 1870.

[^17]:    ${ }^{1}$ Possibly, the simplest example of a non-holonomic constraint is a set of inequalities describing the hard walls confining the motion of particles in a closed volume. Non-holonomic constraints are better dealt with other methods, e.g., by imposing proper boundary conditions on the (otherwise unconstrained) motion.
    ${ }^{2}$ See, e.g., MA Eq. (10.7).

[^18]:    ${ }^{3}$ For a concise introduction to the field see, e.g., I. Gelfand and S. Fomin, Calculus of Variations, Dover, 2000 or L. Elsgolc, Calculus of Variations, Dover, 2007. An even shorter review may be found in Chapter 17 of Arfken and Weber - see MA Sec. 16. For a more detailed discussion, using many examples from physics, see R. Weinstock, Calculus of Variations, Dover, 2007.
    ${ }^{4}$ See, e.g., MA Eq. (4.2). In all formulas of this section, all summations over index $j$ are from 1 to $J$, while those over the particle number $k$ are from 1 to $N$.

[^19]:    ${ }^{5}$ It had been spelled out in a 1743 work by J.-B. le Rond d'Alembert, though the core of this result has been traced to an earlier work by J. Bernoulli (1667-1748).
    ${ }^{6}$ Note that since the dimensionality of generalized coordinates may be arbitrary, that of generalized forces may also differ from the newton.

[^20]:    ${ }^{7}$ They were derived in 1788 by J.-L. Lagrange who pioneered the whole field of analytical mechanics - not to mention his key contributions to number theory and celestial mechanics.

[^21]:    ${ }^{8}$ Note that due to the possible time dependence of $U$, Eq. (17) does not mean that forces $\mathbf{F}_{k}$ have to be conservative - see the next section for more discussion. With this understanding, I will still use for function $U$ the convenient name of "potential energy".

[^22]:    ${ }^{9}$ This expression for $T \equiv(m / 2)\left(\dot{x}^{2}+\dot{y}^{2}+\dot{z}^{2}\right)$ may be readily obtained either by the formal differentiation of Eq. (2) over time, or just by noticing that the velocity vector has two perpendicular components: one along the ring (with magnitude $R \dot{\theta}$ ) and another one normal to the ring plane (with magnitude $\omega \rho=\omega R \sin \theta$ - see Fig. 1).
    ${ }^{10}$ Let me hope that this traditional notation would not lead to the confusion between the inductance and the Lagrange function.

[^23]:    ${ }^{11}$ See, e.g., EM Sec. 9.8.

[^24]:    ${ }^{13}$ This is just one of many theorems bearing the name of the mathematics genius L. Euler (1707-1783).
    ${ }^{14}$ Such functions are called quadratic-homogeneous.

[^25]:    ${ }^{15}$ Such coordinates are frequently called cyclic, because in some cases (like in the second example considered below) they represent periodic coordinates such as angles. However, this terminology is misleading, because some "cyclic" coordinates (e.g., $x$ in our first example) have nothing to do with rotation.
    ${ }^{16}$ This fact may be considered a particular case of a more general mathematical statement called the Noether theorem (named after its author, A. E. Nöther, sometimes called the "greatest woman mathematician ever lived"). For its discussion see, e.g., Sec. 13.7 in H. Goldstein et al., Classical Mechanics, $3^{\text {rd }}$ ed. Addison Wesley, 2002.
    ${ }^{17}$ Note that here $\dot{r}^{2}$ is just the square of the scalar derivative $\dot{r}$, rather than the square of vector $\dot{\mathbf{r}}=\mathbf{v}$.

[^26]:    ${ }^{18}$ More discussion of the Josephson effect and the physical sense of the variable $\varphi$ may be found, for example, in EM Sec. 6.4 and QM Secs. 2.3 and 2.8 of this lecture note series.

[^27]:    ${ }^{1}$ Those terms may be important only in the very special case then $\kappa_{\text {ef }}$ is exactly zero, i.e. when a fixed point is an inflection point of function $U_{\text {ef }}(q)$.
    ${ }^{2}$ In what follows, I will assume that the effective mass $m_{\text {ef }}$ is positive, which is true in most (but not all!) dynamic systems. The changes necessary if it is negative are obvious.

[^28]:    ${ }^{3}$ Mathematically, the growing part vanishes at some special (exact) initial conditions which give $c_{+}=0$. However, the futility of this argument for real physical systems should be obvious for anybody who had ever tried to balance a pencil on its sharp point.
    ${ }^{4}$ Note that Eq. (19) coincides with Eq. (2.25). This is a good sanity check illustrating that the procedure (5)-(6) of moving of a term from the potential to kinetic energy within the Lagrangian function is indeed legitimate.
    ${ }^{5}$ For this particular problem, the values of $\theta$ that differ by a multiple of $2 \pi$, are physically equivalent.

[^29]:    ${ }^{6}$ See, e.g., MA Eqs. (5.2) and (5.3).

[^30]:    ${ }^{7}$ This terminology comes from quantum mechanics which shows that actually a particle (or rather its wavefunction) can, to a certain extent, penetrate the "classically forbidden range" where $H<U_{\text {ef }}(x)$.

[^31]:    ${ }^{11}$ Here index $z$ stands for the coordinate perpendicular to the motion plane. Since other components of the angular momentum are equal zero, the index is not really necessary, but I will still use it, just to make a clear distinction between the angular momentum $L_{z}$ and the Lagrangian function $L$.
    ${ }^{12}$ One of three laws deduced almost exactly 400 years ago by J. Kepler ( $1571-1630$ ), from the extremely detailed astronomical data collected by T. Brahe (1546-1601). In turn, the set of three Kepler laws were the main basis for Isaac Newton's discovery of the gravity law (1.16). That's how physics marched on...

[^32]:    ${ }^{13}$ One may claim that this fact should have been evident from the very beginning, because the effective particle of mass $m$ moves in a potential field $U(r)$ which conserves energy.
    ${ }^{14}$ Note that this reduction has been done in a way different from that used for our testbed problem (shown in Fig. 2.1) in Sec. 2 above. (The reader is encouraged to analyze this difference.) In order to emphasize this fact, I will keep writing $E$ instead of $H$ here, though for the planetary problem we are discussing now these two notions coincide.

[^33]:    ${ }^{15}$ In the opposite case when the interaction is repulsive, $U(r)>0$, the addition of the positive angular energy term only increases the trend, and only the scattering scenario is possible.

[^34]:    ${ }^{16}$ See, e.g., MA Eq. (6.3a).
    ${ }^{17}$ It may be proved that for the power-law interaction, $U \propto r^{\nu}$, the orbits are closed line only if $v=-1$ (i.e. our current case of the Coulomb potential) or $v=+2$ (the 3D harmonic oscillator) - the so-called Bertrand theorem.

[^35]:    ${ }^{18}$ Mathematicians prefer a more solemn terminology: parameter $2 p$ is called the latus rectum of the elliptic trajectory - see Fig. 7.
    ${ }^{19}$ In this figure, the constant participating in Eqs. (58)-(59) is assumed to be zero. It is evident that a different choice of the constant corresponds just to a constant turn of the ellipse about the origin.

[^36]:    20 The energy conservation law is frequently emphasized by calling this process elastic scattering.
    ${ }^{21}$ Indeed, at $r \gg b$, the definition $\mathbf{L}=\mathbf{r} \times(m \mathbf{v})$ yields $L_{z}=b m v_{\infty}$, where $v_{\infty}=(2 E / m)^{1 / 2}$ is the initial (and hence the final) velocity of the particle.

[^37]:    ${ }^{22}$ Alternatively, this result may be recovered directly from Eq. (59) whose parameters, at $E>0$, may be expressed via the same dimensionless parameter $(2 E b / \alpha): p=b(2 E b / \alpha), e=\left[1+(2 E b / \alpha)^{2}\right]^{1 / 2}>1$.
    ${ }^{23}$ This terminology stems from the fact that an integral of $d \sigma d \Omega$ over the full solid angle, called the full crosssection $\sigma$, has the dimension of area: $\sigma=N / n$, where $N$ is the total number of scattered particles.

[^38]:    ${ }^{24}$ This divergence, which persists at the quantum-mechanical treatment of the problem, is due to particles with large values of $b$, and disappears at an account, for example, of a finite concentration of the scattering centers.

[^39]:    ${ }^{25}$ Solving this problem is a very good preparation for the analysis of symmetric top rotation in Sec. 6.5.

[^40]:    ${ }^{26}$ It was not the first confirmation, though. The first one came 4 years earlier from A. Einstein himself, who showed that his theory may qualitatively explain the difference between the rate of Mercury orbit's precession, known from earlier observations, and the nonrelativistic theory of this effect.

[^41]:    ${ }^{3}$ Here I treat Eq. (5) as a phenomenological model, but in statistical mechanics such dissipative term may be derived as an average force exerted on a body by its environment whose numerous degrees of freedom are in random, though possibly thermodynamically-equilibrium states. Since such environmental force also has a random component, the dissipation is fundamentally related to fluctuations, and the latter effects may be neglected (as they are in this course) only if the oscillation energy is much higher than the energy scale of random fluctuations of the environment - in the thermal equilibrium at temperature $T$, the larger of $k_{\mathrm{B}} T$ and $\hbar \omega_{0} / 2$ - see, e.g., SM Chapter 5 and QM Chapter 7.
    ${ }^{4}$ Systems with very high damping ( $\delta>\omega_{0}$ ) can hardly be called oscillators, and though they are used in engineering and physics experiment (e.g., for the shock, vibration, and sound isolation), for their discussion I have to refer the interested reader to special literature - see, e.g., C. Harris and A. Piersol, Shock and Vibration Handbook, $5^{\text {th }}$ ed., McGraw Hill, 2002. Let me only note that at very high damping, $\delta \gg \omega_{0}$, the system may be adequately described with just one parameter: the relaxation time $1 / \lambda_{+} \approx 2 \delta / \omega_{0}^{2} \gg \omega_{0}$.

[^42]:    ${ }^{5}$ Operator Re, used in Eq. (3), may be dropped here, because for any physical (real) force, the imaginary components of the sum compensate each other. This imposes the following condition on the complex Fourier amplitudes: $f_{-\omega}=f_{\omega}{ }^{*}$, where the star means the complex conjugation.
    ${ }^{6}$ In physics, this mathematical property of linear equations is frequently called the linear superposition principle.

[^43]:    ${ }^{7}$ This is true for all systems in which $f(t)$ represents a cause, and $q(t)$ its effect. Following tradition, I discuss the frequency-domain expression of this causality relation (called the Kramers-Kronig relations) in the Classical Electrodynamics part of this lecture series - see EM Sec. 7.3.

[^44]:    ${ }^{8}$ This is a very unfortunate, but common jargon, meaning "the system described by linear equations of motion".
    ${ }^{9}$ For a reminder of the basic properties of the $\delta$-function, see MA Sec. 14.

[^45]:    ${ }^{10}$ The same result may be obtained from Eq. (28) with the response function $\chi(\omega)$ given by Eq. (19). This, more cumbersome, way is left for reader's exercise.

[^46]:    ${ }^{11}$ See, e.g., EM Sec. 2.7, and QM Sec. 2.2.
    ${ }^{12}$ Again, "nonlinear oscillations" is a generally accepted slang term for oscillations in systems described by nonlinear equations of motion.

[^47]:    ${ }^{13}$ The same flexible approach is necessary to approximations used in quantum mechanics. The method discussed here is close in spirit (but not identical) to the WKB approximation (see, e.g., QM Sec. 2.4) rather to the perturbation theory varieties (QM Ch. 6).
    ${ }^{14}$ In various texts, one can meet references to either the small parameter method or asymptotic methods. The list of scientists credited for the development of this method and its variations notably includes J. Poincaré, B. van der Pol, N. Krylov, N. Bogolyubov, and Yu. Mitroplolsky. Expression (41) itself is frequently called the RotatingWave Approximation - RWA. (The origin of the term will be discussed in Sec. 6 below.) In the view of the pioneering role of B. van der Pol in the development of this approach, in some older textbooks the rotating-wave approximation is called the "van der Pol method".
    ${ }^{15}$ This equation is frequently called the Duffing equation (or the equation of the Duffing oscillator), after G. Duffing who was the first one to carry out its (rather incomplete) analysis in 1918.

[^48]:    ${ }^{16}$ For a mathematically rigorous treatment of the higher approximations, see, e.g., Yu. Mitropolsky and N. Dao, Applied Asymptotic Methods in Nonlinear Oscillations, Springer, 2004. A more laymen (and somewhat verbose) discussion of various oscillatory phenomena may be found in the classical text A. Andronov, A. Vitt, and S. Khaikin, Theory of Oscillators, Dover, 2011.
    ${ }^{17}$ Using the second of Eqs. (44), cos $\omega t$ may be rewritten as $\cos (\Psi+\varphi) \equiv \cos \Psi \cos \varphi-\sin \Psi \sin \varphi$. Then using the trigonometric identity $\cos ^{3} \Psi=(3 / 4) \cos \Psi+(1 / 4) \cos 3 \Psi-$ see, e.g., MA Eq. (3.4) results in Eq. (46).

[^49]:    ${ }^{18}$ One may ask why cannot we stick to the just one, most compact, complex-amplitude form (57b) of the RWA equations. The main reason is that when function $f(q, \dot{q}, t)$ is nonlinear, we cannot replace its real arguments, such as $q=A \cos (\omega t-\varphi)$, with their complex-function representations like $a \exp \{-i \omega t\}$ (as could be done in the linear problems considered in Sec. 4.1), and need to use real variables, such as either $\{A, \varphi\}$ or $\{u, v\}$, anyway.

[^50]:    ${ }^{19}$ For that, one needs to use the trigonometric identity $\sin ^{3} \Psi=(3 / 4) \sin \Psi-(1 / 4) \sin 3 \Psi-$ see, e.g., MA Eq. (3.4).

[^51]:    ${ }^{20}$ Actually, this result should be evident, even without calculations, from the comparison of Eqs. (60) and (63).
    ${ }^{21}$ This equation is ubiquitous in phase locking systems, including even some digital electronic circuits used for that purpose.

[^52]:    22 A modulation of pendulum's mass (say, by periodic pumping water in and out of a suspended bottle) gives a qualitatively similar result. Note, however, that parametric oscillations cannot be excited by modulating any oscillator's parameter - for example, oscillator's damping coefficient (at least if it stays positive at all times), because its does not change system's energy, just the energy drain rate.

[^53]:    ${ }^{23}$ Such calculations may be substantially simplified by the use of the so-called Floquet theorem, which is also the mathematical basis for the discussion of wave propagation in periodic media - see the next chapter.
    ${ }^{24}$ This region describes, for example, the counter-intuitive stability of an inverted pendulum with the periodically modulated length, within a limited range of the modulation depth $\mu$.

[^54]:    ${ }^{25}$ Autonomous systems described by a single second-order differential equation, say $F(q, \dot{q}, \ddot{q})=0$, also belong to this class, because we may treat velocity $\dot{q} \equiv v$ as a new variable, and use this definition as one first-order differential equation, and the initial equation, in the form $F(q, v, \dot{v})=0$, as the second first-order equation.

[^55]:    ${ }^{26}$ In terms of linear algebra, $\lambda_{ \pm}$are the eigenvalues, and the corresponding sets $\left[c_{1}, c_{2}\right]_{ \pm}$, the eigenvectors of matrix M with elements $M_{i j}$.
    ${ }^{27}$ The asymptote direction may be found by plugging the value $\lambda_{+}$back into Eq. (89) and finding the corresponding ratio $c_{1} / c_{2}$.
    ${ }^{28}$ The term "saddle" is due to the fact that system's dynamics in this case is qualitatively similar to those of particle's motion in the 2D potential $U\left(\widetilde{q}_{1}, \widetilde{q}_{2}\right)$ having the shape of a horse saddle (or a mountain pass).

[^56]:    ${ }^{29}$ Named after J. H. Poincaré (1854-1912) who is credited, among many other achievements, for his contributions to special relativity (see, e.g., EM Chapter 9) and the idea of deterministic chaos (to be discussed in Chapter 9 below).
    ${ }^{30}$ This notion of phase plane rotation is the basis for the rotating-wave approximation's name. (Word "wave" has sneaked in from this method's wide application in classical and quantum optics.)

[^57]:    ${ }^{31}$ In addition, the Euler method is not time-reversible - the handicap which may be essential for integration of Hamiltonian systems described by systems of second-order differential equations. However, this drawback may be readily overcome by the so-called leapfrogging - the overlap of time steps $h$ for a generalized coordinate and the corresponding generalized velocity.

[^58]:    ${ }^{32}$ The most popular approaches in such cases are the Richardson extrapolation, the Bulirsch-Stoer algorithm, and a set of prediction-correction techniques, e.g. the Adams-Bashforth-Moulton method - see the literature recommended in MA Sec. 16 (iii).
    ${ }^{33}$ All numerical results shown in this section have been obtained by the $4{ }^{\text {th }}$-order Runge-Kutta method with the automatic step adjustment which guarantees the relative error of the order of $10^{-4}$ - much smaller than the pixel size in the plots.

[^59]:    ${ }^{34}$ In this particular case, the higher harmonic contents is about $0.5 \%$, dominated by the $3^{\text {rd }}$ harmonic whose amplitude and phase are in a very good agreement with Eq. (50).
    ${ }^{35}$ This method is used in practice, for example, for the generation of electromagnetic waves with frequencies in the terahertz range $\left(10^{12}-10^{13} \mathrm{~Hz}\right)$ which still lacks efficient electronic self-oscillators.

[^60]:    ${ }^{36}$ This term had been coined in 1957 by R. Bellman in the context of the optimal control theory (where the dimensionality typically means the number of parameters affecting the system under control), but gradually has spread all over quantitative sciences using numerical methods.
    ${ }^{37}$ In EM Sec. 1.2, I discuss implications of the curse implications for a different case, when both analytical and numerical solutions to the same problem are possible.

[^61]:    ${ }^{38}$ See, e.g., MA Eq. (15.1).

[^62]:    ${ }^{1}$ Here it is assumed that the particles are constrained to move in only one dimension (shown horizontal).

[^63]:    ${ }^{2}$ It is useful to rewrite Eq. (12) as $Z_{1} c_{1}= \pm Z_{2} c_{2}$, where $Z_{1,2} \equiv\left(\kappa_{1,2} m_{1,2}\right)^{1 / 2}$ are of the partial oscillator impedances the notion already mentioned in Chapter 4, and to be discussed in more detail in Sec. 4 below.

[^64]:    ${ }^{3}$ In physics, term "mode" is typically used for a particular type of variable distribution in space (in our current case, a certain set of distribution coefficients $c_{1,2}$ ), that sustains oscillations at a single frequency.
    ${ }^{4}$ One more property of weakly coupled oscillators, a periodic slow transfer of energy from one oscillator to the other and back, is more important for quantum rather than for classical mechanics. This is why I refer the reader to QM Secs. 2.5 and 5.1 for a detailed discussion of this phenomenon.

[^65]:    ${ }^{5}$ Fortunately, very effective algorithms have been developed for this matrix diagonalization task - see, e.g., references in MA Sec. 16(iii)-(iv). For example, the popular MATLAB package was initially created for this purpose. ("MAT" in its name stands for "matrix" rather than "mathematics".)

[^66]:    ${ }^{6}$ Named after P. Debye who developed this theory in 1912, in the context of specific heat of solids at low temperatures (beating nobody else than A. Einstein on the way :-) - see, e.g., SM Sec. 2.6.

[^67]:    ${ }^{7}$ This term is purely historical. Though the usual sound waves in air belong to this class, the waves we are discussing may have frequency both well below and well above human ear's sensitivity range.
    ${ }^{8}$ The waveform deformation due to dispersion (which we are considering now) should be clearly distinguished from its possible change due to attenuation, i.e. energy loss - which is not taken into account is our energyconserving model (23) - cf. Sec. 5 below.

[^68]:    ${ }^{9}$ Taking into account the next term in the Taylor expansion of function $\omega(q)$, proportional to $d^{2} \omega / d q^{2}$, we would find that actually the dispersion leads to a gradual change of the envelope form. Such changes play an important role in quantum mechanics, so that I discuss them in that part of my notes (see QM Sec. 2.1).

[^69]:    ${ }^{10}$ This property has especially important implications for quantum properties of periodic structures, e.g., crystals. It means, in particular, that the product $\hbar k$ cannot present the actual momentum of the particle (which is not conserved in periodic systems), but rather serves as its quasi-momentum (or "crystal momentum") - see, e.g., QM Sec. 2.5.

[^70]:    ${ }^{11}$ The direct calculation of the energy (per unit length) is a simple but useful exercise, left for the reader.

[^71]:    ${ }^{12}$ Sorry, one more traditional usage of letter $T$. I do not think there any chance to confuse it with the kinetic energy.

[^72]:    ${ }^{13}$ This equation could be also obtained using Eq. (42), as the condition of balance of the forces exerted on the interface particle with $j=0$ from the left and right - again, neglecting the inertia of that particle.
    ${ }^{14}$ See, e.g., corresponding parts of my lecture notes: QM Sec. 2.3 and EM Sec. 7.4. In 2D and 3D systems, Eqs. (53) are valid for the normal wave incidence only, otherwise they have to be modified - see, e.g., EM Sec. 7.4.

[^73]:    ${ }^{16}$ Actually, this result may be also obtained from Eq. (60) and hence is valid for an arbitrary ratio $\omega_{n} / \omega_{0}$.
    ${ }^{17}$ Equation (65), as well as its multi-dimensional generalizations, is frequently called the Helmholtz equation, named after H. von Helmholtz (1821-1894).

[^74]:    ${ }^{18}$ In engineering, the attenuation coefficient of wave-carrying systems is most frequently characterized by a logarithmic measure called decibel per meter (or just dB/m): $\alpha_{\mathrm{dB} / \mathrm{m}} \equiv 10 \log _{10} \alpha$.

[^75]:    ${ }^{19}$ In optics, the nonlinearity is implemented using transparent crystals such as lithium niobate $\left(\mathrm{LiNbO}_{3}\right)$, with the cubic-nonlinear dependence of the electric polarization as a function of the applied electric field: $\mathcal{P} \propto \mathcal{\varepsilon}+\alpha \boldsymbol{\mathcal { E }}^{3}$.

[^76]:    ${ }^{20}$ See, e.g., the classical monograph by N. Bloembergen, Nonlinear Optics, $4^{\text {th }}$ ed., World Scientific, 1996, or a more modern treatment by R. W. Boyd, Nonlinear Optics, $3^{\text {rd }}$ ed., Academic Press, 2008.
    ${ }^{21}$ Which is, surprisingly, not much more complex than the classical theory - see, e.g., QM Sec.5.5.
    ${ }^{22}$ See, e.g., QM Secs. 8.5 and 10.1, correspondingly.
    ${ }^{23}$ The classical (and perhaps still the best) monograph on the subject is Ya. Zeldovich, Physics of Shock Waves and High-Temperature Phenomena, Dover, 2002.

[^77]:    ${ }^{24}$ The reader familiar with the WKB approximation in quantum mechanics (see, e.g., QM Sec. 2.4) is welcome to adapt it for this classical application. Another possible starting point is the rotating-wave approximation (RWA), discussed in Sec. 4.3 above, which should be translated from the time domain to the space domain.
    ${ }^{25}$ This is a good model for small oscillations of linear molecules such as $\mathrm{CO}_{2}$ (for which the values of elastic constants $\kappa$ and $\kappa$ ' are well known).

[^78]:    ${ }^{1}$ Actually, all symbols for particle masses, coordinates and velocities should carry the particle index, say $k$, over which the summation is carried out. However, for the sake of notation simplicity, this index is just implied.

[^79]:    ${ }^{2}$ Hopefully, there is a little chance of confusion between the angular momentum $\mathbf{L}$ (a vector) and its Cartesian components $L_{j}$ (scalars with an index) on one hand, and the Lagrange function $L$ (a scalar without an index) on the other hand.
    ${ }^{3}$ See, e.g., MA Eq. (7.5).

[^80]:    ${ }^{4}$ Note that according to Eq. (22), other Cartesian components of the angular momentum, $L_{x}=I_{x z} \omega_{z}$ and $L_{y}=I_{y z} \omega_{z}$ may be different from zero, and even evolve in time. (Indeed, if axes $x$ and $y$ are fixed in lab frame, $I_{x z}$ and $I_{y z}$ may change due to body's rotation.) The corresponding torques $\tau_{x}^{(\mathrm{ext})}$ and $\tau_{y}^{(\text {ext })}$, which obey Eq. (33), are automatically provided by external forces which keep the rotation axis fixed.

[^81]:    ${ }^{5}$ Such beautiful experimental physics does not come cheap: the total Gravity Probe B project budget was about $\$ 750 \mathrm{M}$. Even at this price tag, the declared main goal of the project, an accurate measurement of a more subtle relativistic effect, the so-called frame-dragging drift (or "the Schiff precession"), predicted to be about 0.04 arc seconds per year, has not been achieved.
    ${ }^{6}$ This is also true for an asymmetric top, i.e. an arbitrary body (with, say, $I_{1}<I_{2}<I_{3}$ ), but in this case the alignment of vector $\mathbf{L}$ with axis $\mathbf{n}_{2}$, corresponding to the intermediate moment of inertia, is unstable.

[^82]:    ${ }^{7}$ Much more compact (and much less accurate) gyroscopes used, e.g., in smartphones and tablet computers, are based on the effect of rotation on oscillator frequency, and implemented as micro-electromechanical systems (MEMS) on silicon chip surface - see, e.g., Chapter 22 in V. Kaajakari, Practical MEMS, Small Gear Publishing, 2009.

[^83]:    Free precession frequency

[^84]:    ${ }^{8}$ For Earth, the free precession amplitude it so small (below 10 m of linear displacement on the Earth surface) that this effect is of the same order as other, irregular motions of the rotation axis, resulting from the turbulent fluid flow effects in planet's interior and its atmosphere.
    ${ }^{9}$ It is frequently called the Poinsot ellipsoid, after L. Poinsot (1777-1859) who has made several pioneering contributions to the rigid body mechanics.

[^85]:    ${ }^{10}$ These equations are of course valid in the simplest case of the fixed rotation axis as well. For example, if $\omega=$ $\mathbf{n}_{z} \omega$, i.e. $\omega_{x}=\omega_{y}=0$, Eq. (66) is reduced to Eq. (38).

[^86]:    ${ }^{11}$ Such discussion may be found, e.g. in Sec. 37 of L. Landau and E. Lifshitz, Mechanics, $3{ }^{\text {rd }}$ ed., ButterworthHeinemann, 1976.

[^87]:    ${ }^{12}$ Of the several choices more convenient in the absence of fast rotation, the most common is the set of so-called Tait-Brian angles (called the yaw, pitch, and roll) that are broadly used in airplane and maritime navigation.

[^88]:    ${ }^{13}$ Indeed, since the Lagrangian does not depend on time explicitly, $H=$ const, and since the full kinetic energy $T$ is a quadratic-homogeneous function of the generalized velocities, $E=H$.

[^89]:    ${ }^{14}$ In that simple case the body continues to rotate about the vertical symmetry axis: $\theta(t)=0$. Note, however, that such motion is stable only if the spinning speed is sufficiently high - see below.
    ${ }^{15}$ Indeed, the derivative of the fraction $1 / 2 I_{A} \sin ^{2} \theta$, taken at the point $\cos \theta=L_{z} / L_{3}$, is multiplied by the numerator, $\left(L_{z}-L_{3} \cos \theta\right)^{2}$, which at this point vanishes.

[^90]:    ${ }^{16}$ Details of this calculation may be found, e.g., in Sec. 5.8 of the textbook by H. Goldstein, C. Poole, and J. Safko, Classical Mechanics, $3^{\text {rd }}$ ed., Addison Wesley, 2002.

[^91]:    ${ }^{17}$ For this problem, all other inertial "forces", besides the Coriolis force (see below) vanish, while the latter force is directed perpendicular to the ring and does not affect the bead's motion along it.
    18 Named after G.-G. Coriolis (1792-1843), who is also credited for the first unambiguous definitions of mechanical work and kinetic energy.

[^92]:    19 The same force causes also the counter-clockwise circulation inside our infamous "Nor'easter" storms, in which velocity $\mathbf{v}$, caused by lower atmospheric pressure in the middle of the cyclone, is directed toward its center. ${ }^{20}$ Note again the difference between the negative sign before the (always positive) second term, and the positive sign before the similar positive second term in Eq. (3.44). As was already discussed in Chapter 3, this difference hinges on different background physics: in the planetary problem, the angular momentum (and hence its component $L_{z}$ ) is fixed, while the corresponding angular velocity $\dot{\varphi}$ is not. On the opposite, in our current discussion, the angular velocity $\omega$ (of the reference frame) is fixed, i.e. is independent on particle's motion.

[^93]:    ${ }^{21} \partial L / \partial \mathbf{v}$ is just a shorthand for a vector with Cartesian components $\partial L / \partial v_{j}$. In a different language, this is the gradient of $L$ in the velocity space.
    ${ }^{22}$ A very similar situation arises at the motion of a particle with electric charge $q$ in magnetic field $\mathbf{B}$. In that case the role of the additional term $\boldsymbol{p}-\mathbf{p}=m \omega \times \mathbf{r}$ is played by product $q \mathbf{A}$, where $\mathbf{A}$ is the vector-potential of the field $(\mathbf{B}=\nabla \times \mathbf{A})-$ see, e.g., EM Sec. 9.7, and in particular Eqs. (9.183) and (9.192).
    ${ }^{23}$ Note that by definition (1.36), angular momenta $\mathbf{L}$ of particles merely add up. As a result, Eq. (102) is valid for an arbitrary system of particles.

[^94]:    ${ }^{1}$ Since both $d \mathbf{q}$ and $d \mathbf{r}$ are legitimate physical vectors (whose Cartesian components are properly transformed as the transfer between reference frames), the $3 \times 3$ matrix with elements $\partial q_{j} / \partial r_{j}$; is indeed a legitimate physical tensor - see the discussion in Sec. 6.2.
    ${ }^{2}$ See, e.g., MA Eq. (13.2).

[^95]:    ${ }^{3}$ The traditional European notation for Tr is Sp (from German Spur meaning "trace" or "track").
    ${ }^{4}$ Actually, the tensor theory shows that the trace does not depend on the particular choice of the coordinate axes.

[^96]:    ${ }^{5}$ See, e.g., MA Eqs. (10.1) and (10.7).

[^97]:    ${ }^{6}$ It is frequently called the Cauchy stress tensor, partly to honor A.-L. Cauchy (1789-1857) who introduced it, and partly to distinguish it from and other possible definitions of the stress tensor, including the $1^{\text {st }}$ and $2^{\text {nd }}$ PiolaKirchhoff tensors. (For the infinitesimal deformations discussed in this course, all these notions coincide.)

[^98]:    ${ }^{7}$ Named after R. Hooke (1635-1703) who was first to describe the law in its simplest, 1D version.
    ${ }^{8}$ The inclusion of coefficients 2 and 3 into Eq. (34) is justified by the simplicity of some of its corollaries - see, e.g., Eqs. (38) and (43) below.
    ${ }^{9}$ Since the strain tensor elements, defined by Eq. (5), are dimensionless, while the strain defined by Eq. (18) has the dimensionality of pressure (force by unit area), so do the elastic moduli $K$ and $\mu$.

[^99]:    ${ }^{10}$ It may be proved that such situation may be implemented not only in a fluid with pressure $P$, but also by placing a solid sample of an arbitrary shape into a compressed fluid.

[^100]:    ${ }^{11}$ For the derivation and detailed discussion of Eq. (40) see, e.g., SM Sec. 3.1
    ${ }^{12}$ See, e.g., SM Sec. 1.3.

[^101]:    ${ }^{13}$ Though the analysis of compression in this situation gives similar results, in practical experiments a strong compression may lead to the loss of horizontal stability - the so-called buckling - of the rod.
    ${ }^{14}$ According to Eq. (47), $E$ may be thought of as the force per unit area, which would double sample's length, if only our theory was valid for deformations that large.

[^102]:    ${ }^{15}$ It is probably somewhat higher (up to $2,000 \mathrm{GPa}$ ) in such nanostructures as carbon nanotubes and monoatomic sheets (graphene), though there is still a substantial uncertainty in experimental values of elastic moduli of these structures - see, e.g., C. Lee et al, Science 321, 5887 (2008) and J.-U. Lee et al., Nano Lett. 12, 4444 (2012). ${ }^{16}$ The only known exceptions are certain exotic media with very specific internal microstructure - see, e.g., R. Lakes, Science 235, 1038 (1987) and references therein.

[^103]:    ${ }^{17}$ For clarity, let me reproduce a similar integration for the 1D motion of a particle on a spring. In this case, $\delta U=$ $-\delta W=-F \delta x$, and if spring's force is elastic, $F=-\kappa x$, the integration yields $U=\kappa x^{2} / 2=F x / 2$.
    ${ }^{18}$ As follows from Eqs. (50), the coefficient before the first sum in Eq. (53) is just the shear modulus $\mu$, while that before the second sum is equal to $(K+\mu / 3)$.
    ${ }^{19}$ See, e.g., MA Eq. (11.3).

[^104]:    ${ }^{20}$ If this is not immediately evident, have a look at MA Eq. (10.11) with $\mathbf{f}=f_{r}(r) \mathbf{n}_{r}$.
    ${ }^{21}$ See, e.g., MA Eq. (10.10) with $\mathbf{f}=q(r) \mathbf{n}_{r}$

[^105]:    ${ }^{22}$ Indeed, according to Eq. (50), the material-dependent factor in the second of Eqs. (63) is just $1 / 4 \mu$.

[^106]:    ${ }^{23}$ Strictly speaking, this is only true if the pressure difference is not too small, namely, if $\left|P_{1}-P_{2}\right| \gg P_{1,2} t / R$.

[^107]:    ${ }^{24}$ Strictly speaking, that dashed line is the intersection of the neutral surface (the continuous set of such neutral lines for all cross-sections of the rod) with the plane of drawing.
    ${ }^{25}$ Indeed, for $(d x / d z)^{2} \ll 1$, the general formula MA Eq. (4.3) for curvature (with the appropriate replacements $f$ $\rightarrow x$ and $x \rightarrow z)$ is reduced to $1 / R=d^{2} x / d z^{2}=d(d x / d z) / d z=d\left(\tan \varphi_{y}\right) / d z \approx d \varphi_{y} / d z$.
    ${ }^{26}$ In particular, this is the reason why the usual electric wires are made not of a solid copper core, but rather a twisted set of thinner sub-wires, which may slip relative to each other, increasing the wire flexibility.

[^108]:    ${ }^{27}$ As clear from their derivation, Eqs. (76)-(79) are valid for any distribution of parameters $A, E, I$, and $\rho$ over the rod's length, provided that the rod is quasi-uniform, i.e. its parameters' changes are so slow that the local relation (78) is still valid at any point.

[^109]:    ${ }^{28}$ For this problem, with purely shear deformation, using alternative elastic moduli $E$ and $v$ would be rather unnatural. If needed, we may always use the second of Eqs. (50): $\mu=E / 2(1+v)$.

[^110]:    ${ }^{29}$ I would not be terribly shocked if the reader skipped the balance of this section at the first reading. Though the following calculation is very elegant and instructive, its results will not be used in other parts of these notes.

[^111]:    ${ }^{30}$ In geophysics, the longitudinal waves are known as $P$-waves (with letter $P$ standing for "primary"), because due to their higher velocity (see below) they arrive at the detection site (from a distant earthquake or explosion) before waves of other types.

[^112]:    ${ }^{33}$ However, if the initial wave is an arbitrary mixture (109) of longitudinal and transverse components, these components, propagating with different velocities, will "run from each other".

[^113]:    ${ }^{34}$ Named after N. Umov who introduced this concept in 1874. Ten years later, a similar concept for electromagnetic waves (see, e.g., EM Sec. 6.4) was suggested by J. Poynting, so that some textbooks use the term "Umov-Poynting vector". In a dissipation-free, elastic medium, the Umov vector obeys the following continuity equation, $\partial\left(\rho v^{2} / 2+u\right) / \partial t+\nabla \cdot p=0$, with $u$ given by Eq. (52), which expresses the conservation of the total (kinetic plus potential) energy of elastic deformation.

[^114]:    ${ }^{35}$ See, e.g., EM Sec. 7.5.
    ${ }^{36}$ Their discussion may be also found in EM Sec. 7.5.

[^115]:    ${ }^{37}$ Named, respectively, after Lord Rayleigh (born J. Strutt, 1842-1919) who has theoretically predicted the very existence of surface acoustic waves, and A. Love (1863-1940).
    ${ }^{38}$ See, e.g., Sec. 24 in L. Landau and E. Lifshitz, Theory of Elasticity, $3^{\text {rd }}$ ed., Butterworth-Heinemann, 1986.
    ${ }^{39}$ See, for example, K. Aki and P. G. Richards, Quantitative Seismology, $2^{\text {nd }}$ ed., University Science Books, 2002, and D. Morgan, Surface Acoustic Waves, ${ }^{\text {nd }}$ ed., Academic Press, 2007.

[^116]:    ${ }^{40}$ Due to this reason, the tensile waves can be called longitudinal only in a limited sense: while the stress wave is purely longitudinal $\sigma_{x x}=\sigma_{y y}=0$, the strain wave is not: $s_{x x}=s_{y y}=-\sigma \pi_{z z} \neq 0$, i.e. $\mathbf{q}(\mathbf{r}, t) \neq \mathbf{n}_{z} q_{z}$.

[^117]:    ${ }^{41}$ Note that since the "moment of inertia" $I_{y}$, defined by Eq. (72), may depend on the bending direction (unless the cross-section is sufficiently symmetric), the dispersion relation (138) may give different results for different directions of the bending wave polarization.

[^118]:    ${ }^{42}$ For acoustic waves, such condition is easy to implement. Indeed, from Sec. 7 we already know that the strong inequality of wave impedances $Z$ is sufficient for such reflection. The numbers of Table 1 show that, for example,

[^119]:    ${ }^{1}$ As was discussed in Sec. 7.3 in the context of Table 7.1, this is an excellent approximation, for example, for human-scale experiments with water.
    ${ }^{2}$ The equation, and the SI unit of pressure $1 \mathrm{~Pa}=1 \mathrm{~N} / \mathrm{m}^{2}$, are named after B. Pascal (1623-1662) who has not only pioneered hydrostatics, but also invented the first mechanical calculator and made several other important contributions to mathematics - and Christian philosophy!
    ${ }^{3}$ An example of such a problem is given by fluid equilibrium in coordinate systems rotating with a constant angular velocity. Here the real bulk forces should be complemented by the centrifugal "force" - the only inertial force which does not vanish at constant $\omega$ and $\mathbf{r}-$ see Eq. (6.92).

[^120]:    ${ }^{4}$ If $\gamma$ of the interface of certain two fluids is negative, it self-reconfigures to decrease $U_{s}$ by the interface area, i.e. fragments the system into a solution.
    ${ }^{5}$ This equality readily follows from the general Eq. (7.32), with the stress tensor elements expressed by Eq. (2), but in this simple case of the net stress force $d \mathbf{F}=\left(P_{1}-P_{2}\right) d \mathbf{A}$ parallel to the interface element vector $d \mathbf{A}$, it may be even more simply obtained just from the definition of work $\delta W=d \mathbf{F} \cdot \delta \mathbf{r}$ at the virtual displacement $\delta \mathbf{r}=\mathbf{n} \delta r$. ${ }^{6}$ This general formula may be verified by elementary means for a sphere of radius $r$ (for which $R_{1}=R_{2}=r$ and $d A$ $=r^{2} d \Omega$, so that $\delta(d A) / d A=\delta\left(r^{2}\right) / r^{2}=2 \delta r / r$ ), and a round cylindrical interface of radius $R$ (for which $R_{1}=r, R_{2}=$ $\infty$, and $d A=r d \varphi d z$, so that $\delta(d A) / d A=\delta r / r)$.
    ${ }^{7}$ This formula (not to be confused with Eq. (12), called the Young's equation) was derived in 1806 by P.-S. Laplace (of the Laplace operator/equation fame) on the basis of the first analysis of the surface tension effects by T. Young a year earlier.

[^121]:    ${ }^{8}$ Note that this is not true for tubes with different shapes of their cross-section.
    ${ }^{9}$ One of them is the sound propagation, where particle displacements $\mathbf{q}$ are typically small, so that results of Sec. 7.7 are applicable. As a reminder, they show that in fluids, with $\mu=0$, the transverse sound cannot propagate (formally, has zero velocity and impedance), while the longitudinal sound's velocity is finite - see Eq. (7.116).

[^122]:    ${ }^{10}$ The operator relation $d / d t=\partial / \partial t+(\mathbf{v} \cdot \nabla)$, applicable to an arbitrary (scalar or vector) function, is frequently called the convective derivative. (Alternative adjectives, such as "Lagrangian", "substantial", or "Stokes", are sometimes used for this derivative as well.) The relation has numerous applications well beyond the fluid dynamics - see, e.g., EM Chapter 9 and QM Chapter 1.

[^123]:    ${ }^{11}$ If the reader still needs a reminder, see MA Eq. (12.1).
    ${ }^{12}$ See, e.g., EM Sec. 4.1, QM Sec. 1.4, and SM Sec. 5.6.
    ${ }^{13}$ It was derived in 1755 by the same L. Euler whose name has already been (reverently) mentioned several times in this course.

[^124]:    ${ }^{14}$ It readily follows, for example, from MA Eq. (11.6) with $\mathbf{g}=\mathbf{f}=\mathbf{v}$.
    ${ }^{15}$ Perhaps the most spectacular manifestation of the vorticity conservation are the famous toroidal vortex rings (see, e.g., nice photo and movie at https://en.wikipedia.org/wiki/Vortex ring), predicted in 1858 by H. von Helmholtz, and then demonstrated by P. Tait in a series of spectacular experiments with smoke in air. The persistence of such a ring, once created, is only limited by fluid's viscosity - see the next section.
    ${ }^{16}$ First formulated verbally by H. von Helmholtz.
    ${ }^{17}$ Its proof may be found, e.g., in Sec. 8 of L. Landau and E. Lifshitz, Fluid Mechanics, $2^{\text {nd }}$ ed., ButterworthHeinemann, 1987.

[^125]:    ${ }^{18}$ See, e.g., EM Secs. 2.3 and 2.4.
    ${ }^{19}$ Evidently, motion of the cylinder, with constant velocity $\left(-\mathbf{v}_{0}\right)$, in the otherwise stationary fluid leads to exactly the same problem - in the reference frame bound to the moving body.
    ${ }^{20}$ See, e.g., MA Eq. (10.3).
    ${ }^{21}$ Let me hope that letter $\rho$, used here for the magnitude 2D radius-vector $\rho=\{x, y\}$, will not be confused with fluid's density - which does not participate in this boundary problem.
    ${ }^{22}$ See, e.g., EM Eq. (2.112). Note that the most general solution of Eq. (29) also includes a term proportional to $\varphi$, but this term should be zero for such a single-valued function as the velocity potential.

[^126]:    ${ }^{23}$ They may be found by integration of the evident equation $d y / d x=v_{y}(x, y) / v_{x}(x, y)$. For our simple problem this integration may be done analytically, giving the relation $y\left[1-R^{2} /\left(x^{2}+y^{2}\right)\right]=$ const, where the constant is specific for each streamline.
    ${ }^{24}$ The alternative, historic term "gravity waves" for this phenomenon may nowadays lead to a confusion with the relativistic effect of gravity waves (which may propagate in vacuum), whose direct detection is a focus of so much current experimental effort.
    ${ }^{25}$ Such a wave is "plane" only in direction $x$ (perpendicular to the propagation direction $z$, see Fig. 4).

[^127]:    ${ }^{26}$ Probably the most important effect we miss by neglecting $\zeta$ is the attenuation of (longitudinal) acoustic waves, into which the second viscosity makes a major (and in some cases, the main) contribution.
    ${ }^{27}$ Actually, at even lower temperatures (for $\mathrm{He} 4, T<T_{\lambda} \approx 2.17 \mathrm{~K}$ ), helium becomes a superfluid, i.e. looses viscosity completely, as result of the Bose-Einstein condensation - see, e.g., SM Sec. 3.4.
    ${ }^{28}$ Named after C.-L. Navier (1785-1836) who had suggested the equation, and G. Stokes (1819-1903) who has demonstrated its relevance by solving it for several key situations.

[^128]:    ${ }^{29}$ This is essentially an additional experimental fact, but may be readily understood as follows. A solid may be considered as an ultimate case of a fluid (with infinite viscosity), and the tangential component of velocity should be a continuous an interface between two fluids, in order to avoid infinite stress - see Eq. (50).

[^129]:    ${ }^{30}$ It was solved theoretically by G. Stokes in 1845 in order to explain Eq. (60) that had been formulated by G. Hagen and J. Poiseuille in 1839-1840 on the basis of their experimental results.

[^130]:    ${ }^{31}$ For example, the Green's function method (see, e.g., EM Sec. 2.7).
    ${ }^{32}$ For more details see, e.g., R. J. Leveque, Finite Difference Methods for Ordinary and Partial Differential Equations, SIAM, 2007.

[^131]:    ${ }^{33}$ Note that value (65) is exactly the same as given for $v_{\max }=\left.v\right|_{\rho=0}$ by the analytical formula (58) for the round cross-section with radius $R=a / 2$. This is not an occasional coincidence. The velocity distribution given by (58) is a quadratic function of both $x$ and $y$. For such functions, with all derivatives higher than $\partial^{2} / \partial r_{j}^{2}$ being equal to zero, equation (64) is exact rather than approximate.
    ${ }^{34}$ See, e.g., C. Johnson, Numerical Solution of Partial Differential Equations by the Finite Element Method, Dover, 2009, or T. J. R. Hughes, The Finite Element Method, Dover, 2000.

[^132]:    ${ }^{37}$ The time scale of some problems may be different from $l / v$; for example, for forced oscillations of a fluid flow it is given by the reciprocal oscillation frequency $f$. For such problems, ratio $S \equiv f(l / v)$ serves as another, independent dimensionless constant, commonly called either the Strouhal number or the reduced frequency.
    ${ }^{38}$ For substantially compressible fluids (e.g., gases), the most important additional dimensionless parameter is the Mach number $M \equiv v / v_{l}$, where $v_{l}=(K / \rho)^{1 / 2}$ is the velocity of the longitudinal sound - which is, as we already know, the only wave mode possible in an infinite fluid. Especially significant for practice are supersonic effects (including the shock wave in the form of the famous Mach cone with the half-angle $\theta_{\mathrm{M}}=\sin ^{-1} M^{-1}$ ) which arise at $M>1$. For a more thorough discussion of these issues, I have to refer the reader to more specialized texts e e.g., Chapter IX of the Landau and Lifshitz volume cited above, or Chapter 15 in I. M. Cohen and P. K. Kundu, Fluid Mechanics, $4^{\text {th }}$ ed., Academic Press, 2007 - which is generally a good book on the subject. Another popular, rather simple textbook is R. A. Granger, Fluid Mechanics, Dover, 1995.

[^133]:    ${ }^{39}$ Note that the "dynamic" viscosity $\eta$ participates in this number (and many other problems of fluid dynamics) only in the combination $\eta / \rho$ that thereby has deserved a special name of kinematic viscosity.
    ${ }^{40}$ For example, the values of $\eta$ and $\rho$ for water listed in Table 1 imply that for a few-meter object, $R e>1,000$ at any speed above just $\sim 1 \mathrm{~mm} / \mathrm{s}$.
    ${ }^{41}$ A rare exception is the relatively recent theoretical result by S. Orszag (1971) for the turbulence threshold in a flow of an incompressible fluid through a gap of thickness $t$ between two parallel plane walls: $R e_{t} \approx 5,772$ (for $l=$ $\left.t / 2, v=v_{\max }\right)$. However, this result does not predict the turbulence patterns at $R e>R e_{t}$.
    ${ }^{42}$ The crucial condition of correct modeling is the equality of the Reynolds numbers (74) (and if relevant, also of the Froude numbers and/or the Mach numbers) of the object of interest and its model.
    ${ }^{43}$ See, e.g., P. A. Davidson, Turbulence, Oxford U. Press, 2004.
    ${ }^{44}$ The following famous quote is attributed to W. Heisenberg on his deathbed: "When I meet God, I will ask him two questions: Why relativity? And why turbulence? I think he will have an answer for the first question." Though probably inaccurate, this story reflects rather well the understandable frustration of the fundamental physics community, known for their reductionist mentality, with the enormous complexity of phenomena which obey simple (e.g., Navier-Stokes) equations.

[^134]:    ${ }^{45}$ See, e.g., EM Secs. 2.6, 3.3, and 4.3.

[^135]:    ${ }^{46}$ See, e.g., EM Sec. 2.5(iv) and/or QM Sec. 3.6.

[^136]:    ${ }^{1}$ In this context, this term is understood as "systems described by deterministic differential equations".
    ${ }^{2}$ Actually, the notion of quasi-random dynamics due to the exponential divergence of trajectories may be traced back at least to (apparently independent) works by J. Poincaré in 1892 and by J. Hadamard in 1898. Citing Poincaré, "...it may happen that small differences in the initial conditions produce very great ones in the final phenomena. [...] Prediction becomes impossible."
    ${ }^{3}$ Its chaotic properties were first discussed in 1976 by R. May, though the map itself is one of simple ecological models repeatedly discussed earlier, and may be traced back at least to the 1838 work by P. Verhulst.
    ${ }^{4}$ Since the maximum value of function $f(q)$, achieved at $q=1 / 2$, equals $r / 4$, the mapping may be limited by segment $x=[0,1]$, if parameter $r$ is between 0 and 4 . Since all interesting properties of the map, including chaos, may be found within these limits, I will focus on this range.

[^137]:    ${ }^{5}$ The reader should remember that just as the usual ("nature") experiments, numerical experiments also have limited accuracy, due to unavoidable rounding errors.
    ${ }^{6}$ The geometry of these regions are essentially fractal, i.e. has a dimensionality intermediate between 0 (which any final set of geometric points would have) and 1 (pertinent to a 1D continuum). An extensive discussion of fractal geometries, and their relation to the deterministic chaos may be found, e.g., in the book by B. B. Mandelbrot, The Fractal Geometry of Nature, W. H. Freeman, 1983.
    ${ }^{7}$ This does not mean that the chaos development is a monotonic function of $r$. As Fig. 2 shows, within certain intervals of this parameter chaos suddenly disappears, being replaced, typically, with a few-point limit cycle, just to resume on the other side of the interval. Sometimes (but not always!) the "route to chaos" on the borders of these intervals follows the same Feigenbaum sequence of period-doubling bifurcations.

[^138]:    ${ }^{8}$ After A. Lyapunov (1857-1918), famous for his studies of stability of dynamic systems.
    ${ }^{9} \mathrm{~N}$-dimensions maps, which relate $N$-dimensional vectors rather than scalars, may be characterized by $N$ Lyapunov exponents rather than one. In order to have chaotic behavior, it is sufficient for just one of them to become positive. For such systems, another measure of chaos, the Kolmogorov entropy, may be more relevant. This measure, and its relation with the Lyapunov exponents, are discussed, e.g., in SM Sec. 2.2.
    ${ }^{10}$ See, e.g., Chapters 2-4 in H. G. Schuster and W. Just, Deterministic Chaos, $4^{\text {th }}$ ed., Wiley-VCH, 2005, or Chapters 8-9 in J. M. T. Thompson and H. B. Stewart, Nonlinear Dynamics and Chaos, $2^{\text {nd }}$ ed., Wiley, 2002.

[^139]:    ${ }^{11}$ In the actual simulation, a small term $\varepsilon q$, with $\varepsilon \ll 1$, has been added to the left-hand part of this equation. This term slightly somewhat tames the trend of the solution to spread along $q$ axis, and makes the presentation of results easier, without affecting the system dynamics too much.

[^140]:    ${ }^{12}$ In some cases, it is possible to predict a parameter region where chaos cannot happen, due to lack of any instability-amplification mechanism. Unfortunately, typically the analytically predicted boundaries of such region form a rather loose envelope of the actual (numerically simulated) chaotic regions.

[^141]:    ${ }^{13}$ A mathematically-strict formulation of this statement is called the Poincaré-Bendixon theorem, which was proved by I. Bendixon as early as in 1901.
    ${ }^{14}$ Since a typical dynamic system with one degree of freedom is described by two such equations, the number of the first-order equations describing a dynamic system is sometimes called the number of half-degrees of freedom. This notion is very useful and popular in statistical mechanics - see, e.g., SM Sec. 2.2 and on.

[^142]:    ${ }^{15}$ A more scientific-sounding name for such a reflection is specular (from Latin "speculum" meaning a metallic mirror).
    ${ }^{16}$ Indeed, it is fully described by Lagrangian function $L=m v^{2} / 2-U(\rho)$, with $U(\rho)=0$ for 2D radius-vectors $\rho$ belonging to the table area, and $U(\rho)=+\infty$ outside of the area.

[^143]:    ${ }^{17}$ Superficially, Eq. (17) is also valid for a plane wall, but as was discussed above, a billiard with such walls features a full correlation between sequential reflections, so that angle $\varphi$ always returns to its initial value. In a Sinai billiard, such correlation disappears. Because of that, concave walls may also make a billiard chaotic. A famous example is the stadium billiard, suggested by L. Bunimovich, with two straight, parallel walls connecting two semi-circular, concave walls. Another example, which allows a straightforward analysis, is the Hadamard billiard: an infinite (or rectangular) table with non-horizontal surface of negative curvature.
    18 Billiards are also a convenient platform for a discussion of a conceptually important issue of quantum properties of classically chaotic systems (sometimes improperly named "quantum chaos").
    ${ }^{19}$ Actually, quantitative characterization of the fraction is not trivial, because it may have fractal dimensionality. Unfortunately, due to lack of time I have to refer the reader interested in this issue to special literature, e.g., the monograph by B. Mandelbrot (cited above) and references therein.

[^144]:    ${ }^{20}$ It was first studied in 1964 by M. Hénon and C. Heiles as a simple model of star rotation about a gallactic center. Most studies of this equation have been carried out for the following particular case: $m_{2}=2 m_{1}, m_{1} \omega_{1}{ }^{2}=$ $m_{2} \omega_{2}^{2}$. In this case, introducing new variables $x \equiv \varepsilon q_{1}, y \equiv \varepsilon q_{2}$, and $\tau \equiv \omega_{1} t$, it is possible to rewrite Eqs. (18)-(20) in parameter-free forms. All the results shown in Fig. 9 below are for this case.
    ${ }^{21}$ Generally, it has a trajectory in 4D space, e.g., that of coordinates $q_{1,2}$ and their time derivatives, although the first integral of motion (20) means that for each fixed energy $E$, the motion is limited to a 3D sub-space. Still, this is too much for convenient representation of the motion.

[^145]:    ${ }^{22}$ See, e.g., M. V. Berry, in: S. Jorna (ed.), Topics in Nonlinear Dynamics, AIP Conf. Proc. No. 46, AIP, 1978, pp. 16-120.
    ${ }^{23}$ This fact complies with the necessary condition of chaos, discussed in the end of Sec. 2, because Eqs. (19) may be rewritten as a system of four differential equations of the first order.

[^146]:    ${ }^{24}$ An important milestone on that way was the work by S. Newhouse et al., Comm. Math. Phys. 64, 35 (1978), who proved the existence of a strange attractor in a rather abstract model of fluid flow.
    ${ }^{25}$ See, e.g., U. Frisch, Turbulence: The Legacy of A. N. Kolmogorov, Cambridge U. Press, 1996.
    ${ }^{26}$ The reader interested in the deterministic chaos as such, may also like to have a look at a very popular book by S. Strogatz, Nonlinear Dynamics and Chaos, Westview, 2001.

[^147]:    ${ }^{1}$ Due to not only W. Hamilton (1805-1865), but also and C. Jacobi (1804-1851).
    ${ }^{2}$ Actually, this differential has already been used in Sec. 2.3 to derive Eq. (2.35).

[^148]:    ${ }^{3}$ Of course, the right-hand part of each equation (7) generally can include coordinates and momenta of other degrees of freedom as well, so that the equations of motion for different $j$ are generally coupled.

[^149]:    ${ }^{4}$ Named after S. Poisson - of the Poisson equation and the Poisson statistical distribution fame.

[^150]:    ${ }^{5}$ See, e.g., QM Sec. 2.1.
    ${ }^{6}$ There is of course a conceptual difference between the "usual" products of function derivatives participating in the Poisson brackets, and the operator "products" (meaning their sequential action on a state vector - see, e.g., QM Sec. 4.1) forming the commutator.

[^151]:    ${ }^{7}$ See, e.g., QM Sec. 4.6.
    ${ }^{8}$ Various aspects of this problem and its quantum-mechanical extension were first discussed by L. Le Cornu (1895), Lord Rayleigh (1902), H. Lorentz (1911), P. Ehrenfest (1916), and M. Born and V. Fock (1928).
    ${ }^{9}$ This term has come from thermodynamics and statistical mechanics, where it implies not only a slow parameter variation, but also the thermal insulation of the system - see, e.g., SM Sec. 1.3. Evidently, the latter condition is irrelevant in our current context.
    ${ }^{10}$ In Sec. 4.6, we discussed this plane for the particular case of sinusoidal oscillations - see Fig. 9

[^152]:    ${ }^{11}$ This is the most critical point of this proof, because at any finite rate of parameter change the oscillations are, strictly speaking, non-periodic. Because of the approximate nature of this conjecture (which is very close to the assumptions made at the derivation of the RWA equations in Sec. 4.3), new, more strict (but also much more

[^153]:    ${ }^{12}$ For certain particular oscillators, e.g., a mathematical pendulum, Eq. (42) may be also proved directly - an exercise highly recommended to the reader.
    ${ }^{13}$ This, again, is a plausible argument but not a strict proof. Indeed, though, according to its definition (39), $J$ is nothing more than a sum of several (formally, infinite number of) values of momentum $p$, they are not independent, but have to be selected on the same closed trajectory on the phase plane. For more mathematical vigor, the reader is referred to Sec. 45 of Mechanics by Landau and Lifshitz (which was repeatedly cited above), which discusses the general rules of the so-called canonical transformations from one set of Hamiltonian arguments to another one - say from $\{p, q\}$ to $\{J, \Theta\}$.

[^154]:    ${ }^{14}$ See, e.g., Chapter 6 in J. Jose and E. Saletan, Classical Dynamics, Cambridge U. Press, 1998.

[^155]:    ${ }^{15}$ Please note that despite a close relation between the abbreviated action $S_{0}$ and the action variable $J$ defined by Eq. (39), these notions are not identical. Most importantly, $J$ is an integral over a closed trajectory, while $S_{0}$ in defined for an arbitrary point of a trajectory.
    ${ }^{16}$ See, e.g., QM Sec. 2.3.

[^156]:    ${ }^{17}$ Eq. (58) was the starting point for R. Feynman's development of his path-integral formulation of quantum mechanics - see, e.g., QM Sec. 5.3.
    18 As a reminder, we have run into a similar situation at our discussion of the non-degenerate parametric excitation in Sec. 5.5.

[^157]:    ${ }^{19}$ See, e.g., Chapters 6-9 in I. C. Percival and D. Richards, Introduction to Dynamics, Cambridge U. Press, 1983.
    ${ }^{20}$ See, e.g., T. P. Bertsekas, Dynamic Programming and Optimal Control, vols. 1 and 2, Aetna Scientific, 2005 and 2007. The reader should not be deceived by the unnatural term "dynamic programming" that was invented by the founding father of this field, R. Bellman, to lure government bureaucrats into funding his research, which had been deemed too theoretical at that time, but now has a broad range of important applications.

[^158]:    ${ }^{1}$ For remedial reading, virtually any undergraduate text on electricity and magnetism may be used; I can recommend either the classical text by I. Tamm, Fundamentals of Theory of Electricity, Mir, 1979, or the more readily available textbook by D. Griffiths, Introduction to Electrodynamics, $3^{\text {rd }}$ ed., Prentice-Hall, 1999.
    ${ }^{2}$ Discovered experimentally in the early 1780 s, and formulated in 1785 by C.-A. de Coulomb.
    ${ }^{3}$ On the top of the more general notions of classical Cartesian space, point particles and forces, which are used in classical mechanics - see, e.g., CM Sec. 1.1. (Acronyms CM, SM, and QM refer to other three parts of my lecture note series. In those parts, this Classical Electrodynamics part is referred to as EM.)
    ${ }^{4}$ As in all other parts of my lecture notes, chapter numbers are omitted in references to equations, figures, and sections within the same chapter.

[^159]:    ${ }^{5}$ In the formal metrology, one coulomb is defined as the charge carried over by a constant current of one ampere (see Ch. 5 for its definition) during one second.
    ${ }^{6}$ Constant $\varepsilon_{0}$ is called either the electric constant or the free space permittivity; from Eq. (2) with the free-space speed of light $c \approx 3 \times 10^{8} \mathrm{~m} / \mathrm{c}, \varepsilon_{0} \approx 8.85 \times 10^{-12}$ SI units. For more accurate values of the constants, and their brief discussion, see appendix CA: Selected Physical Constants.
    ${ }^{7}$ Physically this is a very strong statement: it means that Eq. (1) is valid for any pair of charges regardless of presence of other charges, i.e. not only in the free space, but in also placed into an arbitrary medium. The apparent modification of this relation by conductors (Ch. 2) and dielectrics (Ch. 3) is just the result of appearance of additional electric charges within those media.

[^160]:    ${ }^{8}$ Moreover, there are some widely used approximations, e.g., the Kohn-Sham equations in the density functional theory of multiparticle systems, which essentially violate this law, thus limiting the accuracy and applicability of these approximations - see, e.g., QM Sec. 8.4.
    ${ }^{9}$ The 2D (areal) charge density $\sigma$ and 1D (linear) density $\lambda$ may be defined absolutely similarly: $d Q=\sigma d^{2} r, d Q=$ $\lambda d r$. Note that a finite value of $\sigma$ and $\lambda$ means that the volume density $\rho$ is infinite in the charge location points; for example for a plane $z=0$, charged with a constant areal density $\sigma, \rho=\sigma \delta(z)$.

[^161]:    ${ }^{10}$ Note that for a continuous, smooth charge distribution, integral (9) does not diverge at $\mathbf{R} \equiv \mathbf{r}-\mathbf{r}^{\prime} \rightarrow 0$, because in this limit the fraction under the integral increases as $R^{-2}$, i.e. slower than the decrease of the elementary volume $d^{3} r^{\prime}$, proportional to $R^{3}$.
    ${ }^{11}$ See, e.g., Sec. 14 of the Selected Mathematical Formulas appendix, referred below as MA.

[^162]:    ${ }^{12}$ Actually, the term "curse of dimensionality" was coined in the 1950s by R. Bellman in the context of the optimal control theory, and only later spread to other sciences that heavily rely on numerical calculations.

[^163]:    ${ }^{13}$ See, e.g., MA Eq. (12.2). Note that the scalar product under the integral in Eq. (25) is nothing more that the divergence of vector $\mathbf{E}$ - see, e.g., MA Eq. (8.4).
    ${ }^{14}$ See, e.g., MA Secs. 8-10.
    ${ }^{15}$ In the Gaussian units, just as in the initial Eq. (5), $\varepsilon_{0}$ has to be replaced with $1 / 4 \pi$, so that the Maxwell equation (27) looks like $\nabla \cdot \mathbf{E}=4 \pi \rho$, while Eq. (28) stays the same.
    ${ }^{16}$ This follows, for example, from the direct application of MA Eq. (10.11) to the spherically-symmetric vector function $\mathbf{f}=\mathbf{E}(\mathbf{r})=E(r) \mathbf{n}_{r}$ field of a point charge placed at the origin, giving $f_{\theta}=f_{\varphi}=0$ and $\partial f_{r} / \partial \theta=\partial f_{r} / \partial \varphi=0$.
    ${ }^{17}$ See, e.g., MA Eq. (10.10) for this particular case (when $\partial / \partial \theta=\partial / \partial \varphi=0$ ).

[^164]:    ${ }^{18}$ See, e.g., CM Sec. 1.4.
    ${ }^{19}$ Eq. (28) could be also derived from this relation, because according to vector algebra, any gradient field has vanishing curl - see, e.g., MA Eq. (11.1).

[^165]:    ${ }^{20}$ This may be done either by Cartesian components or using the well-known expression $\nabla f=(d f / d r) \mathbf{n}_{r}$ valid for any spherically-symmetric scalar function $f(r)$ - see, e.g., MA Eq. (10.8) for the particular case $\partial / \partial \theta=\partial / \partial \varphi=0$.

[^166]:    ${ }^{21}$ Named after S. D. Poisson (1781-1840), also famous for the Poisson distribution - one of the central results of the probability theory - see, e.g., SM Sec. 5.2.
    ${ }^{22}$ After mathematician (and astronomer) P. S. de Laplace (1749-1827) who, together with A. Clairault, is credited for the development of the very concept of potential.

[^167]:    ${ }^{23}$ See, e.g., MA Eq. (10.8) for $\partial / \partial \theta=\partial / \partial \varphi=0$.

[^168]:    ${ }^{24}$ The nature of this additional factor $1 / 2$ is absolutely the same as in the well-known formula $U=(1 / 2) k x^{2}$ for the potential energy of an elastic spring providing returning force $F=-\kappa x$ proportional to the deviation $x$ from equilibrium.
    ${ }^{25}$ This transformation follows from the divergence theorem MA (12.2) applied to vector function $\mathbf{f}=\phi \nabla \phi$, taking into account the 3D differentiation rule MA Eq. (11.4a): $\nabla \cdot(\phi \nabla \phi)=(\nabla \phi) \cdot(\nabla \phi)+\phi \nabla \cdot(\nabla \phi)=(\nabla \phi)^{2}+\phi \nabla^{2} \phi$.

[^169]:    ${ }^{26}$ In the Gaussian units, the standard replacement $\varepsilon_{0} \rightarrow 1 / 4 \pi$ turns the last of Eqs. (67) into $u(\mathbf{r})=E^{2} / 8 \pi$.
    ${ }^{27}$ Note that $U \rightarrow \infty$ at $R \rightarrow 0$. Such divergence appears at application of Eq. (67) to any point charge. Since it does not affect the force acting on the charge, the divergence does not create any technical difficulty for analysis of charge statics or non-relativistic dynamics, but it points to a conceptual problem of classical electrodynamics as the whole. This issue will be discussed in the very end of the course (Sec. 10.6).

[^170]:    ${ }^{28}$ This is only the simplest one of the whole family of reciprocity theorems in electromagnetism. (Sometimes it is called "Green's reciprocity theorem", but historically it is more fair to reserve the last name for the generalization to surface charges, using Eq. (2.210), to be discussed in Sec. 2. 7 below.)

[^171]:    ${ }^{1}$ More detailed discussions may be found, e.g., in Sec. 13.5 of J. Hook and H. Hall, Solid State Physics, $2^{\text {nd }}$ ed., Wiley, 1991, or the section on electric field screening in Chapter 17 of N. Ashcroft and N. Mermin, Solid State Physics, Brooks Cole, 1976.
    ${ }^{2}$ This term, used for electric field, should not be confused with shielding - the word used for the description of magnetic field reduction by magnetic materials - see Chapter 5 below.

[^172]:    ${ }^{3}$ See, e.g., MA Eq. (12.1).

[^173]:    ${ }^{4}$ This scale originates from the quantum-mechanical effects of electron motion, characterized by the Bohr radius $r_{\mathrm{B}} \approx 0.5 \times 10^{-10} \mathrm{~m}-$ see, e.g., QM Eq. (1.13).
    ${ }^{5}$ Here $e$ denotes the positive fundamental charge, $e \approx 1.6 \times 10^{-19} \mathrm{C}$, so that the electron charge equals $(-e)$.
    ${ }^{6}$ See, e.g., SM Sec. 3.1.
    ${ }^{7}$ This equation and/or its straightforward generalization to the case of charged particles (ions) of several kinds is frequently (especially in the theories of electrolytes and plasmas) called the Debye-Hückel equation.

[^174]:    ${ }^{8}$ There is a good reason for making an estimate of $\lambda_{\mathrm{D}}$ for this case: the electric field created by the gate electrode of a field-effect transistor, penetrating into doped silicon by a depth $\sim \lambda_{\mathrm{D}}$, controls current in this most important electronic device - on whose back all the current information revolution rides. Because of that, $\lambda_{\mathrm{D}}$ establishes the possible scale of semiconductor circuit shrinking which is the basis of the well-known Moore's law. (Practically, the scale is determined by integrated circuit patterning techniques, and Eq. (8) may be used to find the proper charge carrier density $n$ and hence the level of silicon doping.)
    ${ }^{9}$ See, e.g., SM Sec. 2.8. For a more detailed derivation of Eq. (10), see SM Chapter 3.
    ${ }^{10}$ In good metals this equation is valid up to the fields $\sim E_{\mathrm{F}} / e \lambda_{\mathrm{TF}} \sim 10^{9} \mathrm{~V} / \mathrm{m}$, very high by the usual standards. For example, the electric breakdown threshold for vacuum (or air-filled) gaps is $\sim 3 \times 10^{6} \mathrm{~V} / \mathrm{m}$.
    ${ }^{11}$ See, e.g., SM Sec. 3.3.

[^175]:    ${ }^{12}$ In the Gaussian units, using the standard replacement $4 \pi \varepsilon_{0} \rightarrow 1$, this relation takes a remarkably simple form: $C$ $=R$, good to remember. Generally, in the Gaussian units (but not in the SI system!) the capacitance has the dimensionality of length, i.e. is measured in centimeters. Note also that a convenient fractional SI unit, 1 picofarad $\left(10^{-12} \mathrm{~F}\right)$ is very close to the Gaussian unit: $1 \mathrm{pF}=\left(1 \times 10^{-12}\right) /\left(4 \pi \varepsilon_{0} \times 10^{-2}\right) \approx 0.8998 \mathrm{~cm}$.
    ${ }^{13}$ These arguments are somewhat insufficient to say which size should be used for $a$ in the case of narrow, extended conductors, e.g., a thin, long wire of length $L$ and diameter $D \ll L$. In the Very soon we will see that in such cases the electrostatic energy, and hence $C$, should mostly depend on the larger size of the conductor.

[^176]:    ${ }^{14}$ See, e.g., CM Chapter 2.
    ${ }^{15}$ A word of caution: in condensed matter physics, voltage is usually defined differently, as the difference of electrochemical rather than electrostatic potentials - see, e.g., SM Sec. 6.4. These two definitions coincide if the conductors have equal workfunctions (for example, if they are made of the same material), and in this course their difference will be ignored.

[^177]:    $C_{m}$ of planar capacitor

[^178]:    ${ }^{16}$ Frequently referred to "fringe" fields resulting in an additional "stray" capacitance $C_{m}{ }^{\prime} \sim \varepsilon_{0} a$.
    ${ }^{17}$ Just as in Sec. 1, in order for the estimate to be realistic, I took into account the additional factor $\varepsilon_{r}$ (for aluminum oxide, close to 10 ) which should be included into the numerator of Eq. (28) to make it applicable to dielectrics - see Chapter 3 below.

[^179]:    ${ }^{18}$ In electrical engineering, such constant-potential conductor is called the ground. This term stems from the fact that in many cases the Earth surface may be considered a good electric ground, because its potential is unaffected by laboratory-scale electric charges.

[^180]:    ${ }^{19}$ See, e.g. MA Eq. (9.1).

[^181]:    ${ }^{20}$ See, e.g., MA Eq. (10.3).
    ${ }^{21}$ See, e.g., MA Eq. (10.2).

[^182]:    ${ }^{22}$ Alternative names for this surface are "degenerate ellipsoid", "ellipsoid of rotation", and "spheroid".

[^183]:    ${ }^{23}$ I have called disk's potential $V$, to distinguish it from the potential $\phi$ at an arbitrary point of space.

[^184]:    ${ }^{24}$ If you seriously worry about the formal infinity of charge density at $r \rightarrow R$, please remember that this mathematical artifact disappears for any nonvanishing disk thickness.
    ${ }^{25}$ The complex variable $z$ should not be confused with the (real) $3^{\text {rd }}$ spatial coordinate $z$ ! We are considering 2D problems now, with the potential independent of $z$.

[^185]:    ${ }^{26}$ The analytic (or "holomorphic") function may be defined as the one that may be expanded into the complex Taylor series, i.e. is infinitely differentiable in the given point. (Almost all "regular" functions, such as $\boldsymbol{z}^{n}, \boldsymbol{z}^{1 / n}$, $\exp \boldsymbol{z}, \ln \boldsymbol{z}$, etc. and their combinations are analytic at all $\boldsymbol{z}$, maybe besides certain special points.) If the reader needs to brush up his or her background on this subject, I can recommend a popular (and very inexpensive :-) textbook by M. Spiegel et al., Complex Variables, ${ }^{\text {nd }}$ ed., McGraw-Hill, 2009.
    ${ }^{27}$ These relations may be, in particular, to prove the famous Cauchy integral formula - see, e.g., MA Eq. (15.1).
    ${ }^{28}$ Let me remind the reader that in mathematics, term cylindrical describes a surface formed by translation, along a straight line, of an arbitrary curve, and hence more general than the usual circular cylinder. (In this terminology, for example, a prism is also a particular form of cylinder, formed by translating a polygon.)

[^186]:    ${ }^{29}$ See, e.g., textbook by P. Grivet, Electron Optics, $2^{\text {nd }}$ ed., Pergamon, 1972, or the review collection A. Septier (ed.), Focusing Charged Particles, vol. I, Academic Press, 1967, in particular the review by K.-J. Hanszen and R. Lauer, pp. 251-307.

[^187]:    ${ }^{30}$ Integral (70) includes only $(N-1)$ rather than $N$ poles, because polygon's shape is completely determined by $(N$ - 1) positions $\boldsymbol{\omega}_{j}$ of its vertices and $(N-1)$ angles $\pi k_{j}$. In particular, since the algebraic sum of all external angles of a polygon equals $\pi$, the last angle parameter $k_{j}=k_{N}$ is uniquely determined by the set of the previous ones.

[^188]:    ${ }^{31}$ See, e.g., MA Eq. (3.5).

[^189]:    ${ }^{32}$ This result could also be obtained using the so-called elliptical (not ellipsoidal!) coordinates.
    ${ }^{33}$ Another graphical representation of the electric field distribution, by field lines, is much less convenient. As a reminder, the field lines are defined as lines to whom the (in our current case, electrostatic) field vectors are tangential at each point. By this definition, the field lines are always normal to the equipotential surfaces, so that it is always straightforward to sketch them from the equipotential surface pattern - such as shown in Fig. 10.

[^190]:    ${ }^{34}$ Such distributions may be implemented in practice using so-called mosaic electrodes consisting of many electrically-insulated and individually-biased panels.

[^191]:    ${ }^{35}$ Note that according to Eqs. (91)-(92), as the spatial dimensions $a$ and $b$ of the system are increased, the distances between adjacent eigenvalues tend to zero. This fact implies that for spatially-infinite, non-periodic systems, the eigenvalue spectra are continuous, so that the sums of the type (84) become integrals. A few problems of this type are provided in Sec. 9 for reader's exercise.

[^192]:    ${ }^{36}$ See, e.g., MA Eq. (10.3) with $\partial / \partial z=0$.

[^193]:    ${ }^{38}$ This problem does belong to our current topic of electrostatic fields between conductors, because the uniform electric field may be created by a large plane capacitor.

[^194]:    ${ }^{39}$ Exceptions are possible only for highly symmetric configurations when the external field are crafted to make $a_{1}$ $=0$. In this case the solution is led by the first nonvanishing term of the series (121).

[^195]:    ${ }^{40}$ See，e．g．，MA Eq．（10．3）．
    ${ }^{41}$ Please note that this normalization is specific for each value of the variable separation parameter $\gamma$ ．Also，note that the normalization is meaningless for $\gamma=0$ ，i．e．for the case $Z(z)=$ const．However，if we need partial solutions for this value of $\gamma$ ，we can use Eqs．（108）－（109）．

[^196]:    ${ }^{42}$ For a more complete discussion of these functions, see the literature listed in MA Sec. 16, for example, Chapter 9 (written by F. Olver) in the collection compiled and edited by Abramowitz and Stegun.

[^197]:    ${ }^{43}$ These two formulas for the Bessel function peak are strictly valid for $n \gg 1$, but may be used for reasonable estimates starting already from $n=1$; for example, $\max _{\xi}\left[J_{1}(\xi)\right]$ is close to 0.58 and is reached at $\xi \approx 2.4$, just about $30 \%$ away from the values given by the asymptotic formulas.
    ${ }^{44}$ Eq. (135) and Fig. 16 clearly show the close analogy between the Bessel functions and the usual trigonometric functions, sine and cosine. In order to emphasize this similarity, and help the reader to develop more gut feeling of the Bessel functions, let me mention one fact of the elasticity theory: while sine functions describe, in particular, possible modes of standing waves on a guitar string, functions $J_{n}(\xi)$ describe, in particular, possible standing waves on an elastic round membrane, with $J_{0}(\xi)$ describing their lowest (fundamental) mode.

[^198]:    ${ }^{48}$ See, e.g., MA Eq. (6.7a). I used word "almost" because the gamma-function tends to infinity at all non-positive integer values of its argument $(s=0,-1 .-2, \ldots)$.
    ${ }^{49}$ They are also sometimes called the Neumann functions, and denoted as $N_{\wedge}(\xi)$.

[^199]:    ${ }^{50}$ A pair of independent linear functions，used for presentation of the general solution of the Bessel equation，may be also chosen in a different way，using the so－called Hankel functions

    $$
    H_{n}^{(1,2)}(\xi) \equiv J_{n}(\xi) \pm i Y_{n}(\xi) .
    $$

    For representing the general solution of Eq．（130），this alternative is completely similar to using the pair of complex functions $\exp \{ \pm i \alpha x\}=\cos \alpha x \pm i \sin \alpha x$ instead of the pair of real functions $\{\cos \alpha x, \sin \alpha x\}$ for representing the general solution of Eq．（89）for $X(x)$ ．

[^200]:    ${ }^{51}$ These complex functions still obey the general relations (143) and (146), with $\xi$ replaced with $\boldsymbol{z}$.

[^201]:    ${ }^{52}$ Later in the course we will also run into the so-called spherical Bessel functions $j_{n}(\xi)$ and $y_{n}(\xi)$, which may be expressed via the Bessel functions of a semi-integer order. Surprisingly enough, the spherical Bessel functions turn out to be much simpler than $J_{n}(\xi)$ and $Y_{n}(\xi)$.
    ${ }^{53}$ See, e.g., MA Eq. (10.9).

[^202]:    ${ }^{54}$ Just for reader's reference: if $l$ is not integer, the general solution of Eq. (2.168) may be represented as a linear combination of the so-called Legendre functions (not polynomials!) of the first and second kind, $\mathcal{P}_{1}(\xi)$ and $Q_{l}(\xi)$.

[^203]:    ${ }^{55}$ As a result, there is not practical sense, at least for the purposes of this course, in pursuing (more complex) solutions to Eq. (168) for non-integer values of $l$.

[^204]:    ${ }^{56}$ In quantum mechanics, letter $n$ is typically reserved used for the "main quantum number", while the azimuthal functions are numbered by index $m$. However, I will keep using $n$ as their index, because for this course's purposes, this seems more logical in the view of the similarity of the spherical and cylindrical functions.

[^205]:    ${ }^{57}$ In quantum mechanics, it is more convenient to use a slightly different set of basic functions, namely complex functions called spherical harmonics,

    $$
    Y_{l}^{n}(\theta, \varphi) \equiv\left[\frac{2 l+1}{4 \pi} \frac{(l-n)!}{(l+n)!}\right]^{1 / 2} P_{l}^{n}(\cos \theta) e^{i n \varphi},
    $$

    which are defined for both positive and negative $n$ (within the limits $-l \leq n \leq+l$ ), because they form a full set of orthonormal eigenfunctions of angular momentum operators $L^{2}$ and $L_{z}-$ see, e.g., QM Secs. 3.6 and 5.6.

[^206]:    ${ }^{58}$ According to Eq. (179), these functions involve only the Legendre polynomials $\mathcal{P}_{l} \equiv \mathcal{P}_{l}^{0}$.

[^207]:    59 Actually, this term (for which the author of these notes should be blamed :-) is misleading: operation of the "single-electron transistor" is based on the interplay of discrete charges (multiples of $e$ ) transferred between conductors, and sub-single-electron polarization charges - see, e.g., K. K. Likharev, Proc. IEEE 87, 606 (1999).

[^208]:    ${ }^{60}$ For more discussion of workfunction, and its effect on electron kinetics, see, e.g., SM Sec. 6.4.

[^209]:    ${ }^{61}$ The practical development of such "cold" cathodes is strongly affected by the fact that any nanoscale surface irregularity (a protrusion, an atomic cluster, or even a single "adatom" stuck to the surface) may cause a strong increase of the local field well above the average applied field $E_{0}$ (see, for example our discussion in Sec. 4 above), making the emission reproducibility an issue.

[^210]:    ${ }^{62}$ In geometry, such points, with $d d^{\prime}=R^{2}$, are referred to as the result of mutual inversion in a sphere of radius $R$.

[^211]:    ${ }^{63}$ See, e.g., CM Sec. 4.1, QM Secs. 2.2, 7.2 and 7.4, and SM Sec. 5.5.
    ${ }^{64} G$ so defined is sometimes called the Dirichlet function.

[^212]:    ${ }^{65}$ See, e.g., MA Eq. (12.3). Actually, this theorem is a ready corollary of the divergence theorem, MA Eq. (12.2).
    ${ }^{66}$ This symmetry, virtually evident from Eq. (204), may be formally proved by applying Eq. (207) to functions $f$ $(\mathbf{r}) \equiv G\left(\mathbf{r}, \mathbf{r}^{\prime}\right)$ and $g(\mathbf{r}) \equiv G\left(\mathbf{r}, \mathbf{r}^{\prime \prime}\right)$. With this substitution, the left-hand part becomes equal to $-4 \pi\left[G\left(\mathbf{r}^{\prime \prime}, \mathbf{r}^{\prime}\right)-G\left(\mathbf{r}^{\prime}\right.\right.$, $\left.\mathbf{r}^{\prime \prime}\right)$, while the right-hand part is zero, due to Eq. (205).

[^213]:    ${ }^{67}$ In some textbooks, the sign before the surface integral is negative, because their authors use the outer normal of the free-space region $V$ rather than that occupied by conductors - as I do.
    ${ }^{68}$ Indeed, if all parts of the cut plane are grounded, a narrow cut does not change the field distribution, and hence the Green's function, significantly.

[^214]:    ${ }^{69}$ See, for example, MA Secs. 16 (iii) and (iv).
    ${ }^{70}$ For more details see, e.g., R. Leveque, Finite Difference Methods for Ordinary and Partial Differential Equations, SIAM, 2007.

[^215]:    ${ }^{71}$ See, e.g., C. Johnson, Numerical Solution of Partial Differential Equations by the Finite Element Method, Dover, 2009, or T. J. R. Hughes, The Finite Element Method, Dover, 2000.

[^216]:    ${ }^{72}$ This fact should not be surprising, because Eq. $\left(^{*}\right)$ is essentially the conformal map $\boldsymbol{z}=c \cosh \boldsymbol{\omega}$, where $\boldsymbol{z}=x+$ $i y$, and $\boldsymbol{\mu}=\alpha+i \beta$ - see the discussion in Sec. 4 .

[^217]:    ${ }^{73}$ As a reminder, the double factorial (also called "semifactorial") operator (!!) is similar to the usual factorial operator (!), but with the product limited to numbers of the same parity as its argument (in our particular case, of the odd numbers in the numerator, and even numbers in the denominator).

[^218]:    ${ }^{74}$ In this context, weak junction means a tunnel junction with transparency so low that the tunneling electron's wavefunction looses its quantum-mechanical coherence before the electron has time to tunnel back. In a typical junction of a macroscopic area this condition is fulfilled if the effective tunnel resistance of the junction is much higher than the quantum unit of resistance (see, e.g., QM Sec. 3.2), $R_{Q} \equiv \pi \hbar / 2 e^{2} \approx 6.5 \mathrm{k} \Omega$.

[^219]:    ${ }^{75}$ Here the notation $\tan ^{-1}$ is used for the multi-valued function (alternatively called Arctan) which is reciprocal to $\tan$. (Due to the $\pi$-periodicity of the tan, function $\tan ^{-1}$ is defined to an arbitrary additive multiple of $\pi$.) At the value interval $[-\pi / 2,+\pi / 2], \tan ^{-1}$ is usually called arctan.

[^220]:    ${ }^{1}$ See, e.g., MA Eq. (2.11b).
    ${ }^{2}$ The third term (responsible for quadrupole effects), as well as all the following, multipole terms would require a tensor (rather then vector) representation.

[^221]:    ${ }^{3}$ Accordingly, a localized system of charges with $Q=0$, but $\mathbf{p} \neq 0$, is called an (electric) dipole.

[^222]:    ${ }^{4}$ Other examples of dipole fields are given by two more systems discussed in Chapter 2 - see Eqs. (2.215) and (2.219). Those systems, however, do have higher-order multipole moments, so that for them, Eq. (7) gives only the long-distance approximation.
    ${ }^{5}$ See, e.g., MA Eq. (10.8) with $\partial / \partial \varphi=0$.

[^223]:    ${ }^{6}$ See, e.g., SM Sec. 3.5.
    ${ }^{7}$ The equivalence may be proved, for example, by using MA Eq. (11.6) with $\mathbf{f}=\mathbf{p}=$ const and $\mathbf{g}=\mathbf{E}_{\text {ext }}$, taking into account that according to the general Eq. (1.28), $\nabla \times \mathbf{E}_{\text {ext }}=0$.

[^224]:    ${ }^{8}$ See, e.g., the end of Sec. 4.1 in the textbook by J. Jackson, Classical Electrodynamics, $3^{\text {rd }}$ ed., Wiley, 1999.

[^225]:    ${ }^{9}$ To prove this (almost evident) formula strictly, it is sufficient to apply the divergence theorem given by MA Eq. (12.2), to vector function $\mathbf{f}=\mathbf{P}\left(\mathbf{r}^{\prime}\right) /\left|\mathbf{r}-\mathbf{r}^{\prime}\right|$, in the "source space" of radius-vectors $\mathbf{r}$ '.

[^226]:    ${ }^{10}$ Note that the dimensionality of $\mathbf{D}$ in SI units is different from that of $\mathbf{E}$. In contrast, in the Gaussian units the electric displacement is defined as $\mathbf{D}=\mathbf{E}+4 \pi \mathbf{P}$, so that $\nabla \cdot \mathbf{D}=4 \pi \rho$ (the relation $\rho_{\mathrm{ef}}=-\nabla \cdot \mathbf{P}$ remains the same as in SI units), and the dimensionalities of $\mathbf{D}$ and $\mathbf{E}$ coincide. Philosophically, this coincidence is a certain handicap, because it is frequently convenient to consider Cartesian components of $\mathbf{E}$ as a generalized force, and those of $\mathbf{D}$ as a generalized coordinate (see Sec. 6 below), and it is comforting to have their dimensionality different.

[^227]:    ${ }^{11}$ Note, however, that such averaging does not include the inner-dipole fields which is (approximately) described by the second term of Eq. (25).
    ${ }^{12}$ In anisotropic materials, such as crystals, a susceptibility tensor may be necessary to give an adequate description of the linear relation of vectors $\mathbf{P}$ and $\mathbf{E}$. Fortunately, in most important crystals (such as silicon) the anisotropy of polarization is small, so that they may be reasonably well characterized by scalar susceptibility.

[^228]:    ${ }^{13}$ Note that in electrical engineering literature, the dielectric constant is often denoted by letters $\kappa$ or $K$.
    ${ }^{14}$ In Gaussian units, $\chi_{e}$ is defined by relation $\mathbf{P}=\chi_{e} \mathbf{E}$, while $\varepsilon$ is still defined as $\mathbf{D}=\varepsilon \mathbf{E}$. Because of that, $\varepsilon$ is dimensionless and equals $\left(1+4 \pi \chi_{e}\right)$. Note that $(\varepsilon)_{\text {Gaussian }}=\left(\varepsilon / \varepsilon_{0}\right)_{\mathrm{SI}}=\varepsilon_{\mathrm{r}}$, and $\left(\chi_{e}\right)_{\mathrm{SI}}=4 \pi\left(\chi_{e}\right)_{\text {Gaussian }}$, sometimes creating a confusion with the numerical values of the latter parameter.

[^229]:    ${ }^{15}$ Note that for all materials listed in Table $1, \varepsilon_{r}>1$, i.e. $\alpha_{\text {mol }}>0$. Actually, this is true for all stable dielectrics. Let me postpone a discussion of this fact until Sec. 5.5 where I will compare physical mechanisms of the electric and magnetic polarization.
    ${ }^{16}$ A more accurate model of atomic polarization is discussed in QM Chapter 6.
    ${ }^{17}$ See, e.g., SM Secs. 1.4 and 3.1.
    ${ }^{18}$ Such radius is defined by the requirement that the volume of the corresponding sphere, used in the van-derWaals equation (see, e. g., SM Sec. 4.1) gives the best fit to the experimental equation of state $n=n(P, T)$.

[^230]:    ${ }^{19}$ Actually, selecting the slit size $d$ much less that the characteristic scale of the field change, we can apply the following arguments to any external field distribution.

[^231]:    ${ }^{20}$ This is true for any ellipsoid, at arbitrary external field orientation.

[^232]:    ${ }^{21}$ The reader may wonder how have we managed to proof Eq. (24), at least for this particular case, using only the relations based on the dipole approximation (7) for the field, which does not cover the inter-dipole fields responsible for Eq. (24) - see Fig. 3 and its discussion. The reason is that according to Eq. (30), the additional field $\mathbf{E}_{\text {self }}$ inside the sphere may be considered as been created by effective charges, of density $\rho_{\text {ef }}$, distributed on sphere's surface. For these charges, field $\mathbf{E}_{\text {ef }}$ is internal, similar to the field between two charges, shown in Fig. 3.

[^233]:    ${ }^{22}$ This qualifier is important: $\mathbf{E}$ is the long-range (dipole field) average participating in the macroscopic Maxwell equations, rather than the exact average that would include the inner-dipole fields, for which Eq. (24) would be valid.
    ${ }^{23}$ This geometry, due to its isotropy, most fairly represents the relation between $\mathbf{E}$ and $\mathbf{E}_{0}$.

[^234]:    ${ }^{24}$ It was derived by in 1869 by L. Lorenz and then (in 1878) independently by H. Lorentz. Actually, they discussed optical frequencies at which $\varepsilon_{r}$ should be understood as the square of the refraction coefficient at the wave frequency (see Chapter 7), but since the optical wavelengths $\sim 10^{-4} \mathrm{~m}$ are much longer than interatomic distances $a \sim 10^{-9} \mathrm{~m}$, the derivation remains absolutely the same in electrostatics.
    ${ }^{25}$ Any quantitative description of this transition should account of for thermal fluctuations of the molecular dipoles, which reduce the dipole-dipole ordering and hence suppress the transition to the ferroelectric phase until temperature has been lowered to a certain Curie temperature $T_{\mathrm{C}}$ - named after P. Curie (1859-1906). Right above that temperature, the dielectric remains linear, but has a high, temperature-dependent dielectric constant that diverges at $T \rightarrow T_{\mathrm{C}}$. Such materials are frequently called paraelectric, and the paraelectric-to-ferroelectric transition at $T_{\mathrm{C}}$ in crystals is a typical example of a continuous (or "second-order") phase transition - see, e.g., SM Sec. 4.4. (As will be discussed in Sec. 5.5 below, some magnetic materials exhibit a very similar phase transition between their ferromagnetic and paramagnetic phases.) Moreover, in non-crystalline materials, such as bulk ceramics and thin films, the ferroelectric behavior is further complicated by different, field-dependent

[^235]:    directions of polarization $\mathbf{P}$ in individual "domains" of the sample, making the average hysteresis more smooth (Fig. 11a) and dependent on sample's polarization history - for example the amplitude of the applied ac electric field (Fig. 11b).
    ${ }^{26}$ See, e.g., J. F. Scott, Ferroelectric Memories, Springer, 2000.
    ${ }^{27}$ For a detailed coverage of ferroelectrics, I can recommend an encyclopedic monograph by M. Lines and A. Glass, Principles and Applications of Ferroelectrics and Related Materials, Oxford U. Press, 2001, and a recent collection of reviews by K. Rabe, C. Ahn, and J.-M. Triscone (eds.), Physics of Ferroelectrics: A Modern Perspective, Springer, 2010.

[^236]:    ${ }^{28}$ See, e.g., MA Eq. (11.4a).
    ${ }^{29}$ Again, in Gaussian units this expression should be divided by $4 \pi$.

[^237]:    ${ }^{30}$ This is the point where the SI units, prescribing fields $\mathbf{E}$ and $\mathbf{D}$ different dimensionalities, are more revealing than the Gaussian units.
    ${ }^{31}$ See, e.g., CM Sec. 1.5. Note that as Eq. (84) clearly illustrates, once again, that the difference between potential energies $g$ and $U$, usually discussed in courses of statistical physics and/or thermodynamics as the difference between the Gibbs and Helmholtz free energies (see, e.g., SM 1.6), exists regardless of statistics or thermal motion.

[^238]:    ${ }^{32}$ In electrical engineering, such materials (typically, synthetic polymers) are frequently called electrets. As an approximation, this condition may be applied to hard ferroelectrics, if the external or self-induced electric fields are not too high.

[^239]:    ${ }^{1}$ Just as a (hopefully, unnecessary :-) reminder, in the SI units the current is measured in amperes (A). In the legal metrology, the ampere (rather than the coulomb, which is defined as $1 \mathrm{C}=1 \mathrm{~A} \times 1 \mathrm{~s}$ ) is a primary unit. I will mention its formal definition in the next chapter. In the Gaussian units, Eq. (1) remains the same, so that the current's unit is the so-called statampere - defined as statcoulomb per second.

[^240]:    ${ }^{2}$ Similar differential relations are valid for the density of any conserved quantity, for example for mass in classical fluid dynamics (see, e.g., CM Sec. 8.2), and for the probability in statistical physics (SM Sec. 5.6) and quantum mechanics (QM Sec. 1.4).

[^241]:    ${ }^{3}$ In SI units, the conductivity is measured in siemens per meter, where one siemens $(S)$ is the reciprocal of one ohm: $1 \mathrm{~S} \equiv(1 \Omega)^{-1} \equiv 1 \mathrm{~A} / 1 \mathrm{~V}$. The constant reciprocal to conductivity, $1 / \sigma$, is called resistivity, and is commonly denoted by letter $\rho$. I will, however, try to avoid using this notion, because I am already overusing this letter.

[^242]:    ${ }^{4}$ As will be discussed in Chapter 6, such simple analysis is only valid if $\sigma$ is not too high.
    ${ }^{5}$ It was suggested by P. Drude in 1900.

[^243]:    ${ }^{6}$ For such a discussion see, e.g., SM Sec. 6.3.
    ${ }^{7}$ Electrodynamic properties of superconductors are so interesting (and important) that I will discuss them in more detail in Chapter 6.

[^244]:    ${ }^{8}$ Unfortunately, these notes are not an appropriate platform to discuss details of the floating-gate memory technology. However, I think that every educated physicist should know its basics, because such memories are presently the driver of all semiconductor integrated circuit technology development, and hence of the whole information technology progress. Perhaps the best available book is J. Brewer and M. Gill (eds.), Nonvolatile Memory Technologies with Emphasis on Flash, IEEE, 2008.

[^245]:    ${ }^{9}$ The first of Eqs. (21) is essentially the integral form of the Ohm law (8), and is valid not only for a uniform wire, but for any Ohmic conductor with a geometry in which $I$ and $V$ may be clearly defined.

[^246]:    ${ }^{10}$ Such situations are even more natural in 2D situations, for example, think about a wire soldered, in a small spot, to a thin metallic foil. (Note that here the current density distribution law is different, $j \propto 1 / r$ rather than $1 / r^{2}$.)

[^247]:    ${ }^{11}$ In practice, the current injection may be produced, due to electrochemical reactions, by an ore mass itself, so that one need only measure (and interpret :-) the resulting potential distribution - the so-called self-potential method - see, e.g., Sec. 6.1 in monograph by W. Telford et al., Applied Geophysics, $2^{\text {nd }}$ ed., Cambridge U. Press, 1990.
    ${ }^{12}$ Since the electric field and hence the electrostatic energy are time-independent, this means that the energy is replenished at the same rate from the current source(s).

[^248]:    ${ }^{13}$ As was mentioned in Sec. 4.2 of the lecture notes, the assumption of constant (charge-density-independent) mobility is most suitable for semiconductors.

[^249]:    ${ }^{1}$ The most important case when the electroneutrality does not hold is the motion of electrons in vacuum. In this case, magnetic forces coexist with (typically, stronger) electrostatic forces - see Eq. (3) below and its discussion. In some semiconductor devices, local violations of electroneutrality also play an important role.
    ${ }^{2}$ Most notably, by H. C. Ørsted, J.-B. Biot and F. Savart, and A.-M. Ampère.
    ${ }^{3}$ In the Gaussian units, coefficient $\mu_{0} / 4 \pi$ is replaced with $1 / c^{2}$ (i.e., implicitly with $\mu_{0} \varepsilon_{0}$ ) where $c$ is the speed of light, in modern metrology considered exactly known - see, e.g., appendix CA: Selected Physical Constants.

[^250]:    ${ }^{4}$ The discovery and initial studies of such a subtle, relativistic phenomenon as magnetism in the early 19th century was much facilitated by the relative abundance of natural ferromagnets, materials with spontaneous magnetic polarization, whose strong magnetic field may be traced back to relativistic effects (such as spin) in atoms. (The electrostatic analogs of such materials, electrets, are much more rare.) I will briefly discuss the ferromagnetism in Sec. 5 below.

[^251]:    ${ }^{5}$ In particular, Eq. (7) is used for the legal definition of the SI unit of current, one ampere (A), via the SI unit of force (the newton, N ), with coefficient $\mu_{0}$ fixed as listed above.

[^252]:    ${ }^{6}$ The SI unit of the magnetic field is called tesla, T - after N. Tesla, an electrical engineering pioneer. In the Gaussian units, the already discussed constant $1 / c^{2}$ in Eq. (1) is equally divided between Eqs. (8) and (9), so that in them both, the constant before the integral is $1 / c$. The resulting Gaussian unit of field $\mathbf{B}$ is called gauss (G); taking into account the difference of units of electric charge and length, and hence current density, 1 G equals exactly $10^{-4} \mathrm{~T}$. Note also that in some textbooks, especially old ones, $\mathbf{B}$ is called either the magnetic induction, or the magnetic flux density, while the term "magnetic field" is reserved for vector $\mathbf{H}$ that will be introduced Sec. 5 below.
    Named after H. Lorentz, who received a Nobel prize for his explanation of the Zeeman effect, but is more famous for his numerous contributions to the development of special relativity - see Chapter 9. To be fair, the magnetic part of the Lorentz force was correctly calculated first by O. Heaviside.

[^253]:    ${ }^{8}$ See, e.g., MA Eq. (7.5).
    ${ }^{9}$ Just in electrostatics, one needs to exercise due caution at transfer from these expressions to the limit of discrete classical particles, and extended wavefunctions in quantum mechanics, in order to avoid the (non-existing) magnetic interaction of a charged particle upon itself.

[^254]:    ${ }^{10}$ In the Gaussian units, Eq. (27) remains the same, and hence in Eq. (28), coefficient $\mu_{0} / 4 \pi$ is replaced with $1 / c$.
    ${ }^{11}$ See, e.g., MA Eq. (11.2).
    ${ }^{12}$ See, e.g., MA Eq. (11.3).

[^255]:    ${ }^{13}$ As in all earlier formulas for the magnetic field, in the Gaussian units the coefficient $\mu_{0}$ in this relation has to be replaced with $4 \pi / c$.
    ${ }^{14}$ See, e.g., MA Eq. (12.1) with $\mathbf{f}=\mathbf{B}$.

[^256]:    ${ }^{15}$ Applying the Ampère law to a circular contour of radius $\rho$, coaxial with the solenoid, we see that the field outside (but not inside!) it has an azimuthal component $B_{\varphi}$, similar to that of the straight wire (see Eq. (38) above) and hence (at $N \gg 1$ ) much weaker than the longitudinal field inside the solenoid - see Eq. (40).

[^257]:    ${ }^{16}$ See, e.g., MA Eq. (11.1).
    ${ }^{17}$ The use of term "gauge" (originally meaning "a measure" or "a scale") in this context is purely historic, so the reader should not try to find too much hidden sense in it.
    ${ }^{18}$ See, e.g., MA Eq. (10.3).

[^258]:    ${ }^{19}$ See, e.g., MA Eq. (10.5) with $\partial / \partial \varphi=\partial / \partial z=0$.
    ${ }^{20}$ Since the magnetic field at the wire axis has to be zero (otherwise, being perpendicular to the axis, where would it be directed?), the integration constant in Eq. (50) should be zero.
    ${ }^{21}$ See, e.g., MA Eq. (10.6).
    ${ }^{22}$ See, e.g., MA Eq. (8.5).
    ${ }^{23}$ See, e.g., QM Sec. 3.2.

[^259]:    ${ }^{24}$ This relation remains the same in the Gaussian units, because in those units both Eq. (28) and Eq. (54) should be stripped of their $\mu_{0} / 4 \pi$ coefficients.
    ${ }^{25}$ For that, we may use MA Eq. (11.7) with $\mathbf{f}=\mathbf{A}$ and $\mathbf{g}=\mathbf{B}$, giving $\mathbf{A} \cdot(\nabla \times \mathbf{B})=\mathbf{B} \cdot(\nabla \times \mathbf{A})-\nabla \cdot(\mathbf{A} \times \mathbf{B})$.

[^260]:    ${ }^{26}$ The transfer to the Gaussian units in Eqs. (77)-(78) may be accomplished by the usual replacement $\mu_{0} \rightarrow 4 \pi$, thus giving, in particular, $u=B^{2} / 8 \pi$.
    ${ }^{27}$ As evident from Eq. (60), these coefficients depend only on the geometry of the system. Moreover, in the Gaussian units, in which Eq. (60) is valid without the factor $\mu_{0} / 4 \pi$, the inductance coefficients have the dimension of length (centimeters). The SI unit of inductance is called the henry, abbreviated H-after J. Henry, 1797-1878, who in particular discovered the effect of electromagnetic induction (see Sec. 6.1) independently of M. Faraday. ${ }^{28}$ Note that the matrix of the mutual inductances $L_{i j}$, is very much similar to the matrix of reciprocal capacitance coefficients $p_{k k^{\prime}}$ - for example, compare Eq. (62) with Eq. (2.21).

[^261]:    ${ }^{29}$ The SI unit of magnetic flux is called weber, abbreviated Wb - after W. Weber, who in particular co-invented (with C. Gauss) the electromagnetic telegraph, and in 1856 was first, together with R. Kohlrausch, to notice that the value of (in modern terms) $1 /\left(\varepsilon_{0} \mu_{0}\right)^{1 / 2}$, derived from electrostatic and magnetostatic measurements, coincides with the independently measured speed of light $c$, giving an important motivation for Maxwell's theory.

[^262]:    ${ }^{30}$ Numerous applications of this Neumann formula to electrical engineering problems may be found, for example, in the classical text F. Grover, Inductance Calculations, Dover, 1946.

[^263]:    ${ }^{31}$ As a reminder, the mutual capacitance $C$ between the conductors of such a system was calculated in Sec. 2.3. As will be discussed in Chapter 7 below, the pair of parameters $L$ and $C$ define the propagation of the most important, TEM mode of electromagnetic waves along the cable.

[^264]:    ${ }^{32}$ See, e.g., MA Eq. (6.13) for $a=1$.

[^265]:    ${ }^{33}$ Its solution may be found, for example, just after Sec. 34 of L. Landau et al., Electrodynamics of Continuous Media, $2^{\text {nd }}$ ed., Butterwort Heinemann, 1984.
    ${ }^{34}$ See, e.g., MA Eq. (12.3) with additional condition $\left.j_{n}\right|_{S}=0$, pertinent for space-restricted currents.

[^266]:    ${ }^{35}$ In the Gaussian units, definition (91) is kept valid, so that Eq. (90) is stripped of the factor $\mu_{0} / 4 \pi$.

[^267]:    ${ }^{36}$ In SI units, $m_{e} \approx 0.91 \times 10^{-30} \mathrm{~kg}$, so that $\mu_{\mathrm{B}} \approx 0.93 \times 10^{-23} \mathrm{~J} / \mathrm{T}$.
    ${ }^{37}$ See, e.g., QM Sec. 4.1 and beyond.
    ${ }^{38}$ Another way to arrive at the same estimate is to take $I \sim e f=e \omega / 2 \pi$ with $\omega \sim 10^{16} \mathrm{~s}^{-1}$ being the typical frequency of radiation due to atomic interlevel quantum transitions.

[^268]:    ${ }^{39}$ Similarly to the situation with the electric dipoles (see Eq. (3.24) and its discussion), it may be shown that the magnetic field of any closed current loop (or any system of such loops) satisfies the following equality:

    $$
    \int_{r<R} \mathbf{B}(\mathbf{r}) d^{3} r=(2 / 3) \mu_{0} \mathbf{m}
    $$

    where the integral is over any sphere confining all the currents. On the other hand, for field (99), derived from the asymptotic approximation (90), such integral vanishes. In order to get a course-grain description of the magnetic field of a small system located at $r=0$, which would be valid everywhere (though at $r \sim a$, only approximately), Eq. (99) should be modified as follows:

    $$
    \mathbf{B}_{c g}(\mathbf{r})=\frac{\mu_{0}}{4 \pi}\left(\frac{3 \mathbf{r}(\mathbf{r} \cdot \mathbf{m})-\mathbf{m} r^{2}}{r^{5}}+\frac{8 \pi}{3} \mathbf{m} \delta(\mathbf{r})\right) .
    $$

    Hence, strictly speaking, the macroscopic field $\mathbf{B}$ participating in Eq. (106) and beyond is the average long-range field of the magnetic dipoles (plus of the stand-alone currents $\mathbf{j}$ ) rather than the genuine average magnetic field.
    ${ }^{40}$ This confusion is exacerbated by the fact that in Gaussian units, Eq. (108) has the form $\mathbf{H}=\mathbf{B}-4 \pi \mathbf{M}$, and hence fields $\mathbf{B}$ and $\mathbf{H}$ has one dimensionality (and are equal in free space!) - though the unit of $\mathbf{H}$ has a different name (oersted, abbreviated as Oe). Mercifully, in the SI units, the dimensionality of $\mathbf{B}$ and $\mathbf{H}$ is different, with the unit of $\mathbf{H}$ being called ampere per meter.

[^269]:    ${ }^{41}$ According to Eq. (110) (i.e. in SI units), $\chi_{m}$ is dimensionless, while $\mu$ has the same the same dimensionality as $\mu_{0}$. In the Gaussian units, $\mu$ is dimensionless, $(\mu)_{\text {Gaussian }}=(\mu)_{\mathrm{SI}} / \mu_{0}$, and $\chi_{m}$ is also introduced differently, as $\mu=1+$ $4 \pi \chi_{m}$, Hence, just as for the electric susceptibilities, these dimensionless coefficients are different in the two systems: $\left(\chi_{m}\right)_{\mathrm{SI}}=4 \pi\left(\chi_{m}\right)_{\text {Gaussian }}$. Note also that $\chi_{m}$ is formally called the volume magnetic susceptibility, in order to distinguish it from the molecular susceptibility $\chi$ defined by a similar relation, $\mathbf{m} \equiv \chi \mathbf{H}$, where $\mathbf{m}$ is the average induced magnetic moment of a single dipole - e.g., a molecule. Evidently, in a dilute medium, i.e. in the absence of substantial dipole-dipole interaction, $\chi_{m}=n \chi$, where $n$ is the dipole density.

[^270]:    ${ }^{42}$ The proportionality of $\left|\left\langle p_{0}\right\rangle\right|$ (and hence $P$ ) to $E$ is a result of a dynamic balance between the dipole-orienting torque (101) and disordering thermal fluctuations. A qualitative description of such balances is one of the main tasks of statistical mechanics - see, e.g., SM Chapters 2 and 4. However, the very fact of proportionality $P \propto E$ in low fields may be readily understood as the result of the Taylor expansion of function $P(E)$ at $E \rightarrow 0$.
    ${ }^{43}$ After J. Larmor (1857-1947) who first described the torque-induced precession mathematically.

[^271]:    ${ }^{44}$ For a detailed discussion of the effect see, e.g., CM Sec. 6.5.
    ${ }^{45}$ The quantum-mechanical treatment (see, e.g., QM Sec. 6.4) confirms this qualitative picture, while giving quantitative corrections to the classical result for $\chi_{m}$.

[^272]:    ${ }^{46}$ See, e.g., D. J. Jiles, Introduction to Magnetism and Magnetic Materials, $2^{\text {nd }}$ ed., CRC Press, 1998, or R. C. O'Handley, Modern Magnetic Materials, Wiley, 1999.
    ${ }^{47}$ Materials with very high coercivity $H_{C}$ are frequently called hard ferromagnets or permanent magnets.

[^273]:    ${ }^{48}$ A discussion of such transitions may be found, in particular, in SM Chapter 4.
    49 "A magnetic head slider [the read/write head - KKL] flying over a [rather uneven - KKL] disk surface with a flying height of 25 nm with a relative speed of 20 meters/second is equivalent to an aircraft flying at a physical spacing of $0.2 \mu \mathrm{~m}$ at 900 kilometers/hour." B. Bhushan, as quoted in a (generally good) book by G. Hadjipanayis, Magnetic Storage Systems Beyond 2000, Springer, 2001.

[^274]:    ${ }^{50}$ The reader is highly encouraged to carry out a similar analysis of fields inside narrow gaps cut in a linear magnetic, similar to that carried out for linear dielectrics in Sec. 3.3 - see Fig. 3.6 and its discussion.

[^275]:    ${ }^{51}$ This similarity may seem strange, because earlier we have seen that parameter $\mu$ is physically more similar to $1 / \varepsilon$. The reason for this paradox is that in magnetostatics, the introduced potential $\phi_{m}$ is traditionally used to describe the "would-be field" $\mathbf{H}$, while in electrostatics, potential $\phi$ describes the real (average) electric field $\mathbf{E}$. (This tradition persists from the old days when $\mathbf{H}$ was perceived as a genuine magnetic field.)
    ${ }^{52}$ Instead of differentiating the $\phi_{m}$ given by Eq. (125a), we may use the absolute similarity of Eqs. (3.13) and (99), to derive from Eq. (3.17) a similar expression for the magnetic potential of an arbitrary magnetic dipole:

    $$
    \phi_{m}=\frac{1}{4 \pi} \frac{m \cos \theta}{r^{2}} .
    $$

    Now comparing this formula with the second term of Eq. (125a), we immediately get Eq. (125b).

[^276]:    ${ }^{53}$ From the standpoint of mathematics, this happens because the solution to a boundary problem is determined by not only the differential equation inside the system (in our case, the Laplace equation for potential $\phi_{m}$ ), but also by boundary conditions - which are affected by magnetics - see Eqs. (118)-(119).
    ${ }^{54}$ Note that in this respect, the analogy with electrostatics is incomplete. Indeed, according to Eq. (3.82), in electrostatics the role of a generalized coordinate is played by would-be field $\mathbf{D}$, and that of the generalized force, by the real (average) electric field $\mathbf{E}$. This difference may be traced back to the fact that electric field $\mathbf{E}$ may perform work on a moving charged particle, while the magnetic part of the Lorentz force (10), $\mathbf{v} \times \mathbf{B}$, is always perpendicular to particle's velocity, and its work equals zero. However, this difference does not affect the full analogy of expressions (3.79) and (127) for field energy density in linear media.

[^277]:    ${ }^{57}$ Such system, producing a highly uniform field near its center, is called the Helmholtz coils, and is broadly used in physics experiment.

[^278]:    ${ }^{58}$ It was invented by M. Faraday in 1821, i.e. well before his celebrated work on electromagnetic induction. The adjective "homopolar" refers to the constant "polarity" (sign) of the current; the alternative term is "unipolar".

[^279]:    ${ }^{59}$ See, e.g., MA (6.13).

[^280]:    ${ }^{60}$ This problem is of an evident relevance for the perpendicular magnetic recording (PMR) technology, which presently dominates the high-density digital magnetic recording, with the density already approaching $1 \mathrm{~Tb} / \mathrm{in}^{2}$.

[^281]:    ${ }^{1}$ The induction e.m.f. was discovered independently by J. Henry and M. Faraday, but is was a brilliant experiment series of the latter physicist, carried out in 1831, which resulted in this general formulation of the law.
    ${ }^{2}$ In Gaussian units, the right-hand part of this formula has the additional coefficient $1 / c$.
    ${ }^{3}$ If necessary, see MA Eq. (12.1) again.

[^282]:    ${ }^{4}$ Let me admit that from the beginning of the course, I was carefully sweeping under the rug a very important question: in what exactly reference frame(s) all the equations of electrodynamics are valid? I promise to discuss this issue in detail later in the course (in Chapter 9), and for now would like to get away with a very short answer: all the formulas discussed so far are valid any inertial reference frame, as defined in classical kinematics - see, e.g., CM Chapter 1. It is crucial, however, to have fields $\mathbf{E}$ and $\mathbf{B}$ measured in the same reference frame.
    ${ }^{5}$ See, e.g., MA Eq. (11.1).

[^283]:    ${ }^{6}$ See, e.g., MA Eq. (7.6).

[^284]:    ${ }^{7}$ Actually, Eq. (14) is just an integral version of Eq. (5.128).
    ${ }^{8}$ Actually, the absence of time-dependent corrections to other Maxwell equations in the quasistatic approximation should be considered as an additional experimental fact.

[^285]:    ${ }^{9}$ Due to the simple linear relation between fields $\mathbf{B}$ and $\mathbf{H}$, it does not matter too much which of them is used for the solution of this problem. A slight preference is for $\mathbf{H}$, due to the simplicity of the boundary condition (5.118).

[^286]:    ${ }^{10}$ Another important opportunity to exploit the linearity of Eq. (6.20) (as well as any linear, homogeneous differential equation) is to use the spatial-temporal Green's function approach to explore the dependence of its solutions on various initial conditions. Unfortunately, because of lack of time, I have to leave such exploration for reader's exercise.
    ${ }^{11}$ This common name is awkward, because Eq. (26) results from macroscopic Maxwell equations (16), but is justified as the counterpart to the "macroscopic" boundary condition (30), to be discussed in a minute.

[^287]:    ${ }^{12}$ They are frequently called eddy currents, because of the loop form of their lines. (In the 1D geometry explored above these loops are implicit, closing at infinity.)
    ${ }^{13}$ Notice that vectors $\mathbf{j}$ and $\mathbf{E}$ are parallel, and have the same time dependence. This means that the time average of the power dissipation $\mathbf{j} \cdot \mathbf{E}$ is finite. We will return to its discussion later in this chapter.

[^288]:    ${ }^{14}$ A brief discussion of the mean free path may be found, for example, in SM Chapter 6. In very clean metals at low temperatures, $\delta_{\mathrm{s}}$ may approach $l$ at frequencies as low as $\sim 1 \mathrm{GHz}$, though at room temperature the crossover from the normal to the anomalous skin affect takes place at $\sim 100 \mathrm{GHz}$.
    ${ }^{15}$ See, e.g., A. Abrikosov, Introduction to the Theory of Normal Metals, Academic Press, 1972.
    ${ }^{16}$ Discovered experimentally in 1911 by H. Kamerlingh Onnes.

[^289]:    ${ }^{17}$ Named to acknowledge the pioneering theoretical work of brothers F. and H. London - see below.
    ${ }^{18}$ It is hardly fair to shorten the name to just the "Meissner effect", as it is frequently done, because of the reportedly crucial contribution made by R. Ochsenfeld, then W. Meissner's student, into the discovery.

[^290]:    ${ }^{19}$ A qualitative discussion of the Bose-Einstein condensation of bosons may be found in SM Sec. 3.4, though the full theory of superconductivity is more complex, because it describes the condensation taking place simultaneously with the formation of effective bosons (Cooper pairs). For a more detailed coverage of physics of superconductors, the reader may be referred, for example, to the already cited monograph by M. Tinkham, Introduction to Superconductivity, $2^{\text {nd }}$ ed., McGraw-Hill, 1996.
    ${ }^{20}$ See, e.g., QM Sec. 1.4, in particular Eq. (1.47).
    ${ }^{21}$ I am sorry to use traditional notations $\mathbf{p}$ and $\mathbf{P}$ for the momenta - the same symbols which were used for the electric dipole moment and polarization in Chapter 3. I hope there will be no confusion, because the latter notions are not used in this section.
    ${ }^{22}$ See, e.g., CM Sec. 10.1, in particular Eq. (10.26).

[^291]:    ${ }^{23}$ This is the so-called London gauge which, for our geometry, is also the Coulomb gauge.
    ${ }^{24}$ Since not all electrons of a superconductor form Cooper pairs, at any frequency $\omega \neq 0$ they provide Joule losses which are not described by Eq. (48). These losses become very substantial when frequency $\omega$ becomes so high that the skin-effect length $\delta_{s}$ of the material (as measured with superconductivity suppressed, say by high magnetic field) becomes less than $\delta_{\mathrm{L}}$. For typical metallic superconductors, this happens at frequencies of a few hundred GHz , so that even for microwaves, Eq. (51) gives a fairly good description of the field penetration.

[^292]:    ${ }^{25}$ Of course, this analogy sweeps under the rug the real physics of the Meissner-Ochsenfeld effect. In particular, in superconductors the role of the surface "magnetization currents" with effective density $\mathbf{j}_{\text {ef }}=\nabla \times \mathbf{M}$ (see Fig. 5.11 and its discussion) is played by the real, persistent surface supercurrents (48).
    ${ }^{26}$ The interested reader may be referred, e.g., to Chapter 5 of M. Tinkham's monograph cited above.

[^293]:    ${ }^{27}$ Independently and virtually simultaneously by two groups: B. Deaver and W. Fairbank, and R. Doll and M. Näbauer, so that their reports were published back-to-back in Phys. Rev. Lett.
    ${ }_{28}$ Actually, the ring is not entirely necessary. In 1957, A. Abricosov used the Ginzburg-Landau equations (see below) to explain the counter-intuitive behavior of the so-called type-II superconductors, known experimentally as the Shubnikov phase since the 1930s. He showed that high magnetic field may penetrate into such

[^294]:    ${ }^{31}$ This derivation belongs to L. Aslamazov and A. Larkin, JETP Lett. 9, 87 (1969). If the reader is not interested in this topic, he or she may safely skip it, jumping directly to the text following Eq. (68).
    ${ }^{32}$ At $T \rightarrow T_{\mathrm{c}}$, where $n_{s} \rightarrow 0$, the Taylor expansion of the nonlinear function in Eq. (60) may be limited to just one term proportional to $|\psi|^{2} \propto n_{s}$. In this limit, Eq. (60) is called the Ginzburg-Landau equation - see SM (4.58). Derived by V. Ginzburg and L. Landau in 1950 from phenomenological arguments (see, e.g., SM Sec. 4.3) , i.e. before the advent of the BSC theory, this simple equation, solved together with Eq. (48) and the Maxwell equations, may describe a very broad range of macroscopic quantum effects including the Abrikosov vortices, critical fields and currents, etc. - see, e.g., M. Tinkham' monograph cited above.

[^295]:    ${ }^{33}$ The name is due to the deep analogy between this phenomenon and the interference between two waves, to be discussed in detail in Sec. 8.4.

[^296]:    ${ }^{34}$ For a more detailed discussion of the AB effect, which also takes place for single quantum particles, see, e.g., QM Sec. 3.2.
    ${ }^{35}$ Later, similar experiments were carried out with electron beams, and then even with "normal" (meaning nonsuperconducting) solid-state conducting rings. In this case, the effect is due to interference of the wavefunction of a single charged particle (an electron) with itself, and if of course is much harder to observe that in SQUIDs. In particular, the ring size has to be very small, and temperature low, to avoid "dephasing" effects due to unavoidable interactions of the particles with environment.
    ${ }^{36}$ The sign before $L I$ would be positive, as in Eq. (5.61), if $I$ was the current flowing into the inductance. However, in order to keep the sign in Eq. (69) intact, I should mean the current flowing into the Josephson junction, i.e. from the inductance, thus changing the sign of the term.

[^297]:    ${ }^{37}$ For more on that technology, see, e.g., the review paper by P. Bunyk et al., Int. J. High Speed Electron. Syst. 11, 257 (2001) and references therein.
    ${ }^{38}$ Since the induced e.m.f. $V_{\text {ind }}$ cannot drop on the superconducting path between the Josephson junction electrodes 1 and 2 (Fig. 3), it should equal to $(-V)$, where $V$ is the voltage across the junction.
    ${ }^{39}$ It may be also obtained from simple Schrödinger equation arguments - see, e.g., QM Sec. 2.2.

[^298]:    ${ }^{40}$ In experiment, this condition is hard to implement, due to relatively high inductance of the current leads providing de voltage supply. However, these complications do not change the main conclusion of the analysis.
    ${ }^{41}$ This 1962 prediction by B. Josephson was confirmed experimentally - implicitly (by phase locking of the oscillations with an external oscillator) in 1963, and explicitly (by the detection of microwave radiation) in 1967.
    ${ }^{42}$ For more on the Josephson effect and other macroscopic quantum phenomena in superconductivity, see, e.g., Chapters 6 and 7 in the monograph by M. Tinkham, which was cited above.

[^299]:    ${ }^{43}$ If the resistance is substantial, it may be represented, in calculations, by a separate lumped circuit element (resistor) connected in series with the coil.
    ${ }^{44}$ Starting from the pioneering experiments by M. Faraday - who invented such devices.

[^300]:    ${ }^{45}$ Interestingly, these effects include the wave propagation in periodic $L C$ circuits, despite still staying within the quasistatic approximation! However, within this approximation, speed $1 /(L C)^{1 / 2}$ of these waves is much lower than speed $1 /(\varepsilon \mu)^{1 / 2}$ of electromagnetic waves in the surrounding medium - see the next chapter.

[^301]:    ${ }^{46}$ Again, see MA Eq. (11.2) if you need.
    ${ }^{47}$ No physicist should be ashamed of doing this. J. C. Maxwell himself has arrived at his equations with a heavy use of mechanical engineering arguments. (His main book, A Treatise of Electricity and Magnetism, is full of drawings of gears and levers.) More generally, the whole history of science teaches us that snobbishness toward engineering and other "not-a-real-physics" disciplines is a sure way toward producing nothing of either practical value or fundamental importance. In real science, any method leading to novel, correct results should be welcome. ${ }^{48}$ This is of course just the integral form of the continuity equation (85).

[^302]:    ${ }^{49}$ This vector form of the equations, magnificent it its symmetry and simplicity, was developed in 1884-85 by O . Heaviside, with substantial contributions by H. Lorentz. (The original Maxwell's result, circa 1861, looked like a system of 20 equations for Cartesian components of the vector and scalar potentials.)
    ${ }^{50}$ Despite numerous efforts, no other corrections (e.g., additional terms) to Maxwell equations have been ever found, and these equations are still considered exact within the range of their validity, i.e. while the electric and magnetic fields may be considered classically. Moreover, even in quantum case, these equations are believed to be strictly valid as relations between the Heisenberg operators of the electric and magnetic field.
    ${ }^{51}$ Let me emphasize that this is only possible due to the "displacement current" term $\partial \mathbf{D} / \partial t$.
    ${ }^{52}$ The fact that $T$ cancels shows (or rather hints) that these estimates are valid for waves of arbitrary frequency.

[^303]:    ${ }^{53}$ See, e.g., MA Eq. (11.7) with $\mathbf{f}=\mathbf{E}$ and $\mathbf{g}=\mathbf{H}$.

[^304]:    ${ }^{54}$ Called after J. Poynting, though this fact was independently discovered by O. Heaviside, while a similar expression for the intensity of mechanical elastic waves had been derived earlier by N. Umov.
    ${ }^{55}$ Actually, an addition to $\mathbf{S}$ of the curl of an arbitrary vector function $\mathbf{f}(\mathbf{r}, t)$ does not change Eq. (103). Indeed, we may use the divergence theorem to transform the corresponding change of the surface integral in Eq. (103) to a volume integral of scalar function $\nabla \cdot(\nabla \times \mathbf{f})$ that equals zero at any point - see, e.g., MA Eq. (11.2).
    ${ }^{56}$ Later in the course we will show that the Poynting vector is also directly related to the density of momentum of the electromagnetic field.

[^305]:    ${ }^{62}$ See, e.g., CM Sec. 5.3.

[^306]:    ${ }^{1}$ Though B rather then $\mathbf{H}$ is the actual (microscopically-averaged) magnetic field, it is mathematically more convenient (just as in Sec. 6.2) to use the latter vector in our current discussion, because at sharp media boundaries, $\mathbf{H}$ obeys the boundary condition (5.118) similar to that for $\mathbf{E}-$ see Eq. (3.47).

[^307]:    ${ }^{2}$ In Gaussian units, $E$ and $H$ have the same dimensionality (in particular, in a free-space wave, $E=H$ ), making the (very useful) notion of the wave impedance less manifestly exposed - and in some textbooks not mentioned at all.

[^308]:    ${ }^{3}$ Due to the linearity of Eqs (2), operator Re in Eq. (11) may be ignored until the end of almost any calculation. Because of that, the exponential presentation of monochromatic variables is more convenient than manipulation with sine and cosine functions. (See also CM Sec. 4.1.)

[^309]:    ${ }^{4}$ In the convention that dominates research and engineering literature (but unfortunately is not universal), the wave is called right-polarized (RP) if it is described by the lower sign in Eqs. (18)-(20), and left-polarized (LP) in the opposite case. Another popular term for these cases is the "waves of negative / positive helicity".

[^310]:    ${ }^{5}$ For further reading about the Stokes parameters, as well as about many optics topics I will not have time to cover (especially the geometrical optics and the diffraction-imposed limits on optical imaging resolution), I can recommend the classical text by M. Born et al., Principles of Optics, $7^{\text {th }}$ ed., Cambridge U. Press, 1999.
    ${ }^{6}$ In an isotropic media, vectors $\mathbf{E}, \mathbf{P}$, and hence $\mathbf{D}=\varepsilon_{0} \mathbf{E}+\mathbf{P}$, are all parallel, and for the notation simplicity I will drop the vector sign. I am also assuming that $\mathbf{P}$ at any point $\mathbf{r}$ is only dependent on the electric field at the same point, and hence drop term $i k z$ from the exponent's argument. This assumption is valid if wavelength $\lambda$ is much larger than the elementary media dipole size $a$. In most systems of interest, the scale of $a$ is atomic ( $\sim 10^{-10} \mathrm{~m}$ ), so that the last approximation is valid up to very high frequencies, $\omega \sim c / a \sim 10^{18} \mathrm{~s}^{-1}$, corresponding to hard X-rays. ${ }^{7}$ Note that this condition (which excludes, in particular, the molecular-field effects discussed in Sec. 3.5) is not mentioned in most E\&M textbooks. If the molecular fields are important, Eq. (21) and its corollaries are only valid for the relation between $\mathbf{P}$ and the effective local electric field $\mathbf{E}_{\text {ef }}$.

[^311]:    ${ }^{8}$ A discussion of the temporal Green's functions in application to classical oscillations may be also found in CM Sec. 4.1.

[^312]:    ${ }^{9}$ It may be tempting to attribute this effect to wave absorption, i.e. the dissipation of the wave's energy, but we will see very soon that wave attenuation may be also due to effects different from absorption.
    ${ }^{10}$ The reader is probably familiar with the most noticeable effect of the dispersion, namely the difference between that group velocity $v_{\mathrm{gr}} \equiv d \omega / d k^{\prime}$, giving the speed of the envelope of a wave packet with a narrow frequency spectrum, and the phase velocity $v_{\mathrm{ph}} \equiv \omega / k^{\prime}$ of the component waves. The second-order dispersion effect, proportional to $d^{2} \omega / d^{2} k^{\prime}$, leads to the deformation (gradual broadening) of the envelope itself. Following tradition,

[^313]:    ${ }^{14}$ See, e.g., QM Chapters 5 and 9.

[^314]:    ${ }^{15}$ For an arbitrary plane wave the total average power flow may be calculated as an integral of Eq. (42) over all frequencies. By the way, combining this integral and the Poynting theorem (6.103), one can also prove the following interesting expression for the average electromagnetic energy density in an arbitrary dispersive (but linear and isotropic) medium:

    $$
    \bar{u}=\frac{1}{2} \int_{\omega}\left[\frac{d(\omega \varepsilon)}{d \omega} E_{\omega} E_{\omega}^{*}+\frac{d(\omega \mu)}{d \omega} H_{\omega} H_{\omega}^{*}\right] d \omega .
    $$

[^315]:    16 Alternatively, according to Eq. (45), it is possible (and in infrared spectroscopy, conventional) to attribute the ac response of a medium at all frequencies to effective complex conductivity $\sigma_{\text {ef }}(\omega)=\sigma(\omega)-i \omega \varepsilon(\omega)=-i \omega \varepsilon_{\mathrm{ef}}(\omega)$.

[^316]:    ${ }^{17}$ It may be also derived from the Boltzmann kinetic equation in the so-called relaxation-time approximation (RTA) - see, e.g., SM Sec. 6.2.
    ${ }^{18}$ See, e.g., MA Eq. (15.2).

[^317]:    ${ }^{19}$ Strictly speaking, this also requires $|f(\Omega)|$ to decrease faster than $\Omega^{-1}$ at the real axis (at $\Omega{ }^{\prime \prime}=0$ ), but due to nonvanishing inertia of charged particles, this requirement is fulfilled for all realistic models of dispersion - see, e.g., Eq. (36).
    ${ }^{20}$ I am typesetting this symbol in a Roman font, to exclude any possibility of its confusion with media's polarization.

[^318]:    ${ }^{21}$ For example, the function $\varphi(\omega) \equiv E_{\omega} d P_{\omega}$, in the Lorentz oscillator model, does not obey the Kramers-Kronig relations. This is evident not only from the fact that $E(t)$ is not a causal function of $P(t)$, but even mathematically. Indeed, the Green's function describing a causal relationship has to tend to zero at small time delays $\theta \equiv t-t^{\prime}$, so that its Fourier image has to tend to zero at $\omega \rightarrow \pm \infty$. This is certainly true for the function $f(\omega)$ given by Eq. (32), but not for the reciprocal function $\varphi(\omega) \equiv 1 / f(\omega) \propto\left(\omega^{2}-\omega_{0}^{2}\right)-2 i \delta \omega$, which diverges at large frequencies.

[^319]:    ${ }^{22}$ For example, the first of conditions (66) may be obtained by integrating the full (time-dependent) Maxwell equation $\nabla \times \mathbf{E}+\partial \mathbf{B} / \partial t=0$ over a narrow and long rectangular contour with dimensions $l$ and $d(d \ll l)$ stretched along the interface. In the Stokes theorem, the first term gives $\Delta E_{l} l$, which the contribution of the second term is proportional to product $d l$ and vanishes as $d / l \rightarrow 0$. The proof of the second boundary condition is similar - as was already discussed in Sec. 6.2.

[^320]:    ${ }^{23}$ Please note that only the media impedances (rather than wave velocities) are important for the reflection in this case! Unfortunately, this fact is not clearly emphasized in some textbooks that discuss only the case $\mu_{ \pm}=\mu_{0}$, when $Z=\left(\mu_{0} / \varepsilon\right)^{1 / 2}$ and $v=1 /\left(\mu_{0} \varepsilon\right)^{1 / 2}$ are proportional to each other.
    ${ }^{24}$ See, e.g., the discussion of elastic waves of mechanical deformations in CM Secs. 5.3, 5.4, 7.7, and 7.8.
    ${ }^{25}$ Before the advent of computers, specially lined paper (called the Smith chart) was commercially available for performing this recalculation graphically; it is occasionally used even nowadays for result presentation.

[^321]:    ${ }^{26}$ This ratio is sometimes also called the transmission coefficient, but in order to avoid its confusion with $T$, it is better to call it the power transmission coefficient.

[^322]:    ${ }^{27}$ See, e.g., QM Sec. 2.3.
    ${ }^{28}$ In a typical metal, $\tau \sim 10^{-13} \mathrm{~s}$, so that this approximation work well all the way up to $\omega \sim 10^{13} \mathrm{~s}^{-1}$, i.e. up to the far-infrared frequencies.

[^323]:    ${ }^{29}$ This relation is traditionally called the Snell law, after a $17^{\text {th }}$ century's author W. Snellius, though it has been traced back to a circa 984 manuscript by Abu Saad al-Ala ibn Sahl.

[^324]:    ${ }^{30}$ Note that we may calculate the reflection and transmission coefficients $R$ ' and $T^{\prime}$ for the wave traveling in the opposite direction just by making parameter swaps $Z_{+} \leftrightarrow Z_{-}$and $\theta \leftrightarrow r$, and that the resulting coefficients satisfy the following Stokes relations: $R^{\prime}=-R$, and $R^{2}+T T^{\prime}=1$, for any $\mathrm{Z}_{ \pm}$.

[^325]:    ${ }^{31}$ After A.-J. Fresnel (1788-1827), one of the pioneers of the wave optics, who is credited, among many other contributions (see in particular Ch. 8), for the concept of light as a purely transverse wave.
    ${ }^{32}$ A very simple interpretation of Eq. (93) is based on the fact that, together with the Snell law (82), it gives $r+\theta$ $=\pi / 2$. As a result, vector $\mathbf{E}_{+}$is parallel to vector $\mathbf{k}$.', and hence oscillating dipoles of medium at $z>0$ do not have the component which could induce the transverse electric field $\mathbf{E}$.' of the reflected wave.
    ${ }^{33}$ This effect is used in practice to obtain linearly polarized light, with the electric field vector perpendicular to the plane of incidence, from the natural light with its random polarization. An even more practical application of the effect is a partial reduction of undesirable glare from wet surfaces (for the water/air interface, $n_{+} / n_{-} \approx 1.33$, giving $\theta_{\mathrm{B}} \approx 50^{\circ}$ ) by making car light covers and sunglasses of vertically-polarizing materials.
    ${ }^{34}$ Despite some important background theoretical work by A. Schuster (1904), L. Mandelstam (1945), D. Sivikhin (1957), and especially V. Veselago (1966-67), the negative refractivity effects have only recently become a subject of intensive scientific research and engineering development.

[^326]:    ${ }^{35}$ Inspired by this fact, in some publications the left-hand materials are prescribed a negative index of refraction $n$. However, this prescription should be treated with care (for example, it complies with the first form of Eq. (84), but not its second form), and the sign of $n$, in contrast to that of wave vector $\mathbf{k}$, is the matter of convention.

[^327]:    ${ }^{36}$ For a recent review, see, e.g., B. Wood, Comptes Rendus Physique 10, 379 (2009).

[^328]:    ${ }^{37}$ Note that for the notation simplicity, I am dropping index $\omega$ in the complex amplitudes of the field components, and later will drop argument $\omega$ in $k_{z}$ and $Z$, though they may depend on the wave frequency rather substantially see below.

[^329]:    ${ }^{38}$ The wave equation presented in the form (101) is called the (in our particular case, 2D) Helmholtz equation, after H. von Helmholtz (1821-1894) - the mentor of H. Hertz and M. Planck, among many others.

[^330]:    ${ }^{39}$ The alternative is to have a virtually plane wave, which propagates along the transmission line conductors, and whose fields are just slightly deformed in their vicinity. Such a wave cannot be "guided" by the conductors, and hardly deserves the name of a "wave in the waveguide".

[^331]:    ${ }^{40}$ The coaxial cable was first patented by O. Heaviside in 1880.

[^332]:    ${ }^{41}$ The twisting reduces mutual induction ("crosstalk") between the lines, and parasitic radiation at their bends.
    ${ }^{42}$ For that, one of these two linear equations should be first vector-multiplied by $\mathbf{n}_{z}$. Note that this approach could not be used to analyze TEM waves, because for them $k_{t}=0, E_{z}=0, H_{z}=0$, and Eqs. (121) yield uncertainty.

[^333]:    ${ }^{43}$ An interesting recent twist in the ideas of electromagnetic metamaterials (mentioned in Sec. 5 above) is the socalled $\varepsilon$-near-zero materials, designed to have the effective product $\varepsilon \mu$ much lower than $\varepsilon_{0} \mu_{0}$ within certain frequency ranges. Since at these frequencies the speed $v(4)$ becomes much lower than $c$, the cutoff frequency (123) virtually vanishes. As a result, waves may "tunnel" through very narrow sections of metallic waveguides filled with such materials - see, e.g., M. Silveirinha and N. Engheta, Phys. Rev. Lett. 97, 157403 (2006).

[^334]:    ${ }^{44}$ Let me hope that the solution of equations of the type $d^{2} X / d x^{2}+k_{x}^{2} X=0$ does not present a problem for the reader, due to his or her prior experience with problems such as standing waves on a guitar string, wavefunctions in a flat 1D quantum well, or (with the replacement $x \rightarrow t$ ) a classical harmonic oscillator.

[^335]:    ${ }^{45}$ The reader is encouraged to find a simple interpretation of this equality．

[^336]:    ${ }^{46}$ In Chapter 2, it was natural to take the angular dependence in the sin-cos form, which is equivalent to adding a similar term with $n \rightarrow-n$ to the right-hand part of Eq. (141). However, since the functions $f$ we are discussing now are already complex, it is easier to do calculations in the exponential form - though it is vital to restore real fields before calculating any of their nonlinear forms, e.g., the wave power.
    ${ }^{47}$ The lowest root of Eq. (142) with $n=0$, i.e. $\xi^{\prime}{ }_{00}$, equals 0 , and would yield $k=0$ and hence a constant field $H_{z}$, which, according to the first of Eqs. (121), would give vanishing electric field.

[^337]:    ${ }^{48}$ Actually, Eq. (144) does describe a circularly polarized wave, while the real and imaginary parts of this expression describing two mutually perpendicular quasi-linearly-polarized waves.
    ${ }^{49}$ Electric field lines in the $H_{01}$ mode (as well as all higher $H_{0 m}$ modes) are directed straight from the axis to the walls, reminding those of TEM waves in the coaxial cable. Due to this property, these modes provide, at $\omega \gg \omega_{c}$, much lower power losses (see Sec. 10 below) than the fundamental $H_{11}$ mode, and are sometimes used in practice, despite all inconveniences of working in the multimode frequency range.

[^338]:    ${ }^{50}$ This formula ignores the fact that, according to our analysis, some modes (with $n=0$ and $m=0$ for $H$ modes, and $n=0$ or $m=0$ for $E$ modes, are forbidden. However, for $N \gg 1$, the associated corrections of Eq. (147) are negligible.
    ${ }^{51}$ For a comprehensive description of this vital technology see, e.g., A. Yariv and P. Yeh, Photonics, $6^{\text {th }}$ ed., Oxford U. Press, 2007.

[^339]:    ${ }^{52}$ Each frequency band shown in Fig. 26a, at a typical signal-to-noise ratio $S / N>10^{5}(50 \mathrm{db})$, corresponds to the Shannon bandwidth $\Delta f \log _{2}(S / N)$ exceeding $10^{14}$ bits per second, five orders of magnitude (!) higher than that of a modern Ethernet cable. And this is only per one fiber; an optical cable may have hundreds of them.
    ${ }^{53}$ The silica-based fibers were suggested in 1966 by C. Kao (the 2009 Nobel Prize in physics), but the very idea of using optical fibers for communications may be traced back to at least the 1963 work by J. Nishizawa.

[^340]:    ${ }^{54}$ I believe that the following calculation is important - both for practice, and as a good example of Maxwell theory application. However, its results will not be used in the following sections/chapters of the course, so that if the reader is not interested in this topic, he or she may safely jump to the beginning Sec. 9 .

[^341]:    ${ }^{55}$ This fact becomes less surprising if we recall that in the circular metallic waveguide, discussed in Sec. 7, the lowest mode ( $H_{11}$, Fig. 23) also corresponded to $n=1$ rather than $n=0$.

[^342]:    ${ }^{56}$ This is the core assumption of this approximate theory which accounts only for the most important effect of the difference of dielectric constants $\varepsilon_{+}$and $\varepsilon_{-}$: the opposite signs of the differences $\left(k_{+}^{2}-k_{z}^{2}\right)=k_{t}^{2}$ and $\left(k_{-}^{2}-k_{z}^{2}\right)=-$ $\kappa_{t}^{2}$. For more discussion of accuracy of this approximation and some exact results, let me refer the interested reader either to the monograph by A. Snyder and D. Love, Optical Waveguide Theory, Chapman and Hill, 1983, or to Chapter 3 and Appendix B in the monograph by Yariv and Yeh, which was cited above.

[^343]:    ${ }^{57}$ For an axially-symmetric fiber with a smooth function $\varepsilon(\rho)$, the first derivative $d \varepsilon / d \rho$ should vanish at $\rho=0$.
    ${ }^{58}$ Such approach is invalid at arbitrary (large) $\zeta$. Indeed, in the macroscopic Maxwell equations, $\varepsilon(\mathbf{r})$ is under the differentiation sign, and the exact Helmholtz-type equations for fields have additional terms containing $\nabla \varepsilon$.

[^344]:    ${ }^{59}$ See, e.g., QM Sec. 2.6.

[^345]:    ${ }^{60}$ This task should be easier after reviewing results of field's momentum analysis in Sec. 9.8, in particular Eqs. (9.235) and (9.237).
    ${ }^{61}$ Theoretically, the possibility of separating of the angular momentum of an electromagnetic wave to the "spin" and "orbital" parts may be traced back to at least the 1943 work by J. Humblet; however, this issue had not been discussed in literature too much until the spectacular 1992 experiments by L. Allen et al. who demonstrated a simple way of generating such helical optical beams. (For reviews of this and later work see, e.g., G. MolinaTerriza et al., Nature Physics 3, 305 (2007) and/or L. Marrucchi et al., J. Opt. 13, 064001 (2011), and references therein.) Presently there are efforts to use this approach for so-called "orbital angular moment (OAM) multiplexing" of waves for high-rate information transmission - see, e.g., J. Wang et al., Nature Photonics 6, 488 (2012).
    ${ }^{62}$ The device is named after its inventors, M. Fabry and A. Pérot; and is also called the Fabry-Pérot etalon (meaning "gauge"), because of its initial usage for the light wavelength measurement.
    ${ }^{63}$ The resonators formed by well conducting (usually, metallic) walls are frequently called the resonant cavities.

[^346]:    ${ }^{64}$ In this form, the equations are valid even in the presence of dispersion, but with the frequency-dependent wave speed: $v^{2}=1 / \varepsilon(\omega) \mu(\omega)$.
    ${ }^{65}$ This is of course the expression of the first of the general boundary conditions (104). The second if these conditions (for the magnetic field) is satisfied automatically for the transverse waves we are considering.

[^347]:    ${ }^{66}$ In most electrical engineering handbooks, the index corresponding to the shortest side of the resonator is listed last, so that the fundamental mode is nominated as $H_{110}$ and its eigenfrequency as $\omega_{110}$.

[^348]:    Oscillation mode density

[^349]:    ${ }^{67}$ This fact becomes evident from plugging Eq. (196) into the Maxwell equation $\nabla \cdot \mathbf{E}=0$. The resulting equation, $k_{x} E_{1}+k_{y} E_{2}+k_{z} E_{3}=0$, with the discrete, equidistant spectrum (197) for each wave vector component, may be satisfied by two linearly independent sets of constants $E_{1,2,3}$.
    ${ }^{68}$ See, e.g., QM Sec. 1.1 and SM Sec. 2.6.

[^350]:    Energy
    in filling dielectric

[^351]:    ${ }^{70}$ As follows from Eq. (78), which may be used for estimates even in cases of arbitrary incidence, this condition is necessary for low attenuation: $\alpha \ll k$ only if $F \ll 1$.

[^352]:    ${ }^{71}$ For a normally-incident plane wave, this formula would bring us back to Eq. (78).

[^353]:    ${ }^{72}$ As losses grow, the oscillation waveform deviates from sinusoidal one, and the very notion of "oscillation frequency" becomes vague. As a result, parameter $Q$ is well defined only if it is much higher than 1 .
    ${ }^{73}$ See, e.g., CM Sec. 4.1.

[^354]:    ${ }^{74}$ This is the acronym for "Full Width at Half-Maximum".
    ${ }^{75}$ See, e.g., MA Eq. (15.2).

[^355]:    ${ }^{76}$ This function $E(t)$ is of course proportional to the well-known step function $\theta$ - see, e.g., MA Eq. (14.3). I am not using this notion just to avoid a possible confusion between two different uses of the Greek letter $\theta$. ${ }^{77}$ And in more detail in CM Sec. 5.3, and especially in QM Sec. 2.1.

[^356]:    ${ }^{1}$ When necessary (e.g., at the discussion of the Cherenkov radiation in Sec. 10.4), it will be not too hard to generalize these results to dispersive media.
    ${ }^{2}$ Such thinking would not prevent the results from being valid for the case when $\rho(\mathbf{r}, t)$ and $\mathbf{j}(\mathbf{r}, t)$ should be calculated self-consistently.

[^357]:    ${ }^{3}$ Admittedly, this expression does not satisfy the continuity equation (4.5), but we will correct this deficiency imminently, at the linear superposition stage - see Eq. (17) below.
    ${ }^{4}$ Let me emphasize that this is not the general solution to Eq. (6). For example, it does nor describe the fields created by other sources, that pass by the considered charge $q(t)$. However, such fields are irrelevant for our current task: to calculate the field created by the charge $q(t)$ itself.
    ${ }^{5}$ See, e.g., MA Eq. (10.9).
    ${ }^{6}$ See also CM Sec. 5.3.

[^358]:    ${ }^{7}$ For relativistic particles, moving with velocities of the order of speed of light, one has to be more careful. As the result, I will postpone the discussion of their radiation until Chapter 10, i.e. until after the discussion of special relativity in Chapter 9.
    ${ }^{8}$ From the first of Eqs. (1), for the electric field, in the first approximation (23), we would get $-\partial \mathbf{A} / \partial t=-(1 / 4 \pi \varepsilon v r)$ $\ddot{\mathbf{p}}(t-r / v)=-(Z / 4 \pi r) \ddot{\mathbf{p}}(t-r / v)$. The transverse component of this vector (see Fig. 2) is the proper wave field $\mathbf{E}=$ $Z \mathbf{H} \times \mathbf{n}$, while its longitudinal component is exactly compensated by $(-\nabla \phi)$ in the next term of expansion of Eq. (17a) with respect to small parameter $r / \lambda \ll 1$.

[^359]:    Full instant power

[^360]:    ${ }^{9}$ In the Gaussian units, for free space $(v=c)$, this important formula reads $P=\left(2 / 3 c^{3}\right) \ddot{p}^{2}$. It was first derived in 1897 by J. Larmor for the particular case of a single point charge $q$ moving with acceleration $\ddot{\mathbf{r}}$, when $\ddot{\mathbf{p}}=q \ddot{\mathbf{r}}$ and hence $\mathcal{P}=\left(2 q^{2} / 3 c^{3}\right) \dot{r}^{2}$. As a result, Eq. (27) is sometimes referred to as the Larmor formula.

[^361]:    ${ }^{10}$ Actually, the formula needs a numerical coefficient adjustment to account for electron's orbital (rather than linear) motion - the task left for reader's exercise. However, this adjustment does not affect the order-ofmagnitude estimate given above.

[^362]:    ${ }^{11}$ A partial list of popular software packages of this kind includes both publicly available codes such as NEC - 2 (whose various versions are available online, e.g., at http://alioth.debian.org/projects/necpp/ and http://www.qsl.net/4nec2/), and proprietary packages - such as Momentum from Aglient Technologies (now owned by Hewlett-Packard), FEKO from EM Software \& Systems, and XFdtd from Remcom.
    ${ }^{12}$ Named after M. Born, one of the founding fathers of quantum mechanics. Note, however, the basic idea of this approach was developed much earlier (in 1881) by Lord Rayleigh - see below.

[^363]:    ${ }^{13} \mathrm{As}$ Eq. (7.30) shows, this calculation is also valid for an oscillator with eigenfrequency $\omega_{0} \ll \omega$.

[^364]:    ${ }^{14}$ Named after Sir J. J. Thomson (1856-1940), the discoverer of the electron - and isotopes as well! He is not to be confused with his son, G. P. Thomson, who discovered (simultaneously with C. Davisson and L. Germer) quantum-mechanical wave properties of the same electron.
    ${ }^{15}$ In the Gaussian units, this formula looks like $r_{c}=q^{2} / m c^{2}$ (giving, of course, the same numerical value: for the electron, $r_{c} \approx 2.82 \times 10^{-13} \mathrm{~cm}$ ). This classical quantity should not be confused with particle's Compton wavelength $\lambda_{c} \equiv h / m c$ (for the electron, close to $2.24 \times 10^{-12} \mathrm{~cm}$ ), which naturally arises in quantum electrodynamics - see a brief discussion in the next chapter, and QM Chapter 9 for more detail.
    ${ }^{16}$ It is fascinating how smartly has the relativistic expression $m c^{2}$ sneaked into the result (40), which was obtained using a non-relativistic equation of particle motion. This was possible because the calculation engaged electromagnetic waves that propagate with the speed of light, and whose quanta (photons), as a result, may be frequently treated as relativistic (moreover, ultra-relativistic) particles - see the next chapter.

[^365]:    ${ }^{17}$ Named after Lord Rayleigh (born J. Strutt, 1842-1919), whose numerous contributions to science include the discovery of argon. He has also pioneered (for the special case we are considering now) the basic idea of what is presently called the Born approximation.
    ${ }^{18}$ These values are approximate because both $n$ and $\left(\varepsilon_{r}-1\right)$ vary through the atmosphere.

[^366]:    ${ }^{19}$ In quantum electrodynamics, $\hbar \mathbf{q}$ has the sense of the momentum transferred from the scattering object to the scattered photon, and this terminology sometimes creeps even into the classical electrodynamic texts.

[^367]:    ${ }^{20}$ Named after Sir William Bragg and his son, Sir William Lawrence Bragg, who in 1912 demonstrated X-ray diffraction by atoms in crystals. The Braggs' experiments have made the existence of atoms (before that, a hypothetical notion ignored by many physicists) indisputable.

[^368]:    ${ }^{21}$ This experiment was described as early as in 1803 by T. Young - one more universal genius of science, who has also introduced the Young modulus in the elasticity theory (see, e.g., CM Chapter 7), besides numerous other achievements - including deciphering Egyptian hieroglyphs! The two-slit experiment has firmly established the wave picture of light, to be replaced by the dualistic photon-vs-wave picture, formalized by quantum electrodynamics, only $100+$ years later.
    ${ }^{22}$ Since the observation point's position $\mathbf{r}$ does not participate in this formula explicitly, the prime sign in $\mathbf{r}$ ' could be dropped, but I keep it as a reminder that the integral is taken over points $\mathbf{r}$ ' of the scattering object.

[^369]:    ${ }^{23}$ Named after C. Huygens (1629-1695) who had conjectured the wave theory of light (that remained controversial for more than a century, until T. Young's experiments), and A.-J. Fresnel (1788-1827) who has developed the mathematical theory of diffraction.

[^370]:    ${ }^{24}$ The fact that the Huygens principle is valid for any field component should not too surprising. Due to condition $a \gg \lambda$, the real boundary conditions at the orifice edges are not important; what is only important that the screen, that limits the orifice, is opaque. Because of this, the Huygens principle's expression (71) is a part of the so-called scalar theory of diffraction. (In this course I will not have time to go beyond this approximation.)

[^371]:    ${ }^{25}$ See, e.g., MA Eq. (6.10).
    ${ }^{26}$ This result very is natural, because $\exp \{i k R\}$ oscillates fast with the change of $\mathbf{r}$ ', so that the contributions from various front point are averaged out. Indeed, the only reason why the central part of plane [ $x^{\prime}, y^{\prime}$ ] gives a nonvanishing contribution (76) to $f_{\omega}(z)$ is that the phase exponents stops oscillating at $\left(x^{, 2}+y^{, 2}\right)$ below $\sim z / k-$ see Eq. (73).
    ${ }^{27}$ This proof was given in 1882 by G. Kirchhoff.

[^372]:    ${ }^{28}$ Actually, this is a somewhat nontrivial point of the proof. Indeed, it may be shown that the solution of Eq. (79) identically equals to zero if $f\left(\mathbf{r}^{\prime}\right)$ and $\partial f\left(\mathbf{r}^{\prime}\right) / \partial n^{\prime}$ vanish together at any part of the boundary. As a result, building the solution with the account of exact boundary conditions (which is the task of the vector theory of diffraction) is possible but cumbersome. Here we base our solution on the physical intuition.
    ${ }^{29}$ It follows, e.g., from Eq. (16) with a monochromatic source $q(t)=q_{\omega} \exp \{-i \omega t\}$, at the value $q_{\omega}=4 \pi \varepsilon$ that fits the right-hand part of Eq. (80).
    ${ }^{30}$ With the integration extended over all boundaries of volume $V$, this would be an exact result.

[^373]:    ${ }^{31}$ The phase shift $\varphi$ vanishes at the normal incidence of a plane wave on the holes. Note, however, that the spatial shift of the interference pattern following from Eq. (90), $\Delta x=-(z / k a) \varphi$, is extremely convenient for the experimental measurement of the phase shift between two waves, especially if it is induced by some factor (such as insertion of a transparent object into one of interferometer's arms, etc.) that may be turned on/off at will.

[^374]:    ${ }^{32}$ Note also that since in this limit $k a^{2} \ll z$, Eq. (97) shows that even the maximum value $S(0, z)$ of the diffracted wave intensity is much less than intensity $S_{0}$ of the incident wave. This is natural, because the incident power $S_{0} a$ per unit length of the slit is now distributed over a much larger width $\delta x \gg a$, so that $S(0, z) \sim S_{0}(a / \delta x) \ll S_{0}$. ${ }^{33}$ Slightly different definitions of these functions, mostly affecting constant factors, may also be met in literature.

[^375]:    ${ }^{34}$ Note that this condition may be also rewritten as $a \sim \delta x$, i.e. $z / a \sim a / \lambda$.

[^376]:    ${ }^{39}$ The rudimentary diffraction grating effect, produced by parallel fibers of bird feathers, was discovered as early as in 1673 by J. Gregory - who has also invented the reflecting ("Gregorian") telescope.

[^377]:    ${ }^{40}$ If you need, see, e.g., MA Eq. (7.5).

[^378]:    ${ }^{41}$ In electrostatics, the symmetric, zero-trace tensor $Q$ determines the next term in the potential expansion (3.5):

    $$
    \phi(\mathbf{r})=\frac{1}{4 \pi \varepsilon_{0}}\left(\frac{1}{r} Q+\frac{1}{r^{2}} \sum_{j=1}^{3} n_{j} p_{j}+\frac{1}{2 r^{3}} \sum_{j, j^{\prime}=1}^{3} n_{j} n_{j^{\prime}} Q_{i j^{\prime}}+\ldots\right) .
    $$

[^379]:    ${ }^{42}$ As a math reminder, tensor is a matrix describing a physical reality independent of the reference frame choice, so that the Cartesian elements of the tensor have to change according to certain geometric rules if the reference frame is changed - e.g., rotated. This notion is very similar to a physical vector, that may be described by an ordered set of its Cartesian components, which change according to certain rules as the result of the reference frame' change. We may be confident that a matrix represents a tensor if it provides a linear relation between components of two physical vectors - such a $\mathbf{Q}$ and $\mathbf{n}$ in Eq. (128).

[^380]:    ${ }^{43}$ As was emphasized in Sec. 2, this is a reasonable guess rather than a controllable approximation. The exact (rather involved!) theory shows that this assumption gives errors $\sim 5 \%$.

[^381]:    ${ }^{1}$ Let me hope that the reader does not need a reminder that in order for Eq. (1) to be valid, the reference frames 0 and 0 ' have to be inertial - see, e.g., CM Sec. 1.3.
    ${ }^{2}$ It had been first formulated by G. Galilei as early as in 1638 - four years before I. Newton was born!
    ${ }^{3}$ Note a very unfortunate term "boost", used sometimes for the transform between the reference frames. (It is especially unnatural in the special relativity, not describing any accelerations.) In these notes, this term is avoided.

[^382]:    ${ }^{4}$ Discussions in this chapter and most of the next chapter will be restricted to the free-space (and hence dispersion-free) case; some media effects on radiation by relativistic particles will be discussed in Sec.10.4.
    ${ }^{5}$ It is interesting that the Schrödinger equation, whose fundamental solution for a free particle is a similar monochromatic wave (albeit with a different dispersion law), is Galilean-invariant, with a certain addition to the wavefunction's phase - see, e.g., QM Chapter 1.
    ${ }^{6}$ See, e.g., CM Secs. 5.5 and 7.7.
    ${ }^{7}$ In the ancient Greek mythology, aether is the clear upper air breathed by the gods residing on Mount Olympus.

[^383]:    ${ }^{8}$ Through the $20^{\text {th }}$ century, the Michelson-Morley-type experiments were repeated using more and more refined experimental techniques, always with the zero result for the apparent ether motion speed. For example, recent experiments, using cryogenically cooled optical resonators, have reduced the upper limit for such speed to just $3 \times 10^{-15} \mathrm{c}$-see H. Müller et al., Phys. Rev. Lett. 91, 020401 (2003).
    ${ }^{9}$ The zero result of a slightly later experiment, namely precise measurements of the torque which should be exerted by the moving ether on a charged capacitor, carried out in 1903 by F. Trouton and H. Noble (following G. FitzGerald's suggestion), seconded the Michelson and Morley's conclusions.
    ${ }^{10}$ The theoretical work toward this goal (which I do not have time to review in detail) included important contributions by W. Voigt (in 1887), H. Lorentz (1892-1904), J. Larmor (1897 and 1900), and H. Poincaré (1900 and 1905).

[^384]:    ${ }^{11}$ Note that though the relativity principle excludes the notion of the special ("absolute") spatial reference frame, its verbal formulation still leaves the possibility of the Galilean "absolute time" open. The quantitative relativity theory kills this option - see Eqs. (6) and their discussion below.

[^385]:    ${ }^{12}$ One more function of $\beta$, the rapidity defined as $\beta \equiv \tanh \varphi$ (so that $\psi=i \varphi$ ), is also useful for some calculations. ${ }^{13}$ Still, in some cases below, it will be more convenient to use Eqs. (6) rather than Eqs. (19).
    ${ }^{14}$ All attempts to rationally conjecture particles moving with $v>c$, called tachyons, have failed (so far, at least :-). Possibly the strongest objection against their existence is the notice that tachyons could be used to communicate back in time, thus violating the causality principle - see, e.g., G. Benford et al., Phys. Rev. D 2, 263 (1970).

[^386]:    ${ }^{15}$ A posteriori, the Lorenz transform may be used to show that consensus-creating procedures (such as clock synchronization) are indeed possible. The basic idea of the proof is that at $v \ll c$ the relativistic corrections to space and time intervals are of the order of $(v / c)^{2}$, they have negligible effects on clocks being brought together into the same point for synchronization very slowly, with velocity $v \ll c$. The reader interested in detailed discussion of this and other fine points of special relativity may be referred to, e.g., either H. Arzeliès, Relativistic Kinematics, Pergamon, 1966, or W. Rindler, Introduction to Special Relativity, $2^{\text {nd }}$ ed., Oxford U. Press, 1991.

[^387]:    ${ }^{16}$ See, e.g., J. Hafele and R. Keating, Science 177, 166 (1972).

[^388]:    ${ }^{17}$ With an account of the well-known trigonometric identity $\tan (a+b)=(\tan a+\tan b) /(1-\tan a \tan b)$ and Eq. (15), Eq. (25) shows that that rapidities $\varphi$ add up exactly as longitudinal velocities at non-relativistic motion, making that notion very convenient for the analysis of transfer between several frames.

[^389]:    ${ }^{18}$ Strictly speaking, in order to reconcile the geometries shown in Fig. 1 (for which all our formulas, including Eq. (27), are valid) and Fig. 8 (giving the traditional scheme of the aberration), it is necessary to invert signs of $\mathbf{u}$ (and hence $\sin \theta^{\prime}$ and $\cos \theta^{\prime}$ ) and $\mathbf{v}$, but as evident from Eq. (27), all the minus signs cancel, and the formula is valid as is.
    ${ }^{19}$ See, e.g., CM Secs. 6.4-6.5.

[^390]:    ${ }^{20}$ Strictly speaking, Eq. (32) is valid to an additive constant, but for notation simplicity, it may be always made equal to zero by selecting (at it has already been done in all relations of Sec. 1) the reference frame origins and/or clock turn-on times so that at $t=0$ and $x=0, t^{\prime}=0$ and $x^{\prime}=0$ as well.

[^391]:    ${ }^{21}$ The same fact, ignored by crackpots, is also valid for other favorite points of their attacks, including the Universe expansion and quantum mechanics in physics, and the evolution theory in biology.

[^392]:    ${ }^{22}$ After H. Minkowski who was first to recast (in 1907) the special relativity relations in a form in which space coordinates and time (or rather $c t$ ) are treated on an equal footing.

[^393]:    ${ }^{23}$ I have opted against using special indices (e.g., $\boldsymbol{\beta}_{u}, \gamma_{u}$ ) to distinguish Eqs. (17) and (61) here and below, in a hope that the suitable velocity (of a reference frame or of a particle) will be always clear from the context.

[^394]:    ${ }^{24}$ I am sorry for using, as in Sec. 6.3, for particle's momentum, the same traditional notation (p) as had been used for the dipole electric moment. However, since the latter notion will be virtually unused in the balance of the notes, this may hardly lead to confusion.
    ${ }^{25}$ Indeed, such a derivation uses additional assumptions, however natural (such as the Lorentz-invariance of $\Omega$ ), so it can hardly be considered as a real proof of the final results, so that they require experimental confirmation. Fortunately, such confirmations have been numerous - see below.
    ${ }^{26}$ See, e.g., CM Sec. 10.3.
    ${ }^{27}$ See, e.g., CM Sec. 2.1.

[^395]:    ${ }^{28}$ See, e.g., CM Sec. 2.3.
    ${ }^{29}$ Let me hope that the reader understands that all the layman talk about the "mass to energy conversion" is only valid in a very limited sense of the word. While the Einstein relation (73) does allow the conversion of "massive" particles (with $m \neq 0$ ) into massless particles such as photons, each of the latter particles also has a nonvanishing relativistic mass $M$, and simultaneously the energy $\mathcal{E}$ related to $M$ by Eq. (73).

[^396]:    ${ }^{30}$ Please note one more useful relation following from Eqs. (70) and (73): $\mathbf{p}=\left(\mathrm{E} / \mathrm{c}^{2}\right) \mathbf{u}$.
    ${ }^{31}$ It may be tempting to interpret this relation as the perpendicular-vector-like addition of the rest energy $m c^{2}$ and the "kinetic energy" $p c$, but from the point of view of the total energy conservation (see below), a better definition of the kinetic energy is $T(u) \equiv \mathcal{E}(u)-\mathcal{E}(0)$.
    ${ }^{32}$ Briefly reviewed in QM Chapter 9.

[^397]:    ${ }^{33}$ Note that according to this definition, the c.o.m.'s radius-vector is $\mathbf{R}=\Sigma_{k} M_{k} \mathbf{r}_{k} / \Sigma_{k} M_{k}=\Sigma_{k} \gamma_{k} m_{k} \mathbf{r}_{k} / \Sigma_{k} \gamma_{k} m_{k}$, generally different from the well-known expression $\Sigma_{k} m_{k} \mathbf{r}_{k} / \Sigma_{k} m_{k}$ of the non-relativistic mechanics.

[^398]:    ${ }^{34}$ This compact notation may take some time to be accustomed to, but can hardly lead to any confusion, due to the following rule: the summation is implied always (and only) when an index is repeated twice, once on the top and another at the bottom. In these notes, this shorthand notation will be used only for 4 -vectors, but not for the usual (spatial) vectors.
    ${ }^{35}$ Note also that, by definition, for any two 4-vectors, $A_{\alpha} B^{\alpha}=B^{\alpha} A_{\alpha}$.

[^399]:    ${ }^{36}$ These forms are 4 -vector extensions of the notions of contravariance and covariance introduced in the 1850s by J. Sylvester for the description of 3D vector change at transfer between different reference frames - e.g., axes rotation - cf. Fig. 3. In this case, the contravariance or covariance of a vector is uniquely determined by its nature: if Cartesian coordinates of a vector (such as the non-relativistic velocity $\mathbf{v}=d \mathbf{r} / d t$ ) are transformed similarly to the radius-vector $\mathbf{r}$, it is called contravariant, while the vectors (such as $\partial f / \partial \mathbf{r} \equiv \nabla f$ ) that require the reciprocal transform, are called covariant. In the Minkowski space, both forms may be used for any 4 -vector.
    ${ }^{37}$ Just as 4 -vectors, 4 -tensors with two top indices are called contravariant, and those with two bottom indices, covariant. Tensors with one top and one bottom index are called mixed.

[^400]:    ${ }^{39}$ As was mentioned above, this is also a property of the "usual" transform of 3D vectors.

[^401]:    ${ }^{40}$ It is straightforward to check that transfer between the contravariant and covariant forms of the same tensor may be readily achieved using the same metric tensor $g$ : $T_{\alpha \beta}=g_{\alpha \gamma} T^{\gamma \delta} g_{\delta \beta}, T^{\alpha \beta}=g^{\alpha \gamma} T_{\gamma \delta} g^{\delta \beta}$.
    ${ }^{41}$ Note that in some texts, the equations preserving their form at a transform are called "covariant", creating a possibility for confusion with covariant vectors and tensors. On the other hand, calling such equations "invariant" does not distinguish them properly from invariant quantities, such as scalar products of 4 -vectors.

[^402]:    ${ }^{42}$ In the Gaussian units, the scalar potential should not be divided by $c$.
    ${ }^{43}$ In the Gaussian units, coefficient $\mu_{0}$ in the right-hand part of Eq. (119) should be replaced, as usual, with $4 \pi / c$.
    ${ }^{44}$ Named after J.-B. d'Alembert (1717-1783). Note that in older textbooks, notation $\square^{2}$ may be met for this operator.

[^403]:    ${ }^{46}$ To be fair, note that just as Eq. (127), Eq. (129) this is also a set of four scalar equations - in the latter case with indices $\alpha, \beta$, and $\gamma$ taking any three different values of the set $\{0,1,2,3\}$.

[^404]:    ${ }^{47}$ This term is very popular in the of particle scattering - see, e.g., CM Sec. 3.7.

[^405]:    ${ }^{48}$ In the next chapter, we will re-derive them in a different way.
    ${ }^{49}$ It is straightforward to use Eq. (140) and the linear superposition principle to calculate, for example, the magnetic field of a string of charges moving along the same line, and separated by equal distances $\Delta x=a$ (so that the average current, as measured in frame 0 , is $q u / a$ ), and to show that the time-average of the magnetic field is given by Eq. (5.20) of magnetostatics, with $b$ instead of $\rho$.

[^406]:    ${ }^{50}$ See, e.g., CM Eq. (1.20) with $d \mathbf{p} / d t=\mathbf{F}=q \mathbf{E}$. (As a reminder, the magnetic field cannot affect particle's energy, because the magnetic component of the Lorentz force is perpendicular to its velocity.)
    51 As was emphasized earlier in this course, in statics this contribution has to be ignored. In dynamics, this is generally not true; these self-action effects will be discussed in Sec. 10.6.

[^407]:    ${ }^{52}$ For more on this topic, I have to refer the interested reader to special literature, for example either S. Lee, Accelerator Physics, $2^{\text {nd }}$ ed., World Scientific, 2004, or E. Wilson, An Introduction to Particle Accelerators, Oxford U. Press, 2001.

[^408]:    ${ }^{53}$ As a reminder, a trochoid may be described as the trajectory of a point on a rigid disk rolled along a straight line. Its canonical parametric presentation is $x=\Theta+a \cos \Theta, y=a \sin \Theta$. (For $a>1$, the trochoid is prolate, if $a<$ 1 , it is curtate, and if $a=1$, it is called the cycloid.) Note, however, that for our problem, the trajectory in the lab frame is exactly trochoidal only in the non-relativistic limit $v \ll c$ (i.e. $E / c \ll B$ ), because otherwise the Lorentz contraction in the drift direction squeezes the cyclotron orbit from a circle into an ellipse.

[^409]:    ${ }^{54}$ See, e.g., CM Sec. 4.4.

[^410]:    ${ }^{55}$ See, e.g., Sec. 12.4 in J. D. Jackson, Classical Electrodynamics, $3{ }^{\text {rd }}$ ed., Wiley, 1999.
    ${ }^{56}$ See, e.g., CM Sec. 2.2 and beyond.

[^411]:    ${ }^{57}$ See, e.g., CM Sec. 2.1.
    ${ }^{58}$ Alternatively called the "Lagrangian derivative"; for its (rather simple) derivation see, e.g., CM Sec. 8.3.

[^412]:    ${ }^{59}$ With regrets, I have to use the same (common) notation as was used earlier for the electric polarization - which is not discussed below.
    ${ }^{60}$ In Gaussian units, Eq. (192) has the form $\mathbf{P}=\mathbf{p}+q \mathbf{A} / c$.

[^413]:    ${ }^{64}$ See, e.g., CM Sec. 10.2.

[^414]:    ${ }^{65}$ For the further reading on this technology, the reader may be referred, for example, to a simple monograph by F. C. Chen, Introduction to Plasma Physics and Controllable Fusion, vol. 1, $2^{\text {nd }}$ ed., Springer, 1984, and/or a graduate-level theoretical treatment by R. D. Hazeltine and J. D. Meiss, Plasma Confinement, Dover, 2003.

[^415]:    ${ }^{66}$ See, e.g., CM Sec. 10.1.
    ${ }^{67}$ Equation (209) is also the basis for discussion of numerous other magnetic field phenomena, including the Aharonov-Bohm and quantum Hall effects - see, e.g., QM Secs. 3.1-3.2.

[^416]:    ${ }^{68}$ As a reminder, the homogeneous Maxwell equations (129) are satisfied by the very structure (125) of the field strength tensor.
    ${ }^{69}$ Here the implicit summation over index $\alpha$ plays the role similar to the convective derivative (188) in replacing the full derivative over time, in a way that reflects the symmetry of time and space in special relativity. I do not want to spend more time to justify Eq. (214) because of the reasons that will be clear very soon.
    ${ }^{70}$ In the Gaussian units, the coefficient is $(-1 / 16 \pi)$.

[^417]:    ${ }^{71}$ Since the Lagrange equations of motion are homogeneous, the simultaneous change of sign of $T$ and $U$ does not change them. Thus, it is not important which of two energy densities, $u_{e}$ or $u_{m}$, we count as the potential energy.

[^418]:    ${ }^{72}$ In this way, we are using Eqs. (214) and (221) just as a useful guesses, leading to the definition of $\theta^{\alpha \beta}$, and may leave their strict justification for more serious field theory courses.

[^419]:    Electric field's

[^420]:    ${ }^{74}$ This impulse is sometimes called the hidden momentum; this term makes sense if the field sources have finite masses, so that their velocity change at the field variation is measurable.
    ${ }^{75}$ See, e.g., CM Sec. 7.2.
    ${ }^{76}$ Note that the field-to-particle interaction gives a vanishing contribution into the net integral, as it should for any internal interaction between internal parts of a system.

[^421]:    ${ }^{77}$ By the way, repeating these arguments for a plane capacitor filled with a linear dielectric, we may readily see that Eq. (239) may be generalized for this case by replacing $\varepsilon_{0}$ for $\varepsilon$. The similar replacement ( $\mu_{0} \rightarrow \mu$ ) is valid for Eq. (241) in a linear magnetic medium.
    ${ }^{78}$ The causal relation is not important here. Especially in the case of a superconductor, the magnetic field may be induced by another source, with the surface supercurrent $\mathbf{j}$ just shielding the superconductor's bulk from its penetration - see Sec. 6.

[^422]:    ${ }^{79}$ Of course, this condition may hold "forever" only for solenoids with superconducting wiring, but even in normal-metal solenoids with practicable inductances, the flux relaxation constants $L / R$ may be rather large (practically, up to a few minutes), quite sufficient to carry out the force measurement.

[^423]:    ${ }^{80}$ Such a decay may happen, for example, with a neutral pion.
    ${ }^{81}$ This the famous Compton scattering problem.

[^424]:    ${ }^{1}$ As Fig. 1 shows, there is always another point $\left\{\mathbf{r} ", t^{\prime \prime}\right\}$, with $t^{\prime \prime}>t$, that is formally also a solution of Eq. (4), but it does not fit Eqs. (1), because the field induced at that point would violate the causality principle.

[^425]:    ${ }^{2}$ Note the following identities: $\gamma^{2}=1 /\left(1-\beta^{2}\right)$ and $\left(\gamma^{2}-1\right)=\beta^{2} /\left(1-\beta^{2}\right)=\gamma^{2} \beta^{2}$, which may be very handy for the relativity-related algebra.
    ${ }^{3}$ They were derived in 1898 by A.-M. Liénard and (apparently, independently) in 1900 by E. Wiechert.

[^426]:    ${ }^{4}$ Note that this time compression effect (linear in $\beta$ ) has nothing to do with the Lorentz time dilation (9.21), which is quadratic in $\beta$. (Indeed, all our arguments above are referred to the same, lab frame.) Rather, it is close in nature to the Doppler effect.

[^427]:    ${ }^{7}$ A similar calculation of magnetic field components from Eq. (20b) gives the results identical to Eqs. (9.140).
    ${ }^{8}$ If the direction of radiation, $\mathbf{n}$, does not change in time, this formula does not contain the observation point $\mathbf{r}$. Hence, from this point on, index $r$ may be safely dropped for brevity, though we should always remember that $\beta$ in Eq. (30) is the reduced velocity of the particle at the instant of radiation's emission, not detection.

[^428]:    ${ }^{9}$ The second form of Eq. (10.37), frequently more convenient for applications, may be readily obtained from the first one by applying MA Eq. (7.7a) to the vector product.

[^429]:    ${ }^{10}$ See, e.g., https://www6.slac.stanford.edu/.

[^430]:    ${ }^{11}$ For proton accelerators, such energy loss is much less of a problem, because $\gamma$ of an ultra-relativistic particle (at fixed $\mathcal{E}$ ) is proportional to $1 / m$, so that the estimates, at the same $R$, should be scaled back by $\left(m_{p} / m_{e}\right)^{4} \sim 10^{13}$. Nevertheless, in the giant modern accelerators such as the LHC (with $R \approx 4.3 \mathrm{~km}$ and $\varepsilon \approx 7 \mathrm{TeV}$ ), the synchrotron radiation loss per revolution is rather noticeable ( $\mathcal{P} \Delta t^{\prime} \sim 6 \mathrm{keV}$ ), leading not as much to particle deceleration as to substantial photoelectron emission from the beam tube walls, creating harmful defocusing effects.

[^431]:    ${ }^{12}$ If the observation point is off-plane, or if the rotation speed is much less than $c$, the radiation is virtually monochromatic, with frequency $\omega_{c}$.

[^432]:    ${ }^{13}$ In contrast to the single-frequency case (i.e. a monochromatic wave), we may avoid taking real part of the complex function $\left(\mathbf{E}_{\omega} e^{-i \omega}\right)$ if we require that $\mathbf{E}_{-\omega}=\mathbf{E}_{\omega}{ }^{*}$. However, it is important to remember the factor $1 / 2$ required for the transition to a monochromatic wave of frequency $\omega_{0}$ : $\mathbf{E}_{\omega}=\mathbf{E}_{0}\left[\delta\left(\omega-\omega_{0}\right)+\delta\left(\omega+\omega_{0}\right)\right] / 2$.
    ${ }^{14}$ Note that the expression under the integral differs from $d \mathcal{P} / d \Omega$ defined by Eq. (29) by the absence of term (1$\beta \cdot \mathbf{n})=\partial t^{\prime} / \partial t$. This is natural, because this is the wave energy arriving at the observation point $\mathbf{r}$ during time interval $d t$ rather than $d t$ '.

[^433]:    ${ }^{15}$ See, e.g. MA Eq. (14.3a).
    16 The notion of spectral density may be readily generalized to random processes - see, e.g., SM Sec. 5.4.
    17 Note that for our current purposes of calculation of spectral density of radiation by a single particle, factor $\exp \{i \omega r / c\}$ has got cancelled. However, as we have seen in Chapter 8, this factor plays the central role at

[^434]:    interference of radiation from several (many) sources. In the context of synchrotron radiation, such interference becomes important in undulators and free-electron lasers - the devices to be (qualitatively) discussed below.
    ${ }^{18}$ Actually, this simplification is not occasional. According to Eq. (10b), the expression under the derivative is just the transverse component of the vector-potential $\mathbf{A}$ (give or take a constant factor), and from the discussion in Sec. 8.2 we know that this component determines the electric dipole radiation of the particle (which dominates the radiation field in our current case of uncompensated electric charge).

[^435]:    ${ }^{19}$ By the way, this expression shows that the in-plane ( $x$ ) component of the electric field is an odd function of $t$ ' (and hence $t$-see its sketch in Fig. 7), while the perpendicular component is an even function of time. Also notice that for an observer exactly in the rotation plane $\left(\theta_{0}=0\right)$ the latter component vanishes.

[^436]:    ${ }^{20}$ The law of the spectral density decrease at large $v$ may be readily obtained from the second of Eqs. (2.158) which is valid even for any (even non-integer) Bessel function index $n: a_{x} \propto a_{y} \propto v^{-1 / 2} \exp \{-v\}$. Here the exponential factor is certainly most important.
    ${ }^{21}$ For that, and many other details, the interested reader may be referred, for example, to the fundamental review collection by E. E. Koch et al. (eds.) Handbook on Synchrotron Radiation (in 5 vols.), North-Holland, 1983-1991, or a more concise monograph by A. Hofmann, The Physics of Synchrotron Radiation, Cambridge U. Press, 2007.

[^437]:    ${ }^{22}$ By modern standards, this energy is not too high. The distinguished feature of NSLS-II is its unprecedented electron beam intensity (planned average beam current up to 500 mA ) which should allow an extremely high synchrotron "brightness" $I(\omega)$.

[^438]:    ${ }^{23}$ A small problem for the reader: use Eqs. (20) and (63) to explain the difference between the shapes of pulses generated at opposite magnetic poles of the wiggler, which is schematically shown in Fig. 12a.

[^439]:    ${ }^{24}$ This important formula may be also interpreted in the following way. Due to the relativistic length contraction (9.20), the undulator structure period as perceived by beam electrons is $\lambda^{\prime}=\lambda / \gamma$, so that the central frequency of radiation is $\omega_{0}{ }^{\prime}=2 \pi c / \lambda^{\prime}=2 \pi c / / \lambda$. For the lab-frame observer, this frequency is Doppler-upshifted according to Eq. (9.44): $\omega_{0}=\omega_{0}{ }^{\prime}[(1+\beta) /(1-\beta)]^{1 / 2} \approx 2 \gamma \omega_{0}{ }^{\prime}$, giving the same result as Eq. (74).
    ${ }^{25}$ Much of the difference is due to the fact that that those plots show the spectral density of the number of photons $n=\varepsilon / \hbar \omega$ per second, which peaks above the density of power, i.e. energy $\varepsilon$ per second.
    ${ }^{26}$ This name is somewhat misleading, because in contrast to the usual ("quantum") lasers, the free-electron laser operation is essentially classical and very similar to that of vacuum-tube microwave generators (such as magnetrons briefly discussed in Sec. 9.6) - see, e.g., E. Salin et al., The Physics of Free Electron Lasers, Springer, 2000.
    ${ }^{27}$ Such X-ray radiation had been observed experimentally, though not correctly interpreted by N. Tesla in 1887, i.e. before the radiation was studied in detail (and much publicized) by W. Röntgen.

[^440]:    ${ }^{28}$ In publications on this topic (whose development peak was in the 1920s and 1930s), Gaussian units are more common, and letter $Z$ is usually reserved for expressing charges as multiples the fundamental charge $e$, rather than for the wave impedance. This is why, in order to avoid confusion, in this section I will use $1 / \varepsilon_{0} c \equiv Z_{0}$ for the free-space wave impedance and, still sticking to the same SI units as used through my lecture notes, will write the coefficients in a form that makes the transfer to the Gaussian units trivial: it is sufficient to replace all $\left(q q^{\prime} / 4 \pi \varepsilon_{0}\right)_{\text {SI }}$ with $\left(q q^{\prime}\right)_{\text {Gaussian. }}$. In the (rare) cases when I spell out the charge values, I will use a different font: $q \equiv \mathcal{Z}^{e}, q^{\prime} \equiv \mathcal{\xi}^{\prime} e$.
    ${ }^{29}$ A more careful analysis shows that this approximation is actually quite reasonable up to much higher frequencies of the order of $\gamma^{2} / \tau$.
    ${ }^{30}$ Evidently, this result (but not the general Eq. (76)!) may be derived from Eq. (8.27) as well.
    ${ }^{31}$ Please note the font-marked difference between this variable $(\boldsymbol{q})$ and particle's electric charge $(q)$.

[^441]:    ${ }^{32}$ See, e.g., CM Sec. 3.7.
    ${ }^{33}$ See, e.g., CM Eq. (3.72) with constant $\alpha=q q$ ' $/ 4 \pi \varepsilon_{0}$. In the form used in Eq. (80), the Rutherford formula is also valid for small-angle scattering of relativistic particles, the criterion being $|\Delta \boldsymbol{\beta}| \ll 2 / \gamma$.
    ${ }^{34}$ Angle $\theta$ ' and differential $d \Omega$ ', describing the direction of scattered particles, should not be confused with $\theta$ and $d \Omega$ describing directions of the radiation emitted at the scattering event.

[^442]:    ${ }^{35}$ The modifications of this formula necessary for the relativistic case description are surprisingly minor - see, e.g., Chapter 15 of J. D. Jackson, Classical Electrodynamics, $3^{\text {rd }}$ ed., Wiley 1999. For more detail, the standard reference monograph on bremsstrahlung is W. Heitler, The Quantum Theory of Radiation, $3^{\text {rd }}$ ed., Oxford U. Press 1954 (reprinted in 2010 by Dover).
    ${ }^{36}$ See, e.g., QM Secs. 6.3, 9.3, 9.5, and 9.7.
    ${ }^{37}$ See, e.g., MA Eq. (6.14).
    ${ }^{38}$ According to Eq. (9.139), $E_{z}=0$, and the net impulse of the longitudinal force $q^{\prime} E_{x}$ is zero.

[^443]:    39 A quantum analysis (carried out by H. Bethe in 1940) replaces, in Eq. (95), $\ln B$ with $\ln \left(2 \gamma^{2} m u^{2} / \hbar\langle\omega\rangle\right)-\beta^{2}$, where $\langle\omega\rangle$ is the average frequency of the atomic quantum transitions weight by their oscillator strength. This refinement does not change the estimate given below. Note that both the classical and quantum formulas describe, a fast increase (as $1 / \beta$ ) of the energy loss rate $(-d \varepsilon / d x)$ at $\gamma \rightarrow 1$ and its slow increase (as $\ln \gamma$ ) at $\gamma \rightarrow \infty$, so that the losses have a minimum at $(\gamma-1) \sim 1$.

[^444]:    ${ }^{40}$ Actually, the above analysis has neglected the change of momentum of the incident particle. This is legitimate at $m^{\prime} \ll m$, but for $m=m$ ' the change approximately doubles the energy losses. Still, this does not change the order of magnitude of the estimate.
    ${ }^{41}$ All integrals here and below are in infinite limits, unless specified otherwise.
    ${ }^{42}$ As was discussed in Sec. 7.2, the Ohmic conductivity of the medium (generally, also a function of frequency) may be readily incorporated into the dielectric permittivity: $\varepsilon(\omega) \rightarrow \varepsilon_{\mathrm{ef}}(\omega)+i \sigma(\omega) / \omega$. In this section, I will assume that such incorporation, which is especially natural for high frequencies, has been performed, so that the current density $\mathbf{j}(\mathbf{r}, \mathrm{t})$ describes only stand-alone currents - for example, the current (105) of the incident particle.

[^445]:    ${ }^{43}$ See, e.g., MA Eq. (6.5a).
    ${ }^{44}$ As a reminder, the main properties of these functions are listed in Sec. 2.5 of these notes - see, in particular, Fig. 2.20b and Eqs. (2.157)-(2.158).

[^446]:    ${ }^{45}$ Strictly speaking, inequality $\kappa^{2}<0$ does not make sense for a medium with complex $\varepsilon(\omega) \mu(\omega)$ and hence complex $\kappa^{2}(\omega)$. However, in a typical medium where particles can propagate over substantial distances, the imaginary part of product $\delta(\omega) \mu(\omega)$ does not vanish only in very limited frequency intervals, much more narrow that the intervals which we are now discussing - please have one more look at Fig. 7.5.
    ${ }^{46}$ This radiation was observed experimentally by P. Cherenkov (in older Western texts, "Čerenkov") in 1934, with the observations explained by I. Frank and E. Tamm in 1937. Note, however, that the effect had been predicted theoretically as early as in 1889 by the same O. Heaviside whose name was mentioned so many times above - and whose genius I believe is still underappreciated.

[^447]:    ${ }^{47}$ See, e.g., a brief discussion in CM Sec. 8.6.

[^448]:    48 See, e.g., http://delphiwww.cern.ch/offline/physics/delphi-detector.html. For a broader view at radiation detectors (including Cherenkov ones), the reader may be referred to the classical text by G. F. Knoll, Radiation Detection and Measurement, $4^{\text {th }}$ ed., Wiley, 2010, and a newer treatment by K. Kleinknecht, Detectors for Particle Radiation, Cambridge U. Press, 1999.
    ${ }^{49}$ The effect was predicted theoretically in 1946 by V. Ginzburg and I. Frank, and only later observed experimentally.

[^449]:    ${ }^{50}$ See, e.g., Sec. 5.3 in K. Kleinknecht's monograph cited above.

[^450]:    ${ }^{51}$ This formula may be readily generalized to the relativistic case:

    $$
    F_{\text {self }}^{\alpha}=\frac{2}{3 m c^{3}} \frac{q^{2}}{4 \pi \varepsilon_{0}}\left[\frac{d^{2} p^{\alpha}}{d \tau^{2}}+\frac{p^{\alpha}}{(m c)^{2}}\left(\frac{d p_{\beta}}{d \tau} \frac{d p^{\beta}}{d \tau}\right)\right],
    $$

[^451]:    ${ }^{52}$ Note: this operation cannot be interpreted as describing a quantum spread due to the finite extent of point particle's wavefunction. In quantum mechanics, parts of wavefunction of the same charged particle do not interact with each other!

[^452]:    ${ }^{53}$ See, e.g., CM Sec. 6.6.
    ${ }^{54}$ See, e.g., QM Chapter 9 and references therein.

[^453]:    ${ }^{55}$ See, e.g., EM Sec. 9.3, in particular Eq. (9.53) and its discussion.
    ${ }^{56}$ As the Maxwell equation for $\nabla \times \mathbf{H}$ shows, such field distribution cannot be created in any nonvanishing volume of free space. However, it may be created on a line - e.g., on particle's straight trajectory.

[^454]:    ${ }^{1}$ For remedial reading, I can recommend, for example, D. Griffith, Quantum Mechanics, $2^{\text {nd }}$ ed., Cambridge U. Press, 2016.
    ${ }^{2}$ This expression was used in a 1900 talk by Lord Kelvin (born W. Thomson) in reference to the blackbody radiation measurements and Michelson-Morley experiment results, i.e. the precursors of the quantum mechanics and relativity theory.
    ${ }^{3}$ See, e.g., EM Sec. 7.9. The degeneracy factor 2 in Eq. (1) is due to two possible polarizations of transverse electromagnetic waves. For waves of other physical nature, which obey with the linear ("acoustic") dispersion law, similar relations are also valid, though possibly with a different degeneracy factor - see, e.g., CM Sec. 7.7. ${ }^{4}$ See, e.g., SM Sec. 2.2.
    ${ }^{5}$ In the SI units, used through these notes, $k_{\mathrm{B}} \approx 1.38 \times 10^{-23} \mathrm{~J} / \mathrm{K}$. Note that in many theoretical papers (and in the SM part of my notes), $k_{\mathrm{B}}$ is taken for 1 , i.e. temperature is measured in energy units.

[^455]:    ${ }^{6}$ M. Planck himself wrote $\hbar \omega$ as $h v$, where $v=\omega / 2 \pi$ is the "cyclic" frequency, measured in Hz (periods per second), so that in early texts the term "Planck's constant" referred to $h \equiv 2 \pi \hbar$, while $\hbar$ was called "the Dirac constant" for a while.

[^456]:    ${ }^{7}$ As a reminder, A. Einstein received his only Nobel Prize (in 1922) for exactly this work, which essentially started quantum mechanics, rather than for his relativity theory.
    ${ }^{8}$ For most metals, $W$ is between 4 and 5 electron-volts (eV), so that the threshold corresponds to $\lambda_{\max }=2 \pi c / \omega_{\min }=$ $c h / W \approx 300 \mathrm{~nm}$ - approximately at the border between the visible light and ultraviolet radiation.
    ${ }^{9}$ See, e.g., SM Sec. 2.5.
    ${ }^{10}$ See, e.g., EM Sec. 8.2.

[^457]:    ${ }^{11}$ Besides very small corrections due to the finite ratio of the electron mass $m_{e}$ to that of the nuclei, and minor spin-orbital and relativistic effects - see Secs. 6.3 and 9.7 below.
    ${ }^{12}$ Unfortunately, another mane, "Rydberg constant" is also frequently used for either this atomic energy unit or its half, $E_{H} / 2 \approx 13.6 \mathrm{eV}$. To add to the confusion, the same term "Rydberg constant" is sometimes used for the reciprocal free-space wavelength $\left(1 / \lambda_{0}=\omega_{0} / 2 \pi c\right)$ corresponding to frequency $\omega_{0}=E_{\mathrm{H}} / 2 \hbar$.

[^458]:    ${ }^{13}$ This fact was noticed and discussed in detail in 1923 by L. de Broglie, so that instead of discussing wavefunctions, especially of free particles, we are still frequently speaking of de Broglie waves.
    ${ }^{14}$ This effect was observed (in 1922) and explained a year later by A. Compton.
    ${ }^{15}$ See, e.g., EM Sec. 9.3.

[^459]:    ${ }^{19}$ Actually, in wave mechanics, the spin of the described particle has not to be equal zero. Rather, it is assumed that the spin effects are negligible - as they are, for example, for a non-relativistic electron moving in a region without an appreciable magnetic field.
    ${ }^{20}$ As a reminder, for many systems (including those whose kinetic energy is a quadratic-homogeneous function of generalized velocities, like $m v^{2} / 2$ ), $H$ coincides with the total energy $E-$ see, e.g., CM Sec. 2.3.
    ${ }^{21}$ Note that this restriction is very important. In particular, it excludes from our current discussion the particles whose interaction with environment is irreversible, for example it is the viscosity leading to particle's energy decay. Such systems need a more general quantum-mechanical description that will be discussed in Chapter 7 .
    ${ }^{22}$ Generally, quantum mechanics, as any theory, may be built on different sets of postulates ("axioms") leading to the same conclusions. In this text, I will not try to beat down the number of postulates to the absolute minimum, not only because this would require longer argumentation, but chiefly because such attempts typically result in making certain implicit assumptions hidden from the reader - the practice as common as regrettable.
    ${ }^{23}$ I will imply such perfect conditions until the discussion of particle's interaction with environment, and realistic ("physical") measurements in Chapter 7.

[^460]:    ${ }^{24}$ This is one more important caveat. As we will see in Chapter 7, in many cases even the Hamiltonian particles cannot be described by a certain wavefunction, and allow only a more general (and less precise) description, e.g., by the density matrix.
    ${ }^{25}$ This key measurement postulate is sometimes called the Born rule.

[^461]:    ${ }^{26}$ For an electrically charged particle in magnetic field, this relation is valid for its canonical momentum - see Sec. 3.1 below.
    ${ }^{27}$ See, e.g., Secs. 8-10 of the Selected Mathematical Formulas appendix (below, referred to as MA). Note that according to these formulas, the del operator follows all the geometric rules of the usual ( $c$-number) vectors. This is, by definition, true for other vector operators of quantum mechanics to be discussed below.
    ${ }^{28}$ See, e.g., CM Sec. 10.3.
    ${ }^{29}$ See, e.g., CM Sec. 7.7 and/or EM Sec. 7.1.

[^462]:    ${ }^{30}$ For infinite space ( $V \rightarrow \infty$ ), Eq. (31) yields $a \rightarrow 0$, i.e. wavefunction (29) vanishes. This formal problem may be readily resolved considering sufficiently long wave packets - see Sec. 2.2 below.

[^463]:    ${ }^{31}$ See, e.g., SM Secs. 5.8 and 6.2, respectively.

[^464]:    ${ }^{32}$ Note that this requirement is not extended to the relativistic quantum theory - see Chapter 9 below.

[^465]:    ${ }^{33}$ As a reminder, such description is valid not only for potential forces (in that case $U$ has to be timeindependent), but also for any force $\mathbf{F}(\mathbf{r}, t)$ which may be presented via the gradient of $U(\mathbf{r}, t)$ - see, e.g., CM Chapters 2 and 10. (A good example when such a description is impossible is given by the magnetic component of the Lorentz force - see, e.g., EM Sec. 9.7, and also Sec. 3.1 of this course.)
    ${ }^{34}$ Historically, this was the main step made (in 1926) by E. Schrödinger on the background of L. de Broglie's idea. The probabilistic interpretation of the wavefunction was put forward, almost simultaneously, by M. Born. ${ }^{35}$ In Chapter 4, we will discuss a more general family of Hermitian operators, which have this property.
    ${ }^{36}$ See, e.g., MA Eq. (11.4a), combined with the del operator's definition $\nabla^{2} \equiv \nabla \cdot \nabla$.
    ${ }^{37}$ See, e.g., MA Eq. (12.2).

[^466]:    ${ }^{38}$ See, e.g., respectively, CM 7.2 and EM Sec. 4.1.
    ${ }^{39}$ By the way, if any equality involving operators is valid for an arbitrary wavefunction, the latter is frequently dropped from notation, resulting in an operator equality. In particular, Eq. (53) may be readily used to prove that the operators are commutative: $\hat{A}_{2}+\hat{A}_{1}=\hat{A}_{1}+\hat{A}_{2}$, and associative: $\left(\hat{A}_{1}+\hat{A}_{2}\right)+\hat{A}_{3}=\hat{A}_{1}+\left(\hat{A}_{2}+\hat{A}_{3}\right)$.

[^467]:    ${ }^{40}$ It may seem strange that the linear Schrödinger equation correctly describes quantum properties of systems whose classical dynamics is described by nonlinear equations of motion (e.g., an anharmonic oscillator - see, e.g., CM Sec. 4.2). Note, however, that equations of classical physical kinetics (see, e.g., SM Chapter 6) also have this property, so it is not specific to quantum mechanics.
    ${ }^{41}$ This argumentation, leading to variable separation, is very common in mathematical physics - see, e.g., its discussion in EM Sec. 2.5.

[^468]:    ${ }^{42}$ In contrast, the initial Eq. (24) is frequently called the time-dependent or nonstationary Schrödinger equation.
    ${ }^{43}$ From German root eigen meaning "particular" or "characteristic".
    ${ }^{44}$ Eigenvalues of energy are frequently called eigenenergies, and it is often said that eigenfunction $\psi_{n}$ and eigenenergy $E_{n}$ together characterize $n$-th stationary eigenstate of the system.

[^469]:    ${ }^{45}$ By using the term "quantum well" for what is essentially a potential well I bow to a common, but a very unfortunate convention. Indeed, this term seems to imply that the particle's confinement in such a "quantum well" is a phenomenon specific for quantum mechanics, while as we will repeatedly see in this course, that the opposite is true: quantum effects do as much as they only can to overcome particle's confinement in a potential well, letting the particle to partly penetrate the "classically forbidden" regions.
    ${ }^{46}$ Rewritten as $\nabla^{2} f+k^{2} f=0$, this is the Helmholtz equation, which describes scalar waves of any nature (with wave vector $\mathbf{k}$ ) in a uniform, linear media - see, e.g., CM Sec. 5.5 and/or EM Secs. 7.7-7.9.

[^470]:    ${ }^{47}$ The front coefficient is selected in a way that ensures the (ortho)normality condition (64).

[^471]:    ${ }^{48}$ In some systems (e.g., a particle interacting with a finite-depth quantum well), a discrete energy spectrum within a certain interval of energies may coexist with a continuous spectrum in a complementary interval. However, the conceptual philosophy of eigenfunctions and eigenvalues remains the same in this case as well.

[^472]:    ${ }^{49}$ For a more detailed discussion of this point, the reader may be referred, e.g., to CM Secs. 5.4 (in the context of 1D mechanical waves), because it is valid for waves of any nature.

[^473]:    ${ }^{50}$ Many textbooks on quantum mechanics jump to solution of 1D without such discussion, and most of my beginning graduate students did not understand that in realistic physical systems, such dimensionality restriction is only possible under very specific conditions.
    ${ }^{51}$ The term "quantum confinement", sometimes used to describe this phenomenon, is as unfortunate as the "quantum well", because of the same reason: the confinement is a purely classical effect, and as we will repeatedly see in this course, quantum mechanics reduces it, allowing a partial penetration of the particle into the classically forbidden regions with $E>U(\mathbf{r})$.
    ${ }^{52}$ The last term in Eq. (86) is frequently referred to as the (partial) confinement energy; despite its inclusion to $U_{\text {ef }}$, it is important to remember about the kinetic-energy origin of this contribution.

[^474]:    ${ }^{53}$ In the frequent case when motion in the $[x, y]$ plane is free (or almost free), the set of quantum states with the same quantum number $n_{z}$ is frequently called a subband, because their energies form a (quasi-) continuum of eigenenergies $E_{x, y}$.
    ${ }^{54}$ To be discussed in Sec. 3.2.
    ${ }^{55}$ See, e.g., P. Harrison, Quantum Wells, Wires, and Dots, $3^{\text {rd }}$ ed., Wiley, 2010.
    ${ }^{56}$ This is a reasonable first approximation, for example, for electron motion potential in so-called quantum wires, for example in the now-famous carbon nanotubes - see, e.g., the same monograph by P. Harrison.

[^475]:    1D number

[^476]:    ${ }^{57}$ Despite the theorem's name, H. Hellmann (in 1937) and R. Feynman (in 1939) were not the first in the long list of physicists who have (apparently, independently) discovered this fact. Indeed, it may be traced back at least to a 1922 paper by W. Pauli, and was carefully proved by P. Güttinger in 1931.

[^477]:    ${ }^{58}$ You may like to start from reading about the finite-difference method - see, e.g., CM Sec. 8.5 or EM Sec. 2.8.

[^478]:    ${ }^{1}$ Eq. (13) may be proved even if $\langle x\rangle$ and $\left\langle p_{x}\right\rangle$ are not equal to zero, by making the following replacements, $x \rightarrow x$ $\langle x\rangle, \partial / \partial x \rightarrow \partial / \partial x+i\langle p\rangle / \hbar$, in Eq. (7), and then repeating all the calculations - which become rather bulky. We will re-derive the uncertainty relations, in a more efficient way, in Chapter 4.

[^479]:    ${ }^{2}$ From this point on, in this chapter I will drop index $x$ in notation for $x$-component of vectors $\mathbf{k}$ and $\mathbf{p}$.
    ${ }^{3}$ This may be readily proven using the well-known integral of the Gaussian function ("bell curve") given by Eq. (17) - see, e.g., MA Eq. (6.9b). It is also straightforward to use MA Eq. (6.9c) to prove that for wave packet (16), parameter $\delta x$ is indeed the r.m.s. uncertainty (1.34) of coordinate $x$, thus justifying its notation.

[^480]:    ${ }^{4}$ For notation's brevity, from this point on the infinite limit signs will be dropped in all 1D integrals.
    ${ }^{5}$ The fact that the argument shift is imaginary is not important, because function under the integral is analytical, and tends to zero at $\operatorname{Re} x^{\prime} \rightarrow \pm \infty$.

[^481]:    ${ }^{6}$ Note that this packet is equivalent to Eq. (16) and hence is properly normalized to 1 - see Eq. (3). Hence the wave packet introduction offers a natural solution to the problem of infinite wave normalization, which was mentioned in Sec. 1.2.

[^482]:    ${ }^{7}$ See, e.g., brief discussions in CM Sec. 5.3 and EM Sec. 7.2.
    ${ }^{8}$ By the way, in the particular case of de Broglie wave described by dispersion relation (1.30), Eq. (28) is exact, because $\omega=E / \hbar$ is a quadratic function of $k=p / \hbar$, and all higher derivatives of $\omega$ over $k$ vanish for any $k_{0}$.

[^483]:    ${ }^{9}$ Its standard notation by letter $G$ stems from the fact that the propagator is essentially the spatial-temporal Green's function of Eq. (2.18), defined very similarly to Green's functions of other ordinary and partial differential equations describing various physics systems - see, e.g., CM Sec. 4.1 and/or EM Sec. 2.7 and 7.3.

[^484]:    ${ }^{10}$ Note that this initial condition is not equivalent to a $\delta$-functional initial probability density (2).

[^485]:    ${ }^{11}$ It was predicted theoretically by B. Josephson (then a graduate student!) in 1962 and observed experimentally in less than a year. More recently, analogs of this effect were also observed in superfluid helium and atomic BoseEinstein condensates.
    ${ }^{12}$ See, e.g., SM Sec. 3.4.
    ${ }^{13}$ For more on this notion see, e.g. SM Sec. 6.4.
    ${ }^{14}$ Later, Eq. (55) has been shown to be valid for other weak link types as well, though deviations from have also been found. These deviations, however, do not affect the fundamental $2 \pi$-periodicity of function $I(\varphi)$ - see, e.g., EM Sec. 6.4. As a result, no deviations from the fundamental relations (56)-(57) have been found (yet :-).

[^486]:    ${ }^{15}$ See, e.g., CM Sec. 4.4.
    ${ }^{16}$ If $\omega$ is not too high, this effect may be adequately described combining Eqs. (54)-(55). Let me leave this task for the reader.
    ${ }^{17}$ The most precise proof that the Josephson frequency-to-voltage ratio $f_{\mathrm{J}} / V$ does not depend on superconducting material (to at least 15 decimal places!) has been carried out by the group led by J. Lukens here at Stony Brook see J.-S. Tsai et al., Phys. Rev. Lett. 51, 316 (1983).

[^487]:    ${ }^{18}$ Note that this is not the eigenproblem like the one we have solved in Sec. 1.4 for a quantum well. Indeed, now energy $E$ is considered fixed - e.g., by the initial conditions that launch a long wave packet upon the potential step, from the left.

[^488]:    ${ }^{19}$ Our earlier discarding of the particular solution $\exp \{\kappa x\}$, now becoming $\exp \left\{-i k^{\prime} x\right\}$, is still valid, but now on a different grounds: this term would describe a wave packet incident on the potential step from the right, and this is not the problem under our consideration.
    ${ }^{20}$ These formulas are completely similar to those for the partial reflection of classical waves from a sharp interface between two uniform media, at normal incidence (see, e.g., CM Sec. 5.4 and EM Sec. 7.4), with the effective impedance $Z$ of de Broglie waves proportional to their wave number $k$.

[^489]:    ${ }^{21}$ See, e.g., G. Fursey, Field Emission in Vacuum Microelectronics, Kluwer, New York, 2005.
    ${ }^{22}$ See, e.g., G. Binning and H. Rohrer, Helv. Phys. Acta 55, 726 (1982).
    ${ }^{23}$ See, e.g., V. Sverdlov et al., IEEE Trans. on Electron Devices 50, 1926 (2003).

[^490]:    ${ }^{24}$ Philosophically, this space-domain method is very close to the time-domain rotating wave approximation (RWA) used, for example, in the classical and quantum theory of oscillations - see, e.g., CM Secs. 4.2-4.5, and Secs. 6.5, 7.6, 7.7, 9.2, and 9.4 of this course.
    ${ }^{25}$ Such perturbation theories will be discussed in Chapter 6.

[^491]:    ${ }^{26}$ For certainty, I will use the discretion given by Eq. (82) to define $k(x)$ as the positive root of its right-hand part.

[^492]:    ${ }^{27}$ An alternative way to solve the connection problem, without involving the Airy functions but using an analytical extension of WKB formulas to the plane of complex argument, may be found, e.g., in Sec. 47 of textbook by L. Landau and E. Lifshitz, Quantum Mechanics, Non-Relativistic Theory, 3rd ed. Pergamon, 1977.

[^493]:    ${ }^{28}$ The following (exact!) integral formulas,

    $$
    \operatorname{Ai}(\zeta)=\frac{1}{\pi} \int_{0}^{\infty} \cos \left(\frac{\xi^{3}}{3}+\zeta \xi\right) d \xi, \quad \operatorname{Bi}(\zeta)=\frac{1}{\pi} \int_{0}^{\infty}\left[\exp \left\{-\frac{\xi^{3}}{3}+\zeta \xi\right\}+\sin \left(\frac{\xi^{3}}{3}+\zeta \xi\right)\right] d \xi
    $$

[^494]:    ${ }^{29}$ Note that at motion in more than one dimension, a closed classical trajectory may have no turning points. In this case, the constant $1 / 2$ in the parentheses of Eq. (109), arising from the turns, should be dropped. The simplest example is the circular motion of the electron about the proton in Bohr's picture of the hydrogen atom, for which the modified quantization (109) condition takes form (1.10) postulated by N. Bohr. (A similar relation for the radial motion is sometimes called the Sommerfeld-Wilson quantization rule.)

[^495]:    ${ }^{30}$ Sorry, but the same letter, $d$, is used here for the barrier thickness (defined in this case as the classically forbidden region length, $x_{c}{ }^{\prime}-x_{c}$ ), and the constant in one of the wave amplitudes - see Eq. (116). Let me hope that the difference between these uses is absolutely evident from the context.

[^496]:    ${ }^{31}$ Note, however, that in the most important case $T_{\mathrm{wKB}} \ll 1$, Eq. (117) may be simply derived from Eqs. (105) an exercise left for the reader.
    ${ }^{32}$ It was carried out by E. Kemble in 1935. Notice that mathematically the Kemble formula is similar to the Fermi distribution in statistical physics, with effective temperature $T_{\text {ef }}=\hbar \omega_{0} / 2 \pi k_{\mathrm{B}}$. This similarity has some interesting implications for the statistics of Fermi gas tunneling.

[^497]:    ${ }^{34}$ In older literature, it is sometimes called the Ramsauer (or "Townsend", or "Ramsauer-Townsend") effect. However, it is currently more common to use that name(s) only for a similar 3D effect, especially at scattering of low-energy electrons on rare gas atoms - this is how it was first observed, independently, by C. Ramsauer and J. Townsend in the early 1920s.
    ${ }^{35}$ See also , e.g., EM Sec.7.9.
    ${ }^{36}$ The exact equality $T_{\max }=1$ is correct only if both component barriers are exactly equal.
    ${ }^{37}$ Probability $W(t)$ should not be confused with the delta-functional barrier's "area" $w$, defined by Eq. (122).

[^498]:    ${ }^{38}$ This almost evident assumption finds its formal justification in the perturbation theory to be discussed in Chapter 6.

[^499]:    ${ }^{39}$ Essentially the only requirement is to have the attempt time $\Delta t_{A}$ to be much longer than the effective time (instanton time, see Sec. 5.3 below) of tunneling through the barrier. In the delta-functional approximation for the barrier, the latter time vanishes, so that this requirement is always fulfilled.

[^500]:    ${ }^{40}$ Here I dare to refer the reader to my own old work K. Likharev, Int. J. Theor. Phys. 21, 311 (1982) that presented a constructive proof that at reversible computation (introduced in 1973 by C. Bennett) the energy dissipation may be lower than this apparent "quantum limit".
    ${ }^{41}$ See, e.g., a detailed discussion of this issue in the monograph by V. Braginsky and F. Khalili, Quantum Measurement, Cambridge U. Press, 1992.
    ${ }^{42}$ This argument is especially convincing if the particle detection time is much shorter than the time $t_{c}=2 v_{\mathrm{gr}} t / c$, where $c$ is the speed of light in vacuum, i.e. the maximum velocity of any information transfer ("signaling").

[^501]:    ${ }^{43}$ This formula will be easier to prove after we have discussed properties of Pauli matrices in Chapter 4.

[^502]:    ${ }^{44}$ Historically, the development of the fully quantum theory of $\mathrm{H}_{2}$ bonding by W. Heitler and F. London in 1927 was the breakthrough decisive for the acceptance of then-emerging quantum mechanics by chemists.
    ${ }^{45}$ Due to the opposite spins, the Pauli principle allows them to be in the same orbital ground state - see Chapter 8 .

[^503]:    ${ }^{46}$ Unit reminder: $1 \mathrm{~kJ} / \mathrm{mol} \approx 0.0434 \mathrm{eV}$.

[^504]:    WKB
    result for coupling energy

[^505]:    ${ }^{47}$ Since it is not true for potential (167), one should not be surprised that the resulting Eq. (189) is invalid for our initial problem, giving $\delta_{n}$ twice larger than the correct expression (178).

[^506]:    ${ }^{48}$ In solid state (especially semiconductor) physics and electronics, term bandgaps is more common.
    ${ }^{49}$ This expectation is implicitly confirmed by Fig. 20: at $\alpha \gg 1$, the highest resonance peak in each group tends to $k a=\pi n$, and the lowest peak also tend to a position independent of $N$ (though dependent on $\alpha$ ).

[^507]:    ${ }^{50}$ I am ashamed to confess that, due to the lack of time, this was virtually the only "lecture demonstration" in my QM courses.
    ${ }^{51}$ Named after F. Bloch who applied this concept to wave mechanics in 1929, i.e. very soon after its formulation. Admittedly, in mathematics, an equivalent statement, usually called the Floquet theorem, has been known since at least 1883.
    ${ }^{52}$ I will address this rigor in two steps. Later in this section, we will see that the function obeying Eq. (193) is indeed $a$ solution of the Schrödinger equation. However, to save time/space, it will be better for us to postpone the proof that any eigenfunction of the equation, with periodic boundary conditions, obeys the Bloch theorem, until Chapter 4. As a partial reward for the delay, that proof will be valid for an arbitrary spatial dimensionality.
    ${ }^{53}$ Product $\hbar q$, which has the dimensionality of momentum, is called either the quasi-momentum or (especially in the solid state physics) the "crystal momentum" of the particle.

[^508]:    ${ }^{54}$ Perhaps a more important reason for taking $q$ as the argument is that for motion in a general potential $U(x)$, particle's momentum $\hbar k$ is not a constant of motion, while (according to the Bloch theorem), the quasi-momentum $\hbar q$ is.

[^509]:    ${ }^{55}$ Below, we will see several other examples of this behavior. This alternation rule is also in accordance with the Bohr-Sommerfeld quantization condition

[^510]:    ${ }^{56}$ The benefits of my unusual choice of the summation index ( $l$ " instead of, say, $l$ ) will be clear in a few lines.

[^511]:    ${ }^{57}$ Note that we have essentially proved that the Bloch wavefunction (210) is indeed $a$ solution of Eq. (61), provided that the quasi-momentum $q$ is selected in a way to make the system of linear equation (215) compatible, i.e. is a solution of its characteristic equation - see, e.g., Eq. (223) below.
    ${ }^{58}$ Besides the constant potential $U_{0}$ that, as we know from Sec. 2, may be included into energy in a trivial way, so that we may take $U_{0}=0$.
    ${ }^{59}$ This method is so powerful that its multi-dimensional version is not much more complex than the 1D version described here - see, e.g., Sec. 3.2 in the classical textbook by J. M. Ziman, Principles of the Theory of Solids, $2^{\text {nd }}$ ed., Cambridge U. Press, 1979.

[^512]:    ${ }^{62}$ From that figure, it is also clear that in the weak potential limit, width $\Delta E_{n}$ of the $n$-th energy band is just $E^{(n)}-$ $E^{(n-1)}$ - see Eq. (221). Note that this is exactly the distance between adjacent energy levels of the simplest 1D quantum well of infinite depth - cf. Eq. (1.77).
    ${ }^{63}$ See, e.g., CM Sec. 5.1 and in particular Fig. 5.2.
    ${ }^{64}$ Actually, we could obtain this diagram earlier in this section, for the system of two weakly coupled quantum wells (Fig. 23), if we assumed the wells to be slightly dissimilar.

[^513]:    ${ }^{65}$ This equation, first studied in the 1860 s by É. Mathieu in the context of a rather practical problem of vibrating elliptical drumheads (!), has many other important applications in physics and engineering, notably including the parametric excitation of oscillations - see, e.g., CM Sec. 4.5.

[^514]:    ${ }^{66}$ Such plots, for several particular values of parameters, may be found, for example, in Figs. 8.11-8.13 of E. Merzbacher's textbook cited above.

[^515]:    67 A generalization of this expression to the case of essential interband transitions is not difficult using the Heisenberg picture of quantum mechanics (which will be discussed in Chapter 4 of this course) - see, e.g., Sec. 55 in E. M. Lifshitz and L. P. Pitaevskii, Statistical Physics, Part 2, Pergamon, 1980.

[^516]:    ${ }^{68}$ For a Gaussian packet, the spreading is described by Eq. (39), with the replacement $k \rightarrow q$; it is curious that at the inflection points with $d^{2} \omega / d q^{2}=0$ (which are present in each energy band) the packet does not spread.
    ${ }^{69}$ The proof of Eq. (237) is not difficult, but becomes more compact in the bra-ket formalism, to be discussed in Chapters 4 and 5. This is why I recommend the proof to the reader as an exercise after reading those two chapters.

[^517]:    ${ }^{70}$ The language is which the hole has a positive charge and mass has an additional convenience for states on the top of the valence band whose single-particle states are normally filled. Then the simplest, single-particle excitation of this multi-particle ground state may be created by giving one electron enough energy to lift it to a reference (e.g., Fermi-energy) level $E_{\mathrm{F}}$ that is, by definition of the valence band, is higher than all values $E(q)$. Then it is natural to prescribe to the excitation a positive mass $m_{\mathrm{ef}}$, because the energy $\Delta E=E_{\mathrm{F}}-E_{-}(q)$ necessary for the excitation grows with the deviation of $q$ from $q_{m}$.
    ${ }^{71}$ Intuition tells us (and statistical physics duly confirms :-) that this may be readily done, for example, by weakly coupling the system to a low-temperature environment, and letting it to relax to the lowest possible energy.

[^518]:    72 This phenomenon may be also discussed from the point of view of the reduced zone picture, but then it requires the introduction of instant jumps between the Brillouin zone boundary points (see the dashed red line in Fig. 32) that correspond to physically equivalent states of the particle. Evidently, this language is more artificial.

[^519]:    ${ }^{73}$ See, e.g., CM Sec. 1.5.
    ${ }^{74}$ In semiconductor device physics and engineering, such plots are called the band edge diagrams, and are the virtually unavoidable components of any discussion or publication.

[^520]:    ${ }^{75}$ In systems with many independent particles (such as semiconductors), the detection problem is exacerbated by phase incoherence of the Bloch oscillations performed by each particle. This drawback is absent in atomic BoseEinstein condensates whose Bloch oscillations (in a periodic potential created by standing optical waves) were eventually observed by M. Ben Dahan et al., Phys. Rev. Lett. 76, 4508 (1996).
    ${ }^{76}$ A simple analysis of phase locking of a classical oscillator may be found, e.g., in CM Sec. 4.4.
    ${ }^{77}$ A qualitative theory of such transitions will be discussed in Sec. 6.6 and then in Chapter 7.
    ${ }^{78}$ E. Mendez et al., Phys. Lev. Lett. 60, 2426 (1988).
    ${ }^{79}$ L. Kuzmin and D. Haviland, Phys. Rev. Lett. 67, 2890 (1991).

[^521]:    ${ }^{80}$ This unfortunate slip in the formula numbering can hardly lead to any misunderstanding.
    ${ }^{81}$ Of course, the dimensionality of $m_{\text {ef }}$ so defined is different from kg .
    ${ }^{82}$ This term has originated from the fact that the right-hand part of Eq. (253) equals to the single quantum unit $\left(\Phi_{0}\right)$ of the magnetic flux in superconductors - see Sec. 3.1 below.
    ${ }^{83}$ See, e.g., P. Bunyk et al., Int. J. on High Speed Electronics and Systems 11, 257 (2001).

[^522]:    ${ }^{84}$ Eq. (254) tells us that quasi-charge $Q$ has the simple physical sense of the external electric charge being inserted into the junction by the external current $I_{\text {ex }}$ - just like the physical sense of quasi-momentum $\hbar q$ of a mechanical particle, according to Eq. (237), is the contribution to particle's momentum by the external force $F$.
    ${ }^{85}$ D. Averin et al., Sov. Phys. - JETP 61, 407 (1985).
    ${ }^{86}$ Phase locking of the Bloch oscillations, with frequency (258), as well as that of very similar SET oscillations of frequency $f_{\mathrm{SET}}=I / e$, by a signal of well characterize frequency, enable fundamental standards of dc current. The experimentally achieved accuracy of such standards is close to $10^{-8}$, a few times worse than that of a less direct way - using the Josephson voltage standard and the resistance standard based on the quantum Hall effect.

[^523]:    ${ }^{87}$ It was predicted independently by L. D. Landau, Phys. Z. Sowjetunion 2, 46 (1932) and C. Zener, Proc. R. Soc. London A 137, 696 (1932).

[^524]:    ${ }^{88}$ Note that Eq. (264) is still limited to the hyperbolic dispersion relation, i.e. (in the band theory) to the weak potential limit. In the opposite, tight-binding limit, the interband tunneling may be treated as an excitation of the upper band states by sinusoidal Bloch oscillations, and is completely suppressed at $\hbar \omega_{\mathrm{B}}<\Delta_{1}$.

[^525]:    ${ }^{89}$ In Chapter 6, Eq. (266) will be derived using a different method based on the Golden Rule of quantum mechanics.
    ${ }^{90}$ See, e.g., SM Secs. 1.5 and 6.4.

[^526]:    ${ }^{91}$ See, e.g., CM Sec. 4.4.
    ${ }^{92}$ If not yet, I am inviting him or her to check this fact now by the direct substitution of solution (269) into the differential equation (268), simultaneously proving Eq. (270).
    ${ }^{93}$ Quantitatively, as was already mentioned in Sec. 2.1, $x_{0}=\sqrt{ } 2 \delta x=\left\langle 2 x^{2}\right\rangle^{1 / 2}$.

[^527]:    ${ }^{94}$ See, e.g., http://www.ligo.caltech.edu/, and a recent update by T. Feder, Phys. Today 68, No. 9, 20 (2015).
    ${ }^{95}$ According to the recent announcement by B. Abbott et al., Phys. Rev. Lett. 116, 061102 (2016), this sensitivity was sufficient for the first direct detection of gravitational waves emitted at a merger of two black holes.

[^528]:    ${ }^{96}$ These stationary states of the harmonic oscillator are sometimes called its Fock states, to distinguish them from other fundamental solutions (such as Glauber states) which will be discussed in Sec. 5.5 and beyond..
    ${ }^{97}$ In mathematics, a slightly more general statement, valid for a broader class of ordinary linear differential equations, is frequently called the Sturm oscillation theorem, and is a part of the Sturm-Liouville theory of such equations - see, e.g., Chapter 10 in the handbook by G. Arfken et al. recommended in MA Sec. 16.

[^529]:    ${ }^{98}$ The constant $P$ is called the force's impulse. (In higher dimensionalities, it is a vector - just as the force is.)
    ${ }^{99}$ Solving this problem is a good preparation to the use of the full variational method in the next two problems (and beyond).

[^530]:    100 With $F=m g$, this is just the well-known bouncing ball problem.
    ${ }^{101}$ See, e.g., Sec. 8.2 below.

[^531]:    ${ }^{102}$ In applications to electrons in solid-state crystals, the delta-functional quantum wells model the attractive potential of atomic nuclei, while $U_{0}$ represents the workfunction, i.e. the energy necessary for the extraction of an electron from the crystal to the free space - see, e.g., EM Sec. 2.6 and SM Sec. 6.4.

[^532]:    ${ }^{103}$ This system was used as the analytical mechanics "testbed problem" in the CM part of this series, and the reader is welcome to use any relations derived there - but remember that they pertain to the classical mechanics domain!

[^533]:    ${ }^{1}$ See, e.g., MA Eq. (10.9).

[^534]:    ${ }^{2}$ For a proof of Eq. (8), see, e.g., EM Sec. 8.5.
    ${ }^{3}$ A possible (and reasonable) concern about the application of Eq. (7) to the field in the slits is that it ignores the effect of opaque parts of the partition. However, as we know from Chapter 2, the main role of the classically forbidden region is providing the reflection of the incident wave towards its source (i.e. to the left in Fig. 1). As a result, the contribution of this reflection to the field inside the slits is insignificant is $A_{1,2} \gg \lambda^{2}$, and even in the opposite case provides just some rescaling of the amplitudes $a_{1,2}$, which is unimportant for our conceptual discussion.

[^535]:    ${ }^{4}$ See, e.g., a detailed discussion in EM Sec. 8.4.
    ${ }^{5}$ See, e.g., Sec. 5.1. Note that Eq. (14), as well as all other formulas of this course, are in the SI units; in Gaussian units, all terms which include either $\boldsymbol{B}$ or $\mathbf{A}$ should be divided by $c$, the speed of light in free space.

[^536]:    ${ }^{6}$ See, e.g., EM Sec. 9.7.
    ${ }^{7}$ See, e.g., EM Sec. 6.7, in particular Eqs. (6.106).
    ${ }^{8}$ Just for reader's reference, the classical Lagrangian corresponding to Hamiltonian (19) is

[^537]:    ${ }^{10}$ See, e.g., EM Sec. 5.3.
    ${ }^{11}$ I personally prefer the latter, less personable name, because the effect had been actually predicted by W. Ehrenberg and R. Siday in 1949, before it was rediscovered by Y Aharonov and D. Bohm in 1959. To be fair to Aharonov and Bohm, it was their work that triggered a wave of interest to the phenomenon, resulting in its first

[^538]:    ${ }^{13}$ One more bad, though common, term - a wire can (super)conduct, but a quantum hardly can!

[^539]:    ${ }^{14}$ For more detail, see EM Sec. 6.3.
    ${ }^{15}$ It was predicted in 1949 by F. London and experimentally discovered (independently and virtually simultaneously) in 1961 by two experimental groups: B. Deaver and W. Fairbank, and R. Doll and M. Näbauer.
    ${ }^{16}$ A brief review of these effects, and recommendations for further reading may be found in EM Sec. 6.4.

[^540]:    ${ }^{17}$ It was first observed in 1980 by K. von Klitzing and coworkers.
    18 Discovered in 1879 by E. Hall.

[^541]:    ${ }^{19}$ Recently, the quantum Hall effect was observed at room temperature in the graphene (a virtually perfect 2D sheet of carbon atoms, see Sec. 4 below) - see K. Novoselov et al., Science 315, 1379 (2007).

[^542]:    ${ }^{20}$ The explanation of this paradox may be obtained in terms of the so-called quantum edge channels - the quasi1D regions of width (51), along the lines were the Landau levels cross the Fermi surface. Particle motion along these channels, which is responsible for electron transfer, is effectively one-dimensional and thus cannot be affected by modest uniformities of the potential distribution $U(x, y)$.
    ${ }^{21}$ This fractional quantum Hall effect was discovered in 1982 by D. Tsui, H. Stormer, and A. Gossard. In contrast, the effect described by Eq. (55) with integer $i$ (Fig. 7) is now called the integer quantum Hall effect.
    ${ }^{22}$ For a comprehensive discussion of these effects I can recommend, e.g., either the monograph by D. Yoshioka, The Quantum Hall Effect, Springer, 1998, or the review by D. Yennie, Rev. Mod. Phys. 59, 781 (1987).

[^543]:    ${ }^{23}$ See, e.g., CM Sec. 3.7.
    ${ }^{24}$ In optics, this limit is called the Fraunhofer diffraction - see, e.g., EM Secs. (8.6) and (8.8).
    ${ }^{25}$ For example, in the simplest task of derivation of the so-called Rutherford formula for scattering of a charged non-relativistic particle by a point fixed charge, due to their Coulomb interaction - see, e.g., CM Sec. 3.7.

[^544]:    Born approximation

[^545]:    ${ }^{26}$ Named after M. Born, who was the first one to apply this approximation in quantum mechanics. However, the basic idea of this approach had been developed much earlier (in 1881) by Lord Rayleigh in the context of electromagnetic wave scattering - see, e.g., EM Sec. 8.3. Note that the contents of that section repeats much of our current discussion - regrettably but unavoidably so, because the Born approximation is a centerpiece of scattering theory for both electromagnetic and de Broglie waves.

[^546]:    ${ }^{27}$ Please notice both the similarity and difference between this Green's function and the propagator discussed in Sec. 2.1. In both cases, we use the linear superposition principle to solve wave equations, but while Eq. (68) gives the solution of the inhomogeneous equation (67), Eq. (2.44) does that for a homogeneous Schrödinger equation in which the wave sources are presented by initial conditions rather than by equation's right-hand part.
    ${ }^{28}$ See, e.g., EM Sec. 1.2.

[^547]:    ${ }^{29}$ See, e.g., EM Sec. 8.2.

[^548]:    ${ }^{30}$ It is easy to prove that this form is an asymptotic form of any solution $\psi_{s}$ of the scattering problem (even that beyond the Born approximation) at sufficiently large distances $r \gg a, k^{-1}$.
    ${ }^{31}$ Note that function $f$ has the dimension of length, and does not account for the incident wave. This is why sometimes a dimensionless function, $S=1+2 i k f$, is used instead. This function $S$ is called the scattering matrix, because it may be considered as a natural generalization of the 1D matrix S, defined by Eq. (2.133), to higher dimensionality.
    ${ }^{32}$ See, e.g., MA Eq. (10.8).

[^549]:    ${ }^{33}$ Note that according to Eq. (88), in the Born approximation the scattering intensity does not depend on the sign of potential $U$, and also that scattering in a certain direction is completely determined by a specific Fourier harmonic of function $U(\mathbf{r})$, namely by the harmonic with the wave vector equal to the scattering vector $\mathbf{q}$.

[^550]:    ${ }^{34}$ The construction of such series may be facilitated by the following observation. If we retain $\psi_{s}$ in the righthand part of Eq. (66), we may write a relation formally similar to Eq. (68) for the full wavefunction $\psi=\psi_{0}+\psi_{s}$ :

    $$
    \psi(\mathbf{r})=\psi_{0}(\mathbf{r})+\frac{2 m}{\hbar^{2}} \int U\left(\mathbf{r}^{\prime}\right) \psi\left(\mathbf{r}^{\prime}\right) G\left(\mathbf{r}, \mathbf{r}^{\prime}\right) d^{3} r^{\prime}
    $$

    This is one of forms of the Lipmann-Schwinger equation that is exactly equivalent to the differential Schrödinger equation (66) but is more convenient for some applications, in particular for the calculation of higher approximations $\psi_{n}$. Unfortunately, I will have not time to discuss this approach in detail and have to refer the reader, for example, to either Chapter 9 of the textbook by L. Schiff, Quantum Mechanics, $3^{\text {rd }}$ ed., McGraw-Hill, 1968, or (for even more details) to monograph by J. Taylor, Scattering Theory, Dover, 2006.

[^551]:    ${ }^{35}$ Named after A. Bravais, the crystallographer who introduced this notion in 1850.
    ${ }^{36}$ The strongest motivation for the band theory is provided by properties of solid crystals. Thus it is not surprising that perhaps the most clear, well illustrated introduction to the Bravais lattices may be found in Chapters 4 and 7 of the famous textbook by N. Ashcroft and N. Mermin, Solid State Physics, Saunders College, 1976.

[^552]:    ${ }^{37}$ It may be best understood as the sum of two fcc lattices of side $a$, mutually shifted by vector $\{1,1,1\} a / 4$, so that the distances between each point of the combined lattice and its 4 nearest neighbors (see the thick gray lines in Fig. 11c) are all equal.
    ${ }^{38}$ This structure is presently very popular due to the recent discovery of graphene - isolated monolayer sheets of carbon atoms arranged in a honeycomb lattice with the interatomic distance of 0.142 nm .
    ${ }^{39}$ A harder case is presented by quasicrystals (whose idea may be traced down to medieval Islamic tilings, but was discovered in natural crystals, by D. Shechtman et al., only in 1984), which obey high (say, 5 -fold) rotational symmetry, but cannot be described by a Bravais lattice with any finite primitive unit cell. For a popular review of quasicrystals see, for example, P. Stephens and A. Goldman, Sci. Amer. 264, \#4, 24 (1991).

[^553]:    ${ }^{40}$ For the 2D case ( $j=1,2$ ), one may use, for example, the first two formulas of Eq. (111) with $\mathbf{a}_{3}=\mathbf{a}_{1} \times \mathbf{a}_{2}$.
    ${ }^{41}$ See, e.g., MA Eq. (7.6).
    ${ }^{42}$ This notion is also the main starting point of X-ray diffraction studies of crystals, because it allows rewriting the well-known Bragg condition for diffraction peaks in an extremely simple form of the momentum conservation law: $\mathbf{k}=\mathbf{k}_{0}+\mathbf{Q}$, where $\mathbf{k}_{0}$ and $\mathbf{k}$ are the wave vectors of the, respectively, incident and diffracted photon.

[^554]:    ${ }^{43}$ See, e.g., MA Sec. 16 (iv).

[^555]:    ${ }^{44}$ Actually, using the same values of $\delta_{n}$ in both directions implies some sort of symmetry of the quasi-localized states. For example, $s$-states of axially-symmetric potentials (see the next section) always have such a symmetry.

[^556]:    ${ }^{45}$ This term is based on a (pretty loose) analogy with the Dirac theory of relativistic quantum mechanics, to be discussed in Chapter 9 below. Namely, in the vicinity of a Dirac point (122), Schrödinger equations (119), and hence the dispersion relation (122), may be obtained from the effective Hamiltonian $\hat{H}_{n}=\hbar v_{n} \hat{\boldsymbol{\sigma}} \cdot \hat{\widetilde{\mathbf{q}}}$. (Since vector $\widetilde{\mathbf{q}}$ is two-dimensional, this Hamiltonian employs only two of three Pauli matrices.) This expression reminds the first term of Dirac's Hamiltonian (9.97), which is defined, however, in a different Hilbert space.
    ${ }^{46}$ See, e.g., a recent review by A. Castro Neto et al., Rev. Mod. Phys. 81, 109 (2009). Note that transport properties of graphene are determined by coupling of $2 p_{z}$ electron states of carbon atoms, whose wavefunctions are proportional to $\exp \{ \pm i \varphi\}$ rather than are axially-symmetric as implied by Eqs. (120). However, due to the lattice symmetry this fact does not affect the dispersion relation $E(\mathbf{q})$.

[^557]:    ${ }^{47}$ This is a reasonable model for the confinement of light atoms, notably hydrogen, in some organic compounds.

[^558]:    ${ }^{48}$ See, e.g., MA Eq. (10.5).

[^559]:    ${ }^{49}$ This effect, whose qualitative features remain the same for all 2D or 3D localized states (see Chapter 6 below), is frequently referred to as the orbital diamagnetism. In magnetic materials consisting of particles with uncompensated spins, this effect competes with another effect, spin paramagnetism - see, e.g., EM Sec. 5.5.
    ${ }^{50}$ It is straightforward to check that Eqs. (133) and hence (135) remain valid even if the magnetic field lines do not touch the particle's trajectory, and the field is localized well inside rotator's ring.
    ${ }^{51}$ Such persistent, macroscopic diamagnetic currents in non-superconducting systems may be experimentally observed, for example, by measuring the weak magnetic field generated by electrons in a system of a large number $\left(\sim 10^{7}\right)$ of similar conducting rings - see, e.g., L. Lévy et al., Phys. Rev. Lett. 64, 2074 (1990). Due to the

[^560]:    ${ }^{55}$ Noting that for the planar rotator（Fig．16）$l / R=\varphi$ ，we can present Eq．（129）in a similar form．This is natural， because the rotator is just a particular case of our current problem－with a rigid confinement along axis $\rho$ ． ${ }^{56}$ See，e．g．，CM Sec．3．5．

[^561]:    ${ }^{57}$ A short summary of properties of these function, plus a few plots and a useful table of values, may be found in EM Sec. 2.4. For more on of Bessel functions, see the literature recommended in MA Sec. 16(ii).
    ${ }^{58}$ See, e.g., MA Eq. (10.9).

[^562]:    ${ }^{59}$ Here, rather regrettably, I had to replace the notation of the integer from $n$ to $m$, in order to comply with the generally accepted convention for this so-called magnetic quantum number. Let me hope that the difference between this integer and particle's mass is absolutely clear from the context.
    ${ }^{60}$ It was carried out by A.-M. Legendre (1752-1833). Just as a historic note: besides many original mathematical results, Dr. Legendre has authored the famous textbook Éléments de Géométrie, which dominated teaching geometry through the 19th century.

[^563]:    ${ }^{61}$ Derived independently by B. O. Rodrigues in 1816, J. Ivory in 1824, and C. Jacobi in 1827.
    ${ }^{62}$ In this behavior, we readily recognize the standing wave pattern typical for all 1D eigenproblems - cf. Fig. 1.7. The quantitative deviation from the sinusoidal waveform is due to the different metric of the sphere.

[^564]:    ${ }^{63}$ Such real functions $Y_{l m}$, which also form the full set of orthonormal eigenfunctions and are frequently called the real spherical harmonics, are more convenient than the complex functions $Y_{l}^{m}$ for several applications, especially when the variables of interest are real by definition.

[^565]:    ${ }^{64}$ The letter names for states with different values of $l$ stem from the history of optical spectroscopy - for example, letter " s ", used for $l=0$, originally denoted the "sharp" optical line series, etc. The sequence of the letters is as follows: $s, p, d, f, g, h$, and further in the alphabetical order.

[^566]:    ${ }^{65}$ Historically，the solution of this problem in 1928，that reproduced the main result（1．8）－（1．9）of the＂old＂ quantum theory developed by N．Bohr in 1912，without its restrictive assumptions，was the decisive step for the general acceptance of Schrödinger＇s wave mechanics．
    ${ }^{66}$ These two scales are obtained from relations $E_{0} \equiv \hbar^{2} / m r_{0}{ }^{2} \equiv C / r_{0}$ ，i．e．from the equality of the natural scales of the potential and kinetic energies，dropping all numerical coefficients．For the most important case of the hydrogen atom，$C=e^{2} / 4 \pi \varepsilon_{0}$ ，these scales are reduced，respectively，to the Bohr radius $r_{\mathrm{B}}(1.13)$ and the Hartree energy $E_{\mathrm{H}}$（1．9）．Note also that for a hydrogen－like atom（or rather ion），with $C=Z\left(e^{2} / 4 \pi \varepsilon_{0}\right)$ ，these two key parameters are rescaled as $r_{0}=r_{\mathrm{B}} / Z, E_{0}=\mathrm{Z}^{2} E_{\mathrm{H}}$ ．

[^567]:    ${ }^{67}$ In Eqs. (187)-(188), $p$ and $q$ are non-negative integers, with no relation whatsoever to particle's momentum or electric charge. Sorry for this notation, but it is absolutely common, and can hardly result in any confusion. ${ }^{68}$ Named after the same B. O. Rodrigues, and belonging to the same class as his another key result, Eq. (165).

[^568]:    ${ }^{69}$ See, e.g., MA Eq. (2.5a).
    ${ }^{70}$ Forgetting for a minute about such new "dark clouds" on the horizon of the modern physics as the hypothetical dark matter and dark energy.
    ${ }^{71}$ Note that even at the largest value of $l$, equal to $(n-1)$, term $l(l+1)$ in Eq. (200) cannot compensate term $3 n^{2}$.

[^569]:    ${ }^{72}$ The first of these relations may be also readily proved using the Heller-Feynman theorem (see Chapter 1); this proof is left for reader's exercise. Note also that the last of the expressions diverges at $l=0$, in particular in the ground state of the system (with $n=1, l=0$ ).
    ${ }^{73}$ Also called the Mendeleev table, after D. Mendeleev who put forward the concept of the periodicity of chemical element properties as functions of $Z$ phenomenologically in 1869. (The explanation of the periodicity had to wait for 60 more years until the quantum mechanics formulation in the late 1920s.)

[^570]:    ${ }^{74}$ Besides very small "fine-structure" corrections - to be discussed in Chapters 6 and 9.
    ${ }^{75}$ As will be discussed in detail in Chapter 8, electrons of the same atom are actually indistinguishable, and their quantum states are not independent, and frequently entangled. These factors are important for several properties of helium atoms (and heavier elements as well), especially for their response to external fields. However, for the atom classification purposes, they are not crucial.

[^571]:    ${ }^{76}$ Chemical valence is a relatively vague term describing the number of atom's electrons involved in chemical reactions. For the same atom, the number may depend on the chemical compound formed.

[^572]:    ${ }^{77}$ Another option is to return to the first column as soon an atom has one electron in $s$ state (like it is in $\mathrm{Cu}, \mathrm{Ag}$, and Au , in addition to the alkali metals).
    ${ }^{78}$ For a bit more detailed (but still very succinct) discussion of valence and other chemical aspects of atomic structure, I can recommend Chapter 5 of the classical text by L. Pauling, General Chemistry, Dover, 1988.

[^573]:    ${ }^{79}$ See, e.g., CM Sec. 8.5 or EM Sec. 2.8.

[^574]:    ${ }^{80}$ See, e.g., CM Sec. 3.7, in particular Eq. (3.72).

[^575]:    ${ }^{81}$ See, e.g., EM Sec. 3.1.

[^576]:    ${ }^{82}$ See, e.g., any of the handbooks recommended in MA Sec. 16(ii).

[^577]:    ${ }^{83}$ Such a fast change happens, for example, at the beta-decay, when one of nucleus' neurons suddenly becomes a proton, emitting a high-energy electron and a neutrino which leave the system very fast (instantly on the atomic time scale), and do not participate in the atom transition's dynamics.

[^578]:    ${ }^{1}$ To my knowledge, the concept of spin as an internal rotation of a particle was first suggested by R. Kronig, then a 20 -year-old student, in January 1925, a few months before two other students, G. Uhlenbeck and S. Goudsmit to whom the idea is usually attributed. The concept was then accepted and developed quantitatively by W. Pauli.
    ${ }^{2}$ See, e.g., EM Sec. 5.4, in particular Eq. (5.100).
    ${ }^{3} \mathrm{~A}$ convenient mnemonic rule is that it is close to $1 \mathrm{~K} / \mathrm{T}$. In the Gaussian units, $\mu_{\mathrm{B}} \equiv \hbar e / 2 m_{e} c \approx 0.9274 \times 10^{-20}$.

[^579]:    ${ }^{4}$ An attentive reader could notice my smuggling term "system" instead of "particle" which was used in the previous chapters. Indeed, the bra-ket formalism allows the description of quantum systems much more complex than a single spinless particle that is a typical (though not the only possible) subject of wave mechanics.
    ${ }^{5}$ As was expressed nicely by A. Peres, one of pioneers of the quantum information theory, "quantum phenomena do not occur in the Hilbert space, they occur in a laboratory".
    ${ }^{6}$ Terms bra and ket were suggested to reflect the fact that pair $\langle\beta|$ and $|\alpha\rangle$ may be considered as the set of parts of combination $\langle\beta \mid \alpha\rangle$ (see Eq. (11) below), which reminds an expression in the usual angle brackets.
    ${ }^{7}$ The Hilbert space of a given system is defined as the set of all its possible state vectors. As should be clear from this definition, it is not advisable to speak about a "Hilbert space of quantum states".

[^580]:    ${ }^{8}$ Mathematicians like to say that the ket- and bra-vectors of the same quantum system are defined in two isomorphic Hilbert spaces.
    ${ }^{9}$ This is one of the differences of bra- and ket-vectors from the usual (geometrical) vectors whose scalar product is always a real scalar.

[^581]:    ${ }^{10}$ If we consider $c$-numbers as a particular type of operators, then according to Eqs. (11) and (21), for them the Hermitian conjugation is equivalent to the simple complex conjugation, so that only a real $c$-number may be considered as a particular case of the Hermitian operator (22).
    ${ }^{11}$ Here "legitimate" means "having a clear sense in the bra-ket formalism". Some examples of "illegitimate" expressions: $|\alpha\rangle \hat{A}, \hat{A}\langle\alpha|,|\alpha\rangle|\beta\rangle,\langle\alpha|\langle\beta|$. Note, however, that the last two expressions may be legitimate if $\alpha$ and $\beta$ are states of different systems, i.e. if their state vectors belong to different Hilbert spaces. We will run into such tensor products of bra- and ket vectors (sometimes denoted, respectively, as $|\alpha\rangle \otimes|\beta\rangle$ and $\langle\alpha| \otimes\langle\beta|$ ) in Chapters 6-8.

[^582]:    ${ }^{12}$ Another popular notation for the anticommutator is $[\hat{A}, \hat{B}]_{+}$; it will not be used in these notes.

[^583]:    ${ }^{13}$ For the sake of formula compactness, below I will use the shorthand notation in which the operands of this equality are just $A_{j j}^{\dagger}$, and $A^{*}{ }_{j j}$. I believe that it leaves little chance for confusion, because the Hermitian conjugation sign $\dagger$ may pertain only to an operator (or its matrix), while the complex conjugation sign * to a scalar - say a matrix element.
    ${ }^{14}$ This equation should look familiar to the reader - see the stationary Schrödinger equation (1.60), which was the focus of our studies in the first three chapters. We will see soon that that equation is just a particular (coordinate) representation of Eq. (66) for the Hamiltonian as the operator of energy.
    ${ }^{15}$ The reciprocal statement is also true: if all eigenvalues of an operator are real, it is Hermitian (in any basis). This statement may be readily proved by applying Eq. (93) below to the case when $A_{k k^{\prime}}=A_{k} \delta_{\mathrm{kk}}$, with $A_{k}{ }^{*}=A_{k}$.

[^584]:    ${ }^{16}$ An alternative way to express Eq. (76) is to write $\hat{U}^{\dagger}=\hat{U}^{-1}$, but I will try to avoid this language.
    ${ }^{17}$ Quod erat demonstrandum (Lat.) - what needed to be proved.

[^585]:    19 A possible slight complication here are degenerate cases when characteristic equation gives certain equal eigenvalues corresponding to different eigenvectors. In this case the requirement of the mutual orthogonality of these states should be additionally enforced.

[^586]:    ${ }^{20}$ Note that though this particular unitary matrix is Hermitian, this is not true for an arbitrary choice of phases $\varphi$. ${ }^{21}$ This is the key point in the electron's spin description, developed by W. Pauli in 1925-1927.
    ${ }^{22}$ For an electron, with its negative charge $q=-e$, the gyromagnetic ratio is negative: $\gamma_{e}=-g_{e} e / 2 m_{\mathrm{e}}$, where $g_{e} \approx 2$ is the dimensionless $g$-factor. Due to quantum electrodynamics effects, the factor is slightly higher than $2: g_{e}=$ $2(1+\alpha / 2 \pi+\ldots) \approx 2.002319304 \ldots$, where $\alpha \equiv e^{2} / 4 \pi \varepsilon_{0} \hbar c \equiv\left(E_{\mathrm{H}} / m_{e} c^{2}\right)^{1 / 2} \approx 1 / 137$ is the fine structure constant. (The origin of its name will be clear from the discussion in Sec. 6.3.)

[^587]:    ${ }^{23}$ If you think about it, word "understand" typically means that we can explain a new, more complex notion in terms of those discussed earlier and considered "known". In our example, we cannot express the spin states by some wavefunction $\psi(\mathbf{r})$, or any other mathematical notion discussed earlier. The bra-ket formalism has been invented exactly to enable mathematical analysis of such "new" quantum states.
    ${ }^{24}$ Here again, just like in Sec. 1.2, the statement implies the abstract (mathematical) notion of "ideal experiments", postponing the discussion of real (physical) measurements until Sec. 7.7.
    ${ }^{25}$ As a reminder, in the end of Sec. 3 we have already proved that such eigenstates corresponding to different $A_{j}$ are orthogonal. If any of these values is degenerate, i.e. corresponds to several different eigenstates, they should be also selected orthogonal, in order for Eq. (118) to be valid.
    ${ }^{26}$ This key relation, in particular, explains the most common term for the (generally, complex) coefficients $\alpha_{j}$, the probability amplitudes.

[^588]:    ${ }^{27}$ This equality reveals the full beauty of Dirac's notation. Indeed, initially the quantum-mechanical brackets just reminded the angular brackets used for statistical averaging. Now we see that in this particular (but most important) case, the angular brackets of these two types may be indeed equal to each other!
    ${ }^{28}$ Note that Eq. (120) may be rewritten in the form similar to Eq. (125): $W_{j}=\langle\alpha| \hat{\Lambda}_{j}|\alpha\rangle$, where $\hat{\Lambda}_{j} \equiv\left|a_{j}\right\rangle\left\langle a_{j}\right|$ is the operator (42) of projection upon the $j^{\text {th }}$ eigenstate $a_{j}$.

[^589]:    ${ }^{29}$ Note that both sides of Eq. (140) are state-specific; the uncertainty relation statement is that this inequality should be valid for any possible quantum state of the system.
    ${ }^{30}$ This inequality is the quantum-mechanical analog of the usual vector algebra result $\alpha^{2} \beta^{2} \geq|\alpha \cdot \beta|^{2}$.

[^590]:    ${ }^{31}$ Moreover, we will be able to derive Eq. (1.25) from Eq. (154) - see Sec. 5.2.
    ${ }^{32}$ Here I intentionally use index $n$ rather than $j$, to emphasize the special role played by the stationary eigenstates $a_{n}$ in quantum dynamics.

[^591]:    ${ }^{33}$ See, e.g., EM Eq. (5.100). As a reminder, we have already used this expression for the derivation of Eq. (3). ${ }^{34}$ See, e.g., CM Sec. 6.5, in particular Eq. (6.72), and EM Sec. 5.5, in particular Eq. (5.114) and its discussion.

[^592]:    ${ }^{35}$ Note also that if the product $\gamma \mathcal{B}$ is positive, so is $\Omega$, so that $E_{\uparrow}$ is negative, while $E_{\downarrow}$ is positive. This is in the correspondence with the classical picture of a magnetic dipole $\mathbf{m}$ having negative potential energy when it is aligned with the external magnetic field $\mathcal{B}$ - see Eq. (162).

[^593]:    ${ }^{36}$ This is one more (hopefully, redundant :-) illustration of the difference between averaging over the statistical ensemble and over time: in Eqs. (170), (173)-(174), and quite a few relations below, only the former averaging has been performed, so the results are still functions of time.
    ${ }^{37}$ Such composite particles as nuclei (and, from the point of view of high-energy physics, even such hadrons as protons) may be characterized by a certain net spin (and hence by certain $\gamma$ ) only if during the considered process their internal degrees of freedom remain in a certain (usually, ground) quantum state.

[^594]:    ${ }^{38}$ We will run into such situations in Chapter 7, but will not need to apply Eq. (186).
    ${ }^{39}$ It may be found, for example, in Chapter 5 of J. Sakurai's textbook - see References.
    ${ }^{40}$ Note this relation is similar in structure to the symbolic Eqs. (94).

[^595]:    ${ }^{41}$ We could of course use this equation result, together with Eq. (157), to obtain all the above results for this system within the Schrödinger picture. In our simple case, the use of Eqs. (161) for this purpose was more straightforward, but in some cases (e.g., for time-dependent Hamiltonians) an explicit calculation of the timeevolution matrix may be the only practicable way to proceed.

[^596]:    ${ }^{42}$ Due to the same reason, $\hat{H}_{\mathrm{H}} \equiv \hat{u}^{\dagger} \hat{H}_{\mathrm{S}} \hat{u}=\hat{u}^{\dagger} \hat{u} \hat{H}_{\mathrm{S}}=\hat{H}_{\mathrm{S}}$; this is why the index of the Hamiltonian operator may be dropped in Eqs. (198)-(199).
    ${ }^{43}$ Reportedly, this equation was derived by P. A. M. Dirac, who was so generous that he himself gave the name of his colleague to this key result, because "Heisenberg was saying something like this".
    ${ }^{44}$ Using commutation relations (155), this equation may be readily generalized to the case of arbitrary magnetic field $\mathcal{B}(t)$ and arbitrary state basis - the exercise highly recommended to the reader.

[^597]:    ${ }^{45}$ See, e.g., CM Eq. (10.17). Also, please excuse my use, for the Poisson bracket, the same (traditional) symbol $\{\ldots, \ldots\}$ as for the anticommutator. We will not run into the Poisson brackets again in the course, leaving very little chance for confusion.
    ${ }^{46}$ Since we have run into the commutator of Heisenberg-picture operators, let me note emphasize again that the "values" of such an operator at different moments of time often do not commute. Perhaps the simplest example is the operator $\hat{x}$ of coordinate of a free 1D particle, with Hamiltonian $\hat{H}=\hat{p}^{2} / 2 m$. Indeed, in this case Eq. (199) yields equations $i \hbar \dot{\hat{x}}=[\hat{x}, \hat{H}]=i \hbar \hat{p} / m$ and $i \hbar \dot{\hat{p}}=[\hat{p}, \hat{H}]=0$, with simple solutions (similar to those for classical motion of the corresponding observables): $\hat{p}(t)=$ const $=\hat{p}(0), \quad \hat{x}(t)=\hat{x}(0)+\hat{p}(0) t / m$, so that $[\hat{x}(0), \hat{x}(t)]=[\hat{x}(0), \hat{p}(0)] t / m=\left[\hat{x}_{\mathrm{S}}, \hat{p}_{\mathrm{S}}\right] t / m=i \hbar t / m \neq 0$, if $t \neq 0$.

[^598]:    ${ }^{47}$ See, e.g., MA Eqs. (13.1) and (13.2).
    ${ }^{48}$ See, e.g. MA Eq. (2.9).

[^599]:    ${ }^{1}$ To recall why this condition is crucial, please revisit the beginning of Sec. 2.3. Note also that, in particular, the mutual phase shifts between different qubits are very important for quantum information processing (see Chapter 7 below), so that most discussions of these applications have to start from Eq. (3) rather than Eq. (4).

[^600]:    ${ }^{2}$ Named after the same F. Bloch who has pioneered the energy band theory that was discussed in Chapters 2-3.
    ${ }^{3}$ In the quantum information literature, ket-vectors $|\uparrow\rangle$ and $|\downarrow\rangle$ of these two states of a qubit are usually denoted as $|1\rangle$ ("quantum one") and $|0\rangle$ ("quantum zero").

[^601]:    ${ }^{4}$ Still, it is crucial to appreciate the difference between the expectation values (5), i.e. c-numbers, and the actual observables $S_{x}, S_{y}$, and $S_{z}$ which are described in quantum mechanics by operators. For example, according to Eq. (4.156), for any position on the Bloch sphere, it is impossible to have exact values of Cartesian components, as it is in the classical picture.
    ${ }^{5}$ The same is true for the angular momentum $\mathbf{L}$ at the classical torque-induced precession - see, e.g., CM Sec.6.5 and in particular Eq. (6.71).
    ${ }^{6}$ In this aspect as well, the information processing systems based on qubits are closer to classical analog computers rather then classical digital ones.

[^602]:    ${ }^{7}$ Notice that in the contrast to the discrete spectrum case, the dimensionality of the bra- and ket-vectors so normalized is different from 1 .

[^603]:    ${ }^{8}$ I do not quite like expressions like $\langle x \mid \Psi\rangle$ used in some papers and even textbooks. Of course, one is free to replace $\alpha$ with any other letter ( $\Psi$ including) to denote a quantum state, but then it is better not to use the same letter to denote the wavefunction, i.e. an inner product of two state vectors, to avoid confusion.

[^604]:    Space-
    local operators

[^605]:    ${ }^{9}$ Of all the operators we will encounter in this course, only the statistical operator $\hat{w}$ is substantially non-local see Sec. 7.2.
    ${ }^{10}$ In the second equality, I have use Eq. (9) for variable $x$.

[^606]:    ${ }^{11}$ The equivalence of the two forms of Eq. (28) may be readily proven, for example, by comparison of their effect on any differentiable function $f\left(x, x^{\prime}\right)$, using its Taylor expansion over argument $x$ at point $x^{\prime}=x$ - a simple but good exercise for the reader.

[^607]:    ${ }^{12}$ In some systems of quantum mechanics postulates, the Schrödinger equation (1.28) itself is considered as a sort of eigenstate/eigenvalue problem (34) for operator $i \hbar \partial / \partial t$. Notice that such construct is very close to that of the momentum operator $-i \hbar \partial / \partial x$, and similar arguments may be given for both expressions, starting from the invariance of the quantum state of a free particle with respect to translations in time and space, respectively.
    ${ }^{13}$ It is not important whether we speak about the Schrödinger or Heisenberg picture here. Indeed, if three operators in the former picture are related as $\left[\hat{A}_{\mathrm{S}}, \hat{B}_{\mathrm{S}}\right]=\hat{C}_{\mathrm{s}}$, then according to Eq. (4.190), in the latter picture

    $$
    \left.\left[\hat{A}_{\mathrm{H}}, \hat{B}_{\mathrm{H}}\right]=\mid \hat{U}^{\dagger} \hat{A}_{\mathrm{H}} \hat{U}, \hat{U}^{\dagger} \hat{B}_{\mathrm{H}} \hat{U}\right]=\hat{U}^{\dagger} \hat{A}_{\mathrm{H}} \hat{U} \hat{U}^{\dagger} \hat{B}_{\mathrm{H}} \hat{U}-\hat{U}^{\dagger} \hat{B}_{\mathrm{H}} \hat{U} \hat{U}^{\dagger} \hat{A}_{\mathrm{H}} \hat{U}=\hat{U}^{\dagger}\left[\hat{A}_{\mathrm{S}}, \hat{B}_{\mathrm{S}}\right] \hat{U}=\hat{U}^{\dagger} \hat{C}_{\mathrm{S}} \hat{U}=\hat{C}_{\mathrm{H}}
    $$

[^608]:    ${ }^{14}$ Since this Hamiltonian is time-independent, we may replace the partial derivative over time $t$ with the full one.

[^609]:    ${ }^{15}$ Indeed, acting exactly as at derivation of Eq. (36), for a space-local Heisenberg operator we get

    $$
    \langle A\rangle(t)=\int \Psi^{*}\left(x, t_{0}\right) \hat{A}_{\mathrm{H}}\left(t, t_{0}\right) \Psi\left(x, t_{0}\right) d x .
    $$

    ${ }^{16}$ The set of equations (49) constitute the Ehrenfest theorem.
    ${ }^{17}$ From this point on, for the sake of brevity I will drop index $x$ in the notation of the momentum - just as it was done in Chapter 2.

[^610]:    18 Repeating the calculation for each Cartesian component of a plane monochromatic wave of arbitrary dimensionality $d$, we get $\psi_{\mathbf{p}}=(2 \pi \hbar)^{-d / 2} \exp \{i(\mathbf{p} \cdot \mathbf{r} / \hbar+\varphi)\}$.

[^611]:    ${ }^{19}$ According to Feynman's memories, his work was motivated by a "mysterious" remark by P. A. M. Dirac in his pioneering 1930 textbook on quantum mechanics.
    ${ }^{20}$ For a more thorough discussion of the path-integral approach, see the famous text R. Feynman and A. Hibbs, Quantum Mechanics and Path Integrals first published in 1965. (For its latest edition by Dover in 2010, the book was emended by D. Styler.) For a more recent monograph that reviews more applications, see L. Schulman, Techniques and Applications of Path Integration, Wiley, 1981.

[^612]:    ${ }^{21}$ A strict proof of this intuitively evident statement would take more space and time than I can afford.

[^613]:    ${ }^{22}$ See, e.g., CM Sec. 2.1.
    ${ }^{23}$ See, e.g., CM Sec. 10.3.

[^614]:    ${ }^{24}$ This fact may be proved by expanding the difference ( $S-S_{\mathrm{cl}}$ ) in the Taylor series in path variations (leaving only the leading quadratic terms) and working out the resulting Gaussian integrals. It is interesting that the integration, together with the pre-exponential coefficient in Eq. (83a), gives exactly the pre-exponential factor that we have already found in Sec. 2.4 when refining the WKB approximation.
    ${ }^{25}$ The same trick is often used in analytical classical mechanics - say, for proving the Hamilton principle, and for the derivation of the Hamilton - Jacobi equations (see, e.g. CM Secs. 10.3-4).

[^615]:    ${ }^{26}$ One can argue that the pre-exponential coefficient in Eq. (91) should be close to 1, just like in Eq. (2.117), especially if the potential is smooth in the sense of Eq. (2.107), where $x$ is the coordinate along the trajectory.
    ${ }^{27}$ For a concise introduction to the field see, e.g., I. Gelfand and S. Fomin, Calculus of Variations, Dover, 2000, or L. Elsgolc, Calculus of Variations, Dover, 2007.
    ${ }^{28}$ In quantum field theory, the instanton concept may be formulated somewhat differently, and has more complex applications - see, e.g. R. Rajaraman, Solitons and Instantons, North Holland, 1987.

[^616]:    ${ }^{29}$ See, e.g., M. Buttiker and R. Landauer, Phys. Rev. Lett. 49, 1739 (1982), and references therein.
    ${ }^{30}$ This normalization is not really necessary, it just makes the following calculations less bulky - and thus more aesthetically appealing.

[^617]:    ${ }^{31}$ For the electromagnetic field oscillators, such excitations are called photons; for the mechanical wave field oscillators, phonons, etc.

[^618]:    ${ }^{32}$ Please note again the radical difference between the null-state in the right-hand part of Eq. (118) and the state described by ket-vector $|0\rangle$ in the left-hand side of that relation. The latter state does exist and, moreover, presents the most important, ground state of the system, with $n=0$ - see Eq. (2.269).

[^619]:    ${ }^{33}$ A useful mnemonic rule is that the $c$-number coefficient in any of these relations is equal to the square root of the largest number of the two states it relates.

[^620]:    ${ }^{34}$ The first line of Eq. (127), evidently valid for any time-independent system, is the simplest of the so-called sum rules, which will be repeatedly discussed below.
    ${ }^{35}$ Still note that operators of the partial (potential and kinetic) energies do not commute with either each other or with the full-energy (Hamiltonian) operator, so that the Fock states $n$ are not their eigenstates.

[^621]:    ${ }^{36}$ See, e.g., CM Chapter 4, especially Eqs. (4.4) and Fig. 4.9 and its discussion.

[^622]:    ${ }^{37}$ I have to confess that such geometric mapping of a quantum state on the phase plane $[x, p]$ is not exactly defined; you may think about colored areas in Fig. 6 as regions of pairs $\{x, p\}$ most probably obtained in measurements. A quantitative definition of such a mapping will be given in Sec. 7.3 using the Wigner function, though, as we will see, even such imaging definition has certain internal contradictions. Still such cartoons may have considerable cognitive/heuristic value, if their limitations are kept in mind.
    ${ }^{38}$ In the quantum theory of measurements, Eqs. (138) are frequently referred to as the standard quantum limit.
    ${ }^{39}$ Named after R. J. Glauber who studied these states in detail in 1965, though they had been discussed in brief by E. Schrödinger as early as in 1926. Another popular name, "coherent", for the Glauber states is very misleading, because all the quantum states we have studied so far (including the Fock states) may be presented as coherent (pure) superpositions of the basis states.

[^623]:    ${ }^{40}$ As will be discussed in Chapter 7, the ground state may be readily formed, for example, by providing a weak coupling of the oscillator to a low-temperature ( $k_{\mathrm{B}} T \ll \hbar \omega_{0}$ ) environment.

[^624]:    ${ }^{41}$ The proof of Eq. (148) may be readily achieved by expanding operator $\hat{f}(\lambda) \equiv \exp \{+\lambda \hat{A}\} \hat{B} \exp \{-\lambda \hat{A}\}$ in the Taylor series in the $c$-number parameter $\lambda$, and then evaluating the result at $\lambda=1$.

[^625]:    ${ }^{42}$ It is also rather counter-intuitive. Indeed, according to Eq. (122), the annihilation operator $\hat{a}$, acting on a Fock state $n$, "beats it down" to the lower-energy state ( $n-1$ ) - see Eq. (119). However, according to Eq. (155), its action on a Glauber state $\alpha$ does not lead to the state change and hence to an energy decrease! The resolution of this paradox may be achieved via representation of the Glauber state as a series of Fock states - see Eq. (165) below. Operator $\hat{a}$ indeed transfers each Fock component to a lower-energy state, but it also re-weighs each term of the expansion, so that the complete energy of the Glauber state remains constant.
    ${ }^{43}$ Note that the spectrum of eigenvalues $\alpha$ of eigenproblem (155) is continuous - it may be any complex number!

[^626]:    ${ }^{44}$ For a discussion and classical theory of this effect, see, e.g., CM Sec. 4.5.
    ${ }^{45}$ See, e.g., Chapter 7 in C. Gerry and P. Knight, Introductory Quantum Optics, Cambridge U. Press, 2005, and the spectacular measurements of the Glauber and squeezed states of electromagnetic (light) oscillators by G. Breitenbach et al., Nature 387, 471 (1997), very large (ten-fold) squeezing in such oscillators by H. Vahlbruch et al., Phys. Rev. Lett. 100, 033602 (2008); and recent first measurements of the (so far, slight) squeezing in mechanical resonators, with eigenfrequency $\omega_{0} / 2 \pi$ as low as 3.6 MHz , by E. Wollman et al., Science 349, 952 (2015).

[^627]:    ${ }^{46}$ See, e.g., MA Eq. (13.2).
    ${ }^{47}$ The importance of this issue stems from the following fact: it is easy (and is hence left to the reader :-) to use Eqs. (5.178) to prove that operators of all $L_{j}$ and of $L^{2}$ commute with the Hamiltonian of a particle in the spherically-symmetric potential $U(r)$, and hence all their eigenstates are the stationary states in such a field.
    ${ }^{48}$ This is just a particular example of Venn diagrams (introduced in the 1880 s by J. Venn) that show possible relations (such as intersections, unions, complements, etc.) between various sets of objects, and are a very useful tool in the general set theory.
    ${ }^{49}$ Note that this particular result is consistent with the classical picture of the angular momentum vector: even when is length is fixed, the vector may be oriented in various directions, corresponding to different values of its Cartesian components. However, in the classical picture, all these component may be fixed simultaneously, while in the quantum picture this is not true.

[^628]:    Spin operators: commutation relations

[^629]:    ${ }^{50}$ The reader is challenged to use the commutation relations discussed above to prove one more important property of the common eigenstates of operators $\hat{L}_{z}$ and $\hat{L}^{2}$ :

    $$
    \langle l, m| \hat{r}_{j}\left|l^{\prime}, m^{\prime}\right\rangle=0, \quad \text { if either } l^{\prime} \neq l \pm 1 \text {, or } m \neq m^{\prime} \text {, or both. }
    $$

    This property is the basis of the selection rules for dipole quantum transitions, to be discussed later in the course, especially in Sec. 9.3.

[^630]:    ${ }^{51}$ As a reminder, in the Standard Model of particle physics, such hadrons as mesons and baryons (notably including protons and neutrons) are essentially composite particles, with the spin equal to the sum of its component quark spins. However, at non-relativistic energies, protons and neutrons may be considered fundamental particles with $s=1 / 2$.

[^631]:    ${ }^{52}$ One may think that Eq. (207) is a trivial corollary of Eq. (199). However, now we should be a bit more careful, because in the Clebsch-Gordan coefficients, these quantum numbers characterize different groups of eigenstates.

[^632]:    ${ }^{53}$ For arbitrary spin $s$, the calculations and even the final expressions for the Clebsch-Gordan coefficients are rather bulky. They may be found, typically in a table form, mostly in special monographs - see, e.g., A. R. Edmonds, Angular Momentum in Quantum Mechanics, Princeton U. Press, 1957.

[^633]:    ${ }^{54}$ For the interested reader I can recommend, either Sec. 17.7 in E. Merzbacher, Quantum Mechanics, $3^{\text {rd }}$ ed., Wiley, 1998, or Sec. 3.10 in J. Sakurai, Modern Quantum Mechanics, Addison-Wesley, 1994.
    ${ }^{55}$ Cf. Problems 4.22, 4.23, 5.2.
    ${ }^{56}$ See, e.g., CM Problem 1.12.

[^634]:    ${ }^{57}$ Named after G. Gamow, who made this calculation as early as in 1928.

[^635]:    ${ }^{58}$ Note that the last task is just a particular case of Problem 4.17 (see also Problem 1).

[^636]:    ${ }^{1}$ Please note its similarity with Eq. (2.215) of the 1D band theory. Indeed, the latter equation is not much more than a particular form of Eq. (6) for 1D wave mechanics, and a specific (periodic) potential $U(x)$ considered as perturbation. Moreover, the approximate treatment of the weak potential limit in Sec. 2.7 was essentially a particular case of the more general perturbation theory we are discussing now.
    ${ }^{2}$ Note that, by definition, $\left\langle n^{,(0)} \mid n\right\rangle^{(0)}=\delta_{n^{\prime} n}$.

[^637]:    ${ }^{4}$ This is exactly the reason why such perturbation theories run into serious problems for systems with continuous spectrum, and other approximate techniques (such as the WKB approximation) are often necessary.
    ${ }^{5}$ Note that the choice of the basis is to some extent arbitrary, because due to the linearity of equations of quantum mechanics, any linear combination of states $n^{\prime(0)}$ is also an eigenstate of the unperturbed Hamiltonian. However, for using Eq. (24), these combinations have to be orthonormal, as was suggested at the derivation of Eq. (6).

[^638]:    ${ }^{6}$ For brevity, I am dropping the upper index (1) in the matrix elements.

[^639]:    ${ }^{7}$ Alternatively, if $a_{x}=0$, then $| \pm\rangle=(1 / \sqrt{ } 2)\left(\left|1^{(0)}\right\rangle \pm i\left|2^{(0)}\right\rangle\right)$. Note that besides a phase coefficient, these states are similar in that they present a coherent superposition of the unperturbed states, with a $50 / 50$ chance to find the perturbed system in any of those states. In that sense, the effects of perturbation coefficients $a_{x}$ and $a_{y}$ are similar. ${ }^{8}$ Since the hydrogen atoms are much lighter, it is more fair to speak about their correlated tunneling around the (nearly immobile) nitrogen atom.
    ${ }^{9}$ In particular, these molecules were used in the demonstration of the first maser by C. Townes' group in 1954.

[^640]:    ${ }^{10}$ If there is any doubt why, please revisit the discussion of Eq. (2.247), in which we should now take $F=q \varepsilon$.

[^641]:    ${ }^{11}$ See, e.g., MA Eq. (6.7d).

[^642]:    ${ }^{12}$ This value approximately corresponds to the threshold of electric breakdown in air, due to the impact ionization on the surface of typical metallic electrodes. (Reducing air pressure only enhances the ionization and lowers the breakdown threshold.) As a result, experiments with higher fields are rather difficult.
    ${ }^{13}$ See, e.g., EM Sec. 9.3, in particular Eq. (9.78) - or any undergraduate text on special relativity.

[^643]:    ${ }^{14}$ See, e.g., EM Sec. 5.1, in particular, Eq. (5.24).
    ${ }^{15}$ It was carried out first by L. Thomas in 1926; see, e.g., R. Harr and L. Curtis, Am. J. Phys. 55, 1044 (1987). ${ }^{16}$ See, e.g., CM Sec. 3.6.

[^644]:    ${ }^{17}$ The factor $l$ in the denominator does not give a divergence at $l=0$, because in this case $j=s=1 / 2$, and the numerator turns into 0 as well. A careful analysis of this case (which may be found, e.g., in G. K. Woolgate, Elementary Atomic Structure, $2^{\text {nd }}$ ed., Oxford, 1983), as well as the exact solution of the Bohr atom problem within the Dirac theory (Chapter 9) show that the final result (60), which is independent of $l$, is valid even in this case.
    ${ }^{18}$ This is natural, because the magnetic interaction of charged particles is an essentially relativistic effect, of the same order $\left(\sim v^{2} / c^{2}\right)$ as the kinetic correction (49a) - see, e.g., EM Sec. 5.1, in particular Eq. (5.3).

[^645]:    ${ }^{19}$ See the Selected Physical Constants appendix for the more exact value of this constant. Its expression in Gaussian units, $\alpha=e^{2} / \hbar c$, makes even more evident the fact that $\alpha$ is the just fundamental constant ratio which characterizes the strength (or rather the weakness :-) of electromagnetic effects in quantum mechanics - that in particular makes the perturbative quantum electrodynamics possible. The alternative expression $\alpha=E_{H} / m_{e} c^{2}$, where $E_{\mathrm{H}}$ is the Hartree energy (1.9), i.e. the scale of all energies $E_{n}$, is also very revealing.
    ${ }^{20}$ It was discovered experimentally in 1896 by P. Zeeman who, amazingly, was fired from the University of Leiden for an unauthorized use of lab equipment for this work - just to receive a Nobel Prize for it in a few years.

[^646]:    ${ }^{21}$ Despite its smallness, the quadratic term is necessary for description of the negative contribution of the orbital motion to the magnetic susceptibility $\chi_{m}$ (the so-called orbital diamagnetism, see EM Sec. 5.5), whose analysis, using Eq. (63), is left for reader's exercise.
    ${ }^{22}$ See, e.g., EM Sec. 5.4, in particular Eqs. (5.95) and (5.100).

[^647]:    ${ }^{23}$ In almost-hydrogen-like, but more complex atoms (such as those of alkali metals), the degeneracy in $l$ is lifted by electron-electron interaction even in the absence of the external magnetic field.

[^648]:    ${ }^{24}$ This formula is frequently used with capital letters $J, S$, and $L$, which denote the quantum numbers of the atom as a whole.

[^649]:    ${ }^{25}$ For a more complete discussion of the Stark, Zeeman, and fine-structure effects in atoms, I can recommend, for example, either the monograph by G. Woolgate cited above, or the one by I. Sobelman, Theory of Atomic Spectra, Alpha Science, 2006.
    ${ }^{26}$ See, e.g., CM Sec. 10.2.

[^650]:    ${ }^{27}$ Even if the problem under analysis may be described by the wave-mechanics Schrödinger equation (1.25), a direct numerical integration of that partial differential equation is typically less convenient than that of the ordinary differential equations (79).
    ${ }^{28}$ This is of course just a more general form of Eq. (1.61) of wave mechanics of time-independent systems.

[^651]:    ${ }^{29}$ The notation of the amplitude operators in Eq. (86) is justified by the fact that the perturbation Hamiltonian has to be self-adjoint (Hermitian), and hence each term in the right-hand part of that relation has to be a Hermitian conjugate of its counterpart, which is evidently true only if the amplitude operators are also the Hermitian conjugates of each other. Note, however, that each of the amplitude operators is generally not Hermitian.

[^652]:    ${ }^{30}$ Strictly speaking, another condition is that the number of "resonant" levels is also not too high - see Sec. 6.
    ${ }^{31}$ The notion of detuning is also very useful in the classical theory of oscillations - see, e.g., CM Chapter 4.
    ${ }^{32}$ Such omission of non-resonant terms is usually called the Rotating Wave Approximation (RWA); it is very instrumental not only in quantum mechanics, but also in the classical theory of oscillations - see, e.g., CM Secs. 4.3-4.5.

[^653]:    ${ }^{33}$ It was derived in 1952 by I. Rabi, in the context of his group's pioneering experiments with microwave excitation of quantum states, using molecular beams in vacuum.
    ${ }^{34}$ In the quantum information science language, this is just a logic operation NOT performed on a single qubit.
    ${ }^{35} \mathrm{We}$, of course, already know what happens to the ground state of an oscillator at its external sinusoidal (or any other) excitation: it turns into the Glauber state, i.e. a superposition of all Fock states - see Sec. 5.5.

[^654]:    ${ }^{36}$ See, e.g., EM Sec. 7.3, in particular, the correspondence between Eqs. (7.55) and (7.56).
    ${ }^{37}$ For introductions see, e.g., J. Wertz and J. Bolton, Electron Spin Resonance, $2^{\text {nd }}$ ed., Wiley, 2007; J. Keeler, Understanding NMR Spectroscopy, $2^{\text {nd }}$ ed., Wiley, 2010.

[^655]:    ${ }^{41}$ Here we have run again, in a more general context, into the "energy-time uncertainty relation" which was already discussed in the end of Sec. 2.5. Let me advise the reader to revisit that important discussion.

[^656]:    ${ }^{42}$ This situation is very much similar to the entropy increase in macroscopic systems, which is postulated in thermodynamics, and justified in statistical physics, even though it is based on time-reversible laws of mechanics - see, e.g., SM Sec. 1.2 and Sec. 2.2.

[^657]:    ${ }^{43}$ The normalization to infinite volume, using Eq. (5.55), is also possible, but less convenient in such problems.

[^658]:    ${ }^{44}$ The condition of its validity is again given by Eq. (117), but with $\omega \rightarrow 0$ in the upper limit.
    ${ }^{45}$ It is straightforward to show that in this form, the estimate is valid for a similar problem of any spatial dimensionality, not just the 1D case we have analyzed.
    ${ }^{46}$ This qualitative picture may be verified, for example, using the experimentally observable effects of dispersive electromagnetic environment on electron tunneling - see P. Delsing et al., Phys. Rev. Lett. 63, 1180 (1989).

[^659]:    ${ }^{47} \operatorname{Sign} \otimes$ is used to denote the formation of a joint ket-vector from kets of independent systems ("belonging to different Hilbert spaces"). Evidently, the order of operands in such a "product" may be changed at will.
    ${ }^{48}$ See, e.g., EM Sec. 3.1, in particular Eq. (3.16), in which letter $\mathbf{p}$ is used for the electric dipole moment.

[^660]:    ${ }^{49}$ The process is evidently spontaneous, i.e. does not require any external agent, and starts as soon as either the interaction (127) has been turned on, or (if it is always on) as soon as system $a$ is placed into the excited state $n^{\prime}{ }_{a}$. ${ }^{50}$ As a reminder, its proof for the particular case of wave mechanics was the subject of Problem 1.4.

[^661]:    ${ }^{51}$ See, e.g., CM Sec. 4.2.

[^662]:    ${ }^{52}$ See, e.g., EM Sec. 5.5, in particular Eqs. (5.127) and (5.112).

[^663]:    ${ }^{1}$ For a broader discussion of statistical mechanics and physical kinetics, including those of quantum systems, the reader is referred to the SM part of this lecture note series.
    ${ }^{2}$ Most of the mixed ensemble analysis in this chapter will pertain also to the cases when the systems of interest are not in a contact with the environment currently, and our knowledge about them is incomplete by some other reason - for example, if they had been in such a contact at some time between their perfect preparation (in a certain quantum state) and the observation, or if such a perfect preparation is impossible (or impracticable, or undesirable :-).
    ${ }^{3}$ See, e.g., SM Sec. 2.1.

[^664]:    ${ }^{4}$ In the opposite case, the very partition of the Universe into the system and the environment is impossible.
    5 Whether this assumption is true is an interesting issue, still being debated (more by philosophers than by physicists), but it is widely believed that its solution is not critical for the validity of the results of this approach. In Sec. 6, I will offer a strong argument for this opinion - albeit not its strict proof.
    ${ }^{6}$ Actually, such coexistence has been implied (but well hidden :-) in the derivation of the quantum-mechanical Golden Rule, which in all fairness, also belongs to the open systems class.

[^665]:    ${ }^{7}$ First suggested in 1927 by J. von Neumann.
    ${ }^{8}$ Of course the "bra-kets" in this expression are not $c$-numbers, because state $\alpha$ is defined in a larger Hilbert space (of the environment plus the system of interest) than the basis states $e_{k}$ (of the environment only).

[^666]:    9 This is essentially an alternative formulation of the basic postulate of statistical physics, called the microcanonical distribution - see, e.g., SM Sec. 2.2.
    ${ }^{10}$ See. e.g., SM Sec. 2.4. The Boltzmann constant $k_{\mathrm{B}}$ is only needed if temperature is measured in non-energy units, say in kelvins.

[^667]:    ${ }^{11}$ See, e.g., SM Sec. 2.8.
    ${ }^{12}$ See, e.g., SM Sec. 2.5 - but mind a different energy reference level, $E_{0}=\hbar \omega$, used in Eqs. (2.68)-(2.69), affecting the expression for $Z$. Actually, the calculation is so straightforward (just the summation of a geometric progression for the enumeration of $Z$ ) that it is highly recommended to the reader as a simple exercise.
    ${ }^{13}$ See, e.g., SM Sec. 2.8.
    ${ }^{14}$ Because of the fundamental importance of Eq. (26) for many fields of physics, let me remind the reader of its main properties. At low temperatures, $k_{\mathrm{B}} T \ll \hbar \omega_{0}$, there are virtually no thermal excitations, $\langle n\rangle \rightarrow 0$, and the average energy of the oscillator is dominated by that of its ground state. In the opposite limit of high temperatures, $\langle n\rangle \rightarrow k_{\mathrm{B}} T / \hbar \omega_{0} \gg 1$, and $\langle E\rangle$ approaches the classical value $k_{\mathrm{B}} T$ (following, for example, from the equipartition theorem, which assigns energy $k_{\mathrm{B}} T / 2$ to each quadratic contribution to system's energy - in the 1 D oscillator case, to one potential and one kinetic energy term).

[^668]:    ${ }^{15}$ For now, I will focus on a fixed time instant (say, $t=0$ ), and hence write $\psi(x)$ instead of $\Psi(x, t)$.
    ${ }^{16}$ This fact is the historic origin of density matrix' name.

[^669]:    ${ }^{17}$ Due to the delta-normalization of the eigenfunction, the density matrix for the free particle (and any system with continuous eigenvalue spectrum) is normalized as

    $$
    \int_{-\infty}^{+\infty} w\left(x, x^{\prime}\right) Z d x^{\prime}=\int_{-\infty}^{+\infty} w\left(x, x^{\prime}\right) Z d x=1
    $$

[^670]:    ${ }^{18}$ I will have no time to discuss this technique, and have to refer the interested reader to special literature. Probably, the most famous text of that field is A. Abrikosov, L. Gor'kov, and I. Dzyaloshinski, Methods of Quantum Field Theory in Statistical Physics, Prentice-Hall, 1963. (Later reprintings are available from Dover.)

[^671]:    ${ }^{19}$ I have to confess that this notation is imperfect, because from the point of view of rigorous mathematics, $w(x$, $x^{\prime}$ ) and $w(x)$ are different functions, and so are $w\left(p, p^{\prime}\right)$ and $w(p)$ used below. In the perfect world, I would use different letters for them all, but I desperately want to stay with " $w$ " for all the probability densities, and there are not so many good different fonts for this letter. Let me hope that the difference between these functions is clear from their arguments, and from the context.
    ${ }^{20}$ It was introduced in 1932 by E. Wigner on the basis of a general (Weyl-Wigner) transform suggested by H. Weyl in 1927, and re-derived in 1948 by J. Ville on a different mathematical basis.

[^672]:    ${ }^{21}$ Note that the last line of Eq. (5.67) is invalid for the density operator $\hat{w}$, because it is not local!
    ${ }^{22}$ Such density, which would express the probability $d W$ to find the system in a small area of the phase plane as $d W=\rho(X, P) d X d P$, is the basic notion of (1D) classical statistics - see, e.g., SM Sec. 2.1.

[^673]:    ${ }^{23}$ Please note that in notations of that section, arguments $\{X, P\}$ of the Wigner function should be replaced with $\{x, p\}$, and capital letters saved for the Cartesian coordinates of the central point (5.133), i.e. the classical complex amplitude of the oscillations.
    ${ }^{24}$ Spectacular experimental measurements of this function (for $n=0$ and $n=1$ ) were carried out recently by E. Bimbard et al., Phys. Rev. Lett. 112, 033601 (2014).

[^674]:    ${ }^{25}$ In many texts, it is called the "Liouville equation", due to the philosophical proximity to the classical Liouville theorem for the distribution function $\rho(X, P)$ or its multi-dimensional analog - see, e.g., SM Sec. 6.1, in particular Eq. (6.5).

[^675]:    ${ }^{26}$ Another example when $W_{j}$ are constant in time, and hence Eq. (66) is valid, is the thermodynamic equilibrium. However, in this case the statistical operator is diagonal in the stationary state basis and hence commutes with the Hamiltonian. Hence the right-hand part of Eq. (66) vanishes, and it shows that the density matrix does not evolve in time at all - as it should.
    27 Though this model works very well in many cases (see the examples given below), it is not adequate for a particle interacting with the environment of similar particles. In this case the methods discussed in the next chapter are more relevant.

[^676]:    ${ }^{28}$ This can be done because we may consider the whole system, including the environment, as a Hamiltonian one - see Eq. (68).

[^677]:    ${ }^{29}$ This assumption is not in any contradiction with the quantum treatment of the two-level system, because a typical environment has very dense energy spectrum, so that the distances between them may be readily bridged by thermal excitations of energies $\sim k_{\mathrm{B}} T \ll 2 a_{z}$, often making its essentially classical.

[^678]:    ${ }^{30}$ The theory of this phenomenon, first observed experimentally by biologist R. Brown in the early 1800 s , was pioneered by A. Einstein in 1905 (see in particular Eq. (206) below) and developed in detail by M. Smoluchowski in 1906-1907, and A. Fokker in 1913.

[^679]:    ${ }^{31}$ This result is valid only if approximation (82) may be applied at time interval $d t$ which, in turn, should be much smaller than $T_{2}$, i.e. if the dephasing time is much longer that the environment's correlation time $\tau_{c}$. This requirement is usually well satisfied, because in most environments, $\tau_{c}$ very short. For example, in the original Brownian motion experiments with few- $\mu \mathrm{m}$ ink particles in water, it is of the order of the average interval between sequential molecular impacts, of the order of $10^{-21} \mathrm{~s}$.
    ${ }^{32}$ See, e.g., MA Eq. (1.2a).

[^680]:    ${ }^{33}$ The most frequent example of violation of these conditions is environment's overheating by the energy flow from the subsystem. I leave it to the reader to estimate the overheating of a standard physical laboratory room by a typical dissipative quantum process - the emission of an optical photon by an atom. (Hint: extremely small.)
    ${ }^{34}$ The FDT was first derived by H. Callen and T. Welton in 1951, on the background of an earlier derivation of its classical limit by H. Nyquist in 1928, and the pioneering 1905 work by A. Einstein - see below.
    ${ }^{35}$ The FDT may be proved in several ways which are different from, and shorter than the one given in this section - see, e.g., either SM Secs. 5.5 and 5.6 (based on H. Nyquist's arguments), or the original paper by H. Callen and T. Welton, Phys. Rev. 83, 34 (1951) - wonderful in its clarity. The longer approach I describe here, besides giving the important Kubo formula (109) as a byproduct, is a very useful exercise in the operator manipulation and the perturbation theory in its integral form, different from the differential form used in Chapter 6. If the reader is not interested in this exercise, he or she may skip the derivation and jump directly to the result expressed by Eq. (134), which uses the notions defined by Eqs. (114) and (123).
    ${ }^{36}$ We can always do that if the local environment is large enough, so that the processes in our subsystem would not depend on the type of boundary between it and the external environment; in particular we may assume the total system closed, i.e. Hamiltonian.
    ${ }^{37}$ For usual ("ergodic") environments, without intrinsic long-term memories, this statistical averaging over an ensemble of environments is equivalent to averaging over relatively short times - much longer than the correlation time $\tau_{c}$ of the environment, but still much shorter than the characteristic time of evolution of the system under analysis, such as the dephasing time $T_{2}$ and the energy relaxation time $T_{1}$ - both still to be calculated. As was already mentioned, in most practical environments, $\tau_{c}$ is very short. Thus, for relatively "massive" (inertial) systems of interest the separation of the averaging into two steps is well justified.

[^681]:    ${ }^{38}$ Here we assume that for the equilibrium, Eq. (92) has zero average, because if this is not so, this average part of force may be always included into the Hamiltonian of subsystem $s$.

[^682]:    ${ }^{39}$ A good sanity check here is that at $\tau=0$, the difference (99) between $K_{F}(\tau)$ and $K_{F}(-\tau)$ vanishes.

[^683]:    ${ }^{40}$ For a more detailed discussion of this function and the causality principle, see, e.g., CM Sec. 4.1.
    ${ }^{41}$ This relation, called the Kubo (or "Green-Kubo") formula, after the works by M. Green (1954) and R. Kubo (1957), does not come up in the easier derivations of the FDT, discussed in the beginning of this section.
    ${ }^{42}$ Due to their practical importance, and certain mathematical issues with their justification for random functions, Eqs. (112)-(113) have their own grand name, the Wiener-Khinchin theorem, though the math rigor aside, they are just a straightforward corollary of the Fourier integral transform (115) - see, e.g., SM Sec. 5.4.

[^684]:    ${ }^{44}$ Using, e.g., MA Eq. (6.5a). (The imaginary parts of the integrals vanish, because integration in infinite limits may be always re-centered to finite points $\pm \hbar \omega$.) A mathematically enlightened reader may have noticed that the integrals might be taken without the introduction of small $\varepsilon$, using the Cauchy theorem - see MA Eq. (15.1).

[^685]:    ${ }^{45}$ Integration in Eq. may be extended to the whole time axis, $-\infty<\tau<+\infty$, if we complement definition (107) of $G(\tau)$ for $\tau>0$ with its definition as $G(\tau)=0$ for $\tau<0$, in correspondence with the causality principle.
    ${ }^{46}$ In order to prove this relation, it is sufficient to plug expression $\hat{x}_{s}=\hat{x}_{\omega} e^{-i \omega t}$, or any sum of such exponents, into Eqs. (107) and then use definition (123). This simple exercise is highly recommended to the reader.
    ${ }^{47}$ The expression $P=F \dot{x}=F v$ used for the instant power flow is evident if $x$ is the usual Cartesian coordinate of a mechanical system. According to analytical mechanics (see, e.g., CM Chapters 2 and 10), it is valid for any generalized coordinate - generalized force pair which forms the interaction Hamiltonian (90).

[^686]:    ${ }^{48}$ A curious feature of the FDT is that Eq. (134) includes the exactly same function of temperature as the average energy (26) of a quantum oscillator of frequency $\omega$, though, as the reader could witness, the notion of the

[^687]:    ${ }^{54}$ See, e.g., CM Sec. 4.1.
    ${ }^{55}$ See, e.g., MA Eq. (6.5a).

[^688]:    ${ }^{56}$ By the way, the simplest way to calculate $S_{F}(\omega)$, i.e. to derive the FDT, is to require that Eqs. (48) and (150) give the same result for an oscillator with any eigenfrequency $\omega$. This is exactly the approach used by H. Nyquist (for the classical case) - see also SM Sec. 5.5.
    ${ }^{57}$ See, for example, R. Koch et al., Phys. Lev. B 26, 74 (1982)..

[^689]:    ${ }^{58}$ Its natural generalizations enable analyses of fluctuations in arbitrary linear systems, i.e. the systems described by linear differential (or integro-differential) equations of motion, including those with many degrees of freedom, and distributed systems (continua).
    ${ }^{59}$ For some calculations, this problem may be avoided by linearization: if we are only interested in small fluctuations, the Heisenberg equations of motion may be linearized about their expectation values (see, e.g., CM Sec. 4.2), and the linear equations for variations solved either as has been shown above, or (if the expectation values evolve in time) by their Fourier expansions.

[^690]:    ${ }^{60}$ As in Sec. 4, the reader not interested in the derivation of the basic equation (181) for the density matrix evolution may immediately jump to the discussion of this equation and its applications.

[^691]:    ${ }^{62}$ A similar analysis of a more general case, when the interaction with environment may be represented as a sum of products of the type (90), may be found in a monograph by K. Blum, Density Matrix Theory and Applications, $3^{\text {rd }}$ ed., Springer, 2012.

[^692]:    ${ }^{63}$ Named after A. Markov (1856-1922; in older literature, "Markoff"), because the result of this approximation is a particular case of the Markov process whose future development is completely determined by its present state.
    ${ }^{64}$ Rather reluctantly, I will use this standard notation, $E_{n}$, for the eigenenergies of our system of interest $(s)$, in hope that the reader would not confuse these discrete energy levels with the quasi-continuous energy levels of its environment, participating in particular in Eqs. (108) and (111). As a reminder, by this stage of our calculations the environment levels have disappeared, leaving behind their "trace functions" $K_{F}(\tau)$ and $G(\tau)$.

[^693]:    ${ }^{65}$ This is essentially the same rotating-wave approximation (RWA) that is so instrumental in other fields of not only quantum mechanics, but classical physics as well - see, e.g., CM Secs. 4.2-4.5.
    ${ }^{66}$ As was already discussed in Sec. 4, the lower-limit substitution $\left(t^{\prime}=-\infty\right)$ in integrals (174) gives zero, due to the finite-time "memory" of the system, expressed by the decay of the correlation and response functions at large values of the time delay $\tau=t-t$ '.

[^694]:    ${ }^{67}$ The master equations, first introduced to quantum mechanics in 1928 by W. Pauli, are sometimes called the "Pauli master equations", or "kinetic equations", or "rate equations".
    ${ }^{68}$ As Eq. (193) shows, the term with $m=n$ would vanish, and thus may be legitimately excluded from the sum.

[^695]:    ${ }^{69}$ As Eq. (193) shows, the result for $\Gamma_{n \rightarrow n^{\prime}}$ is described by Eq. (195) as well, provided that indices $n$ and $n$ ' are swapped in all components of its right-hand part, including the swap $\omega_{n n^{\prime}} \rightarrow \omega_{n^{\prime} n}=-\omega_{n n^{\prime}}$.
    ${ }^{70}$ It is straightforward to show that at relatively low temperatures $\left(k_{\mathrm{B}} T \ll\left|E_{n},-E_{n}\right|\right)$, Eq. (196) gives the same result as the Golden Rate formula (6.134) - see Exercise 2. (The low temperature limit is necessary to ensure that the initial occupancy of the excited level is negligible, as was assumed at the derivation of Eq. (6.134).)

[^696]:    ${ }^{71}$ Because of the reason explained above, this (relatively :-) simple result is not valid for systems with equidistant energy spectra, most importantly, for the harmonic oscillator (while Eq. (7.194) is). For the oscillator, with its simple matrix elements $x_{n n^{\prime}}$, it is straightforward to repeat the above calculations, starting from (7.183), to obtain an equation similar to Eq. (7.200), but with two other terms, proportional to $w_{n \pm 1, n^{\prime} \pm 1}$, in its right-hand part. Since for the harmonic oscillator the Heisenberg-Langevin approach allows obtaining most results in a much simpler way, I will skip the derivation of this equation and the discussion of its solutions. The interested reader may find such a discussion, for example, in a paper by B. Zeldovich et al., Sov. Phys. JETP 28, 308 (1969).
    ${ }^{72}$ Sometimes Eq. (200) (in any of its numerous alternative forms) is called the Redfield equation, after the 1965 work by A. Redfield. Note, however, that several other authors, notably including (in the alphabetical order) H. Haken, W. Lamb, M. Lax, W. Louisell, and M. Scully, also made key contributions into the very fast development of the density-matrix approach to open quantum systems in the mid-1960s.
    ${ }^{73}$ This correction is frequently called the Lamb shift, because it was first observed experimentally in 1947 by W. Lamb and R. Retherford, as a minor, $\sim 1 \mathrm{GHz}$ shift between energy levels of $2 s$ and $2 p$ states of hydrogen, due to the electric-dipole coupling of hydrogen atoms to the free-space electromagnetic environment. (These levels are equal not only in the non-relativistic theory (Sec. 3.6), but also in the relativistic, Dirac theory (Sec. 9.7), if the

[^697]:    ${ }^{75}$ The tunneling may be described without altering Eq. (70), just by adding, to the unperturbed Hamiltonian (69), terms proportional to other Pauli matrices. The reader is encouraged to spell out the equations for the time evolution of the density matrix elements of this system, and analyze their main properties - at least in the lowtemperature limit.

[^698]:    ${ }^{76}$ It was the main result of A. Einstein's pioneering analysis of such Brownian motion in 1905. (The development of this analysis in 1906-1908 by M. Smoluchowski has led in 1912 to the Fokker-Planck theory.)

[^699]:    ${ }^{81}$ Besides the trivial case $\alpha_{j}=\delta_{j j^{\prime}}$ (so that $W_{j}=\delta_{j j^{\prime}}$ ), when the system is in a certain eigenstate $\left(a_{j^{\prime}}\right.$ ) of operator $\hat{A}$. ${ }^{82}$ The reader in doubt is invited to compare entropy $S=-\Sigma_{j} W_{j} \ln W_{j}$, the measure of system's disorder (see, e.g., SM Sec. 2.2) of the pure state $(S=0)$ with that in any state with several nonvanishing values of $W_{j}(S>0)$.

[^700]:    ${ }^{83}$ This scheme may be implemented, for example, using a simple Josephson-junction circuit called the balanced comparator - see, e.g., T. Walls et al., IEEE Trans. on Appl. Supercond. 17, 136 (2007), and references therein. Experiments by V. Semenov et al., IEEE Trans. Appl. Supercond. 7, 3617 (1997) have demonstrated that this system may have measurement accuracy dominated by quantum-mechanical uncertainty at relatively modest cooling (to $\sim 1 \mathrm{~K}$ ). One of advantages of such implementation of this measurement scheme is that it is based on externally-shunted Josephson junctions - devices whose quantum-mechanical model is in a quantitative agreement with experiment - see, e.g., D. Schwartz et al., Phys. Rev. Lett. 55, 1547 (1985). Colloquially, the balanced comparator is an instrument with a "well-documented Hamiltonian" including its part describing coupling to environment.
    ${ }^{84}$ As a reminder, dynamics of this system was discussed in Sec. 2.6 and then again in Sec. 6.1.

[^701]:    ${ }^{85}$ Somewhat counter-intuitively, the latter growth plays a positive role for measurement fidelity. Indeed, it does not affect the intrinsic "signal-to-noise ratio" $\delta x_{s} /\left\langle x_{s}\right\rangle$, while making the intrinsic (say, quantum-mechanical) uncertainty much larger that possible noise contribution by the latter measurement stage(s).

[^702]:    ${ }^{86}$ This name, coined by E. Sudarshan and B. Mishra in 1997 (though the paradox had been discussed in detail by A. Turing in 1954); is due to the apparent similarity of this paradox to classical paradoxes by ancient Greek philosopher Zeno of Elea. By the way, just to have a minute of fun, let us have a look what happens when Mother Nature is discussed by people to do not understand math and physics. The most famous of the classical Zeno paradoxes is the Achilles and Tortoise case: a fast runner Achilles can apparently never overtake a slower Tortoise, because (in the words by Aristotle) "the pursuer must first reach the point whence the pursued started, so that the slower must always hold a lead". For a physicist, the paradox has a trivial resolution, but let us listen what a philosopher (D. Burton) writes about it - not in some year BC, but in 2010 AD: "Given the history of 'final resolutions', from Aristotle onwards, it's probably foolhardy to think we've reached the end." For me, this is a sad symbol of modern philosophy.

[^703]:    ${ }^{87}$ For a detailed survey of this field see, e.g., either V. Braginsky and F. Khalili, Quantum Measurements, Cambridge U. Press, 1992, or H. Wiseman and G. Milburn, Quantum Measurement and Control, Cambridge u. Press, 2010.
    ${ }^{88}$ S. Peil and G. Gabrielse, Phys. Rev. Lett. 83, 1287 (1999).
    ${ }^{89}$ Similar to the one discussed in EM Sec. 2.4 (see in particular Eq. (2.77) and Fig. 2.7), but with additional rotation about one of the axes - either $x$ or $y$.

[^704]:    ${ }^{90}$ I am simplifying the real situation a bit. Actually, in the experiment there was an electron spin's contribution to the interaction Hamiltonian as well, but since the large magnetic field polarized the spins quite reliably, their only role was a constant shift of frequency $\omega_{z}$.

[^705]:    ${ }^{91}$ This simple equation is limited to 1D systems with Hamiltonians of the type (2.50), but the reader should agree that this is a pretty general form.
    ${ }^{92}$ See, e.g., CM Sec. 4.1. Note in particular that function $\sin \omega_{0} \tau\left(\right.$ with $\left.\tau \equiv t-t^{\prime}\right)$ under the integral, divided by $\omega_{0}$, is nothing more than the temporal Green's function $G(\tau)$, of a loss-free harmonic oscillator.

[^706]:    ${ }^{93}$ The physical sense of these relations should be clear from Fig. 5.6: they define a system of coordinates rotating clockwise with angular velocity $\omega$, so that the point representing unperturbed classical oscillations with that frequency is at rest in that rotating frame. (The "probability cloud" presenting a Glauber state is also stationary in coordinates $\left[x_{1}, x_{2}\right]$.) The reader familiar with the classical theory oscillations may notice that $x_{1}$ and $x_{2}$ are essentially the RWA variables $u$ and $v$, i.e. the Poincaré plane coordinates - see, e.g., CM Sec. 4.3-4.6, and especially Fig. 4.9.
    ${ }^{94}$ See, e.g., P. Grangier et al., Nature 396, 537 (1998), and references therein. This was, however, not the first QND implementation in optics - for a review see J. Roch et al., Appl. Phys. B 55, 291 (1992).
    ${ }^{95}$ As it is, for example, for gravitational wave detectors - see the discussion and references in Sec. 2.10.
    ${ }^{96}$ See, e.g., CM Sec. 4.5.
    ${ }^{97}$ For the exact definition of the latter parameter, suitable for the quantum sensitivity range $\left(\Theta_{N} \sim \hbar \omega\right)$ as well, see, e.g., I. Devyatov et al., J. Appl. Phys. 60, 1808 (1986). In the classical noise limit ( $\Theta_{N} \gg \hbar \omega$ ), it coincides with $k_{\mathrm{B}} T_{N}$, where $T_{N}$ is a more popular measure of electronics noise, called the noise temperature.

[^707]:    ${ }^{98}$ This fact was recognized very early - see, e.g., H. Haus and J. Mullen, Phys. Rev. 128, 2407 (1962).
    ${ }^{99}$ See, e.g., the spectacular experiments by B. Yurke et al., Phys. Rev. Lett. 60, 764 (1988).
    ${ }^{100}$ See, e.g., D. Averin, Phys. Rev. Lett. 88, 207901 (2002).

[^708]:    ${ }^{1}$ An important conceptual question is why not treat one particle of such a collection as an open quantum system, and apply to it the powerful methods discussed in the last chapter, based on the separation of the whole Universe into the "system of our interest" and the "environment" - see Fig. 7.1. Such separation is very natural and works very well in cases when one, relative "massive" (inertial) particle, or a specific collective degree of freedom (also relatively inertial), is surrounded by a sea of "lighter particles", which serve the role of an environment frequently in or close to thermal equilibrium. On the other hand, in most systems of identical particles, such separation is more artificial and may lead to errors, because the quantum state of the "particle of interest" may be substantially correlated (in particular, entangled) with that of similar particles of its "environment" - see the discussion later in this section.

[^709]:    ${ }^{2}$ Here by "elementary particles" I mean any of the following two options:
    (i) particles like electrons, which (at least at this stage of development of physics) are considered as structure-less entities;
    (ii) any object (e.g., a hadron or meson) which may be considered as a system of "more elementary" particles (e.g., quarks), but still may be reliably placed in a definite (say, ground) quantum state.

    From that point of view, even complex atoms or molecules of a certain chemical element, each in its ground state, may be considered on the same footing as elementary particles.
    ${ }^{3}$ A very legitimate question is why, in this situation, we need to introduce particle's number to start with. A partial answer is that in this approach it is much simpler to derive (or guess) problem Hamiltonians from the correspondence principle. For example for a system of two spinless particles, each in an external potential $U(\mathbf{r})$, and with the interaction energy $U_{\text {int }}\left(\left|\mathbf{r}_{1}-\mathbf{r}_{2}\right|\right)$, the correct Hamiltonian is

    $$
    \hat{H}=\frac{\hat{p}_{1}^{2}}{2 m}+\frac{\hat{p}_{2}^{2}}{2 m}+U\left(\hat{\mathbf{r}}_{1}\right)+U\left(\hat{\mathbf{r}}_{2}\right)+U_{\mathrm{int}}\left(\left|\hat{\mathbf{r}}_{1}-\hat{\mathbf{r}}_{2}\right|\right)
    $$

    Later in this chapter, we will discuss an alternative approach (the so-called "second quantization") in which tracing a certain particle is avoided. While for indistinguishable particles this is more logical, in that approach writing adequate Hamiltonians (which, in particular, would avoid spurious self-interaction of the particles) is much more challenging - see Sec. 3 below.

[^710]:    ${ }^{4}$ As in many situations we met before, kets (10) and (11) may be multiplied by $\exp \{i \varphi\}$ with an arbitrary real phase $\varphi$. However, until we discuss coherent superpositions of various states $\alpha$, there is no good motivation for taking the phase different from 0 ; that would only clutter the notation.

[^711]:    ${ }^{5}$ Traditionally, people speak about two different "statistics": the Bose-Einstein statistics of bosons, and FermiDirac statistics of fermions, because their statistical distributions in thermal equilibrium are indeed different - see, e.g., SM Sec. 2.8. However, as evident from the above discussion, their difference is deeper, and actually we are dealing with two different quantum mechanics.
    ${ }^{6}$ For a quantitative discussion of the Bose-Einstein condensation see, e.g., SM Sec. 3.4.
    ${ }^{7}$ Such possibility follows from the fact that for the Bose-Einstein condensate of $N \gg 1$ particles, the Heisenberg uncertainty relation may be reduced to $\delta N \delta \varphi>1$, where $\varphi$ is the condensate wavefunction's phase, so that it may have $\delta N /\langle N\rangle \ll 1$ and $\delta \varphi \ll 1$ simultaneously.
    ${ }^{8}$ It was formulated by W. Pauli in 1925, on the basis of less general rules suggested by G. Lewis (1916), I. Langmuir (1919), N. Bohr (1922), and E. Stoner (1924) for the explanation of experimental spectroscopic data.

[^712]:    ${ }^{9}$ Note that in the sense of Eq. (5.197), all three triplet states of a two-electron system behave as a single integer spin with $s=1$; for example, $S^{2}$ equals $2 \hbar^{2}$, rather than 0 as one could expect for the last component of Eq. (21) see Problem 1.
    ${ }^{10}$ In this chapter, I try to use lower-case letters for observables of single particles (in particular, $\varepsilon$ for their energies), in order to distinguish them as clearly as possible from system's variables, including the total energy $E$ of the system, typeset in capital letters.

[^713]:    ${ }^{11}$ It is also very important, since helium makes up more than $20 \%$ of all "ordinary" matter of our Universe.
    ${ }^{12}$ Evidently, the positive ion $\mathrm{He}^{+1}$ of such atom, with just one electron, is very well described by the hydrogenlike atom theory with $Z=2$, whose ground-state energy, according to Eq. (3.191), is $-Z^{2} E_{\mathrm{H}} / 2=-2 E_{H} \approx-55.4 \mathrm{eV}$.

[^714]:    ${ }^{13}$ See also Problems 2.6-2.8, 2.34, and 3.3.

[^715]:    ${ }^{14}$ This example explains why the variational method is broadly used for approximate treatment of complex quantum systems, although it is based more or less intuitive guesses of trial functions, i.e. in contrast with the perturbation theories discussed in Chapters 6 and 7, does not guarantee asymptotically correct results in any particular limit, unless such correctness is manually incorporated into the trial state choice.

[^716]:    ${ }^{15}$ See, e.g., EM Sec. 1.3, in particular Eq. (1.54).
    ${ }^{16}$ Note that the result for $E_{\text {dir }}$ correctly reflects the basic fact that a charged particle does not interacts with itself, even if its wavefunction is quantum-mechanically spread over a finite space volume. Unfortunately, this is not true for some other approximate theories of multi-particle systems - see Sec. 4 below.

[^717]:    ${ }^{17}$ It was invented (first for photons and then for arbitrary bosons) by P. Dirac in 1927, and then modified in 1928 for fermions by E. Wigner and P. Jordan. The term "second quantization" is rather misleading for the nonrelativistic applications we are discussing, but finds certain justification in the quantum field theory.

[^718]:    ${ }^{18}$ The resulting Dirac state is not an eigenstate of every multiparticle Hamiltonian. However, we will see below that for a set of non-interacting particles it is an eigenstate, and thus may be used in the basis for perturbation theories of systems of weakly interacting particles.

[^719]:    ${ }^{19}$ See, e.g., MA Eq. (2.3).

[^720]:    ${ }^{20}$ A by-product of this calculation is a proof that operator (64) counts the number of particles $N_{j}$ (now equal to either 1 or 0 ), just at it does for bosons.

[^721]:    ${ }^{21}$ Equations of motion for creation operators $\hat{a}_{1,2}^{\dagger}$ are just the Hermitian-conjugates of Eqs. (98), and do not add any new information about system's dynamics.

[^722]:    ${ }^{22}$ For the second well's occupancy, the result is complementary, $N_{2}(t)=N_{1}(0) \sin ^{2} \Omega t+N_{2}(0) \cos ^{2} \Omega t$, giving in particular a good sanity check: $N_{1}(t)+N_{2}(t)=N_{1}(0)+N_{2}(0)=$ const.

[^723]:    ${ }^{23}$ For a review of the 1D version of this problem, see, e.g., J. Pendry, Adv. Phys. 43, 461 (1994).
    ${ }^{24}$ To complete this section, I have to note, at least in passing, a different form of the second-quantization formalism, based on the so-called field operators. It will be more natural for me to discuss it in the next chapter.
    ${ }^{25}$ Another important example is the so-called Hubbard model in which there may be only two particles on each of localized sites, with the negligible interaction of particles on different sites - which are only connected by the next-neighbor tunneling - see Eq. (104).
    ${ }^{26}$ The only new feature is a specific order of the indices of the creation operators. Note the mnemonic rule of writing this expression, similar to that for Eq. (79): each term corresponds to moving a pair of particles from states $l$ and $l$ ' to states $j^{\prime}$ and $j$, factored with the corresponding two-particle matrix element (107).

[^724]:    Energy
    correction due to
    fermion interaction

[^725]:    ${ }^{27}$ Constructs (117) are also close to spinors (14), besides that the spin $s$ of a single particle is fixed, so that the spin-orbital should be indexed by spin's orientation $m \equiv m_{s}$ rather than the full spin $s$. Also, the orbital index should be clearly distinguished from $j$ (which, again, is the set of that orbital index and $m$ ). This is why I believe that the frequently met notation of spinors as $\psi_{j, s}(\mathbf{r})$ may lead to confusion.

[^726]:    ${ }^{32}$ See, e.g., A. Szabo and N. Ostlund, Modern Quantum Chemistry, McGraw-Hill, 1989.
    ${ }^{33}$ That method, in particular, allows the calculation of proper linear superpositions of the Dirac states (such as the excited singlet state for $N=2$, discussed above) which are missing in the generic Hartree-Fock approach.
    ${ }^{34}$ It was developed by W. Kohn and coauthors in the mid-1960s, and eventually (in 1998) awarded with a Nobel prize in chemistry.
    ${ }^{35}$ For a uniform, degenerate Fermi-gas of electrons (with the Fermi energy $\varepsilon_{\mathrm{F}} \gg k_{\mathrm{B}} T$ ), the exchange potential may be calculated analytically, giving $u_{\mathrm{ex}}=(3 / 4 \pi) e^{2} k_{\mathrm{F}} / 4 \pi \varepsilon_{0}$, where $k_{\mathrm{F}}$ is the Fermi-surface wave number that defines both the Fermi energy $\varepsilon_{\mathrm{F}}=\left(\hbar k_{\mathrm{F}}\right)^{2} / 2 m$ and the electron density (per unit volume) $n=2(4 \pi / 3) k_{\mathrm{F}}^{3} /(2 \pi)^{3} \equiv$ $k_{\mathrm{F}}^{3} / 3 \pi^{2}$.
    ${ }^{36}$ See, e.g., G. te Velde et al., J. Comp. Chem. 22, 931 (2001), and/or M. D. Segall et al., J. Phys. - Cond. Matt. 14, 2717 (2002), and references therein.

[^727]:    ${ }^{37}$ This popularity is enhanced by the availability of several advanced DFT software packages, some of them (such as SIESTA, http://icmab.cat/leem/siesta/) in public domain.
    ${ }^{38}$ See, e.g., N. Simonian et al., J. Appl. Phys. 113, 044504 (2013).
    ${ }^{39}$ Since these fields are much related, they are often referred to together, under the (somewhat misleading) title of "quantum information".
    ${ }^{40}$ Despite many recent book titles in the field, one of its first surveys, by M. Nielsen and I. Chuang, Quantum Computation and Quantum Information, Cambridge U. Press, 2000, is perhaps still the best one.
    ${ }^{41}$ In some texts, the term qubit (or "Qbit", or "Q-bit") is used instead for the information contents of a two-level system - very much like the classical bit of information (in this context, frequently called "Cbit" or "C-bit") describes the information contents of a classical bistable system - see, e.g., SM Sec. 2.2.
    ${ }^{42}$ The slightly odd aspect of this notation is that at the Bloch sphere representation (Fig. 5.1), the North Pole state (that is traditionally denoted as $\uparrow$ in other fields of quantum mechanics) is taken for 0 , while the South Pole state $\downarrow$ for 1 , so that Eqs. (5.4) take the form $a_{0}=\cos (\theta / 2), a_{1}=\sin (\theta / 2) \exp \{i \varphi\}$.

[^728]:    ${ }^{43}$ Here and in most instances below I use the same shorthand notation as was used in the beginning of this chapter - cf. Eq. (8.1). In this short form, qubit's number is coded by the order of its state index inside the single ketvector, while in the long form, such as in Eq. (129), it is coded by the order of the ket-vector.
    ${ }^{44}$ It follows from the requirement that the sum of two probabilities $W_{j}=\langle\alpha| \hat{P}_{j}|\alpha\rangle$ (where $\hat{P}_{j}=|j\rangle\langle j|$ is the corresponding projection operator, see Sec. 4.5) to find one of qubits in one of its two possible states $j$, equals 1. It is remarkable that the application of this condition to any of the qubits results in the same Eq. (127).

[^729]:    ${ }^{45}$ Numerous modifications of this baseline scheme have been suggested, for example with the number of output qubits different from that of input qubits, etc. Some other options are discussed in the end of this section.
    ${ }^{46}$ The notion of "wires" stems from the similarity between these diagrams and the drawings used to describe classical computation circuits (see, e.g., Fig. 3a below); in the latter case the lines may be indeed understood as physical wires connecting physical devices: logic gates and/or memory cells. In this context note that classical computer components also have nonvanishing time delays, so that even in this case the left-to-right device ordering is useful to indicate the timing of (and frequently the causal relation between) the signals.
    ${ }^{47}$ As we know from Chapter 7, the preparation of pure state (125) is (conceptually :-) straightforward. Placing a qubit into a weak contact with an environment of temperature $T \ll \Delta / k_{\mathrm{B}}$, where $\Delta$ is the difference between energies of eigenstates $|0\rangle$ and $|1\rangle$, we may achieve its relaxation into the lowest-energy state. (Otherwise, the relaxation may be to one of states with equal, or nearly-equal energies, combined with its measurement - see Fig. 7.8 and its discussion.) Then, if the qubit must be set into the opposite state, it may be driven there by the application of a pulse of a proper external classical "force". For example, if actual spin- $1 / 2$ particles are used as qubits, a constant magnetic field may be applied in the $[x, y]$ plane for a half-period of the torque-induced spin precession - see Fig. 5.1c. However, for most qubit implementations, the basis state reversal using a half-period of rf-induced Rabi oscillations (Sec. 6.5) is more convenient.

[^730]:    ${ }^{48}$ Named after D. Deutsch, whose 1985 paper (motivated by an inspirational but not very specific publication by R. Feynman in 1982) launched the whole field of quantum computation.

[^731]:    ${ }^{49}$ Alternatively, we may perform two sequential experiments on the same black box $f$, first recording and then recalling their results.

[^732]:    50 In order to exclude any chance of confusion between the Hadamard transform's operator $\hat{\notin t}$ and the Hamiltonian operator $\hat{H}$, I have typeset them using different fonts.
    ${ }^{51}$ Note that according to Eq. (138), the operator $\hat{H}$ does not belong to the limited class $\hat{U}$ described by Eq. (132). ${ }^{52}$ Since states 0 and 1 form a full basis of the single qubit, Eqs. (139) may be summarized as an operator equality: ${\hat{\mathcal{H}^{2}}}^{2}=\hat{I}$.

[^733]:    ${ }^{53}$ This means that the last Hadamard transform of the target qubit (i.e. the Hadamard gate shown in the lower right corner of Fig. 3b) is not necessary for the Deutsch problem solution - though it should be included if we want the whole circuit to satisfy the general condition (132).

[^734]:    ${ }^{54}$ To comply with our current notation, coefficients $a_{n}$ ' and $a_{n}$ of Sec. 6.5 should be replaced with $a_{0}$ and $a_{1}$. Also note that their definition (6.82) implies that the trivial time evolution (6.81) of unperturbed qubits has been already excluded from these expansion coefficients.

[^735]:    ${ }^{55}$ The assumption of simultaneous time independence of the basis state vectors and the interaction operator (within the time interval $0<t<T$ ) is possible only if the basis state energy difference $\Delta$ of both qubits is exactly the same. For this case, the simple physical explanation of the time evolution (149) follows from Fig. 8.5, which shows the spectrum of the total energy $E=E_{1}+E_{2}$ of the two-bit system. In the absence of interaction, the energies of two basis states, $|01\rangle$ and $|10\rangle$, are equal, enabling even a weak qubit interaction to cause their substantial evolution in time - see Sec. 6.7. If the qubit energies are different (Fig. 5c), the interaction may still be reduced, in the rotating-wave approximation, to Eq. (149), by compensating the energy difference $\left(\Delta_{1}-\Delta_{2}\right)$ with an external rf signal of frequency $\omega=\left(\Delta_{1}-\Delta_{2}\right) / \hbar$ - see Sec. 6.5.

[^736]:    ${ }^{56}$ It Eq. (4.175) shows, each of component unitary transforms $\hat{I} \exp \left\{i \theta^{\prime} \hat{\sigma}_{z}\right\}$ may be created by applying to each qubit, for a time period $T^{\prime}=\hbar \theta^{\prime} / \kappa^{\prime}$, a constant external field described by Hamiltonian $\hat{H}=-\kappa^{\prime} \hat{\sigma}_{z}$. We already know that for a charged, spin- $1 / 2$ particle, such Hamiltonian may be created by applying $z$-oriented external constant magnetic field - see Eq. (4.163). For most other physical implementations of qubits, the organization of such Hamiltonian is also straightforward - see, e.g., Fig. 7.4 and its discussion.
    ${ }^{57}$ As was discussed above, this gate is identical to quantum gate $f$ for $f=f_{3}$, i.e. $f(j)=j$. The implementation of $f$ for 3 other functions $f$ requires straightforward modifications whose analysis is left for reader's exercise.
    ${ }^{58}$ This fundamental importance of the CNOT gate was perhaps a major reason why D. Wineland, the leader of the NIST group that had demonstrated the first experimental implementation in 1995 (following the theoretical suggestion by J. Cirac and P. Zoller), was awarded the 2012 Nobel Prize (shared with S. Haroche, the leader of another leading group working towards quantum computation).
    ${ }^{59}$ For that, the reader may be referred to either the monograph by Nielsen and Chuang, cited above, or to a shorter (but more formal) textbook by N. Mermin, Quantum Computer Science, Cambridge U. Press, 2007.

[^737]:    ${ }^{60}$ His original paper was published only in proceedings of a meeting, but a clear description of the algorithm may be found in several accessible sources including Wikipedia (http://en.wikipedia.org/wiki/Shor's algorithm).
    ${ }^{61}$ Named after R. Rivest, A. Shamir, and L. Adleman, the authors of the first open publication of the code in 1977, but actually invented earlier (in 1973) by C. Cocks.
    ${ }^{62}$ For more details, and a discussion of other possible implementations (such as quantum dots and dopants in crystals) see, e.g., T. Ladd et al., Nature 464, 45 (2010), and references therein.
    ${ }^{63} \mathrm{~A}$ brief discussion of such interactions (so-called Cavity QED) will be given in Sec. 9.4 below.
    ${ }^{64}$ In this field, the condition $\omega=\omega_{10}$, discussed above, is called the nuclear magnetic resonance, or NMR - the term well known due to the broad application of this effect in chemistry and medicine.
    ${ }^{65}$ See Eq. (4.5) and its discussion.
    ${ }^{66}$ This challenge may be partly mitigated using ingenious spin manipulation techniques such as refocusing - see, e.g., either Sec. 7.7 in Nielsen and Chuang, or J. Keeler's monograph cited in the end of Sec. 6.5.
    ${ }^{67}$ B. Lanyon et al., Phys. Rev. Lett. 99, 250505 (2001).

[^738]:    ${ }^{68}$ For the purposes of $E_{J}$ control reasons, it is more convenient to use two-junction configurations called Bloch transistors. Unfortunately, I do not have time to go into these details.
    ${ }^{69}$ See, e.g., EM Sec. 6.4 and references therein.
    ${ }^{70}$ This expression directly follows from combining EM Eqs. (6.57), (6.59), and (6.70).

[^739]:    ${ }^{71}$ This is even more true for the so-called "transmons" (or "Xmons") - the phase qubits versions in which a Josephson junction is just a part of an external resonator, providing it with small nonlineartity (anharmonism) see, e.g., R. Barrens et al., Nature 508, 500 (2014) and references therein.
    ${ }^{72}$ E. Lucero et al., Nature Physics 8, 719 (2012).
    ${ }^{73}$ E. Knill et al., Nature 409, 46 (2001).
    ${ }^{74}$ E. Martin-López et al., Nature Photonics 6, 773 (2012).

[^740]:    ${ }^{75}$ Amazingly, this no-cloning theorem was discovered as late as in 1982 (independently by W. Wooters and W. Zurek, and by D. Dieks) - in the context of work toward quantum cryptography.

[^741]:    ${ }^{76}$ This does not mean that several qubits cannot be put into the same, arbitrary quantum state - theoretically, with arbitrary precision. Indeed, they may be first set into their lowest-energy stationary states as was discussed above, and then driven into an arbitrary state (125) by exerting on them similar classical external "forces". So, the nocloning theorem pertains to only an unknown state $\alpha$ of a qubit.
    ${ }^{77}$ Such state is also the 3-qubit example of the so-called Greeenberger-Horne-Zeilinger (GHZ) states, which are frequently called the "most entangled" states of a system of $N>2$ qubits.

[^742]:    ${ }^{78}$ For example, in the Hilbert space of the qubit, the model Hamiltonian (7.70), which was explored in Sec. 7.3, is diagonal in the $z$-basis of states 0 and 1 , so that the unitary transform it provides during interval $T$ is also diagonal, giving the phase shifts described by Eq. (163), with $\varphi=\frac{1}{\hbar} \int_{0}^{T} f\{\lambda\} d t$. Let me emphasize again that Eq. (162) is valid only if the interaction with environment is a pure dephasing, i.e. does not include the energy relaxation of the qubit or its thermal activation to the higher eigenstate - see Chapter 7 .

[^743]:    ${ }^{79}$ Note that qualifier "quantum" is important here, to distinguish this research direction from the option of classical adiabatic (or "reversible") computation - see, e.g., SM Sec. 3.3 and references therein.

[^744]:    ${ }^{80}$ See, e.g., the experiments on factoring of number $143=13 \times 11$, using nuclear spin relaxation, by $\mathrm{N} . \mathrm{Xu}$ et al., Phys. Rev. Lett. 108, 130501 (2012), though by the moment of this writing, their results remained controversial.
    ${ }^{81}$ Due to the same reason, the implementation is so far limited to most scalable, Josephson-junction (flux) qubits - see, e.g., M. Johnson et al., Nature 473, 194 (2011).
    ${ }^{82}$ For its classical version, see, e.g., SM Eq. (4.23) and its discussion.
    ${ }^{83}$ See S. Boxio et al., Nature Physics 10, 218 (2014) and T. Ronnow et al., arXiv:1401.2910 [quant-ph].
    ${ }^{84}$ This field was pioneered in the 1970s by S. Wisener.
    ${ }^{85}$ This procedure had been first suggested in 1993 by the same C. Bennett, and then repeatedly demonstrated experimentally - see, e.g., the recent paper by L. Steffen et al., Nature 500, 319 (2013), and literature therein.

[^745]:    ${ }^{86}$ All four states (172) are eigenstates of both these operators, so that the measurements do not affect each other and may be done in any order.

[^746]:    ${ }^{87}$ BB84 suggested in 1984 by C. Bennett and G. Brassard, and EPRBE suggested in 1991 by A. Ekert. For details, see, e.g., either Sec. 12.6 in Nielsen and Chuang, or the review by N. Gizin et al., Rev. Mod. Phys. 74, 145 (2002).
    ${ }^{88}$ For their discussion see, e.g., EM Sec. 7.8.
    ${ }^{89}$ See P. Hiskett et al., New J. Phys. 8, 193 (2006), and R. Ursin et al., Nature Physics 3, 481 (2007).

[^747]:    ${ }^{90}$ For more discussion of this and other models of ferromagnetism and antiferromagnetism see SM Chapter 4.
    ${ }^{91}$ For similar particles (in particular, with $\gamma_{1}=\gamma_{2}$ ) the problem is reduced to the previous one.

[^748]:    92 The anomalously large value of its $g$-factor may be qualitatively understood as a result of the three-quark structure of this particle. (The exact quantitative calculation of $g_{p}$ still remains a challenge for quantum chromodynamics.)
    ${ }^{93}$ Correct in the sense of the $1^{\text {st }}$ order of the perturbation theory.

[^749]:    ${ }^{1}$ Note that some material of this chapter is frequently taught as a part of the QFT. I will focus on a few most important results that may be obtained without starting heavy QFT engines.
    ${ }^{2}$ See, e.g., EM Chapter 9.
    ${ }^{3}$ By now this fact has been verified experimentally with an accuracy of at least $\sim 10^{-22} m_{e}-$ see S . Eidelman et al., Phys. Lett. B 592, 1 (2004).
    ${ }^{4}$ In the case of finite energy absorption in the walls, or in the wave propagation media (say, described by complex constants $\varepsilon$ and $\mu$ ), the system would not be energy-conserving (Hamiltonian), i.e. would interact with the dissipative environment. Specific cases of such interaction will be considered in Sections 2 and 3 below.
    ${ }^{5}$ See, e.g., EM Eq. (7.3), for the particular case $\varepsilon=\varepsilon_{0}, \mu=\mu_{0}, v^{2} \equiv 1 / \varepsilon \mu=1 / \varepsilon_{0} \mu_{0} \equiv c^{2}$.

[^750]:    ${ }^{6}$ See, e.g., various problems discussed in EM Chapter 7, especially in Sec. 7.9.
    ${ }^{7}$ See, e.g., EM Sec. 9.8, in particular, Eq. (9.225). I am using use SI units, with $\varepsilon_{0} \mu_{0} \equiv c^{-2}$; in the Gaussian units, coefficients $\varepsilon_{0}$ and $\mu_{0}$ disappear, but there is an additional common factor $1 / 4 \pi$ in the equation for energy. If we modify the normalization conditions accordingly, all the subsequent results look similar in any system of units.

[^751]:    ${ }^{8}$ See, e.g., EM Eq. (7.6).
    ${ }^{9}$ With different normalizations of functions $\mathbf{e}_{j}(\mathbf{r})$ and $\mathbf{b}_{j}(\mathbf{r})$, we could readily arrange any value of $m_{j}$, and the choice corresponding to $m_{j}=1$ is the best one just for the notation simplicity. Note also that I am using notation $q_{j}$ instead of $x_{j}$ for the generalized coordinate of the field oscillator, in order to emphasize the difference between the former variable, defined by Eq. (8), and one of the Cartesian coordinates, i.e. one of arguments of $c$-number functions $\mathbf{e}$ and $\mathbf{b}$.

[^752]:    ${ }^{10}$ It was predicted in 1948 by H. Casimir and D. Polder, and confirmed semi-quantitatively in experiments by M. Sparnaay, Nature 180, 334 (1957) and others. A decisive error bar reduction (to about $\sim 5 \%$ ), providing a quantitative confirmation of the Casimir formula (23), was achieved by S. Lamoreaux, Phys. Rev. Lett. 78, 5 (1997) and U. Mohideen and A. Roy, Phys. Rev. Lett. 81, 004549 (1998).

[^753]:    Casimir
    effect

[^754]:    ${ }^{11}$ For realistic metals, the reduction of $d$ below $\sim 1 \mu \mathrm{~m}$ causes significant deviations from this simple model, and hence from Eq. (23). The reason is that at the important frequencies $\omega \sim c / d$, the depth of field penetration into the metal (see, e.g., EM Secs. 2.1 and 6.2) becomes comparable with $d$, and a theory of the Casimir effect has to involve a certain model of field penetration. (It is curious that in-depth analyses of this problem, pioneered in 1956 by E. Lifshitz, have revealed a deep relation between the Casimir effect and the long-range London dispersion forces which were the subject of Problems 3.7, 5.10 and 6.8 - for a review see, e.g., either I. Dzhyaloshinskii et al., Sov. Phys. Uspekhi 4, 153 (1961), or K. Milton, The Casimir Effect, World Scientific, 2001.) Recent experiments in the $100 \mathrm{~nm}-2 \mu \mathrm{~m}$ range of distances $d$, with accuracy better than $1 \%$, allowed even to distinguish the difference between alternative approximate models of field penetration - see D. Garcia-Sanchez et al., Phys. Rev. Lett. 109, 027202 (2012).

[^755]:    ${ }^{12}$ As a reminder: this relation, with the single-particle expression $\mathbf{d}=q \mathbf{r}$, has already been used several times see, e.g., Eqs. (6.32) and (6.149). In contrast to the former of those cases, now we have to account for the quantum nature of the electromagnetic field $\boldsymbol{\varepsilon}$, so in Eq. (24) it is represented by the (vector) operator (16a).
    ${ }^{13}$ Please note that (as was promised) we have gradually slipped to the analysis of open, irreversible systems, with the detector(s) playing the role of a continuous-spectrum environment for the quantized electromagnetic field.
    ${ }^{14}$ In a multimode field, the modes are typically incoherent, so that the total transition rate may be calculated as the sum of the partial rates of each mode - as we will do for a certain case below.
    ${ }^{15}$ By the way, this expression shows that for the single-particle transitions from the ground state to $n^{\text {th }}$ Fock state, the absorption rate is indeed proportional to the oscillator strength $\left.f_{n} \equiv\left(2 m / \hbar^{2}\right)\left(E_{n}-E_{0}\right)|\langle n| x| 0\right\rangle\left.\right|^{2}$ of the transition, where $x$ is particle's coordinate in the direction of the external field. As was discussed in Chapter 5, the strengths obey the Thomas-Reiche-Kuhn sum rule $\Sigma_{n} f_{n}=1$.

[^756]:    ${ }^{16}$ This is essentially the same rotating wave approximation (RWA) which was already used in Sec. 6.3 - see the transition from Eq. (6.90) to the first of Eqs. (6.94).

[^757]:    ${ }^{17}$ It was pioneered as early as in the mid-1950s (i.e. before the advent of lasers!), by R. Hanbury Brown and R. Twiss. Their first experiment was also remarkable for the rather unusual light source they used - star Sirius! (It was a part of an attempt to improve astrophysics interferometry techniques.)
    ${ }^{18}$ The reader may be interested what is the first-order correlation function. It is usually defined as

    $$
    g^{(1)}(\tau) \equiv\left\langle\hat{\varepsilon}\left(\mathbf{r}_{1}, t\right) \hat{\varepsilon}^{\dagger}\left(\mathbf{r}_{2}, t-\tau\right)\right\rangle /\left[\left\langle\hat{\varepsilon}\left(\mathbf{r}_{1}, t\right) \hat{\varepsilon}^{\dagger}\left(\mathbf{r}_{1}, t\right)\right\rangle\left\langle\hat{\varepsilon}\left(\mathbf{r}_{2}, t\right) \hat{\varepsilon}^{\dagger}\left(\mathbf{r}_{2}, t\right)\right\rangle\right]^{1 / 2}
    $$

    In the single-mode case, and the rotating-wave approximation, the function is proportional to the $c$-number product $\mathbf{e}\left(\mathbf{r}_{1}\right) \mathbf{e}^{*}\left(\mathbf{r}_{2}\right)$, with all creation-annihilation operators cancelled, i.e. is suitable for characterizing interference patterns (30), but not the quantum state of the electromagnetic field.

[^758]:    ${ }^{19}$ H. J. Kimble et al., Phys. Rev. Lett. 39, 691 (1977). For a detailed review of phonon antibunching, see, e.g., H. Paul, Rev. Mod. Phys. 54, 1061 (1982).

[^759]:    ${ }^{20}$ For some field states, including the squeezed ground states $\xi$ discussed in the end of Sec. 5.5 , values $g^{(2)}(0)$ may be even higher than 2 - the so-called super-bunching. Analysis of one particular case of super-bunching is offered to the reader - see the exercise problem list.

[^760]:    ${ }^{21}$ Here I have smuggled back the sum over all electromagnetic field modes $j$ - see Eq. (16). Since in the quasistationary approximation, $k_{j} a \ll 1$, which is necessary for the interaction presentation by Eq. (24), matrix elements (49) are independent on $k_{j}$, the summation is reduced to the calculation of the total $\rho_{\text {fin }}$ for all modes.
    ${ }^{22}$ Note the essential dependence of Eq. (50), and hence of Eq. (53) on the field geometry; all following formulas of this section are valid for free 3D space only. If the same atom is place into a high- $Q$ resonant cavity (see, e.g., EM 7.9), the rate of its photon emission is strongly suppressed at frequencies between the cavity resonances (where $\rho_{\text {fin }} \rightarrow 0$ ) - see, e.g., the review of first experiments by S. Haroche and D. Klepner, Phys. Today 42, 24 (Jan. 1989). On the other hand, the emission is strongly (by a factor $\sim\left(\lambda^{3} / V\right) Q$, where $V$ is cavity's volume) enhanced at resonance frequencies - the so-called Purcell effect, discovered by E. Purcell already in the 1940s. For a brief discussion of these and other quantum effects in cavities, see the next section.
    ${ }^{23}$ An equivalent expression was first obtained in 1930 by V. Weisskopf and E. Wigner, so that the whole calculation is sometimes referred to as the Weisskopf-Wigner theory.
    ${ }^{24}$ See, e.g., EM Sec. 8.2, in particular Eq. (8.28).

[^761]:    ${ }^{25}$ The scale $c \tau$ of the spatial extension of the corresponding wave packet is surprisingly macroscopic - in the range of a few millimeters. Such "human" size of the emitted photons makes the optical table the key component of many optical experiments.
    ${ }^{26}$ As was already mentioned in Sec. 5.6, for a single particle moving in a spherically-symmetric potential (e.g., a hydrogen-like atom), the selection rules are simple: the only allowed electric-dipole transitions are those with $\Delta l \equiv$ $l_{\text {fin }} l_{\text {ini }}= \pm 1$ and $\Delta m \equiv m_{\text {fin }}-m_{\text {ini }}=0$. The simplest example of the transition that does not satisfy this rule is that between states with $n=2$ and $n=1$, both with $l=0$; because of that, the lifetime of the lowest excited $s$-state in hydrogen is as long as $\sim 0.15 \mathrm{~s}$.
    ${ }^{27}$ See, e.g., EM Sec. 8.9.

[^762]:    ${ }^{28}$ Relations (56) and (58) were conjectured, from very general arguments, by A. Einstein as early as in 1916.

[^763]:    ${ }^{29}$ It is straightforward to show that this fact is also true if the field is initially in the Glauber state - which is more typical for lasers.
    ${ }^{30}$ This idea has been traced back at least to an obscure 1939 publication by V. Fabrikant.
    ${ }^{31}$ I can recommend, for example, P. W. Milloni and J. H. Eberly, Laser Physics, ${ }^{\text {nd }}$ ed., Wiley, 2010, and a less technical text by A. Yariv, Quantum Electronics, 3rd ed., Wiley, 1989.
    ${ }^{32}$ This path has been developed (also in the mid-1960s), by several researchers, notably including M. Sully and W. Lamb - see, e.g., M. Sargent III, M. Scully, and W. Lamb, Jr., Laser Physics, Westview, 1977. Note that

[^764]:    ${ }^{38}$ The exact choice of this component is not important, while the formulas simplify if it is proportional to either pure $\sigma_{x}$ or pure $\sigma_{y}$.
    ${ }^{39}$ D. Braak, Phys. Rev. Lett. 107, 100401 (2011).

[^765]:    ${ }^{40}$ It was first proposed and analyzed in 1963 by two electronic engineers, E. Janes and F. Cummings, and it took the physics community a while to recognize and acknowledge the fundamental importance of that work.
    ${ }^{41}$ In most applications, Hamiltonian (78) is augmented by additional term(s) describing, for example, incoming radiation and/or coupling to environment, say due to the electromagnetic energy loss in the cavity walls - see Eq. (7.68).

[^766]:    ${ }^{42}$ Besides the non-degenerate ground state level $E_{g}=-\hbar \Omega / 2$.

[^767]:    ${ }^{43}$ Another important corollary of the level structure shown in Fig. 5 is the Purcell effect already mentioned in Sec. 3. As we already know from Chapter 7, if the system is coupled to environment, the coupling suppresses its quantum coherence, in our case the coherence between components of each pair (82). As a result, if the atom is initially in state $\uparrow$ with higher energy (79), it may perform incoherent (dissipative) transition to the lower-energy state $\downarrow$, giving energy $\hbar \omega$ to the cavity $(n-1 \rightarrow n)$, which rapidly drains it into the environment. Since the total energies of these initial and final states are close (Fig. 5), the rate of such transitions may be much higher than in free space. The quantitative analysis of such enhancement is left for reader's exercise.
    ${ }^{44}$ I can recommend, for example, either C. Gerry and P. Knight, Introductory Quantum Optics, Cambridge U. Press, 2005' or G. Agarwal, Quantum Optics, Cambridge U. Press, 2012.
    ${ }^{45}$ This approach was suggested almost simultaneously in 1926-1927 by (at least) V. Fock, E. Schrödinger, O. Klein and W. Gordon, J. Kudar, T. de Donder and F.-H. van der Dungen, and L. de Broglie.
    ${ }^{46}$ Note that in the sense of Eq. (1), in the non-relativistic column of this table, the energy is referred to the rest energy $m c^{2}$, while in the relativistic column, to zero.

[^768]:    ${ }^{47}$ Due to the same P. A. M. Dirac!

[^769]:    ${ }^{48}$ After such generalization, Eq. (84) is usually called the relativistic Schrödinger equation.
    ${ }^{49}$ The task left for the reader.

[^770]:    ${ }^{50}$ After the "naturally-relativistic" form of the Klein-Gordon equation (84), this apparent return to the nonrelativistic Schrödinger equation may look very counter-intuitive. However, it becomes a bit less surprising taking into account the fact (whose proof is left for the reader) that Eq. (84) may be also recast into form (95) for a twocomponent column-vector (spinor) $\Psi$, with a Hamiltonian which may be represented by a $2 \times 2$ matrix - and hence expressed via the Pauli matrices (4.

[^771]:    ${ }^{52}$ It is straightforward to show that this result remains valid for a particle in the field of central potential $U(\mathbf{r})$.
    ${ }^{53}$ See, e.g., A. Calogeracos and N. Dombey, Contemp. Phys. 40, 313 (1999).
    ${ }^{54}$ For a review see, e.g., T. Robinson, Am. J. Phys. 80, 141 (2012).

[^772]:    ${ }^{55}$ This difference may be traced even by classical means - see, e.g., EM Sec. 5.1.
    ${ }^{56}$ With the $g$-factor still equal to exactly 2 - see Eq. (4.116) and its discussion. In order to describe the small deviation of $g_{e}$ from 2, the electromagnetic field should be quantized (just as this was done in Secs. 1-4), and its potentials $\mathbf{A}$ and $\phi$, participating in Eq. (112) should be treated as operators - rather than as $c$-number functions as was assumed above. The calculation of this deviation is one of the basic problems of quantum field theory. Other small but important effects of electromagnetic interactions, described by the theory, include the so-called Lamb shift of atomic levels - see the end of this chapter for references.

[^773]:    ${ }^{57}$ The only facts immediately evident from Eq. (121) are that the term we are discussing is proportional to the electric field, as required by Eq. (122), and that it is of the proper order of magnitude. Indeed, Eqs. (101)-(102) imply that in the Dirac theory, $c \hat{\boldsymbol{\alpha}}$ plays the role of the velocity operator, so that the expectation values of the term are of the order of $\hbar q v \varepsilon / 2 m c^{2}$. Since the expectation values of the operators participating in Hamiltonian (122) scale as $S \sim \hbar / 2$ and $L \sim m v r$, the spin-orbit interaction energy has the same order of magnitude.
    ${ }^{58}$ As a reminder, in this course the notion of spinor was introduced earlier for two-particle states - see Eq. (8.14). For a single particle, that definition is reduced to $\psi(\mathbf{r})|s\rangle$, whose representation in a particular spin- $1 / 2$ basis is a column similar to Eq. (123). Also note that spinors (123) may be expanded into a series over the spin-orbitals (8.117) discussed in Sec. 8.3, with index $j$ used for numbering both the two directions of spin (i.e. two components of spinor's column) and orbital eigenfunctions.

[^774]:    ${ }^{59}$ Strictly speaking, this requirement is imposed on the expectation values of $U(\mathbf{r})$ in the eigenstates to be found.

[^775]:    ${ }^{60}$ The first term gives a small, spin-independent shift of the energy spectrum, which is very difficult to verify experimentally.
    ${ }^{61}$ Good descriptions of the solution are available in many textbooks (the older the better :-), for example see Sec. 53 in L. Schiff, Quantum Mechanics, $3^{\text {rd }}$ ed., McGraw-Hill (1968).

[^776]:    ${ }^{62}$ For a gradual introduction see, e.g., either L. Brown, Quantum Field Theory, Cambridge U. Press (1994) or R. Klauber, Student Friendly Quantum Field Theory, Sandtrove (2013); on the other hand, M. Srednicki, Quantum Field Theory, Cambridge U. Press (2007) and A. Zee, Quantum Field Theory in a Nutshell, $2^{\text {nd }}$ ed., Princeton (2010), among many others, offer a steeper learning curve.
    ${ }^{63}$ See, e.g., MA Eq. (2.12).

[^777]:    ${ }^{64}$ Here $\psi$ is a function of both $\mathbf{r}$ and $t$, and the lower-case letter is used only to distinguish this two-component spinor from the scalar function $\Psi(\mathbf{r}, t)$ obeying the Klein-Gordon equation.

[^778]:    ${ }^{65}$ Actually, the key relation (3.192), $n \geq l+1$, mathematically stems from the fact that the "genuine" quantum number of the radial problem, $n_{r}$, can only take non-negative integer values.

[^779]:    ${ }^{1}$ I believe that another popular name for this group of issues, "foundations of quantum mechanics", is hardly appropriate. The only reliable foundation of physics (or any other genuine scientific discipline) is a set of experimental facts.
    ${ }^{2}$ As was discussed in Sec. 7.7, Stern-Gerlach-type experiments may be readily made almost "perfect", i.e. virtually unaffected by instrument imperfections, provided that we do not care about the state of the particle after a single-shot measurement.

[^780]:    ${ }^{3}$ This is possible, because the corresponding operators commute: $\left[\hat{p}_{1}-\hat{p}_{2}, \hat{x}_{1}+\hat{x}_{2}\right]=\left[\hat{p}_{1}, \hat{x}_{1}\right]-\left[\hat{p}_{2}, \hat{x}_{2}\right]=0$.
    ${ }^{4}$ Another convenient experimental technique of entangled state generation, frequently used in this field, is the four-wave mixing (FWM) of optical photons. Its brief discussion may be found, for example, in CM Sec. 5.5. ${ }^{5}$ As a reminder, it differs from Eq. (1) only by the sign in the parentheses - see, e.g., Eqs. (4.123).

[^781]:    ${ }^{6}$ In his pioneering book J. von Neumann, Mathematische Grundlagen der Quantenmechanik [Mathematical Foundations of Quantum Mechanics], Springer, 1932. (The first English translation was published only in 1955.)
    ${ }^{7}$ Evidently, it would not satisfy A. Einstein, but reportedly he did not know about von Neumann's result before signing the EPR paper.
    ${ }^{8}$ See, e. g., J. S. Bell, Rev. Mod. Phys. 38, 447 (1966), or J. S. Bell, Foundations of Physics 12, 158 (1982).

[^782]:    ${ }^{9}$ Important milestones on that way were experiments by A. Aspect et al., Phys. Rev. Lett. 49, 91 (1982) and M. Rowe et al., Nature 409, 791 (2001). A detailed review of the experimental situation was given, for example, by M. Genovese, Phys. Repts. 413, 319 (2005); see also more recent experiments by D. Matsukevich et al., Phys. Rev. Lett. 100, 150404 (2008) and D. Salart et al., Nature 454, 861 (2008). Presently, a low-noise demonstration of the Bell inequality violation has become a standard test in each experiment with entangled qubits used for quantum encryption research - see Sec. 8.5.

[^783]:    ${ }^{10}$ A detailed discussion of statistical ensemble's role may be found, e.g., in L. Balentine, Quantum Mechanics, World Scientific, 1998.
    ${ }^{11}$ D. Bohm, Phys. Rev. 85, 165; 180 (1952).
    ${ }^{12}$ If the reader is not satisfied with this "positivistic" approach, and wants to improve the situation, my earnest advice would be to start not from square one, but from reading what other (including some very clever!) people thought about it. A good starting point is the review collection by J. Wheeler and W. Zurek (eds.), Quantum Theory and Measurement, Princeton U. Press, 1983.

[^784]:    ${ }^{1}$ For remedial reading, I can recommend, for example (in the alphabetical order): C. Kittel and H. Kroemer, Thermal Physics, $2^{\text {nd }}$ ed., W. H. Freeman (1980); F. Reif, Fundamentals of Statistical and Thermal Physics, Waveland (2008); D. V. Schroeder, Introduction to Thermal Physics, Addison Wesley (1999).
    ${ }^{2}$ See, e.g., Sec. 4 below. (Note that in these notes, the chapter number is dropped in references to figures, formulas, and sections within the same chapter.)
    ${ }^{3}$ See, e.g., CM Chapters 8 and 9. (Acronyms CM, EM, and QM refer to other of my lecture note series.)
    ${ }^{4}$ See, e.g., QM Chapter 1.

[^785]:    ${ }^{5}$ See, e.g., CM Chapters 2 and 10.

[^786]:    ${ }^{6}$ The notion of entropy was introduced into thermodynamics in the 1850s by R. Clausius, on the background of an earlier pioneering work by S. Carnot (see Sec. 7 below), as a variable related to "useful thermal energy" rather than a measure of disorder. In the absence of any clue of entropy's microscopic origins (which had to wait for decades until the works by L. Boltzmann and J. Maxwell), this was an amazing intellectual achievement.
    ${ }^{7}$ Indeed, as recently as in the late XIX century, the very possibility of irreversible macroscopic behavior of microscopically reversible systems was questioned by some serious scientists, notably by J. Loschmidt in 1876.
    ${ }^{8}$ While quantum-mechanical effects, with their intrinsic uncertainty, are quantitatively important in this example, our qualitative discussion does not depend on them. A good example is the chaotic, but classical motion of a billiard ball on a 2D Sinai table - see CM Fig. 9.8.

[^787]:    ${ }^{9}$ Several other quantities, for example the heat capacity $C$, may be obtained as partial derivatives of the basic variables discussed above. Also, at certain conditions, the number of particles $N$ in the system is not fixed and may be also considered as an (extensive) variable.
    ${ }^{10}$ Admittedly, some of these proofs are based on other (but deeper) postulates, for example the central statistical hypothesis - see Sec. 2.2.
    ${ }^{11}$ Defined as a system completely isolated from the environment, i.e. the system with its internal energy fixed.
    ${ }^{12}$ Implicitly, this statement also postulates the existence, in a closed system, of thermodynamic equilibrium, an asymptotically reached state in which all thermodynamic variables, including entropy, remain constant.

[^788]:    ${ }^{13}$ Here we strongly depend on a very important (and possibly the least intuitive) aspect of the $2^{\text {nd }}$ law, namely that the entropy is the unique measure of disorder, i.e. its only measure which may affect the system's energy, or any other thermodynamic variable.

[^789]:    ${ }^{14}$ Here I have to mention a traditional unit of energy, still used in some fields related to thermodynamics: the calorie; in the most common definition (the so-called thermochemical calorie) it equals exactly 4.148 J .
    ${ }^{15}$ For more exact value of this and other constants, see appendix CA: Selected Physical Constants. Note that both $T$ and $T_{\mathrm{K}}$ define the absolute (also called "thermodynamic") scale of temperature, in contrast to such artificial temperature scales as degrees Celsius ("centigrades"), defined as $T_{\mathrm{C}} \equiv T_{\mathrm{K}}+273.15$, or degrees Fahrenheit: $T_{\mathrm{F}} \equiv$ $(9 / 5) T_{\mathrm{C}}+32$.

[^790]:    ${ }^{16}$ A general (not necessarily adiabatic) process conserving entropy is sometimes called isentropic.

[^791]:    Energy:
    differential

[^792]:    $1^{\text {st }}$ law of thermodynamics

[^793]:    ${ }^{17}$ Let me emphasize that an adiabatic process is reversible, but not vice versa.
    ${ }^{18}$ Such conservation, expressed by Eqs. (18)-(19), is sometimes called the $1^{\text {st }}$ law of thermodynamics. While it (in contrast with the $2^{\text {nd }}$ law) does not present any new law of nature on the top of mechanics, and in particular was already used de-facto to write the first of Eqs. (5) and Eq. (14), such grand name was quite justified in the mid$19^{\text {th }}$ century when the mechanical nature of the internal energy (thermal motion) was not at all clear. In this context, the names of two great scientists, J. von Mayer (who was first to conjecture the conservation of the sum of the thermal and macroscopic mechanical energies in 1841), and J. Joule (who proved the conservation experimentally two years later), have to be reverently mentioned.
    ${ }^{19}$ Actually, the $3^{\text {rd }}$ law (also called the Nernst theorem) as postulated by W. Nernst in 1912 was different - and really meaningful: "It is impossible for any procedure to lead to the isotherm $T=0$ in a finite number of steps." I will discuss this postulate in the end of Sec. 6.
    ${ }^{20}$ By this definition, the full heat capacity of a system is an extensive variable. The capacity per either unit mass or per particle (i.e., an intensive variable), is called the specific heat capacity or just the specific heat. Note, however, that in some texts, the last term is used for the heat capacity of the system as the whole as well, so that some caution is in order.

[^794]:    ${ }^{21}$ A similar duality is possible for other pairs $\left\{q_{j}, Z_{j}\right\}$ of generalized coordinates and forces as well. For example, if a long sample of a dielectric placed is into a parallel, uniform external electric field, value of field $\varepsilon$ is fixed, i.e. does not depend on sample's polarization. However, if a thin sheet of such material is perpendicular to the field, then value of field $D$ is fixed - see, e.g., EM Sec. 3.4.
    ${ }^{22}$ The same is true for work $\mathcal{W}$, and in some textbooks this fact is emphasized by using a special sign for differentials of these variables. I do not do this in my notes, because both $d w$ and $d Q$ are still very much usual differentials: for example, $d w$ is the difference between the mechanical work which has been done over our system by the end of the infinitesimal interval we are considering, and that done by the beginning of that interval.

[^795]:    ${ }^{23}$ From the point of view of mathematics, Eq. (27) is a particular case of the so-called Legendre transformations. Note also that the term $P V$ has a purely mechanical meaning, and that the transfer from $H$ to $E$ just reflects the transfer from the "usual" potential energy of the system to its Gibbs potential energy - see, e.g., CM Sec. 1.4. ${ }^{24}$ This function (as well as the Gibbs free energy G, see below), had been introduced in 1875 by J. Gibbs, though the term "enthalpy" was coined (much later) by H. Onnes.

[^796]:    ${ }^{25}$ Named after H. von Helmholtz (1821-1894). The last term was recommended by the most recent (1988) IUPAC's decision, but I will use the first term, which prevails is physics literature. The origin of the adjective "free" stems from Eq. (32): $F$ is may be interpreted as the internal energy's part that is "free" to be transferred to mechanical work - at a reversible, isothermal process only!

[^797]:    ${ }^{26}$ Note the similarity of this situation with that is analytical (classical) mechanics (see, e.g., CM Chapters 2 and 10): the Lagrangian function may be used to get simple equations of motion if it is expressed as a function of generalized coordinates and velocities, while is order to use the Hamiltonian function in a similar way, it has to be expressed as a function of the generalized coordinates and momenta.

[^798]:    ${ }^{27}$ There is also a wealth of other relations between thermodynamic variables that may be presented as second derivatives of the thermodynamic potentials, including four Maxwell relations such as $(\partial S / \partial V)_{T}=(\partial P / \partial T)_{V}$, etc. (They may be readily recovered from the well-known property of a function of two independent arguments, say, $f(x, y): \partial(\partial f / \partial x) / \partial y=\partial(\partial f / \partial y) / \partial x$.) In this chapter, I will list only the thermodynamic relations that will be used later in the course; a more complete list may found, e.g., in Sec. 16 of the textbook by L. Landau and E. Lifshitz, Statistical Physics, Part 1, $3^{\text {rd }}$ ed., Pergamon, 1980 (and later its re-printings).

[^799]:    ${ }^{28}$ See, e.g., CM Sec. 1.5.
    ${ }^{29}$ There are a few practical systems, notably including the so-called magnetic refrigerators (to be discussed in Chapter 4), when the natural growth of $S$ is so slow that the condition $S=$ const may be closely approached.
    ${ }^{30}$ This equation was first derived from experimental data by E. Clapeyron (in 1834) in the form $P V=n R T_{\mathrm{K}}$, where $n$ is the number of moles in the gas sample, and $R \approx 8.31 \mathrm{~J} / \mathrm{mole} \cdot \mathrm{K}$ is the so-called gas constant. This form is equivalent to Eq. (44), taking into account that $R=k_{\mathrm{B}} N_{\mathrm{A}}$, where $N_{\mathrm{A}} \approx 6.02 \times 10^{23} \mathrm{~mole}^{-1}$ is the so-called Avogadro number, i.e. the number of molecules per mole. (By definition of the mole, $N_{\mathrm{A}}$ is just the reciprocal mass, in grams, of a baryon - more exactly, by convention, of a $1 / 12^{\text {th }}$ part of the carbon- 12 atom.)

[^800]:    ${ }^{31}$ Note, however, that the difference $C_{P}-C_{V}=N$ (if temperature is measured in kelvins, $C_{P}-C_{V}=n R$ ) is independent of $f(T)$. (It is possible to show that the difference $C_{P}-C_{V}$ is fully determined by the equation of state for any medium.)

[^801]:    ${ }^{32}$ This name, of a historic origin, is a bit misleading: as evident from Eq. (52), $\mu$ has a clear physical sense of the average energy cost of adding one more particle to the system of $N \gg 1$ particles.
    ${ }^{33}$ Note that strictly speaking, Eqs. (9), (15), (31), (35) and (39) should be now generalized by adding one more lower index, $N$, to the corresponding derivatives.

[^802]:    ${ }^{34}$ Note that positive sign of the circular integral corresponds to the clockwise rotation of the point, so that work ($w$ done by the working gas is positive at the clockwise rotation (pertinent to heat engines) and negative in the opposite case (implemented in refrigerators and heat pumps).
    ${ }^{35}$ A cycle with an $[S, T]$ shape very close to the Carnot (rectangular) one may be implemented at the already mentioned magnetic (or "adiabatic-demagnetization") refrigeration, using the alignment of either atomic or

[^803]:    ${ }^{36}$ Such a hypothetical (and impossible!) heat engine, which would violate the $2^{\text {nd }}$ law of thermodynamics, is called the "perpetual motion machine of the $2^{\text {nd }}$ kind" - in contrast to the "perpetual motion machine of the $1^{\text {st }}$ kind" with would violate the $1^{\text {st }}$ law, i.e., the energy conservation.

[^804]:    ${ }^{37}$ For a detailed discussion of this issue see, e.g., J. Wilks, The Third Law of Thermodynamics, Oxford U. Press, 1961.

[^805]:    ${ }^{38}$ This name stems from the fact that the cycle is an approximate model of operation of the four-stroke internalcombustion engine, which was improved and made practicable (though not invented!) by N. Otto in 1876.

[^806]:    ${ }^{1}$ For the reader interested in reviewing a more rigorous approach, I can recommend, for example, Chapter 18 of the handbook by G. Korn and T. Korn - see MA Sec. 16(ii).

[^807]:    ${ }^{2}$ The most popular counter-example of a non-ergodic system is an energy-conserving system of particles placed in a potential which is a quadratic form of particle coordinates. Theory of oscillations tells us (see, e.g., CM Sec. 5.2) that this system is equivalent to a set of non-interacting harmonic oscillators. Each of these oscillators conserves its own initial energy $E_{j}$ forever, so that the statistics of $N$ measurements of one such system may differ from that of $N$ different systems with random distribution of $E_{j}$, even if the total energy of the system, $E=\Sigma_{j} E_{j}$, is the same. Such non-ergodicity, however, is a rather feeble phenomenon, and is readily destroyed by any of "mixing" mechanisms, such as weak interaction with environment (leading, in particular, to oscillation damping), nonlinear interaction of the components (see, e.g., CM Ch. 4), and chaos (CM Ch. 9), all of them strongly enhanced by increasing the number of particles in the system, i.e. the number of its degrees of freedom. This is why most real-life systems are ergodic; for those interested in non-ergodic exotics, I can recommend the monograph by V. Arnold and A. Avez, Ergodic Problems of Classical Mechanics, Addison-Wesley, 1989.
    ${ }^{3}$ Here, and everywhere in these notes, angle brackets $\langle\ldots\rangle$ mean averaging over a statistical ensemble, which is generally different from averaging over time - as it will be the case in quite a few examples considered below.

[^808]:    ${ }^{4}$ See, e.g., QM Sec. 7.1.

[^809]:    ${ }^{5}$ Here I use the Schrödinger picture of quantum mechanics in which the matrix elements $f_{n n}$, do not evolve in time.

[^810]:    ${ }^{6}$ The terms "microcanonical", as well as "canonical" (see Sec. 4 below) are apparently due to J. Gibbs, and I could not find out his motivation for these names. ("Canonical" in the sense of "standard" or "common" is quite appropriate, but why "micro"?)
    ${ }^{7}$ Formally, the main result of this section, Eq. (20), is valid for any $M$ (including $M=1$ ), it is just less informative for small $M$ - and trivial for $M=1$.
    ${ }^{8}$ Though I have to move on, let me note that the microcanonical distribution (20) is a very nontrivial postulate, and my advice to the reader to give some thought to this foundation of the whole building of statistical mechanics.

[^811]:    ${ }^{9}$ I will rely on reader's common sense and intuitive understanding what information is, because in the formal information theory this notion is also essentially postulated - - see, e.g., the wonderfully clear text by J. Pierce, An Introduction to Information Theory, Dover, 1980.
    ${ }^{10}$ This is of course just the change of a constant factor: $S(M)=\ln M=\ln 2 \times \log _{2} M=\ln 2 \times I(M) \approx 0.693 I(M)$. A review of Chapter 1 shows that nothing in thermodynamics prevents us from choosing such coefficient arbitrarily, with the corresponding change of the temperature scale - see Eq. (1.9). In particular, in the SI units, Eq. (24b) becomes $S=-k_{\mathrm{B}} \ln W_{m}$, so that one bit of information corresponds to the entropy change $\Delta S=k_{\mathrm{B}} \ln 2 \approx 0.693 k_{\mathrm{B}} \approx$ $0.965 \times 10^{-23} \mathrm{~J} / \mathrm{K}$. By the way, formula " $S=k \log W$ " is engraved on the tombstone of L. Boltzmann (1844-1906) who was the first one to recognize this intimate connection between the entropy and probability.

[^812]:    ${ }^{11}$ See, e.g., MA Eq. (2.3). Despite the intimidating name, Eq. (26) may be very simply derived. Indeed, $N$ ! is just the number of all possible permutations of $N$ balls, i.e. the ways to place them in certain positions - say, inside $M$ boxes. Now in order to take into account that the particular order of the balls in each box is not important, that number should be divided by all numbers $N_{n}$ ! of possible permutations of balls within each box - that's it.
    ${ }^{12}$ See, e.g., MA Eq. (2.10).

[^813]:    ${ }^{13}$ Strictly speaking, I should use notation $\langle S\rangle$ here. However, following the style accepted in thermodynamics, I will drop the averaging sign until we will really need them to avoid confusion. Again, this shorthand is not too bad because the relative fluctuations of entropy (as those of any macroscopic variable) are very small at $N \gg 1$.
    ${ }^{14}$ With the replacement of $\ln W_{m}$ for $\log _{2} W_{m}$ (i.e. division by $\ln 2$ ), Eq. (29) is the famous Shannon (or "Boltzmann-Shannon") formula for average information $I$ per symbol in a long communication string using $M$ different symbols, with probability $W_{m}$ each.
    ${ }^{15}$ In some textbooks, this simple argument is even accepted as the derivation of Eq. (29); however, it is evidently less strict than the one outlined above.

[^814]:    ${ }^{16}$ This is not to say that these definitions are fully equivalent. Despite all the wealth of quantitative relations given by thermodynamics, it still leaves a substantial uncertainty in the definition of entropy (and hence temperature), while Eq. (24) narrows this uncertainty to an unsubstantial constant.
    ${ }^{17}$ See, e.g., QM Secs. 2.10 and 5.4.

[^815]:    ${ }^{18}$ Let me hope that the reader knows that the zero-point energy is experimentally measurable - for example using the famous Casimir effect - see, e.g., QM Sec. 9.1. In Sec. 5.6 below we will discuss another method of experimental observation of that energy.

[^816]:    ${ }^{19}$ Let me offer a very vivid example how slowly does the logarithm function grow at large values of its argument: $\ln$ of the number of atoms in the visible Universe is less than 200.
    ${ }^{20}$ By the same reason, the notion of pressure $P$ in such a system is not clearly defined, and neither are any thermodynamic potentials but $E$ and $F$.
    ${ }^{21}$ Let me hope that using the same letter for the mass and the state number would not lead to reader's confusion. I believe that the difference between these uses is very clear from the context.

[^817]:    ${ }^{22}$ Note again that though we have committed the energy $E_{N}$ of $N$ oscillators to be fixed (in order to apply Eq. (36), valid only for a microcanonical ensemble at thermodynamic equilibrium), single oscillator's energy $E$ in our analysis may be arbitrary - within limits $\hbar \omega \ll E<E_{N} \sim N T$.
    ${ }^{23}$ As a reminder, the Hamiltonian of any system whose classical Lagrangian function is an arbitrary quadratic form its generalized coordinates and the corresponding generalized velocities, may be brought to form (49) by an appropriate choice of "normal coordinates" $q_{j}$ which are certain linear combinations of the original coordinates see, e.g., CM Sec. 5.2.
    ${ }^{24}$ This also means that in the classical limit, the heat capacity of a system is equal to one half the number of its half-degrees of freedom (in SI units, multiplied by $k_{\mathrm{B}}$ ).
    ${ }^{25}$ The reader is strongly urged to solve Exercise 2, whose task is to do a similar calculation for another key ("twolevel") physical system, and to compare the results.

[^818]:    ${ }^{26}$ See, e.g., CM Chapter 9 and literature therein.
    ${ }^{27}$ For the definition of $\lambda$, see, e.g., CM Eq. (9.9).
    ${ }^{28}$ For more discussion, see, e.g., either Sec. 6.2 of the monograph H. G. Schuster and W. Just, Deterministic Chaos, $4^{\text {th }}$ ed., Wiley-VHS, 2005, or the monograph by Arnold and Avez, cited in Sec. 1.
    ${ }^{29}$ While some of these concerns should be treated with due respect (because the ideas of entropy and disorder are indeed highly nontrivial), I have repeatedly run into rather shallow arguments which stemmed from arrogant contempt to the information theory as an "engineering discipline", and unwillingness to accept the notion of information on the equal footing with those of space, time, and energy. Fortunately, most leading physicists are much more flexible, and there are even opposite extremes such as J. A. Wheeler's "it from bit" (i.e. matter from information) philosophy - to which I cannot fully subscribe either.

[^819]:    ${ }^{30}$ This procedure of redefining the statistical ensemble is the central point of the connection between the information theory and physics, and is crucial in particular for any (meaningful :-) discussion of measurements in quantum mechanics - see, e.g., QM Secs. 2.5 and 7.7.

[^820]:    ${ }^{31}$ In the dominating CMOS technology, $\Delta E$ is close to twice the energy $C V^{2} / 2$ of recharging the total capacitance $C$ of the transistor gate electrodes and the wires interconnecting the gates, by the voltage $V$ representing the binary unity. As the technology progresses, $C$ decreases in approximate proportion with the minimum feature size, resulting in the almost proportional decrease of $\Delta E$. (The used voltage $V$ has almost saturated at $\sim 1 \mathrm{~V}-$ the value that stems from the bandgap of $\sim 1 \mathrm{eV}$ of the used semiconductor - silicon.)
    ${ }^{32}$ Unfortunately, this delusion has resulted in a substantial and unjustified shift of electron device research resources toward using "non-charge degrees of freedom" (such as spin) - as if they do not obey the general laws of statistical physics!

[^821]:    ${ }^{33}$ C. Bennett, IBM J. Res. Devel. 17, 525 (1973); see also a later review C. Bennett, Int. J. Theor. Phys. 21, 905 (1982). To the best of my knowledge, the sub- $7 \ln 2$ energy loss per logic step is still to be demonstrated experimentally, but at least one research team is closing at this goal.
    ${ }^{34}$ Reversible computation may also overcome the perceived "fundamental quantum limit", $\Delta E \Delta t>\hbar$, where $\Delta t$ is the time scale of the binary logic operation - see K. Likharev, Int. J. Theor. Phys. 21, 311 (1982).
    ${ }^{35}$ The situation is rather different for quantum computation which may be considered as a specific type of reversible but analog computation - see, e.g., QM Sec. 8.5 and references therein.

[^822]:    ${ }^{36}$ See also exercise problems listed in the end of this chapter.

[^823]:    ${ }^{37}$ Another way to arrive at the same conclusion is to note that the entropy of the canonical ensemble with fixed $E_{m}$ has to be a sum of entropies of its microcanonical sub-ensembles (with different $E_{\Sigma}$ ), which participate in Eq. (55). As a result, the logarithm of the probability $W_{m}$ for our system of interest to have energy $E_{m}$ in the whole (canonical) ensemble is just a sum of Eqs. (57) for sub-ensembles with different $E_{\Sigma}$.
    ${ }^{38}$ The temperature dependence of the type $\exp \{-E / T\}$, especially when showing up in rates of certain events, e.g., chemical reactions, is also frequently called the Arrhenius law - after chemist S. Arrhenius who has noticed this

[^824]:    law in experimental data. In all cases I am aware of, the Gibbs distribution is the underlying reason of the Arrhenius law.
    ${ }^{39}$ This opinion is shared by several authoritative colleagues, including R. Feynman who climbs on this summit already by page 4 (!) of his brilliant book Statistical Mechanics, $2^{\text {nd }}$ ed., Westview, 1998. (Despite its title, this monograph a collection of lectures on a few diverse, mostly advanced topics of statistical physics, rather than its systematic course, so that unfortunately I cannot recommend it as a textbook.)

[^825]:    ${ }^{40}$ In many multiparticle systems, the effect of an external field may be presented as a sum of its effects on each particle - frequently described by interaction energy with structure $-\mathcal{F}_{j} q_{j}^{(k)}$, where $q_{j}^{(k)}$ is a generalized coordinate of $k$-th particle. Generally, this energy has to be included directly into energies of particle states $E_{m}$, used in $Z$, and hence in the free energy $F$ (63). In this case, the thermodynamic equilibrium corresponds to the minimum of $F-$ see Eq. (1.42). On the other hand, for "linear" systems (whose energy is a quadratic-homogeneous form of its generalized coordinates and velocities), equivalent results may be obtained by accounting for the interaction at the thermodynamic level, i.e. by subtracting term $\mathcal{F}_{j}\left\langle q_{j}\right\rangle=\mathcal{F}_{j} N\left\langle q_{j}{ }^{(k)}\right\rangle$ from the free energy $F$ calculated in the absence of the field, and then finding the equilibrium as a minimum of the resulting Gibbs energy $G$ - see Eq. (1.43). In this case, any of the approaches is fine, provided only that the same interaction is not counted twice.
    ${ }^{41}$ A simpler task of making a similar calculation for another key quantum-mechanical object, the two-level system, is left for reader's exercise.

[^826]:    ${ }^{42}$ See, e.g., MA Eq. (2.8b).

[^827]:    ${ }^{43}$ It was first obtained in 1924 by S. Bose, and is frequently called the Bose distribution - a particular case of the Bose-Einstein distribution - to be discussed in Sec. 8 below.

[^828]:    ${ }^{44}$ See, e.g., QM Sec. 2.10.
    ${ }^{45}$ The calculation may be found, e.g., in QM Sec. 7.2.
    ${ }^{46}$ As a quantum mechanics reminder, the ground state energy of the oscillator is not only measurable, but is also responsible for several important phenomena, e.g., the Casimir effect - see, e.g., QM Sec. 9.1.

[^829]:    ${ }^{47}$ See, e.g., EM Sec. 7.9.
    ${ }^{48}$ See, e.g., QM Sec. 9.1.
    ${ }^{49}$ In our current context, the volume should be much larger than $(c \hbar / T)^{3}$, where $c \approx 3 \times 10^{8} \mathrm{~m} / \mathrm{s}$ is the speed of light. For room temperature ( $T \approx k_{\mathrm{B}} \times 300 \mathrm{~K} \approx 4 \times 10^{-21} \mathrm{~J}$ ), that lower bound is of the order of $10^{-16} \mathrm{~m}^{3}$.
    ${ }^{50}$ See, e.g., EM Sec. 7.9, or QM Sec. 1.6.
    ${ }^{51}$ Let me hope the reader knows that the law was first suggested in 1900 by M. Planck as an empirical fit for the experimental data on blackbody radiation, and this was the historic point at which the Planck constant $\hbar$ (or rather $h \equiv 2 \pi \hbar)$ was introduced - see, e.g., QM Sec. 1.1.

[^830]:    ${ }^{52}$ For a recent popular book of this topic, see, e.g., S. Singh, Big Bang: The Origins of the Universe, HarperCollins, 2005.

[^831]:    ${ }^{53}$ Note that the heat capacity $C_{V} \equiv(\partial E / \partial T)_{V}$, following from Eq. (88), is proportional to $T^{3}$ at any temperature, and hence does not obey the trend $C_{V} \rightarrow$ const at $T \rightarrow \infty$. This is the result of the unlimited growth, with temperature, of the number of thermally-exited field oscillators with $\hbar \omega<T$.
    ${ }^{54}$ See, e.g., MA Eqs. (6.8b), (6.6b), and (2.7b).

[^832]:    ${ }^{55}$ See, e.g., EM Sec. 9.8.
    ${ }^{56}$ Please note that according to Eqs. (1.44), (88), and (92), the difference between the equations of state of the photon gas and an ideal gas of non-relativistic particles, expressed in the more usual form - as $P=P(V, T)$, is much more dramatic: $P \propto T^{4} V^{0}$ instead of $P \propto T^{1} V^{1}$.

[^833]:    ${ }^{57}$ Due to low temperature expansion of solids, the difference between their $C_{V}$ and $C_{P}$ is small.
    ${ }^{58}$ In good conductors (e.g., metals), specific heat is contributed (and at low temperatures, dominated) by free electrons - see Sec. 3.3 below.
    ${ }^{59}$ See, e.g., CM Sec. 7.7.
    ${ }^{60}$ See, e.g., CM Sec. 5.3, in particular Fig. 5.5 and its discussion.

[^834]:    ${ }^{61}$ In SI units, Debye temperatures $T_{D}$ are of the order of a few hundred K for most simple solids (e.g., close to 430 K for aluminum and 340 K for copper), with somewhat lower values for crystals with heavy atoms ( $\sim 105 \mathrm{~K}$ for lead), and reach the highest value $\sim 2200 \mathrm{~K}$ for diamond with its relatively light atoms and very stiff lattice.

[^835]:    ${ }^{62}$ This is why there is a general "rule of thumb" in science: if you plot your data on a linear rather than log scale, you better have a good excuse ready. (A valid excuse example: the variable you are plotting changes sign within the important range.)
    ${ }^{63}$ This is the exact solution of a particular 1D model of such a crystal - see CM Chapter 5.
    ${ }^{64}$ This term stems from the fact that at $k \rightarrow 0$, the mechanical waves corresponding to these branches have phase velocities $v_{\mathrm{ph}} \equiv \omega(k) / k$ that are much higher than that of the acoustic waves, and may approach the speed of light. As a result, these waves can strongly interact with electromagnetic (practically, optical) waves of the same frequency, while the acoustic waves cannot.

[^836]:    ${ }^{65}$ The additional index in the new notation $E_{m, N}$ for the energy of the system of interest reflects the fact that its eigenvalue spectrum is generally dependent on the number $N$ of particles in it.

[^837]:    ${ }^{66}$ The average number of particles $\langle N\rangle$ is of course exactly what was called $N$ in thermodynamics (see Ch. 1), but I need to keep this explicit notation here to make a clear distinction between this average value of the variable, and its particular values participating in Eqs. (102)-(110).

[^838]:    ${ }^{67}$ The distribution was first suggested in 1877 by the founding father of statistical physic, L. Boltzmann. For the particular case when $\varepsilon$ is the kinetic energy of a free classical particle (and hence has a continuous spectrum), it is reduced to the Maxwell distribution - see Sec. 3.1 below.

[^839]:    ${ }^{68}$ See, e.g., QM Sec. 8.1.
    ${ }^{69}$ This invites a natural question: what particles are "elementary enough" for the identity? For example, protons and neutrons have an internal structure, in some sense consisting of quarks and gluons; they be considered elementary? Next, if protons and neutrons are elementary, are atoms? molecules? What about really large molecules (such as proteins)? viruses? The general answer to these questions, given by quantum mechanics (or rather experiment :-), is that any particles/systems, no matter how large and complex they are, are identical if they have exactly the same internal structure, and also are exactly in the same internal quantum state - for example, in the ground state of all their internal degrees of freedom.

[^840]:    ${ }^{70}$ As the reader certainly knows, for the electromagnetic field oscillators, such excitations are called photons; for mechanical oscillation modes, phonons. It is important, however, not to confuse these mode excitations with the oscillators as such, and be very careful in prescribing to them certain spatial locations - see, e.g., QM Sec. 9.1.

[^841]:    ${ }^{71}$ See, e.g., MA Eq. (2.2).
    ${ }^{72}$ See also MA Eq. (2.4).

[^842]:    ${ }^{73}$ This is essentially a simpler (and funnier :-) version of the particle scattering model used by L. Boltzmann to prove his famed H-theorem (1872). Besides all the historic significance of that theorem, the model used by Boltzmann (see Sec. 6.2 below) is almost as cartoonish.

[^843]:    74 See, e.g., QM Sec. 4.4. Note that both models assume that the particle's orbital motion (if any) does not contribute to its magnetic moment.
    ${ }^{75}$ See, e.g., EM Sec. 5.5, in particular Eq. (5.111).
    ${ }^{76}$ See, e.g., QM Sec. 5.7, in particular Eq. (5.197).

[^844]:    ${ }^{77}$ For its definition and main properties, see, e.g., MA Eqs. (6.6)-(6.9).
    ${ }^{78}$ It may be reduced to the so-called elliptic theta-function $\theta_{3}(z, \tau)$ for a particular case $z=0$ - see, e.g., Sec. 16.27 in the Abramowitz-Stegun handbook cited in MA Sec. 16(ii). However, you do not need that (or any other :-) handbook to solve this problem.
    ${ }^{79}$ This is a reasonable model of the constraints imposed on small atomic groups (e.g., ligands) by their environment inside some large molecules.

[^845]:    ${ }^{80}$ Note that by the same dispersion law is typical for elastic bending waves in thin rods - see, e.g., CM Sec. 7.8.
    ${ }^{81}$ See, e.g., CM Problem 1.12.
    ${ }^{82}$ In this context, weak junction means a tunnel junction with transparency so low that the tunneling electron's wavefunction looses its quantum-mechanical coherence before the electron has time to tunnel back. In a typical junction of a macroscopic area this condition is fulfilled if the effective tunnel resistance of the junction is much higher than the quantum unit of resistance (see, e.g., QM Sec. 3.2), $R_{Q} \equiv \pi \hbar / 2 e^{2} \approx 6.5 \mathrm{k} \Omega$.

[^846]:    ${ }^{1}$ In more realistic cases when particles do have internal degrees of freedom, but they are in certain (say, ground) quantum states, Eq. (3) is valid as well, with $\varepsilon_{k}$ referred to the internal ground-state energy.
    ${ }^{2}$ See, e.g., QM Sec. 1.2.

[^847]:    ${ }^{3}$ This formula was suggested by J. C. Maxwell as early as in 1860, i.e. well before the Boltzmann and Gibbs distributions. Note also that the term "Maxwell distribution" is often associated with the distribution of particle's momentum (or velocity) magnitude,

    $$
    d W=4 \pi C p^{2} \exp \left\{-\frac{p^{2}}{2 m T}\right\} d p=4 \pi C m^{3} v^{2} \exp \left\{-\frac{m v^{2}}{2 T}\right\} d v, \quad \text { with } 0 \leq p, v<\infty,
    $$

    which immediately follows from Eq. (5) combined with the expression $d^{3} p=4 \pi p^{2} d p$ due to the spherical symmetry of the distribution in the momentum/velocity space.
    ${ }^{4}$ See, e.g., MA Eq. (6.9b).
    ${ }^{5}$ See, e.g., MA Eq. (6.9c).

[^848]:    ${ }^{6}$ Since each particle belongs to the same portion of gas, i.e. cannot be distinguished from others by its spatial position, this requires some internal "pencil mark", for example a specific structure or a specific quantum state of its internal degrees of freedom.
    ${ }^{7}$ As a reminder, we have already used this rule (twice) in Sec. 2.6, with particular values of $g$.

[^849]:    ${ }^{8}$ For the opposite limit when $N=g=1$, Eq. (15) yields the results obtained, by two alternative methods, in Problems 2.5 and 2.6. For $N=1$, the "correct Boltzmann counting" factor $N$ ! equals 1 , so that the particle distinguishability effects vanish - naturally.

[^850]:    ${ }^{9}$ The result presented by Eq. (20), with function $f$ given by Eq. (16b), was obtained independently by O. Sackur and H. Tetrode in 1911, i.e. well before the final formulation of quantum mechanics in the late 1920s.
    ${ }^{10}$ By the way, if an ideal classical gas consists of particles of several different sorts, its full pressure is a sum of independent partial pressures exerted by each component - the so-called Dalton law. While this fact was an important experimental discovery in the early 1800s, from the point of view of statistical physics this is just a straightforward corollary of Eq. (18), because in an ideal gas, the component particles do not interact.

[^851]:    ${ }^{11}$ It is interesting that statistical mechanics of weak solutions is very similar to that of ideal gases, with Eq. (18) recast into the following formula (derived in 1885 by J. van't Hoff), $P V=c N T$, for the partial pressure of the solute. One of its corollaries is that the net force (called the osmotic pressure) exerted on a semipermeable membrane is proportional to the difference of solute concentrations it is supporting.
    ${ }^{12}$ Unfortunately, I do not have time for even a brief introduction into this important field, and have to refer the interested reader to specialized textbooks - for example, P. A. Rock, Chemical Thermodynamics, University Science Books, 1983; or P. Atkins, Physical Chemistry, $5^{\text {th }}$ ed., Freeman, 1994; or G. M. Barrow, Physical Chemistry, $6^{\text {th }}$ ed., McGraw-Hill, 1996.
    ${ }^{13}$ See, e.g., either Chapter 6 in A. Bard and L. Falkner, Electrochemical Methods, $2^{\text {nd }}$ ed., Wiley, 2000 (which is a good introduction to electrochemistry as the whole); or Sec. II.8.3.1 in F. Scholz (ed.), Electroanalytical Methods, $2^{\text {nd }}$ ed., Springer, 2010.
    ${ }^{14}$ In some textbooks, Eq. (26) is also called the Boltzmann distribution, though it certainly should be distinguished from the more general Eq. (2.111).

[^852]:    ${ }^{15}$ The mean free path may be defined by the geometric relation $n \sigma l=1$, where $\sigma$ is the full cross-section of the particle-particle scattering - see, e.g., CM 3.7.
    ${ }^{16}$ The reason of the drop is that the atmosphere, including molecules such as $\mathrm{H}_{2} \mathrm{O}, \mathrm{CO}_{2}$, etc., absorbs Sun's radiation at wavelengths $\sim 500 \mathrm{~nm}$ much smaller than those of the back-radiation of the Earth surface, with the spectrum centered at wavelength $\sim 10 \mu \mathrm{~m}$ - see Eq. (2.87) and its discussion.

[^853]:    ${ }^{17}$ In quantum mechanics, parameter $r_{\mathrm{c}}$ so defined is frequently called the correlation length - see, e.g., QM Sec. 7.2 and in particular Eq. (7.37).

[^854]:    ${ }^{18}$ See, e.g., MA Eq. (6.7a).
    ${ }^{19}$ For reader's reference only: for the upper sign, the integral in Eq. (40) is a particular form (for $s=1 / 2$ ) of a special function called the complete Fermi-Dirac integral $F_{s}$, while for the lower sign, it is a particular case (for $s$ $=3 / 2$ ) of another special function called the polylogarithm $\mathrm{Li}_{s .}$. (In what follows, I will not use these notations.)

[^855]:    ${ }^{20}$ Note that in the electronic engineering literature, $\mu$ is usually called the Fermi level, at any temperature.

[^856]:    ${ }^{21}$ See, e.g., CM Eq. (7.39).
    ${ }^{22}$ Recently, degenerate gases (with $\varepsilon_{F} \sim 5 T$ ) have been formed of weakly interacting Fermi atoms as well - see, e.g., K. Aikawa et al., Phys. Rev. Lett. 112, 010404 (2014) and references therein.
    ${ }^{23}$ See, e.g., QM Sec. 8.4.
    ${ }^{24}$ Note also a huge difference between the very high bulk modulus of metals ( $K \sim 10^{11} \mathrm{~Pa}$ ) and its very low values in usual gases (for them, at ambient conditions, $K \sim 10^{5} \mathrm{~Pa}$ ). About 4 orders of magnitude of this difference in due to that in particles, density $N / V$, but the balance is due to the electron gas' degeneracy. Indeed, in an ideal classical gas, $K=P=N T / V$, so that factor (2/3) $\varepsilon_{F}$ in Eq. (58), of the order of a few eV in metals, should be compared with factor $T \sim 25 \mathrm{meV}$ in the atomic gases at room temperature.

[^857]:    ${ }^{25}$ Data from N. Ashcroft and N. Mermin, Solid State Physics, W. B. Sounders, 1976.
    ${ }^{26}$ Named after A. Sommerfeld, who was the first (in 1927) to apply the then-emerging quantum mechanics to degenerate Fermi gases, in particular to electron in metals, and may be credited for most of the results discussed in this section.

[^858]:    ${ }^{27}$ See, e.g., MA Eqs. (6.8c) and (2.12b), with $n=1$.

[^859]:    ${ }^{28}$ Solids, with their low thermal expansion coefficients, present a virtually fixed-volume confinement for the electron gas, so that the specific heat measured at ambient conditions may be legitimately compared with calculated $c_{V}$.
    ${ }^{29}$ See, e.g., MA Eqs. (6.8b), (2.7b), and (6.6c) with $s=3 / 2$.

[^860]:    ${ }^{30}$ This is, of course, just another form of Eq. (71).

[^861]:    ${ }^{31}$ For the involved dimensionless integral see, e.g., MA Eqs. (6.8b), (2.7b) and (6.7e) with $s=5 / 2$.

[^862]:    ${ }^{32}$ Its detailed discussion may be found, e.g., in: C. Pethick and H. Smith, Bose-Einstein Condensation in Dilute Gases, 2nd ed., Cambridge U. Press, 2008.
    ${ }^{33}$ See, e.g., QM Sec. 8.3.

[^863]:    ${ }^{34}$ See, e.g., QM Eq. (3.28).
    ${ }^{35}$ This is the Meissner-Ochsenfeld (or just "Meissner") effect which may be also readily explained using Eq. (84), combined with the Maxwell equations - see, e.g., EM Sec. 6.3.

[^864]:    ${ }^{36}$ See QM Sec. 2.3, and EM Secs. 6.3 and 6.4. Recently, some of these effects were observed in the BoseEinstein condensates of diluted gases as well.
    ${ }^{37}$ A concise discussion of weak interactions in quantum gases may be found, for example, in Chapter 10 of K. Huang, Statistical Mechanics, $2^{\text {nd }}$ ed., Wiley, 2003.

[^865]:    ${ }^{38}$ Term "virial", from Latin viris (meaning "force"), was introduced to molecular physics by R. Clausius. The motivation for adjective "second" for $B(T)$ is evident from the last form of Eq. (94), with the "first virial coefficient", standing before the $N / V$ ratio and sometimes denoted $A(T)$, equal to 1 - see also Eq. (100) below.

[^866]:    ${ }^{39}$ Indeed, the independent fluctuation-induced components $\mathbf{p}(t)$ and $\mathbf{p}^{\prime}(t)$ of dipole moments of two particles have random mutual orientation, so that the time average of their interaction energy, proportional to $r^{-3}$, vanishes. However, the electric field $\varepsilon$ of each dipole $\mathbf{p}$, proportional as $r^{-3}$, induces a correlated component of $\mathbf{p}$, also proportional to $r^{-3}$, giving a potential energy of their interaction, proportional to $\mathbf{p}^{\prime} \cdot \varepsilon \propto r^{-6}$, with a non-vanishing time average. A detailed theory of this effect, closely related to the Casimir effect in quantum mechanics (see, e.g., QM Sec. 9.1) may be found, e.g., in Secs. 80-82 of E. Lifshitz and L. Pitaevskii, Statistical Mechanics, pt. 2, Pergamon, 1980.
    ${ }^{40}$ Note that the particular form of the first term in the approximation $U(r)=a / r^{12}-b / r^{6}$ (called the Lennard-Jones potential or the "12-6 potential"), suggested in 1924, lacks physical justification and was soon replaced, in professional physics, by better approximations, including the so-called exp-6 model (better fitting most experimental data) and the Morse potential (more convenient for quantum-mechanical calculations - see QM Chapter 2). However, the Lennard-Jones potential still travels from one undergraduate textbook to another, as a trick for simpler calculation of the equilibrium distance between the particles by differentiation.

[^867]:    ${ }^{41}$ The strong inequality between $U$ and $T$ in this model is necessary not only to make calculations simpler. A deeper reason is that if $\left(-U_{\min }\right)$ becomes comparable with, or larger than $T$, particles may become trapped in the potential well formed by this potential, forming a different phase - a liquid or a solid. In such phases, the probability to find more than two particles interacting simultaneously is high, so that approximation (92), on which all our further results are based, becomes invalid.
    ${ }^{42} \mathrm{~L}$. Boltzmann has used that way to calculate the $3^{\text {rd }}$ and $4^{\text {th }}$ virial coefficients for the hardball model - as much as can be done analytically.

[^868]:    ${ }^{43}$ This method was developed in 1937-38 by J. Mayer and collaborators for a classical gas, and generalized to quantum systems in 1938 by B. Kahn and G. Uhlenbeck.

[^869]:    ${ }^{44}$ Actually, the fact that in that case $Z=\langle N\rangle$, could have been noted earlier by comparing Eq. (104) with Eq. (39). ${ }^{45}$ Looking at Eq. (109), one may think that since $\xi=Z+Z^{2} I_{2} / 2+\ldots$ is of the order of at least $Z \sim\langle N\rangle \gg 1$, the expansion (113), which converges only if $|\xi|<1$, is illegitimate. However, the expansion is justified by its result (114), in which the $n$-th term is of the order of $\langle N\rangle^{n}\left(V_{0} / V\right)^{n-1} / n$ !, so that the series does converge if the gas density is sufficiently low: $\langle N\rangle / V \ll 1 / V_{0}$, i.e. $r_{\mathrm{A}} \gg r_{0}$. This is the very beauty of the cluster expansion, whose few first terms present a good approximation even for a gas with $\langle N\rangle \gg 1$ particles.

[^870]:    ${ }^{46}$ A discussion of the energy band theory may be found, e.g., in QM Sec. 2.7 and 3.4. Though the reader is highly encouraged to review the discussions of this (very important) topic, such a review is not required for solving this particular problem.

[^871]:    ${ }^{47}$ It was suggested in 1927, independently, by L. Thomas and E. Fermi.
    ${ }^{48}$ This is, for example, an approximate model for electrons in white dwarf stars, whose Coulomb interaction is mostly compensated by the charge of nuclei of fully ionized helium atoms.

[^872]:    ${ }^{1}$ The plasma phase, in which atoms are partly or completely ionized, in frequently mentioned in the same breath as the three phase listed above, but one has to remember that in contrast to them, a typical electroneutral plasma consists of particles of two different sorts - ions and electrons.
    ${ }^{2}$ Such classification schemes, started by P. Ehrenfest, have been repeatedly modified, and only the "first-order phase transition" is still a generally accepted term.
    ${ }^{3}$ For example, for water the latent heat of vaporization at ambient pressure is as high as $\sim 2.2 \times 10^{6} \mathrm{~J} / \mathrm{kg}$, i.e. $\sim 0.4$ eV per molecule, making this liquid indispensable for many practical purposes - including fire fighting. (The latent heat of water's ice melting is an order of magnitude lower.)

[^873]:    ${ }^{4}$ Due to the phenomenological character of the van der Waals model, one cannot say whether the condensed phase it predicts corresponds to a liquid or a solid. However, in most real substances at ambient conditions, gas coexists with liquid, hence the name I will use.
    ${ }^{5}$ The special choice of numerical coefficients in Eq. (3) is motivated by making the border between two regions to take place exactly at $t=1$, i.e. at temperature $T_{c}$, with the critical point coordinates equal to $P_{c}$ and $V_{c}$.

[^874]:    ${ }^{6}$ Actually, this assumption is not crucial for our analysis of mechanical stability, because if a fluctuation takes place in a small part of the total volume $V$, its other parts play the role of pressure-fixing environment.
    ${ }^{7}$ Frequently, especially for water gas diluted in air (vapor), $P_{0}(T)$ is called the saturated vapor pressure.

[^875]:    Maxwell's
    rule

[^876]:    ${ }^{8}$ An important question is: why does the phase-equilibrium line $P=P_{0}(T)$ stretch all the way from point 1 to point 2 (Fig. 2)? Indeed, branches 1-1' and 2-2' of the single-phase isotherm have negative derivative ( $\partial P / \partial V)_{T}$ and hence are mechanically stable to small perturbations. The answer is that these branches are actually metastable, i.e. have larger Gibbs energy per particle (i.e. $\mu$ ) than the counterpart phase and are hence unstable to larger perturbations - such as foreign microparticles (say, dust), confining wall protrusions, etc. In very controlled conditions, these single-phase "superheated" or "supercooled" states can survive virtually all the way to zeroderivative points 1 ' and 2 ', leading to sudden jumps of the system into the counterpart phase. (For fixed-pressure conditions, such jumps are shown by dashed lines in Fig. 2.) However, at more realistic conditions, perturbations result in the two-phase coexistence extending all the way between (or very close to) points 1 and 2 .

[^877]:    ${ }^{9}$ It is fascinating how well is this Arrhenius exponent hidden in the polynomial van der Waals equation (2)!

[^878]:    ${ }^{10}\left(\mathrm{CH}_{3}-\mathrm{CH}_{2}\right)-\mathrm{O}-\left(\mathrm{CH}_{2}-\mathrm{CH}_{3}\right)$, historically the first popular general anesthetic.
    ${ }^{11}$ It is interesting that very close to the critical point the substance suddenly becomes opaque - in the case of ether, whitish. The qualitative explanation of this effect, called the critical opalescence, is simple: at this point the difference of Gibbs energies per particle (i.e. chemical potentials) of the two phases becomes so small that the unavoidable thermal fluctuations lead to spontaneous appearance and disappearance of relatively large (a-few$\mu \mathrm{m}$-scale) single-phase regions in all the volume. Since the optical refraction coefficients of the phases are slightly different, large concentration of the region boundaries leads to strong light scattering.

[^879]:    ${ }^{12}$ Please note that $P_{t}$ for water is several orders of magnitude lower than $P_{c}$ of the water-vapor transition, so that Fig. 3 b is indeed very much not to scale!
    ${ }^{13}$ Perhaps the most practically important example is the air/water system. For its detailed discussion, based on Eq. (19), the reader may be referred, e.g., to Sec. 3.9 in F. Schwabl, Statistical Mechanics, Springer (2000). Other important applications include metallic alloys - solid solutions of metal elements.

[^880]:    ${ }^{14}$ For ferromagnets, this point is usually referred to at the Curie temperature, and for antiferromagnets, as the Néel temperature.

[^881]:    ${ }^{15}$ As follows from the discussion of Eqs. (1.1)-(1.3), for ferroelectric transitions between phases with different electric polarization, the role of pressure is played by the external electric field $\varepsilon$, while for the ferromagnetic transitions between phases with different magnetization, by the external magnetic field $\mathcal{H}$. As we will see very soon, such fields give such a phase transition a nonvanishing latent heat, making it the first order transition.
    ${ }^{16}$ Unfortunately, I will have no time for these interesting (and practically important) generalizations, and have to refer the interested reader to the famous monograph by R. Stratonovich, Topics in the Theory of Random Noise, in 2 vols., Gordon and Breach, 1963 and 1967, and/or the influential review by H. Haken, Ferstkörperprobleme 10, 351 (1970).

[^882]:    ${ }^{17}$ See, e.g., QM Sec. 4.4.
    ${ }^{18}$ At $J<0$, the first term of Eq. (21) gives a reasonable model of an antiferromagnet, but in this case the external magnetic field effects are more subtle, so I will not have time to discuss it.
    ${ }^{19}$ Named after E. Ising who explored the 1D version of the model in detail in 1925, though a similar model was discussed earlier (in 1920) by W. Lenz.
    ${ }^{20}$ For a more detailed discussion of phase transition theory (including other popular models of the ferromagnetic phase transition, e.g., the Potts model), see, e.g., either H. Stanley, Introduction to Phase Transitions and Critical Phenomena, Oxford U. Press, 1971; or A. Patashinskii and V. Pokrovskii, Fluctuation Theory of Phase Transitions, Pergamon, 1979; or B. McCoy, Advanced Statistical Mechanics, Oxford U. Press, 2010. For a much more concise text, I can recommend J. Yeomans, Statistical Mechanics of Phase Transitions, Clarendon, 1992.

[^883]:    ${ }^{21}$ See, e.g., EM Secs. 5.4-5.5.
    ${ }^{22}$ The form of all temperature functions is selected so that all critical exponents are non-negative.
    ${ }^{23}$ This variable models the real physical magnetic susceptibility $\chi_{m}$ of magnetic materials - see, e.g., EM Eq. (5.111).

[^884]:    ${ }^{24}$ There is some duality of terminology (and notation) in literature on this topic. Indeed, in the Ising model (as in the Heisenberg model), the magnetic field effects are usually accounted at the microscopic level, by the inclusion of the corresponding term into each particular value of energy $E_{m}$. Then, as was discussed in Sec. 1.4, system's equilibrium (at fixed external field $h$, and also $T$ and $N$ ) corresponds to the minimum of the Helmholtz free energy $F$. From this point of view, these problems do not feature either pressure or volume, hence we may take $P V=$ const, so that both thermodynamic potentials effectively coincide: $G \equiv F+P V=F+$ const. On the other hand, it is fair to say that the role of the magnetic field in these problems is very similar to that of pressure (or rather of $P$ ) in the "usual" thermodynamics. Due to this analogy, and taking into account that the equilibrium of a system at fixed $P$ corresponds to the minimum of the Gibbs free energy $G$, in some publications this name is used for the minimized potential. Still, on the microscopic level, there is a difference in the descriptions of field and pressure see the footnote in the end of Sec. 2.4. Due to this reason, I will follow the traditional, first point of view in most of my narrative, but will use the replacements $F \rightarrow G$ and $h \rightarrow-P$ to use thermodynamic formulas (1.39) and (37) when convenient.
    ${ }^{25}$ Admittedly, it belongs to Chapter 1, but I was reluctant to derive it there to avoid a narrative interruption.

[^885]:    ${ }^{26}$ Historically, the last term belongs to the later (1950) extension of the theory by V. Ginzburg and L. Landau see below.

[^886]:    ${ }^{27}$ According to Eq. (30), the correlation radius may be interpreted as the length distance at which the order parameter $\eta$ relaxes to its equilibrium value, if it is deflected from it at some point. Since the law of such spatial change may be obtained by a variational differentiation of $F$, for the actual relaxation law, all major terms of (46) have to be comparable.

[^887]:    ${ }^{28}$ In the phenomenological Ginzburg-Landau theory, charge $q$ remains unspecified, though the wording in their original paper clearly shows that the authors correctly anticipated that this charge might turn out to be different from the single electron charge.

[^888]:    ${ }^{29}$ See, e.g., EM Eq. (5.129).
    ${ }^{30}$ As a useful elementary sanity check, the minimization of $\Delta f$ in the absence of a superconductor, i.e. without the first 3 terms in the right-hand part of Eq. (56), immediately gives the correct result $\mathbf{B}=\mu_{0} \mathbf{H}$.
    ${ }^{31}$ See, e.g., QM Sec. 3.1.
    ${ }^{32}$ From the mathematics standpoint, such term, nonlinear in $|\psi|$, makes Eq. (58) a member of the family of "nonlinear Schrödinger equations". Another important member of this family is the Gross-Pitaevskii equation,

    $$
    a \tau \psi=b|\psi|^{2} \psi-\frac{\hbar^{2}}{2 m} \nabla^{2} \psi+U(\mathbf{r}) \psi
    $$

    which gives a very reasonable (albeit phenomenological and hence approximate) description of Bose-Einstein condensates of neutral atoms at $T \approx T_{\mathrm{c}}$. The differences between the Ginzburg-Landau and Gross-Pitaevskii equations reflect, first, the zero charge $q$ of the neutral atoms and, second, the fact that the atoms forming the

[^889]:    condensates may be readily placed in external potentials $U(\mathbf{r}) \neq$ const (e.g., those trapping the atoms), while in superconductors such potential profiles are much harder to create due to the screening of electric field by metals see, e.g., EM Sec. 2.1.
    ${ }^{33}$ Such penetration had been discovered experimentally by L. Shubnikov in the mid-1930s, but its quantitative explanation had to wait until A. Abrikosov's work (based on the Ginzburg-Landau equations) published in 1957.
    ${ }^{34}$ See, e.g., M. Tinkham, Introduction to Superconductivity, ${ }^{\text {nd }}$ ed., McGraw-Hill, 1996. A short discussion of the Josephson effects may be found in QM Sec. 2.3 and EM Sec. 6.4.
    ${ }^{35}$ See, e.g., Sec. 45 in E. Lifshitz and L. Pitaevskii, Statistical Physics, Part 2, Pergamon, 1980.
    ${ }^{36}$ Since in this naïve approach we neglect the thermal fluctuations of spin, i.e. their disorder, this assumption implies $S=0$, so that $F \equiv E-T S=E$, and we may use either notation for system's energy.

[^890]:    ${ }^{37}$ The fact that stable states always correspond to $\eta= \pm 1$, partly justifies the treatment of $\eta$ as a continuous variable in this crude approximation.
    ${ }^{38}$ For me, it was always surprising how little physics students knew about this fascinating field of modern engineering, which involves so much interesting physics and fantastic electromechanical technology. For getting acquainted with it, I may recommend, for example, the monograph by C. Mee and E. Daniel, Magnetic Recording Technology, $2^{\text {nd }}$ ed., McGraw-Hill, 1996.

[^891]:    ${ }^{39}$ Actually, the thermal stability of many real ferromagnets, with longer-range interaction between spins, is higher than that predicted by the Ising model.
    ${ }^{40}$ In some texts, this approximation is called the mean-field theory. This terminology may lead to confusion, because the molecular-field theory is on a completely different level of phenomenology than, say, Landau's mean-field theory. For example, the molecular-field approach may used for the calculation of parameters $a, b$, and $T_{c}$ participating Eq. (46) - the starting point of Landau's theory.

[^892]:    ${ }^{41}$ This fact may be readily verified by using Eqs. (64) and (68) to calculate $F$. Now condition $\partial F / \partial \eta_{h=0}=0$ returns us to Eq. (71), and calculating the second derivative, for $T<T_{c}$ we get $\partial^{2} F / \partial \eta^{2}>0$ at $\eta= \pm \eta_{0}$ (indicating two stable minima of $F$ ), and $\partial^{2} F / \partial \eta^{2}<0$ at $\eta=0$ (the unstable maximum of $F$ ).

[^893]:    42 It was developed in 1941 by H. Kramers and G. Wannier. Note that the approach is very close to the one used in 1D quantum mechanics - see, e.g., QM Sec. 2.5.

[^894]:    ${ }^{43}$ This is of course a result of the "translational" (or rather rotational) symmetry of the system, i.e. its invariance to the index replacement $j \rightarrow j+1$ in all terms of the energy $E_{m}$ (besides index $N$ which should be replaced with 1 ).

[^895]:    ${ }^{44}$ If the reader is still uncomfortable with this core result of thermodynamics, he or she is strongly encouraged to revisit Eq. (1.42) and its discussion.

[^896]:    ${ }^{45}$ For that, the reader is referred to either Sec. 151 in the textbook by Landau and Lifshitz or Chapter 15 in the text by Huang, both cited above.

[^897]:    ${ }^{46}$ Discussion of such laws in the task of physical kinetics, which will be briefly reviewed in Chapter 6.
    ${ }^{47}$ The calculation of these rates for several particular cases is described in QM Secs. 6.6, 6.7, and 7.6.

[^898]:    ${ }^{48}$ See, e.g., QM Eq. (7.196) for a quantum system bilinearly coupled to an environment in thermal equilibrium. By the way, that formula (as well as results for all realistic physical systems) does not feature the unphysical cusp of function $\Gamma(\Delta)$ at $\Delta=0$, assumed by the popular model (104).
    ${ }^{49}$ Note that the flip changes signs of only $(2 d+1)$ terms in sum (23), i.e. does not require re-calculation of all ( $2 d$ $+1) N$ terms of the sum, so that the computation of $\Delta$ takes just a few add-multiply operations even at $N \gg 1$.

[^899]:    ${ }^{50}$ Developed first in the quantum field theory in the 1950s, it was adapted to statistics by L. Kadanoff in 1966, with a spectacular solution of the so-called Kubo problem by K. Wilson in 1972, later awarded by a Nobel Prize. ${ }^{51}$ This might be expected, because physically $C$ is just a certain constant addition to system's energy. However, the introduction of that constant is mathematically necessary, because Eqs. (107) and (108) may be reconciled only if $C^{\prime} \neq C$.

[^900]:    52 This equation of state, suggested in 1948, describes most real gases better than not only the original van der Waals model, but also its later 2-parameter alternatives, such as the Berthelot, modified-Berthelot, and Dieterici models, though approximations with more fitting parameters (such as the Soave-Redlich-Kwong model) work even better.
    ${ }^{53}$ For real liquids, the model is reasonable only within certain parameter ranges.

[^901]:    ${ }^{54} \mathrm{~A}$ brief discussion of these parameters, as well as of the difference between the type-I and type-II superconductivity, may be found in EM Secs. 6.3-6.4.
    ${ }^{55}$ This model is formally similar to the genuine (quantum) Heisenberg model - see Eq. (21).

[^902]:    ${ }^{1}$ Let me remind the reader that up to this point, the averaging signs $\langle\ldots\rangle$ were dropped in most formulas, for the sake of notation simplicity. In this chapter I have to restore these signs to avoid confusion. The only exception will be temperature whose average, following (bad :-) tradition, will be still call $T$ everywhere besides the last part of Sec. 3 where temperature fluctuations are discussed explicitly.

[^903]:    ${ }^{2}$ Unfortunately, even in some popular textbooks, a few formulas pertaining to fluctuations are either incorrect, or given without specifying the conditions of their applicability, so that reader's caution is advised.

[^904]:    ${ }^{3}$ See, e.g., MA Eq. (2.2).

[^905]:    ${ }^{4}$ Indeed, this is the most popular definition of this major mathematical constant - see, e.g., MA Eq. (1.2a) with $n$ replaced with $-1 / W$.

[^906]:    ${ }^{5}$ As a reminder, in geometry the term "cylinder" does not necessarily means the "circular cylinder"; the shape of base $A$ may be arbitrary; it just should not change with height.

[^907]:    ${ }^{6}$ As already was discussed in Sec. 4.1 in the context of the van der Waals equation, for mechanical stability of a gas (or liquid), derivative $\partial P / \partial V$ has to be negative, so that $\kappa$ is positive.
    ${ }^{7}$ One may meet statements that a similar formula,

    $$
    \left\langle\widetilde{P}^{2}\right\rangle=T\left(-\frac{\partial\langle P\rangle}{\partial\langle V\rangle}\right)_{X}, \quad \quad \text { WRONG! }
    $$

    is valid for pressure fluctuations. However, such statement does not take into account a different physical nature of pressure (Fig. 4), with its very broad frequency spectrum. This issue will be discussed later in this chapter.

[^908]:    ${ }^{8}$ Besides low internal electric noise, the sensor should have a sufficiently large temperature responsivity $d R / d T$, making the noise contribution by the pickup electronics insignificant - see below.

[^909]:    ${ }^{9}$ It was pioneered in the 1950 s by R. Dicke, so that the device is frequently called the Dicke radiometer.
    ${ }^{10}$ Clearly, this is a temporal analog of the spatial correlation function discussed in Sec. 4.2 - see Eq. (4.30).

[^910]:    ${ }^{14}$ See, e.g., MA Eq. (14.4a).
    ${ }^{15}$ The second form of Eq. (59) uses the fact that, according to Eq. (58), $S_{f}(\omega)$ is an even function of frequency just as $K_{f}(\tau)$ is an even function of time.
    ${ }^{16}$ Although Eqs. (58) and (59) look not much more than straightforward corollaries of the Fourier transform, they bear a special name of the Wiener-Khinchin theorem - after mathematicians N. Wiener and A. Khinchin who have proved that these relations are valid even for functions $f(t)$ which are not square-integrable, so that from the point of view of rigorous mathematics, their Fourier transforms are not well defined.

[^911]:    ${ }^{17}$ A popular alternative definition of the spectral density is $S_{f}(\nu) \equiv 4 \pi S_{f}(\omega)$, making average (61) equal to $S_{f}(v) \Delta v$. ${ }^{18}$ Such process is frequently called white noise, because it consists of all frequency components with equal amplitudes, reminding the white light, which consists of many monochromatic components.
    19 Just for one example, such description may be valid for the complex amplitude of an electromagnetic field mode weakly interacting with matter. To emphasize this generality, I will use letter $q$ rather than $x$ for "particle's" coordinate.

[^912]:    ${ }^{20}$ For a usual (ergodic) environment, the primary averaging may be interpreted as that over relatively short time intervals, $\tau_{c} \ll \Delta t \ll \tau$, where $\tau_{c}$ is the correlation time of the environment, while $\tau$ is the characteristic time scale of motion of our "heavy" system of interest.
    ${ }^{21}$ After P. Langevin whose 1908 work was the first systematic development of A. Einstein's ideas on Brownian motion (see below) using this formalism. A detailed discussion of this approach, with numerical examples of its application, may be found, e.g., in the monograph by W. Coffey, Yu. Kalmykov, and J. Waldron, The Langevin Equation, World Scientific, 1996.
    ${ }^{22}$ See, e.g., CM Sec. 4.1. In this and the next sections I assume that variable $f(t)$ is classical, with the discussion of the quantum case postponed until Sec. 6.

[^913]:    ${ }^{23}$ At this stage we restrict our analysis to random, stationary processes $q(t)$, so that Eq. (57) is valid for this variable as well, if the averaging is understood in the $\langle\langle\ldots\rangle\rangle$ sense.
    ${ }^{24}$ See, e.g. MA Eq. (6.5a).

[^914]:    ${ }^{25}$ This means that the phenomenological description of dissipation by bare friction in classical mechanics (see, e.g., CM Sec. 4.1) is only valid approximately, when the energy scale of the process is much larger than $T$.
    ${ }^{26}$ It was published in one of the three papers of Einstein's celebrated 1905 "triad". As a reminder, another paper started the (special) relativity, and one more was the quantum description of photoelectric effect, essentially the prediction of light quanta - photons, which essentially started quantum mechanics. (Not too bad for one year!)

[^915]:    ${ }^{27}$ In solid-state physics and electronics, mobility is more frequently defined as $\left|\mathbf{v}_{\text {drift }} / \mathcal{E}\right|=e\left|\mathbf{v}_{\text {drift }} / \mathcal{Z}_{\text {det }}\right|$ (where $\mathcal{E}$ is the applied electric field), and is traditionally measured in $\mathrm{cm}^{2} / \mathrm{V} \cdot \mathrm{s}$. In these units, the electron mobility in silicon wafers used for integrated circuit fabrication (i.e. the solid most important for engineering practice) at room temperature is close to $10^{3}$.
    ${ }^{28}$ The minus sign is due to the fact that in our notation, current through the resistor equals $(-I)$ - see Fig. 9 .
    ${ }^{29}$ Due to this fact, Eq. (64) is often called the Ohmic model of the environment response, even if the physical nature of variables $q$ and $\mathcal{F}$ is completely different from the electric charge and voltage.

[^916]:    ${ }^{30}$ Named after H. Nyquist who derived this formula in 1928 (independently of the prior work by A. Einstein, M. Smoluchowski, and P. Langevin) to describe the noise which had been just discovered experimentally by his Bell Labs' colleague J. B. Johnson. The derivation of Eq. (73) and hence Eq. (81) in these notes is essentially a twist of the derivation used by Nyquist.
    ${ }^{31}$ Another practically important type of fluctuations in electronic devices is the low-frequency $1 / f$ noise which was already mentioned in Sec. 3 above. I will briefly discuss it in Sec. 8 .

[^917]:    ${ }^{32}$ See, e.g., Y. Naveh et al., Phys. Rev. B 58, 15371 (1998). In practically used metals, $l_{e}$ is of the order of 30 nm even at liquid helium temperatures (and even shorter at ambient conditions), so that the usual "macroscopic" resistors do not exhibit the shot noise.
    ${ }^{33}$ For a review of this effect see, e.g., Ya. Blanter and M. Büttiker, Phys. Repts. 336, 1 (2000).

[^918]:    ${ }^{34}$ Reviewing the calculations leading to Eq. (73), we may see that if the possible real part $\chi^{\prime}(\omega)$ of the susceptibility just adds up to $\left(k-m \omega^{2}\right)$ in the denominator of Eq. (67), resulting in a change of oscillator's eigenfrequency. This renormalization is insignificant if the oscillator-to-environment coupling is weak, i.e. susceptibility $\chi(\omega)$ small, as had been assumed at the derivation of Eq. (69) and hence Eq. (73).
    ${ }^{35}$ It is sometimes called the Green-Kubo (or just "Kubo") formula. This is hardly fair, because, as the reader could see, Eq. (92) is just an elementary generalization of the Nyquist formula (81). Moreover, the corresponding works of M. Green and R. Kubo were published, respectively, in 1954 and 1957, i.e. after the 1950 paper by H. Callen and T. Welton, where a more general result (see below) had been derived. More adequately, the Green / Kubo names are associated with a related relation between the response function and the operator commutator see, e.g., QM Eq. (7.109).
    ${ }^{36}$ See, e.g., QM Sec. 4.6.

[^919]:    ${ }^{37}$ Please note that here (and to the end of this section) brackets $\langle\ldots\rangle$ mean quantum-statistical averaging (2.12). As was discussed in Sec. 2.1, for a classical-mixture state of the environment, this does not create any difference in either mathematical treatment of the averages or their physical interpretation.
    ${ }^{38}$ It was first derived in 1951 by H. Callen and T. Welton (in a somewhat different way). One more derivation of the FDT, which gives the Kubo formula as a by-product, may be found in QM Sec. 7.4.

[^920]:    ${ }^{39}$ K. Likharev and V. Semenov, JETP Lett. 15, 442 (1972).
    ${ }^{40}$ R. Koch et al., Phys. Rev. B 26, 74 (1982).
    ${ }^{41}$ Another one is the Casimir effect - see, e.g., QM Sec. 9.1.
    ${ }^{42}$ See, e.g., QM Sec. 7.4.

[^921]:    ${ }^{43}$ See, e.g., CM Sec. 4.1, part (ii).
    ${ }^{44}$ Only explicitly so, because the complex susceptibility of the environment may depend on temperature as well.
    ${ }^{45}$ See, e.g., CM Sec. 3.4-3.6.

[^922]:    ${ }^{46}$ The generalization of Eq. (107) to higher spatial dimensionality is also straightforward, with the scalar variable $q$ replaced by vector $\mathbf{q}$, and the scalar derivative $d U / d q$ replaced with vector $\nabla U$.
    ${ }^{47}$ See, e.g., CM Secs. 3.2, 4.2, and beyond.
    ${ }^{48}$ See, e.g., Chapters 5 and 6 in W. Coffey et al., The Langevin Equation, World Scientific, 1996.
    ${ }^{49}$ After H. Kramers who, besides solving this important problem in 1940, has made significant contributions to many other areas of physics, including the famous Kramers-Kronig dispersion relations - see, e.g., EM Sec. 7.4.

[^923]:    ${ }^{50}$ If $U_{0}$ is comparable with $T$, system's behavior also depends substantially on the initial probability distribution, i.e., do not follow the universal law (111).
    ${ }^{51}$ See, e.g., either R. Stratonovich, Topics in the Theory of Random Noise, vol. 1., Gordon and Breach, 1963, or Chapter 1 in the monograph by W. Coffey et al., cited above.
    ${ }^{52}$ By the way, the goal of the traditional coefficient 2 in Eq. (77) is exactly to have the fundamental Eq. (114) free of numerical coefficients.

[^924]:    ${ }^{53}$ As will be discussed in Chapter 6, the equation of diffusion also describes several other physical phenomena in particular, heat propagation in a uniform, isotropic solid, and in this context is called the heat conduction equation or (rather inappropriately) just the "heat equation".
    ${ }^{54}$ Both forms of Eq. (117) are similar to the mass conservation law in classical dynamics (see, e.g., CM Sec. 8.2), and the electric charge conservation law in electrodynamics (see, e.g., EM Sec. 4.1).
    ${ }^{55}$ See, e.g., MA Eq. (12.2),

[^925]:    ${ }^{56}$ Named after M. Smoluchowski who developed this formalism in 1906, apparently independently from the slightly earlier Einstein's work, and in much more detail. This equation has important applications in many fields of science, including such surprising topics as statistics of spikes in neural networks.

[^926]:    ${ }^{57}$ If necessary, see MA Eq. (6.9b) again.

[^927]:    ${ }^{58}$ Actually, $\tau_{2}$ describes the characteristic time of the exponential growth of small deviations from the unstable fixed point $q_{2}$ at the barrier top, rather than their decay, as near point $q_{1}$.

[^928]:    ${ }^{59}$ It was derived in 1913 in A. Fokker's PhD thesis work; M. Planck was his thesis adviser.
    ${ }^{60}$ The reader should remember that these solutions embody, as the particular case $T=0$, all classical dynamics of a particle.

[^929]:    ${ }^{61}$ See, e.g., QM Secs. 2.3-2.4.
    ${ }^{62}$ As a reminder, an absolutely similar approximation is used in Exercise Problem 4.3 for the $P(V)$ function, in order to analyze properties of the van der Waals model near the critical temperature.

[^930]:    ${ }^{63}$ The main, exponential factor in this result may be obtained simply by ignoring the difference between $E$ and $U\left(q_{1}\right)$, but the correct calculation of the pre-exponent requires to take this difference, $\hbar \omega_{0} / 2$, into account - see K. Likharev, Physica B 108, 1079 (1981).
    ${ }^{64}$ See, e.g., QM Sec. 2.4.

[^931]:    ${ }^{65}$ The transition from the first line of Eq. (174) to its second one uses the fact that the system is stationary, so that $\langle E(t+\tau)\rangle=\langle E(t)\rangle=\langle E\rangle=$ const.

[^932]:    ${ }^{66}$ Regardless of the physical sense of such function of $\omega$, and of whether its maximum is situated at either zero as in Eq. (177), or at a finite frequency $\omega_{0}$ as in Eq. (68), it is often referred to as the Lorentzian (or "Breit-Wigner") line.

[^933]:    ${ }^{67}$ See, e.g., MA Eq. (6.9c).

[^934]:    ${ }^{68}$ This fact is not in any contradiction with the nonvanishing result (183) which is only valid for a sub-ensemble with a certain (deterministic) initial condition $q_{0}$.
    ${ }^{69}$ The involved table integral may be found, e.g., in MA Eq. (6.11).
    ${ }^{70}$ See, e.g., QM Sec. 7.6.
    ${ }^{71}$ See, e.g., the solutions of the 1D Kramers problem for quantum systems with low damping by A. Caldeira and A. Leggett, Phys. Rev. Lett. 46, 211 (1981), and with high damping by A. Larkin and Yu. Ovchinnikov, JETP Lett. 37, 382 (1983).

[^935]:    ${ }^{72}$ See, e.g., CM Sec. 4.3.
    ${ }^{73}$ See, e.g., EM Sec. 7.6.

[^936]:    ${ }^{1}$ See, e.g., CM Sec. 10.1.
    ${ }^{2}$ Actually, this is just one of several theorems bearing the name of J. Liouville (1809-1882).

[^937]:    ${ }^{3}$ See, e.g., CM Sec. 9.3.
    ${ }^{4}$ From this point on, I return to using the index-free symbol

[^938]:    ${ }^{5}$ Note that the master equations ignores possible quantum coherence of different scattering events, described by off-diagonal elements of the density matrix, because $w$ represents only the diagonal elements of the matrix. However, for ensembles close to thermal equilibrium, this is a reasonable approximation - see Sec. 2.1.
    ${ }^{6}$ One may wonder whether this approximation may work for Fermi particles, for whom the Pauli principle forbids scattering into the already occupied state, so that for scattering $\mathbf{p} \rightarrow \mathbf{p}$ ', the factor $w(\mathbf{r}, \mathbf{p}, t)$ in Eq. (12) has to be multiplied by the probability $\left[1-w\left(\mathbf{r}, \mathbf{p}^{\prime}, t\right)\right]$ that the final state is available. Generally, this is a valid argument, but one should notice that if this modification has been done with both terms of Eq. (12), it yields

    $$
    \left.\frac{\partial w}{\partial t}\right|_{\text {scatteering }}=\int d^{3} p^{\prime} \Gamma_{\mathbf{p} \rightarrow \mathbf{p}^{\prime}}\left\{w\left(\mathbf{r}, \mathbf{p}^{\prime}, t\right)[\mathbf{1}-w(\mathbf{r}, \mathbf{p}, t)]-w(\mathbf{r}, \mathbf{p}, t)\left[\mathbf{1}-w\left(\mathbf{r}, \mathbf{p}^{\prime}, t\right)\right]\right\} .
    $$

    Opening both square brackets, we see that the probability density products cancel, bringing us back to Eq. (12).

[^939]:    ${ }^{7}$ This was the approximation used by L. Boltzmann to prove the famous H-theorem, stating that entropy of the gas described by Eq. (13) may only grow (or stay constant) in time, $d S / d t \geq 0$. Since the model is very approximate, that result does not seem too fundamental nowadays, despite all its historic significance.
    ${ }^{8}$ Sometimes this approximation is called the "BGK model", after P. Bhatnager, E. Gross, and M. Krook who suggested it in 1954. (The same year, a similar model was considered by P. Welander.)
    ${ }^{9}$ See, e.g., CM Sec. 3.7.

[^940]:    ${ }^{10}$ See, e.g., QM Sec. 2.1.

[^941]:    ${ }^{11}$ First obtained by A. Sommerfeld in 1927.
    ${ }^{12}$ See, e.g., QM Secs. 2.7, 2.8, and 3.4. In this case, $\mathbf{p}$ should be understood as the quasi-momentum rather than genuine momentum.
    ${ }^{13}$ As Eq. (27) shows, if the dispersion law $\varepsilon(\mathbf{p})$ is anisotropic, the direction of current density may be different from that of the electric field. In this case, conductivity should be described by a tensor $\sigma_{i j}$, rather than a scalar.

[^942]:    Drude
    formula

[^943]:    ${ }^{14}$ Calculations for a classical gas (which are important, in particular, for most plasmas and non-degenerate semiconductors) are left for the reader - see the first assignment of Problem 5.
    ${ }^{15}$ At least explicitly, because in some particle collision models, $\tau$ may be a function of temperature, which levels out only at some temperature much lower than $\varepsilon_{\mathrm{F}}$.
    ${ }^{16}$ Its was derived in 1900 by P. Drude. Note that Drude also used the same arguments to derive a very simple (and very reasonable) approximation for the complex electric conductivity in the ac field of frequency $\omega$ : $\sigma(\omega)=$ $\sigma(0) /(1-i \omega \tau)$, with $\sigma(0)$ given by Eq. (32); sometimes the name "Drude formula" is used for this expression rather than for Eq. (32) - see Problem 1.

[^944]:    ${ }^{17}$ As a reminder, here it is (see also EM Sec. 4.2): Let $\tau$ be the average time at which scattering causes a particle to loose all the deterministic component of its velocity, $\mathbf{v}_{\text {drift }}$, provided by electric field $\boldsymbol{\mathcal { E }}$, on the top of electron's random thermal motion (which does not contribute to the net current). Using the $2^{\text {nd }}$ Newton law to describe particle's acceleration by the field, $d \mathbf{v}_{\text {drift }} / d t=q \boldsymbol{\mathcal { L }} / \mathrm{m}$, we get $\left\langle\mathbf{v}_{\text {drift }}\right\rangle=\tau q \boldsymbol{\mathcal { E }} / \mathrm{m}$. Multiplying this result by the particle charge $q$ and density $n=N / V$, we get the Ohm law $\mathbf{j}=\sigma \boldsymbol{\varepsilon}$, with $\sigma$ given by Eq. (32).
    ${ }^{18}$ By the way, since the scale of the fastest change of $w_{0}$ in the momentum space is of the order of $\partial w_{0} / \partial p=$ $\left(\partial w_{0} / \partial \varepsilon\right)(d \varepsilon / d p) \sim(1 / T) v_{\mathrm{F}}$, the linear approximation (34) is valid if $e \mathcal{E} \tau<T / v_{\mathrm{F}}$, i.e. if $e d \ll T$, where $l \equiv v_{\mathrm{F}} \tau$ is called the mean free path. This is the promised quantitative condition of the electric field smallness; since the lefthand part of the last inequality is just the average energy given to the particle by the electric field between two scattering events, the condition may be interpreted as the smallness of electron gas' "overheating" by the applied field. However, another condition is also necessary - see the last paragraph of this section.

[^945]:    ${ }^{19}$ So here, as it frequently happens in physics, formulas (or drawings, such as Fig. 4b) give a more clear and unambiguous description of the reality than words - the privilege lacked by many other scientific (and "scientific") disciplines, frequently leading in unending, shallow verbal debates.

[^946]:    ${ }^{20}$ Since we consider $w_{0}$ as a function of two independent arguments $\mathbf{r}$ and $\mathbf{p}$, taking its gradient, i.e. differentiation of this function over $\mathbf{r}$, does not involve its differentiation over the kinetic energy $\varepsilon$ - which is a function of $\mathbf{p}$ only.
    ${ }^{21}$ In electronic engineering literature, variable $q \Phi \equiv \mu+q \phi$, called the local Fermi level, is more frequently used.
    ${ }^{22}$ Relation (42) does not include the phenomenological parameter $\tau$ of the relaxation-time approximation, so that it is more general than the RTA. Indeed, Eq. (42) is based on the relation between the second and third terms in the left-hand part of the rather general Eq. (10).

[^947]:    ${ }^{23}$ Sometimes also called the "electron affinity", though the latter term is mostly used for atoms and molecules.
    ${ }^{24}$ In semiconductor physics and engineering, the situation shown in Fig. 5b is called the flat-band condition, because in semiconductors, any electric field at the surface leads to band bending - a gradual spatial change of the background potential $U_{0}$ and hence of all energy band/gap edges. For a discussion of the band bending and its effects on semiconductor device operation, see, e.g., either Chapter 6 in J. Hook and H. Hall, Solid State Physics, $2^{\text {nd }}$ ed. Wiley, 1991, or Chapter 3 in S. Sze, Semiconductor Devices, $2^{\text {nd }}$ ed., Wiley, 2001.
    ${ }^{25}$ As measured from a common reference value, for example from the vacuum level.
    ${ }^{26}$ In physics literature, it is usually called the contact potential difference, while in electrochemistry (for which it is one of the key notions), the term Volta potential is more common.

[^948]:    ${ }^{27}$ In particular, in physics of semiconductor devices, where electrons in the conduction band, and holes in the valence band, may be frequently treated as nearly-ideal classical gases.
    ${ }^{28}$ Sometimes this term is associated with Eq. (52).
    ${ }^{29}$ And hence, at negligible $\nabla U$, identical to the diffusion equation (5.116).

[^949]:    ${ }^{30}$ See, e.g., CM Sec. 3.7.

[^950]:    ${ }^{31}$ Named after T. Seebeck who experimentally discovered, in 1821 (independently of J. Peltier), the effect expressed by Eq. (62).
    ${ }^{32}$ Again, such independence infers that Eq. (60) should have a broader validity than in our simple model of an isotropic gas. This is indeed the case: at $T \ll \varepsilon_{\mathrm{F}}$, this result turns out to be valid for any form of the Fermi surface, and for any dispersion law $\varepsilon(\mathbf{p})$.

[^951]:    ${ }^{33}$ Both these materials are alloys, i.e. solid solutions: chromel is $10 \%$ chromium in $90 \%$ nickel, while constantan is $45 \%$ nickel and $55 \%$ copper.

[^952]:    ${ }^{34}$ One more way to look at Eq. (63) is as at the difference between the total energy flow density, $\mathbf{j}_{e}=\int_{\varepsilon v} w d^{3} p$, and the product of a constant ( $\mu$ ) by the particle flow density, $\mathbf{j}_{n}=\int_{\mathbf{v}} w d^{3} p=\mathbf{j} / q$.
    ${ }^{35}$ The expression given by the second term of this relation, $\mathbf{j}_{h}{ }^{\prime}=-\kappa \nabla T$, is much more general than our analysis: for small temperature gradients it is valid in virtually any medium - for example, in insulators, where the first term of Eq. (64) vanishes. (In the general case, the thermal conductivity $\kappa$ is of course different from that given by Eq. (66).) As a result, this relation has its own name - the Fourier law, because it has been first suggested by the same universal genius J.-B. J. Fourier - who has not only developed such a key mathematical tool as the Fourier series, but also discovered what is now called the greenhouse effect!
    ${ }^{36}$ The simplicity of this relation (first discovered experimentally in 1854 by W. Thompson, a.k.a. Lord Kelvin) is not occasional. This is one of fundamental Onsager reciprocal relations between kinetic coefficients (L. Onsager, 1931), which are model-independent, i.e. valid within very general assumptions. Unfortunately, I have no time left for a discussion of this interesting topic, and have to refer the interested reader, for example, to Sec. 120 in L . Landau and E. Lifshitz, Statistical Physics, $3^{\text {rd }}$ ed., Pergamon, 1980. Note, however, that the range of validity of the Onsager relations is still debated - see, e.g., K.-T. Chen and P. Lee, Phys. Rev. B 79, 18 (2009).

[^953]:    ${ }^{37}$ It was named after G. Wiedemann and R. Franz who noticed the constancy of ratio $\kappa / \sigma$ for various materials, at the same temperature, as early as in 1853 . The direct proportionality of the ratio to the absolute temperature was noticed by L. Lorenz in 1872. Due to this contribution, the Wiedemann-Franz law is frequently presented as $\kappa / \sigma=$ $L T$, where constant $L$, called the Lorenz number, in SI units is close to $2.45 \times 10^{-8} \mathrm{~W} \cdot \Omega / \mathrm{K}^{2}$. Theoretically, Eq. (69) was derived in 1928 by A. Sommerfeld.

[^954]:    ${ }^{38}$ See, e.g., D. Rowe (ed.), Thermoelectrics Handbook: Macro to Nano, CRC Press, 2005.
    ${ }^{39}$ A much more detailed coverage of this important part of physics may be found, for example, in the textbook by L. Pitaevskii and E. Lifshitz, Physical Kinetics, Butterworth-Heinemann, 1981. A detailed discussion of its applications to mechanical engineering may be found, e.g., in T. Bergman et al., Fundamentals of Heat and Mass Transfer, $7^{\text {th }}$ ed., Wiley, 2011.

[^955]:    ${ }^{1}$ Actually, this leading term was derived by A. de Moivre in 1733, before the J. Stirling’s work.

[^956]:    ${ }^{2}$ Note that definitions of $B_{k}$ (or rather their signs and indices) vary even in the most popular handbooks.
    ${ }^{3} \mathrm{I}$ am confident that the reader is quite capable of deriving relations (3.1) by representing exponent in the elementary relation $e^{i(a \pm b)}=e^{i a} e^{ \pm i b}$ as a sum of its real and imaginary parts, Eqs. (3.3) directly from Eqs. (3.1), and Eqs. (3.2) from Eqs. (3.3) by variable replacement; however, I am still providing these formulas to save his or her time. (Quite a few formulas below are included because of the same reason.)

[^957]:    ${ }^{4}$ Higher-order formulas (e.g., the Bode rule), and other guidance including ready-for-use codes for computer calculations may be found, for example, in the popular reference texts by W. H. Press et al., cited in Sec. 16 below. Besides that, some advanced codes are used as subroutines in the software packages listed in the same section. In some cases, the Euler-Maclaurin formula (2.12) also may be useful for numerical integration.

[^958]:    ${ }^{5}$ A powerful (and free :-) interactive online tool for working out indefinite 1D integrals is available at http://integrals.wolfram.com/index.jsp.
    ${ }^{6}$ Eq. (6.5a) follows immediately from Eq. (6.3d), and Eq. (6.5b) from Eq. (6.2b) - a couple more examples of the (intentional) redundancy of this list.

[^959]:    ${ }^{7}$ Other popular notations for this vector set are $\left\{\mathbf{e}_{j}\right\}$ and $\left\{\hat{\mathbf{r}}_{j}\right\}$.
    ${ }^{8}$ It is easy to use Eq. (7.3) to check that the direction of the product vector corresponds to the well-known "righthand rule" and to the even more convenient corkscrew rule: if we rotate a corkscrew's handle from the first operand toward the second one, its axis moves in the direction of the product.

[^960]:    ${ }^{9}$ One can run into the following notation: $\nabla \equiv \partial / \partial \mathbf{r}$, which is convenient is some cases, but may be misleading in quite a few others, so it will be not used in these notes.
    ${ }^{10}$ In this, and four next sections, all scalar and vector functions are assumed to be differentiable.

[^961]:    ${ }^{11}$ Some other orthogonal curvilinear coordinate systems are discussed in EM Sec. 2.3.
    ${ }^{12}$ In the 2D geometry with fixed coordinate $z$, these coordinates are called polar.

[^962]:    ${ }^{13}$ The coefficient in this equation may be readily recalled by considering its left-hand part as the Fourier-integral presentation of function $f(s) \equiv 1$, and applying Eq. (14.1) to the reciprocal Fourier transform

    $$
    f(s) \equiv 1=\frac{1}{2 \pi} \int_{-\infty}^{+\infty} e^{-i s \xi}[2 \pi \delta(\xi)] d \xi
    $$

[^963]:    ${ }^{14}$ On a personal note, perhaps $90 \%$ of all formula needs throughout my research career were satisfied by a tiny, wonderfully compiled old book: H. Dwight, Tables of Integrals and Other Mathematical Formulas, $4^{\text {th }}$ ed., Macmillan, 1961, whose used copies, rather amazingly, are still available on the Web.
    ${ }^{15}$ An updated version of this collection is now available online at http://dlmf.nist.gov/ .

[^964]:    1 The listed numerical values of the constants are from the most recent (2014) International CODATA recommendation (see, e.g., http://physics.nist.gov/cuu/Constants/index.html), besides a newer result for $k_{\mathrm{B}}$ - see C. Gaiser et al., Metrologia 52, 217 (2015). Please note the planned (but not yet official) adjustment of the SI values - see, e.g. https://www.nist.gov/si-redefinition/meet-constants. In particular, the Planck constant will also get a definite value (within the interval specified in the given table), enabling a new, fundamental standard of the kilogram.

[^965]:    ${ }^{2}$ Note that the selected value of $\mu_{0}$ may be changed (a bit) in a few years - see, e.g., D. Newell, Phys. Today 67, No. 7, pp. 35-41 (2014).

[^966]:    ${ }^{1}$ The list does not include the sources (mostly, recent original publications) cited in the lecture notes and problem solutions, the open-access materials mentioned in the Preface, and the mathematics textbooks and handbooks listed in MA Sec. 16.
