Key words: KoRV, env subtype, koala, KoRV-B, genetic diversity

1

Abstract

Koala retrovirus (KoRV) is a recently endogenised retrovirus associated with neoplasia and immunosuppression in koala populations. The virus is known to display sequence variability and to be present at varying prevalence in different populations, with animals in southern Australia displaying lower prevalence and viral loads than northern animals. This study used a PCR and next generation sequencing strategy to examine the diversity of the KoRV *env* gene in both proviral DNA and viral RNA forms in two distinct populations representative of the "northern" and "southern" koala genotypes. The current study demonstrated that the full range of KoRV subtypes is present across both populations, and in both healthy and sick animals. KoRV-A was the predominant proviral subtype in both populations, but there was marked diversity of DNA and RNA subtypes within individuals. Many of the northern animals displayed a higher RNA viral diversity than evident in their proviral DNA, indicating relatively higher replication efficiency of non-KoRV-A subtypes. The southern animals displayed a lower absolute copy number of KoRV than the northern animals as reported previously and a higher preponderance of KoRV-A in individual animals. These discrepancies in viral replication and diversity remain unexplained but may indicate relative protection of the southern population from KoRV replication due to either viral or host factors and may represent an important protective effect for the host in KoRV's ongoing entry into the koala genome.

1. Introduction

Koala retrovirus (KoRV) is reportedly the youngest endogenized retrovirus (virus integrated in the host's germline and inherited as part of its host's genome), having been integrated in the koala genome only about 22,200–49,900 years ago (Ishida et al., 2015). The low genetic diversity of the long terminal repeat (LTR) regions of KoRV provirus sequences suggests that endogenous KoRV probably arose as part of a single outbreak (Ishida et al., 2015). KoRV is also evident in an apparently exogenous (horizontally infectious) form (Hobbs et al., 2017), with many koalas possessing high levels of KoRV RNA in plasma reflecting active viral replication. KoRV is found at a proviral prevalence of 100% in koala populations in northern regions of Australia (Tarlinton et al., 2005; Simmons et al., 2012) and at much lower prevalence (15-25%) in southern populations (Simmons et al., 2012; Legione et al., 2017). This range of prevalence has led to suggestions that KoRV is currently spreading throughout the Australian koala population following a 'northern to southern' transmission wave (Fiebig et al., 2006; Tarlinton et al., 2008). Other recent work has indicated that, in southern populations that have apparently low KoRV prevalence, KoRV-negative animals may in fact have defective versions of the virus, missing the *pol* and *env* gene portions most commonly used in virus detection studies (Tarlinton et al., 2017).

The outcome of natural KoRV infection is variable, and little is known about the mechanisms of pathogenesis. KoRV is associated with neoplasia and immunosuppression leading to clinical chlamydial disease (Canfield et al., 1988; Hanger et al., 2000; Xu et al., 2013; Fabijan et al., 2017; Gonzalez-Astudillo et al., 2017; Nyari et al., 2017; Burnard et al., 2018). For retroviruses in other species, mutation or recombination events in *env* genes play a significant role in pathogenicity, such as immunosuppression induced by subtypes of feline leukaemia virus (FeLV) (Overbaugh et al., 1988; Anderson et al., 2000; Chandhasin et al., 2005a; Chandhasin et al., 2005b).

Classification of KoRV subtypes (in line with similar naming schemes used for better studied gammaretroviruses such as FeLV) is based around the nucleotide sequence of the *env* gene, which encodes the surface protein (SU) and transmembrane protein (TM) of the virus. The 5' end of this gene, known as the hypervariable region, is of particular importance in subtype classification. This region of the *env* gene encodes the protein most exposed to the host's immune response as it is external to the virus membrane and is therefore typically the most variable portion of a retrovirus. This region of the virus also determines host receptor specificity (and therefore cellular tropism) and is one of the major determinants of pathogenicity in FeLV (Bolin and Levy, 2011). The classification system of KoRV is based around phylogenetic groupings of *env* gene nucleotide sequences. For some subtypes (though not all) receptor binding differences have also been determined. The generally accepted classifications are: KoRV-A (Hanger et al., 2000), which binds to the sodium-dependent phosphate transporter Pit-1, KoRV-B and J which bind to the thiamine transporter encoded by THTR1 (Xu et al., 2013), KoRV-C, KoRV-D (Shojima et al., 2013), KoRV-E, KoRV-F (Xu et al., 2015), KoRV-G, KoRV-H, and KoRV-I (Chappell et al., 2017). The receptor usage of subtypes C, D, E, F, G, H and I have not been determined. KoRV-A is found in every KoRV-positive koala and is considered the endogenous version of KoRV from which other subtypes have arisen (Chappell et al., 2017; Hobbs et al., 2017). The other subtypes of KoRV are possibly not germ line transmitted, as they were present in only low copy number in the koala reference genome animal, and as such were considered putative somatic insertions (Hobbs et al 2017). The same study also reported that KoRV-D and KoRV-E were present only as defective viruses and the authors hypothesised that these subtypes may be transmitted with a replication competent "helper" virus as has been documented for other retroviruses (Hobbs et al., 2017). KoRV-B is thought to be more pathogenic than KoRV-A, having been reported at an increased prevalence in animals with chlamydiosis or neoplasia than in healthy animals (Waugh et al., 2017). KoRV B and J isolates have also been reported to have variable numbers of copies of repeat regions (these are present as single copies in all KoRV A variants) in their LTRs. These types of repeats are known to enhance replication efficiency in other retroviruses such as FeLV (Xu et al., 2013; Chaban et al., 2017; Waugh et al., 2017).

This study explored the evolutionary patterns of KoRV *env* gene subtypes in two koala populations. Patterns of KoRV genetic diversity were investigated in one "northern" genotype in South-East

102 Queensland (QLD) with a KoRV prevalence of 100% and one "southern" genotype in the Mount Lofty
103 Ranges, South Australia (SA), with an unknown prevalence (Figure 1). Patterns of KoRV *env* subtype
104 diversity were compared in paired DNA and RNA samples in a subset of koalas from both populations
105 to understand *env* gene variation in integrated proviral genome (DNA) and in circulating virus (RNA).
106 Further, this study examined the possible relationship of *env* gene subtypes with a diverse range of
107 clinical diseases.

2. Results

109 This study assessed *env* gene diversity of both integrated KoRV provirus DNA and expressed plasma
110 viral RNA. Thirty-three "northern" (Queensland, QLD) koalas were assessed, comprising 28 with
111 paired DNA and RNA samples and five with only DNA as plasma was not available. Twenty-eight
112 "southern" (South Australia, SA) koalas were included, comprising five with paired DNA and RNA
113 samples, and 23 with only DNA samples because plasma was not available (10 animals) or the RNA
114 sample was negative in the *env* gene RT-PCR (13 animals). The overall summary of the demographic
115 details and clinical status of the animals is shown in Table 1 and details are in supplementary file 2.

116 After quality evaluation and filtration, an average of 22719 total reads were generated for each provirus
117 DNA sample, ranging between 6169 to 59558 total reads. However, the number of total reads was
118 higher from amplified RNA, averaging 104894 total reads with a range of 12717 to 245827.

119 **Table 1:** Overall details of study samples (percentages of the total number of animals are given in
120 parentheses). Not all information was available for all koalas.

Variables	Characters	Queensland	South Australia
Sex	Male	n= 20 (60.6%)	n= 14 (50%)
	Female	n= 13 (39.4%)	n= 14 (50%)
	Total	**n= 33**	**n= 28**
Age group	Juvenile	n = 2 (6.3%)	n = 3 (11.5%)
	Young adult	n = 8 (25%)	n = 14 (53.8%)
	Adult	n = 22 (68.8%)	n = 9 (34.6%)
	Total	**n = 32**	**n = 26**
Body condition score	0 to <3	n = 15 (46.9%)	n = 4 (15.4%)
	≥ 3 to 5	n = 17 (53.1%)	n = 22 (84.6%)
	Total	**n = 32**	**n = 26**
Clinical status	Healthy	n = 11 (33.3%)	n = 5 (17.9%)
	Neoplasia	n = 8 (24.2%)	n = 5 (17.9%)
	Oxalate nephrosis	negative	n = 5 (17.9%)
	Chlamydiosis	n = 16 (48.5%)	n = 11 (39.3%)

121

2.1 *Env* subtypes

From deep sequencing, a total of 169 unique sequences were generated after sequence validation from all samples of both populations. Sequence reads are available under Sequence Read Archive accession number SRR8375764. The sequence alignment is shown in supplementary file 3. The Bayesian phylogenetic tree (Figure 2) showed high genetic diversity in the KoRV *env* gene at the population level. The identified sequences were grouped with previously recognized subtypes A, B, D, and I. Subtypes B and I were monophyletic in the tree with posterior probability support of 1.0. Subtype A formed a well-supported monophyletic clade. In contrast, subtype D exhibited multiple sub-clades with relatively long branches, high posterior probability values and sequences that were divergent in the hyper-variable region of the env receptor binding domain (RBD) (Supplementary Files 3 and 4). This subtype D grouping, with posterior probability support of 0.93, contained reference sequences that had been previously identified as subtypes F, G and H in addition to previously assigned subtype D sequences (Chappell et al., 2017). We identified 13 distinct sub-clades within the subtype D grouping; each of these sub-clades was strongly supported with posterior probabilities of 0.99-1.0. Two of these sub-clades contained only KoRV-G or KoRV-H sequences, and for consistency with the literature, we retained these names despite their phylogenetic placement as sub-clades within subtype D. The remaining 11 sub-clades within subtype D were designated D1 to D11. Sequences that had previously been designated KoRV-F by different authors (Xu et al., 2015; Chappell et al., 2017) belonged to two different subtype D sub-clades in our analysis, with the Chappell et al. (2017) sequence strongly clustering with sub-clade D3 and the Xu et al. (2015) sequence clustering with moderate support (posterior probability 0.83) with D9. Previously assigned KoRV-D sequences clustered either with sub-clade D1 (Shojima et al., 2013) or D4 (Chappell et al., 2017). Sequences clustering in sub-clades D2, D5, D6, D7, D8, 10 and D11 were not matched or clustered with any reference sequences. Subtypes C and E, which have been previously described (Miyazawa et al., 2011; Shojima et al., 2013; Xu et al., 2015), clustered together close to but distinct from group D.

Sequences in this study were assigned to all of the afore-mentioned subtypes except for subtypes C, E and H, which were not found in any of our samples. A total of 63 sequences were found from the KoRV-A subtype, 22 from subtype B, 16 from subtype I, and 68 from subtype D. Within the subtype D sequences, most (22) sequences were within the D1 sub-clade, with one sequence in each of D4 and D10, two in each of D6, D8 and KoRV-G, four sequences in each of D2 and D7, five in D3, six in D5, eight sequences in D9, and 11 sequences in the D11 sub-clade.

The average read count of each unique sequence was highly diverse between animals, between RNA and DNA forms in the same animal and within the two koala populations (QLD and SA). The number of different KoRV DNA sequences within an individual, indicative of the number of provirus insertions,

156 was significantly higher (Mann Whitney U, p< 0.0001) in QLD individuals (median 77, range 63-100)
157 in comparison to SA koalas median 59, range 43 – 74).

158 The read count details of unique sequences in individual animals are available in Supplementary File 5
159 and the relative percentage levels of each subtype (group of sequences) are available in Supplementary
160 File 6. There was variation among individuals in overall read count and so read counts of subtypes were
161 converted to the relative percentage of each subtype of the total reads for that individual with following
162 equation:

163 Relative percentage of each specific subtype (for each individual) = (total number of unique
164 sequence reads of the subtype / total read count of all subtypes) x 100

2.2 Env subtype abundance in QLD and SA koala population

166 As shown in Figure 3, the absolute read count values of *env* gene subtypes in the DNA of QLD koalas
167 were significantly higher (p value <0.0001) in comparison to SA koalas. Each koala had multiple *env*
168 subtypes in their genome (Figure 4). In the QLD animals, KoRV-A, KoRV-B, and KoRV-D (sub-clades
169 10 and 11) were present in proviral DNA form at some level in all individuals (supplementary file 5
170 and 6) KoRV-A was the dominant subtype (present at >40% of reads) in proviral DNA in 30 of the 33
171 QLD animals (Figure 4A). The exceptions were two animals where the D1 subclade was in higher
172 abundance and one koala with the D6 subclade as the highest abundance. For the SA koalas, subtypes
173 A, B and sub-clade D10 were present in the DNA of all koalas, while sub-clades D1 (27/28) and D11
174 (27/28) were also represented in the majority of koalas. KoRV-A dominated the proviral DNA subtypes
175 in all SA koalas with a much higher relative percentage than in the QLD animals. The median Shannon
176 diversity index was also significantly lower in the SA than the QLD animals (Mann Whitney U
177 (<0.0001).

178 The subtypes present in the RNA of individual animals differed from those present in the DNA. The
179 median Shannon diversity index was lower for DNA than RNA samples for both populations but did
180 not reach significance (Mann Whitney U test, QLD p=0.4 and SA p=0.5). For the QLD animals subtypes
181 A, B, D2, D3 and D5 were more abundant in the DNA samples and D10 and G more abundant in the
182 RNA samples (FDR p values >0.005). All QLD (n= 28) and SA koalas (n=5) had subtypes or subclades
183 A, B, D1, D10 and D11 at some level in their viral RNA; additionally all SA koalas also had subclades
184 D2 and D3.

185 All five SA koalas showed a very high relative percentage of KoRV-A (92.5-99.9%) in viral RNA. In
186 contrast, none of the RNA samples for QLD koalas showed KoRV-A to be the most abundant subtype,
187 with KoRV-B (n=8), D11 (n=7), D1 (n=3), D3 (n=2), KoRV-I (n=1), D2 (n=1), D5 (n=2), D6 (n=2),

188   D7 (n=1) or D8 (n=1) the most abundant subtypes or subclades within individual koalas (supplementary

189   file 6)

190   **2.3 Distribution differences between viral DNA and RNA of env subtypes**

191   The difference in the distribution of subtypes between viral DNA and RNA of individual koalas was

192   striking, in particular amongst the QLD koalas (Figure 4A and 5 A,C). In some koalas, the predominant

193   viral RNA subtype formed only a very minor proportion of the proviral DNA subtype distribution. As

194   examples, koalas Q2 and Q27 had an overwhelming predominance of subtype/subclades D2 and D8 in

195   their viral RNA, comprising 85% and 88% of their RNA subtype distribution, respectively, whereas

196   these two subtypes comprised only 13% and 8%, respectively, of the proviral DNA subtype distribution

197   in these koalas. Within individual koalas, it is clear that some KoRV proviral subtypes have very high

198   rates of expression while others are poorly expressed.

199   These results probably reflect a greater replication rate (and overall viral load) in the QLD animals with

200   viral diversity increasing in the RNA form of the virus (a greater number and range of non KoRV-A

201   subtypes being produced). In the SA animals where the viral load (and presumably the replication rate)

202   is lower this difference in viral diversity is not seen, with these animals continuing to display a higher

203   preponderance of the ancestral A subtype (both when compared to the QLD animals and when RNA

204   and DNA forms within the SA animals are compared).

205   **2.4 KoRV-A and KoRV-B status based on conventional PCR**

206   Conventional PCR of DNA using KoRV-A and KoRV-B specific primers demonstrated a 100%

207   prevalence of KoRV-A in QLD koalas and 96.4% in SA koalas, while the KoRV-B prevalence was

208   48.5% in QLD and 0% in SA koalas. This is in contrast to the MiSeq deep sequencing results where all

209   animals in both populations were positive for both subtypes. There was a significant differences

210   (p<0.0001) between a positive test for KoRV B with conventional PCR and a Miseq read count of

211   >2700 for KoRV B. With one exception, koalas with raw read counts below 2700 were negative by

212   KoRV-B specific conventional PCR.

213   **2.5 Subtype correspondence with clinical status of respective koalas**

214   Amongst the 33 QLD koalas, 11 were clinically healthy, 13 had chlamydiosis, four had neoplasia, four

215   had both chlamydiosis and neoplasia and one had a non-neoplastic hepatic mass (Table 1 and

216   Supplementary File 2). All DNA and RNA subtypes, including the putative pathogenic KoRV-B, were

217   found in both healthy and diseased animals. Of the 28 SA koalas, 12 had chlamydiosis, five had

218   neoplasia, five had oxalate nephrosis (a genetic kidney disease not commonly found in QLD animals),

219　and six were healthy. As with the QLD animals, all SA koalas had both KoRV-A, KoRV-B and
220　subclades of KoRV-D.

221　There were too few animals (particularly in the SA population) with RNA for a sensible analysis of
222　disease status vs viral subtypes. For proviral DNA there was no clear association between the abundance
223　of any particular subtype and any particular disease syndrome. Graphs of subtypes A, B, combined D
224　and I versus disease categories of healthy, neoplasia, oxalate nephrosis and chlamydiosis for each
225　population are presented in supplementary file 7. There was a trend towards healthy animals (in both
226　the QLD and SA populations) and the oxalate nephrosis animals in the SA population (this disease is
227　thought to have a genetic basic) having a lower viral diversity (with a greater preponderance of KoRV
228　A) than those with neoplasia or chlamydiosis (the diseases thought to be associated with KoRV
229　infection) though a major confounding factor for more robust analysis here was the number of animals
230　with multiple disease syndromes and the small number of animals in some disease categories in each
231　population.

232　**3. Discussion**

233　Despite the high prevalence of KoRV and its potential impact on the health of koalas, there are few
234　reports available about KoRV genetic diversity in the Australian koala population. Most of the
235　information about KoRV diversity comes from studies in overseas captive koalas (Miyazawa et al.,
236　2011; Shojima et al., 2013; Xu et al., 2013; Xu et al., 2015) or wild South-East Queensland (SE QLD)
237　koalas (Chappell et al., 2017), all of which are of the "northern" or mixed genotypes. Here, we made a
238　substantial contribution to knowledge in this field by investigating KoRV *env* gene diversity in diseased
239　and healthy koalas from both "northern" and "southern" genotype populations (SE QLD and Mt Lofty
240　Ranges, SA) highlighting the differences in abundance of KoRV subtypes at both DNA and RNA level
241　between these populations, with the southern animals demonstrating both a lower viral load, a reduced
242　viral diversity and a greater preponderance of KoRV A abundance. The paired DNA-RNA samples in
243　individual koalas also demonstrated that the abundance of different DNA and RNA subtypes within
244　individual koalas do not correspond to each other, with a trend (though not significant) towards a higher
245　diversity in the RNA samples, indicating variable expression of proviral DNA subtypes.

246　Our study demonstrated that the full range of KoRV subtypes was present in both northern and southern
247　koala populations, and in both DNA and RNA forms of the virus. The finding of KoRV-B in all southern
248　animals studied was unexpected and is in contrast to recent PCR-based studies of KoRV-B prevalence
249　which have reported varying (Waugh et al., 2017) or absent (Legione et al., 2017) prevalence rates of
250　KoRV-B in "southern" animals.

251   Phylogenetic analysis of the KoRV *env* genes in this study found four major subtypes; three were

252   strongly supported monophyletic clades clustering with previously designated as A, B and I. The fourth

253   subtype was the large paraphyletic group D, which this study classified into 13 sub-clades comprising

254   previously designated subtypes G and H and newly designated subtypes D1 to D11. Two reference

255   sequences that had previously been designated KoRV-F clustered with two distinct group D subtypes

256   (KoRV-D3 and KoRV-D9). The paraphyletic nature of the subtype D grouping highlights the

257   difficulties of assigning KoRV subtypes. Rather than following convention and designating our newly

258   identified sequences as further alphabetical subtypes (KoRV-K, L, M, N, etc), we recognised that these

259   sequences belong to a large phylogenetic grouping and should not be classified as distinct lettered

260   subtypes, but rather as sub-clades of subtype D. We cannot entirely rule out PCR related recombination

261   of differing loci or PCR based errors in the sequences (particularly for the KoRV-D group) though the

262   parameters set for including sequences in subsequent phylogenetic analysis (sequences present in at

263   least two animals, a minimum read count of four and a 99% clustering threshold) will have removed

264   sequences that appeared only once in the data.

265   KoRV-A, KoRV-B, and KoRV-D sub-clades 1, 10 and 11 were highly prevalent in individuals in this

266   study, while KoRV-C, E and H were not identified. KoRV-C was identified at a Japanese zoo from

267   captive koalas (Shojima et al., 2013) and to date has not been found in any wild koala (Chappell et al.,

268   2017; Hobbs et al., 2017). KoRV-E was identified from a zoo in USA (Xu et al., 2015) and was also

269   not found by Chappell et al. (2017), although a defective form is present in the reference genome animal

270   (Hobbs et al., 2017). KoRV-H is rare, having been found in only one animal in viral RNA form

271   (Chappell et al., 2017); in our study, KoRV-H sequences clustered within a larger KoRV-D clade, so

272   it is possible that this subtype may exist in other geographic ranges. Overall these data highlight the

273   extreme intra-animal variability of KoRV with many subtypes being reported in only a small number

274   of animals.

275   This study is not able to distinguish between endogenous (incorporated into the genome and vertically

276   transmitted) and exogenous (horizontally transmitted) virus. Indeed, in a newly integrated virus like

277   KoRV, this distinction may not be very helpful as there is no reason why the virus cannot be both

278   vertically and horizontally transmitted. The original demonstration of KoRV as an endogenous virus

279   (Tarlinton et al 2006) did not use methods that would distinguish the different KoRV subtypes, though

280   subsequent analysis of the variants present in the reference genome animal (of the northern genotype)

281   (Hobbs et al., 2017) indicated that KoRV-A is endogenous in this animal (present at high copy number)

282   while variants B-I are likely present only as low copy number somatic cell insertions (and so likely not

283   vertically transmitted) though to date this has only been examined in this one individual. A number of

284   sequencing efforts from museum specimens have only demonstrated KoRV-A and not the other variants

285   in historical specimens (though DNA quality is an issue in these specimens). There has been limited

286　sequencing of KoRV strains outside of the variable region of *env*; analysis of the koala reference
287　genome indicated that variants D and E were defective in the source animal (Hobbs et al., 2017). This
288　does not mean that these variants are not horizontally transmitted as there are multiple examples of
289　retroviruses in other species (notably cats and chickens) where defective viruses are transmitted
290　alongside replication competent "helper viruses". KoRV-A might represent remnants of ancestral germ-
291　line infections by exogenous retroviruses with other forms of the virus representing those still active
292　due to continual reinfection or retro-transposition in cis within germ-line cells as reported in other
293　retroviral systems (Boeke and Stoye, 1997; Belshaw et al., 2005). This theory is potentially supported
294　by the phylogenetic pattern evident in the KoRV-A isolates in this study, with the long branch lengths
295　obvious within the KoRV-A cluster (supplementary figure 4) consistent with very closely related
296　endogenous proviruses that have diverged post integration.

297　KoRV-A is at any rate present in all KoRV positive koalas and is consistent with being endogenous
298　(Xu et al., 2015; Legione et al., 2017; Waugh et al., 2017). This study confirms KoRV-A as being
299　present in all KoRV positive koalas as previously reported by many groups. It also highlights the
300　previously described lower viral load in southern animals (Legione et al., 2017, Simmons et al., 2012).
301　This lower viral load corresponds with a reduced viral diversity and a higher relative percentage
302　abundance of KoRV-A in southern koalas. In addition, in the northern animals, the relative percentage
303　of KoRV-A was much higher in the integrated proviral DNA than in the viral RNA, with other subtypes
304　variable among all samples. This may reflect a relatively greater viral diversity in animals with higher
305　viral loads due to the greater rate of mutation in actively replicating virus. This phenomenon is well
306　described in other retroviruses such as HIV where viral diversity increases with viral replication (Theys
307　et al., 2018). Alternatively, some variants of KoRV-A (particularly endogenous loci) may not be very
308　effectively transcribed, either directly or as a result of competition with high copy number of other
309　transcribed subtypes. Another possibility is that a mutation of the provirus may disrupt DNA sequence
310　elements from the promoter which are essential for transcription. Indeed, the original KoRV-A isolate
311　does not replicate efficiently in cell culture, probably due to sequence changes in its LTR when
312　compared with more replication competent clones (Shimode et al., 2014). It is also possible that
313　transcription from individual KoRV-A loci is uneven with some highly transcribed loci responsible for
314　the RNA detected. These particular loci may be less prevalent in QLD animals. Another potential
315　confounding factor in blood samples is that the levels may not directly reflect viral transcription in other
316　tissues (there is likely differential transcription in different tissues as has been demonstrated for many
317　retroviruses, both endogenous and exogenous). However, replicating virus in any tissue likely produces
318　virions spilling over in the blood.

319　Several other studies have reported a linkage between detection of KoRV-B provirus and neoplasia or
320　chlamydial disease occurrence (Chaban et al., 2017; Waugh et al., 2017) (Xu et al., 2013). However,

the current study does not support an association between the presence of particular virus subtypes in either DNA or RNA forms and the occurrence of disease. Previous studies on the association between KoRV-B subtype and disease were based on conventional PCR. The NGS approach used here is not reliant on sequence specific primers for each KoRV subtype and is therefore able to detect a more comprehensive range of subtypes in individual animals. The NGS approach was also more sensitive in detection of KoRV-B, with only 48.5% of QLD animals and no SA animals testing positive for KoRV-B with conventional PCR, in contrast to 100% of the same animals testing positive with the PCR and NGS approach. There was a significant association between higher read counts of KoRV-B in the NGS data and the likelihood of testing positive for KoRV-B on conventional PCR. These findings indicate that previously reported results for an association of KoRV-B with disease in animals might reflect an association between higher viral load and disease rather than the presence of the KoRV-B subtype per se. In terms of koala population management decisions, the findings also indicate that testing for KoRV-B via endpoint PCR, as has been adopted by some zoological collections, is probably not a useful screen for future neoplasia risk.

Indeed, this study does not provide convincing evidence for an association of any particular virus subtype with a particular disease syndrome, although a trend towards a reduced viral diversity and an increased preponderance of KoRV-A is evident in healthy animals and in the SA animals the oxalate nephrosis animals (this is a genetic disease seen predominantly in the southern population). As with the differences in viral diversity between the populations this probably reflects the previously reported relationship between higher viral load (and therefore sequence diversity), neoplasia and clinical chlamydiosis in KoRV affected animals (Tarlinton et al., 2005). Important caveats where are the small numbers of animals in some disease categories, the differences in disease patterns between the two populations and the numbers of animals with multiple diseases which will have confounded this analysis. These confounding factors also made more appropriate statistical analysis techniques for this type of data (like multivariate modelling) inaccurate.

It still remains unexplained why the South Australian animals have a lower level of KoRV replication and a reduced level of abundance of non-KoRV-A subtypes. This study only looked at *env* diversity and there are other factors that can affect viral replication efficiency. In particular the LTR sequences of retroviruses are known to be major determinants of replication efficiency (Pantginis et al., 1997; Chandhasin et al., 2004) and variations in KoRV-B/J isolate LTRs have been reported previously (Shimode et al., 2014) Hobbs et al 2017) that appear to affect replication efficiency. It is also possible that the South Australian population has defects in the receptor for one or more variants of KoRV (KoRV-A and B are known to use different receptors) affecting the efficiency of viral re-infection in these animals, although preliminary analysis of unpublished transcriptome sequences from the two populations would indicate that this is not the case. Other unpublished data indicate that the SA animals

356 may have a defective form of the virus, which is missing most of the *gag, pol* and *env* genes (Tarlinton

357 et al., 2017) and it is possible that this defective virus inhibits replication of the full length virus as has

358 been reported for some other retroviruses (Boeke and Stoye, 1997).

359 Overall, this study analysed KoRV *env* gene diversity in paired samples of provirus DNA and viral

360 RNA within individual koalas from two different zones of koala habitat representing northern and

361 southern koala populations. The identified sequences significantly enhance the number of *env* gene

362 sequences known for KoRV and highlighted significant variation between the abundance of transcribed

363 variants of KoRV present in the RNA of individuals when compared with the provirus complement in

364 the DNA. This probably reflects differential transcription efficiency of different loci and subtypes.

365 KoRV-A is the likely ancestral version of KoRV, with other variants likely generated via mutations,

366 deletions, or recombination events. These other subtypes have now become the predominant transcribed

367 form of KoRV in the Queensland population. It remains unexplained why the southern animals display

368 such lower viral loads and reduced viral diversity than the northern population, along with such a

369 different disease pattern, however this study highlights that this is not as simple as the presence or

370 absence of particular virus subtypes as has been previously hypothesised.

371 **4. Methods**

372 **4.1 Sample collection and preparation**

373 In South-East QLD, animals were sourced from Moggill Koala Hospital, Australia Zoo Wildlife

374 Hospital, RSPCA Wacol and Sea World Paradise Country. South Australian (Mount Lofty Ranges)

375 samples were collected from Fauna Rescue of South Australia (Figure 1, Table 1). Blood (2-3 ml) was

376 collected from live and clinically healthy captive koalas using a sterile 22-gauge butterfly catheter and

377 5 ml syringe. Wild koalas hospitalised due to disease or serious injury following trauma or animal attack

378 were euthanased and necropsied. Koalas were anaesthetised with 0.25 ml Zoletil (Virbac)

379 intramuscularly. Euthanasia was performed with an intravenous injection of pentobarbitone.

380 Immediately following euthanasia, 10 – 15 ml of blood was withdrawn from a femoral vein or by

381 cardiac puncture into EDTA tubes.

382 DNA was extracted from 100 µl EDTA whole blood using Qiagen DNeasy Blood & Tissue Kit

383 according to manufacturer's (Qiagen) instructions. A 1-2 ml aliquot of blood was centrifuged at 3000

384 g for 5 mins and 200 µl of plasma was removed and added to 300 µl of RNAlater stabilisation agent

385 (Qiagen) within 15 min of blood collection. RNA was extracted using Qiagen QIAmp Viral RNA mini

386 kit with on-column Qiagen RNase free DNase steps. Briefly, 140 µl of RNAlater diluted plasma was

387 suspended in 560 µl viral lysis buffer containing carrier RNA and extraction continued following the

388 extraction kit procedures and finally eluted in 30 µl water. The extracted RNA samples were stored at

389 -80°C until required.

4.2 KoRV-A and KoRV-B real-time and conventional PCR

391 To test for the presence of KoRV-A and B, we used real time and conventional PCR. Initially, KoRV

392 positivity of the extracted DNA and RNA was initially assessed with a real-time PCR of the KoRV *pol*

393 gene using published primers and probe (Tarlinton et al., 2005). DNA and RNA samples were amplified

394 using TaqMan gene expression master mix (Applied Biosystem) and SuperScript® III One-Step RT-

395 PCR System with Platinum® Taq DNA Polymerase (Invitrogen) respectively, following

396 manufacturers' instructions, in a BioRad CFX 96. Samples were considered KoRV-positive if the CT

397 value was $\leq$ 35.

398 Conventional PCR of the *env* gene was performed using published primers to specifically amplify each

399 of the KoRV-A and KoRV-B env subtypes (Waugh et al., 2017) as a preliminary assessment of KoRV

400 subtype prevalence. Primers used in this study shown in Table 2. The Qiagen HotStartTaq Plus Master

401 Mix kit was used for PCR of DNA samples following the manufacturer's instructions with 35 cycles of

402 amplification and an annealing temperature of 51°C. KoRV-A and KoRV-B positive samples were

403 directly purified with ExoSAP-IT (Thermo Fisher Scientific), following manufacturer's directions and

404 Sanger sequenced to validate the amplification of this subtype. Sequencing was undertaken using Big

405 Dye Terminators (ThermoFisher Scientific) at the Animal Genetics Laboratory, University of

406 Queensland. Sequences were subjected to BLAST analysis through the NCBI database to determine the

407 percentage of homology to known subtypes.

408 **Table 2:** Primers used in this study for PCR

Region	Forward	Reverse	Reference
Pol	TTGGAGGAGGAATACCGATTACAC	GCCAGTCCCATACCTGCCTT	(Tarlinton et al., 2005)
Env KoRV-A specific	TCCTGGGAACTGGAAAAGAC	GGGTTCCCCAAGTGATCTG	(Waugh et al., 2017)
Env KoRV-B specific	TCCTGGGAACTGGAAAAGAC	GGCGCAGACTGTTGAGATTC	(Waugh et al., 2017)

409 **4.3 Sample preparation for Illumina sequencing**

410 Previously published oligonucleotide primers flanking the hypervariable region of the *env* gene

411 (Chappell et al., 2017) were used to amplify a 500 bp fragment of target sequence by PCR. The primers

412 contained the Illumina adaptor sequences (italics) ligated to *env* gene complementary regions.

413   The Qiagen HotStartTaq Plus Master Mix kit was used to amplify from DNA and the Qiagen OneStep
414   RT-PCR kit was used to amplify from RNA, both following the manufacturer's instructions with an
415   annealing temperature of 58°C and 35 rounds of amplification. We adopted recently established deep
416   sequencing methodology for analysis of the *env* gene hypervariable region, such that consistency was
417   retained between current and previous findings (Chappell et al., 2017). Samples were prepared
418   following the Illumina 16S Metagenomic Sequencing Library Preparation guidelines. The purification
419   and sequencing of PCR amplicons was performed at the Ramaciotti Centre for Genomics (University
420   of New South Wales, Sydney, Australia). Purification was performed using Agencourt AMPure XP
421   beads (Beckman Coulter, USA) and purified DNA was indexed with unique 8 bp barcodes using the
422   Illumina Nextera XT 384 sample Index Kit A-D (Illumina FC-131-1002) following standard PCR
423   conditions. Indexed amplicons were pooled together in equimolar concentrations and sequenced on the
424   MiSeq Sequencing System (Illumina, USA) using paired end sequencing with V3 300bp following
425   manufacturer's protocols.

426   **4.4 Sequence assembly**

427   The overlapped forward and reverse reads of the Illumina next generation sequencing (NGS) were
428   assembled using the OL assembly method in the *dDocent* pipeline (Puritz et al., 2014). The reads were
429   trimmed using Trimmomatic (Bolger et al., 2014) and assembled using *Rainbow* (Chong et al., 2012)
430   and *CD-HIT* (Fu et al., 2012). A series of optimization assemblies were run to assess how the number
431   of contigs would be affected by parameter choice in *dDocent* and the effect of clustering threshold: (a)
432   the minimum number of samples in which a sequence had to be represented (1−10 samples); and (b)
433   the clustering threshold (80−98%). These preliminary optimization runs indicated that the level of
434   clustering did not have a substantial effect on the total number of unique contigs assembled. What did
435   have a major impact was the number of individuals required to represent a sequence: when this was 1,
436   the number of contigs that could be assembled from a single individual was substantially larger then
437   when assemblies required a sequence to be found in ≥2 samples. This result implicates considerable
438   subtype sequence variation, but it is hard to resolve this from technical or sequencing error that may
439   generate false variation. Therefore, the final assembly included the parameter selection of: (i) sequences
440   present in at least two samples, (ii) a minimum read count of four and (iii) a 99% clustering threshold.
441   Graphical view of optimisation assemblies are shown in supplementary file 1.

442   The representative sequences were aligned with KoRV-A (AF151794) and KoRV-B (KC779547.1)
443   using the *ClustalW* alignment in the program *BioEdit* (Hall, 1999) to identify the presence of any
444   anomalous contigs. Sequences that failed to show homology against reference sequences were removed
445   from further analysis. The putative sequences were mapped by *BWA* (Li and Durbin, 2009) with the
446   following parameters: match score = 1, mismatch penalty = 4, gap open penalty = 15. Finally, *SAMTools*

447 (Li et al., 2009) was used to filter the alignment bam files (for a MapQ score of 30) and to extract the
448 counts of reads mapped to each contig.

449 **4.5 Phylogenetic analysis**

450 The representative unique sequences were imported into the Geneious v11.0.4 software package
451 (https://www.geneious.com/) and combined with previously published KoRV env sequences; KoRV-A
452 (AF151794, KX587957.1 and KP792565.1), KoRV-B (KX588002.1, KX588011.1, KX588027.1,
453 KC779547.1, AB822553.1, KX588031.1, KX588053.1), KoRV-C (AB828005.1, KP792564.1),
454 KoRV-D (KX587952.1, KX587991.1, KX588043.1, KX587993.1, KX587972.1, KX587972.1,
455 AB828004.1, KX587997.1), KoRV-E (KU533853.1), KoRV-F (KX588025.1, KX588028.1,
456 KX587994.1, KU533852.1), KoRV-G (KX587961.1 and KX587998.1), KoRV-H (KX588036.1 and
457 KX587979.1), and KoRV-I (KX587976.1 and KX588021.1) were used. Moreover, four other
458 sequences from the viruses previously determined to be the most closely related to KoRV (Simmons et
459 al., 2014) in other were used as outgroups to root the KoRV phylogeny: two Gibbon ape leukaemia
460 virus (GALV) sequences, (KT724047.1, KT724048.1) and two *Melomys burtoni* retrovirus (MbRV)
461 sequences (KF572486.1, KF572485.1). Sequences were aligned using *ClustalW* alignment with a gap
462 opening cost of 15 and a gap extension cost of 7 as implemented in Geneious 11.0.4. The alignments
463 were further edited by hand to fill the blanks at the beginning and end.

464 A Bayesian phylogenetic tree was determined from the aligned reads using the Geneious plugin of
465 MrBayes 3.2.6 (Huelsenbeck and Ronquist, 2001) with a chain length of 10,100,000, a subsampling
466 frequency of 2000 and a burn-in-length of 1,100,100, with all others parameters set at defaults.
467 Sequences were manually allocated to a KoRV subtype based on clustering with previously identified
468 reference subtypes and phylogenetic topology.

469 **4.6 Statistical analysis**

470 The comparison of the number of unique proviral sequences and read counts between QLD and SA
471 populations was statistically evaluated through non-parametric Mann Whitney U test. The concordance
472 of the NGS results with the conventional PCR testing for KoRV-B was assessed through Pearson's chi-
473 squared tests. The taxonomic count data was analysed for statistically significant differences, between
474 QLD vs SA provirus, and DNA vs RNA for both SA and QLD samples, in R (Ihaka and Gentleman,
475 1996) using the EdgeR wrapper (Robinson et al., 2010) as part of the phyloseq package (McMurdie and
476 Holmes, 2013). Diversity statistics were calculated using vegan (Dixon, 2003) and differences were
477 assessed for significance using Mann-Whitney U tests in Prism 8.01 (GraphPad Software Inc. USA).

627 **Figures:**

628 **Fig. 1:** Location of sample collection site. Red dot showing the sample collection cities. From

629 Queensland, samples were collected from Gold Coast, Brisbane, and Sunshine Coast and from South

630 Australia, koalas were collected from Mount Lofty region. Map was adapted from Australian Koala

631 Foundation (AKF) website.

632 **Fig. 2:** Phylogenetic tree from aligned KoRV sequences (including 169 newly identified in this study

633 and 24 previously published sequences with two sequences from GALV and MbRV (used as outgroups

634 to root the tree) generated through Geneious implemented Bayesian approach. Previously published

635 KoRV env sequences; KoRV-A (AF151794, KX587957.1 and KP792565.1), KoRV-B (KX588002.1,

636 KX588011.1, KX588027.1, KC779547.1, AB822553.1, KX588031.1, KX588053.1), KoRV-C

637 (AB828005.1, KP792564.1), KoRV-D (KX587952.1, KX587991.1, KX588043.1, KX587993.1,

638 KX587972.1, KX587972.1, AB828004.1, KX587997.1), KoRV-E (KU533853.1), KoRV-F

639 (KX588025.1, KX588028.1, KX587994.1, KU533852.1), KoRV-G (KX587961.1 and KX587998.1),

640 KoRV-H (KX588036.1 and KX587979.1), and KoRV-I (KX587976.1 and KX588021.1) were used.

641 Outgroup sequences: Gibbon ape leukaemia virus (GALV) sequences, (KT724047.1, KT724048.1) and

642 *Melomys burton*i retrovirus (MbRV) sequences (KF572486.1, KF572485.1). Bayesian value are shown.

643 Paraphyletic KoRV-D has multiple subclades numbered D1 to D11 and also includes previously

644 designated KoRV-G and KoRV-H. Clades color and weight are marked as gradient following posterior

645 probabilities values

646 **Fig. 3:** Comparison of the read counts of KoRV env subtypes A, B, I and D (including subclades) in

647 the proviral DNA form within QLD (n = 33) and SA (n = 28) koala populations. Mean read counts with

648 one standard deviation error bars are shown. Although all SA animals had KoRV-B and D10, their

649 lower level read counts are not observable at this scale.

650 **Fig. 4:** Genetic diversity of KoRV *env* subtypes among paired DNA and RNA samples was illustrated

651 through the relative percentage of total reads of (A) QLD and (B) SA koala populations. Colors indicate

652 the different subtypes. (A) Among 33 QLD koalas, 28 were present in both DNA and RNA forms and

653 (B) among 28 SA koalas, 5 had both DNA and RNA forms.

654 **Fig. 5:** Percentage relative abundance of viral subtypes A (green), B (orange), I (red) and combined D

655 (purple). Compared between QLD and SA animals for A) DNA, B) RNA, C) RNA and DNA for paired

656 QLD samples, and D) RNA and DNA for paired SA samples. Median and interquartile ranges

657 displayed.

658

659

660 **Supplementary Files:**

661 **File 1 (figure):** Preliminary optimisation assemblies using *dDocent*. Two parameters were explored:

662 (1) the minimum number of samples required to represent a sequence in the assembly (colours, see

663 legend), and (2) the clustering thresholds used to group reads into similar sequences. The clear effect

664 of singletons (only requiring a sequence to be represented in one individual) on the number of contigs

665 probably arises from two competing (non-mutually exclusive) hypotheses: firstly, large variation exists

666 within and between individuals; and secondly, technical and sequencing error introduces sequence

667 variation. This problem appears to disappear when the number of samples was ≥2.

668 **File 2:** Details of koala samples used for analysis of *env* gene diversity using 16S Metagenomics

669 sequencing.

670 **File 3 (figure):** Alignment of unique Koala Retrovirus (KoRV) *env* sequences from koalas sampled in

671 Queensland and South Australia.

672 **File 4 (figure):** Simple view of Bayesian phylogenetic tree. Unique sequences were aligned with

673 previously published KoRV env sequences; KoRV-A (AF151794, KX587957.1 and KP792565.1),

674 KoRV-B (KX588002.1, KX588011.1, KX588027.1, KC779547.1, AB822553.1, KX588031.1,

675 KX588053.1), KoRV-C (AB828005.1, KP792564.1), KoRV-D (KX587952.1, KX587991.1,

676 KX588043.1, KX587993.1, KX587972.1, KX587972.1, AB828004.1, KX587997.1), KoRV-E

677 (KU533853.1), KoRV-F (KX588025.1, KX588028.1, KX587994.1, KU533852.1), KoRV-G

678 (KX587961.1 and KX587998.1), KoRV-H (KX588036.1 and KX587979.1), and KoRV-I

679 (KX587976.1 and KX588021.1) using ClustalW alignment programme. Moreover, four other

680 sequences were used as outgroups to root the KoRV phylogeny: two Gibbon ape leukaemia virus

681 (GALV) sequences, (KT724047.1, KT724048.1) and two *Melomys burtoni* retrovirus (MbRV)

682 sequences (KF572486.1, KF572485.1). Alignments were further edited by hand to fill the blanks at the

683   beginning and end. Phylogenetic tree was determined from the aligned reads using the Geneious plugin
684   of MrBayes 3.2.6.

685   **File 5:** The read count of unique KoRV *env* sequences from PCR and next-generation
686   sequencing of individual koala DNA and RNA samples.

687   **File 6:** The relative percentage of each subtype of KoRV *env* gene in individual DNA and RNA
688   samples of koalas.

689   **File 7 (figure) 7:** Pecentage abundance of each major subtype of KoRV (A, B, Combined D, I) in
690   the DNA of individuals compared with disease status (Healthy, Neoplasia, Oxalate Nephrosis,
691   Chlamydiosis). Median and interquartile range displayed.
