Abstract. A fully coupled non-linear effective stress response finite difference (FD) model is built to survey the counter-intuitive recent findings on the reliance of pore water pressure ratio on foundation contact pressure. Two alternative design scenarios for a benchmark problem are explored and contrasted in the light of construction emission rates using the EFFC-DFI methodology. A strain-hardening effective stress plasticity model is adopted to simulate the dynamic loading. A combination of input motions, contact pressure, initial vertical total pressure and distance to foundation centreline are employed, as model variables, to further investigate the control of permanent and variable actions on the residual pore pressure ratio. The model is verified against the Ghosh and Madabhushi high acceleration field test database. The outputs of this work is aimed to improve the current computer-aided seismic foundation design that relies on ground's packing state and consistency. The results confirm that on seismic excitation of shallow foundations, the likelihood of effective stress loss is greater in deeper depths and across free field. For the benchmark problem, adopting a shallow foundation system instead of piled foundation benefitted in a 75% less emission rate, a marked proportion of which is owed to reduced materials and haulage carbon cost.

Keywords: Liquefaction; dynamic; Finite Difference; effective stress; surcharge; non-linear; carbon

1. Introduction

Liquefaction in the context of high - $r_u > 60\%$ after Seed (1987) - pore water pressure induced volumetric deformations is likely to occur in particulate materials including ground rock and mining wastes (James *et al.*, 2011), clean sands and silty sands. Implications of liquefaction in urban settings are floatation - predominantly in underground structures (Chian *et al.* (2014); Sawicki and Mierczyński (2015)) and excessive settlements (Romeo *et al.* 2015). Seismic actions are often sourced from the inertia loads in onshore wind turbines in the event of emergency stop, traffic loads in maglevs (Wichtmann *et al.*, 2004) as well as high speed rails (Naeini and Gholampoor, 2014). Wind turbines, a source of dynamic actions, are attracting increasing interest in the light of legally binding greenhouse gas emissions plans. As an example, the development of onshore wind farms in the UK is expected to continue to year 2020 with an aim to supply over 10 per cent of electricity annually (Simpson, 2013). Planned and built turbines are widely distributed across the country, mostly coastlines and quaysides which are covered with saturated sand alluvium superficial drifts, a ground type which can potentially experience liquefaction under transient loads from turbines. For the renewable energy infrastructure together with the newly planned rail transport infrastructure to be developed in the years to come, the ground engineering practice needs to seek sustainable solutions to deliver a safe design while contributing to emissions reduction pledges. One simple strategy is to explore the opportunity of using gravity bases rather than deep foundations (and stone columns). To do so, revisiting the risk assessment methods and enhancing our understanding of controlling factors of liquefaction is an ambitious, yet promising aim.

Cyclic shearing of saturated sands results in grain rearrangement and irrecoverable volume contraction under constant confining stress, which leads to pore pressure buildup and ultimately a loss in shear strength. Recent works suggest a reverse relationship between permanent overhead loads and liquefaction induced subsidence (Bertalot and Brennan, 2015). With pore pressure building up, the effective stress acting on grains tends to zero, while pore pressure tends to the initial confining pressure. A variation in the stress state affects both the strength and stiffness of soil. Particularly at large strains, K and G decrease and as such modulus reduction G/G_{max} and damping $D\%$ factors are best to be incorporated in design in nonlinear frameworks. Nonlinear soil response models have been practiced since the mid-1970s and benefitted in bringing in the pore pressure development into analysis. Adoption of nonlinear analysis is in particular useful (Wang *et al.*, 2013) when soft soils are assessed under seismic excitation. A number of commercial computer codes take into account soil nonlinearities, although these generally lack in not employing advance constitutive models, including isotropic-kinematic hardening constitutive, hypo-plastic, or incrementally nonlinear models. Good recent contributions include the works of Abate *et al.* (2007) and Abate *et al.* (2008), in which a simple isotropic-kinematic hardening constitutive model was embedded into a commercial code and practical implications were evaluated thereafter- see Abate *et al.* (2010) and Maugeri *et al.* (2013). The advanced constitutive formulations, however, from a practical standpoint, often lack in being couched in part due to their association with specific laboratory tests. Finn model is one simple well-established formulation that incorporates irrecoverable volume-strains ($\Delta\varepsilon_{vd}$) versus cyclic shear-strain amplitude equations into the M-C failure criterion (Martin *et al.*, 1975; Wang *et al.*, 2013).

Identification of the potential of liquefaction and prediction of resulting ground displacements have long been subjects of much research with a suite of shortfalls remained yet to be filled. Disputed matters include the confining stress threshold to which a soil may liquefy, and hence the cost of employing an appropriate amelioration strategy to that critical depth. The soil's liquefying depth is often reported as low as 15m (Steedman *et al.*, 2000; Youd *et al.*, 2001), making piled foundation a viable structural solution; particularly in regions of moderate to high seismicity. A better understanding of the liquefaction mechanism can contribute to the sustainability of ground works and specifically in the adoption of foundation type. For a benchmark problem, dynamic pore pressure calculations is performed employing Finn model within 10 scenarios including 5 acceleration time histories and 2 action combinations (i.e. permanent and variable loads). The performance of the employed plasticity model is examined through comparing measured and predicted pore pressure values gained by a published high acceleration test as a measure of liquefaction risk.

2. Benchmark Problem

The study area is a wide lowland, with moderate seismicity (design peak ground acceleration of 0.3g as recommended by national regulations) along the Caspian Sea coast comprised of deep profiles of clayey silty sand drifts, with water standing at 1mbgl. Ground conditions and characteristic material properties are summarized in Table 1 and Fig. 1.

† Ground properties used as input model parameters are listed in Column 5 'Characteristic parameters' (upper drift)

For the purpose of analysis, five acceleration time histories were adopted (as detailed in Section 3). Baseline-corrected response spectra graphs are illustrated in Fig. 2.

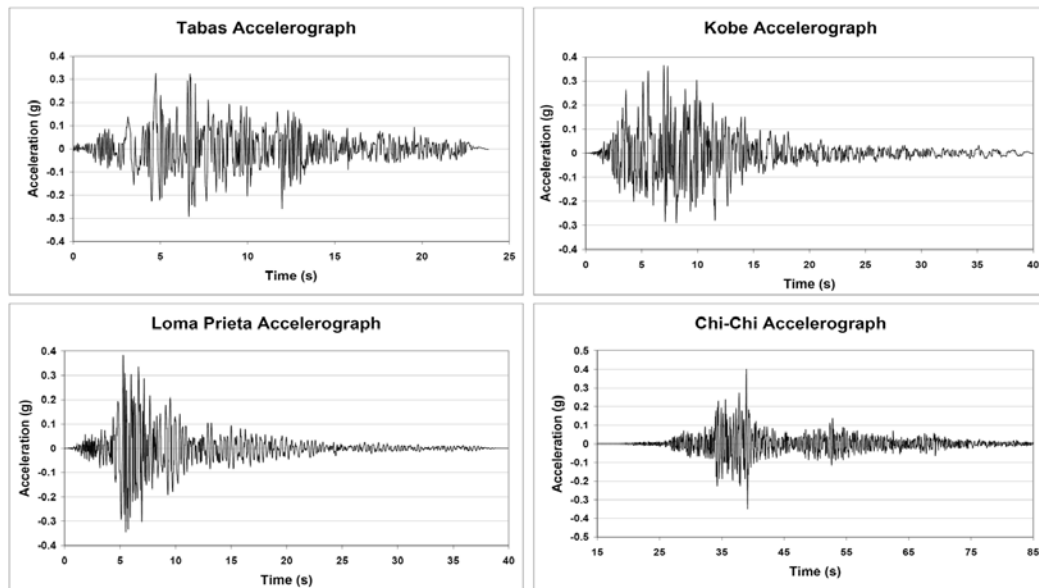

Fig. 2 Baseline-corrected acceleration series

3. Model development

3.1 Soil, Structure, and Soil-Structure Interface

The benchmark problem is modelled using the computer code FLAC - Fast Lagrangian Analysis of Continua (Fig. 3). A 5.5m × 2.0m beam element of 1.5E+8 kN.m² bending stiffness (i.e. linear elastic) is used to model the mat foundation under plane strain conditions, which supports the 4-storey super structure with a contact pressure of 40 kPa. The non-linear response of soil is simulated using the plastic Mohr-Coulomb constitutive relationship, and 4-noded 1-to-2m width soil elements. Pore water pressure buildup and dissipation are simulated using the Finn model. Maximum element size is set at 2m (i.e.

approximately smaller than one-tenth to one-eighth of the wavelength associated with the highest frequency of input wave – see Kuhlemeyer and Lysmer (1973)). The soil-structure interface is modelled using a linear spring-slider system with M-C failure shear strength criterion as 2D plain strain elements of equal normal and tangential stiffness (set to equivalent stiffness of adjoining soil element in the normal direction – see Eq. 1).

$$K_{n(max)} = K_{s(max)} = 10 \times \text{Max} \frac{K + \frac{4G}{3}}{\Delta Z_{min}} \quad (1)$$

where ΔZ_{min} is the smallest dimension of an adjoining zone in the normal direction, K is the bulk modulus of soil and G is the shear modulus of soil.

(a) (b)

Fig. 3(a) Model layout: free-field conditions applying to side boundaries; 3(b) Artistic view of the superstructure on piles (3D scheme)

3.2 Soil constitutive model

The elastic-perfectly plastic Mohr-Coulomb (M-C) constitutive model is adopted to simulate the nonlinear soil behavior under monotonic loading (i.e. gravity) conditions. The M-C model used is based on plane strain conditions and effective stresses. For the subsequent dynamic analysis however, in order to take into account the broadly-agreed increase in pore water pressure on mechanical dynamic loading, the Finn effective stress plasticity strain-hardening with non-associated flow rule model (i.e. formulations embedded in FLAC 2D through the User-Defined Model feature) is adopted. The model is credible for fine granular saturated geomaterials with a relative density of <80%. A hyperbolic relationship is assumed between shear stress and strain, using a flow rule based on the stress ratio ($\eta = \tau/\sigma'$), where τ and σ' are the shear and normal effective stresses on the plane of maximum shear stress, respectively. The model considers the developed pore pressure per cycle as a function of the plastic volumetric strain, rebound soil modulus and pore fluid stiffness. A detailed account of the model calibration against laboratory tests is given in Section 3.4.

The elastic component of soil response is set to be isotropic and characterized by G^E (shear modulus) and B^E (bulk modulus) as detailed in Equation 2.

$$\begin{aligned} G^E &= K_G^E \cdot P_a \cdot \left(\frac{\sigma'}{P_a} \right)^{ne} \\ B^E &= \alpha \cdot G^E \end{aligned} \quad (2)$$

$$\text{where} \quad K_G^E = \frac{\Delta P_f}{\Delta \varepsilon_v} = \frac{\Delta P_f}{8.7 N_{160}^{-1.25} \cdot \left(\gamma - \frac{0.4}{8.7 N_{160}^{-1.25}} \varepsilon_v \right) + \frac{C_3 \varepsilon_v^2}{\gamma + C_4 \varepsilon_v}} \quad (3)$$

Where $\Delta \varepsilon_v$ is the increment of volume decrease, C_3 and C_4 are constant values and ΔP_f is the total pressure.

Upon the first time shear loading, yield surface forms as a function of the current stress state. With

increasing shear stress, the yield surface expands (strain-hardening), inducing plastic shear and volumetric strains. Equation 4 shows the relevance of plastic shear strain increment $d\gamma^p$, with variation in shear stress ratio $d\eta$.

$$d\gamma^p = \frac{1}{G^p/\sigma'} \cdot d\eta \quad (4)$$

in which the plastic shear modulus, G^p , is a hyperbolic function of stress ratio $\eta = \tau/\sigma'$ and γ^p ,

$$G^p = G_i^p \cdot \left(1 - \frac{\eta}{\eta_f} R_f\right)^2 \quad (5)$$

and R_f is the failure ratio of a value 0.7 to 0.98 in order, inversely proportional to the relative density, and η_f is the stress ratio at failure.

The associated increment of plastic volumetric strain, $d\varepsilon_v^p$, is expressed as a function of plastic shear strain increment, $d\gamma^p$, through the flow rule in Equation 6.

$$d\varepsilon_v^p = \left(\sin\phi_{cv} - \frac{\tau}{\sigma'}\right) \cdot d\gamma^p \quad (6)$$

in which ϕ_{cv} is the critical state friction angle. Depending on the ϕ_{cv} , plastic volumetric strain may be either contractive or dilative: for a stress ratio representing a friction angle less than ϕ_{cv} , a contractive behavior could be expected, whereas for $\phi > \phi_{cv}$, soil tends to dilate.

3.3 Model verification

Numerical effective stress modelling needs to be verified experimentally using soil models, which are representative of field stress state. To replicate the ground stress conditions at laboratory scale, base motion can be simulated on prototypes under a $>1g$ acceleration field. The measured timed-trend of excess pore water pressure - by the high acceleration field test - in Ghosh and Madabhushi (2004) is compared with the predicted figures gained by the simulated test model to ensure the consistency. Measured and predicted figures are presented in Fig. 4 for a saturated dense sand soil at the depth of 4.5mbgl, subjected to an acceleration field of 50g under a 150kPa surcharge.

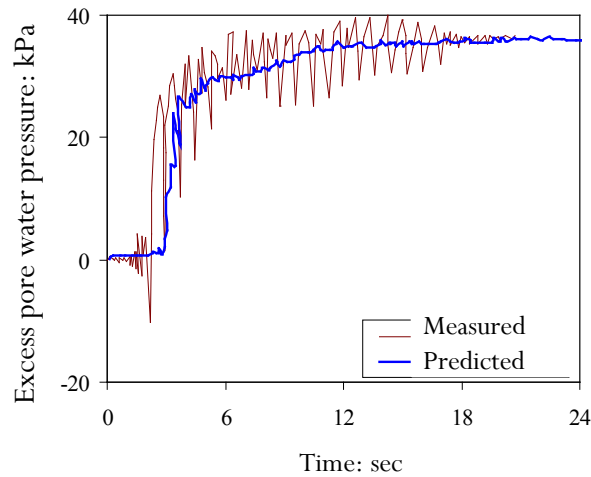

Fig. 4 FLAC predicted excess pore pressures versus experimentally measured figures after cyclic shearing simulation in Ghosh and Madabhushi (2004)

4 Results and Discussion

Each model is subjected to five input ground motions, including a sequence of scaled versions of components of the Loma Prieta (1989), Tabas (1978), Northridge (1994), Chi-Chi (1999), and Kobe (1995).

For the impact of surcharge on liquefaction to be determined, the risk is once measured against depth (at 6 points below ground level) at varied distances from the loaded area, and once for varied surcharge values. To measure the risk, the pore pressure ratio r_u (i.e. normalized excess pore pressure against the initial effective overburden stress) of 0.7 is set threshold beyond which liquefaction is probable. r_u is

plotted against depth beneath the centerline of the loaded area, beneath the boundaries of the loaded area, and at a distance from the loaded area. Frequency cut-off is set at 5Hz (i.e. low pass filter) for a 5% damping ratio. Two load combinations are considered for each of the input time histories: un-factored permanent action (G), and combined permanent (G) and variable actions (Q). Time histories of effective stress against depth under foundation centerline, foundation boundary and the free ground are captured for two load combinations are plotted in Fig. 5.

Fig. 5(a) Time history of effective stress – Chi Chi scenario

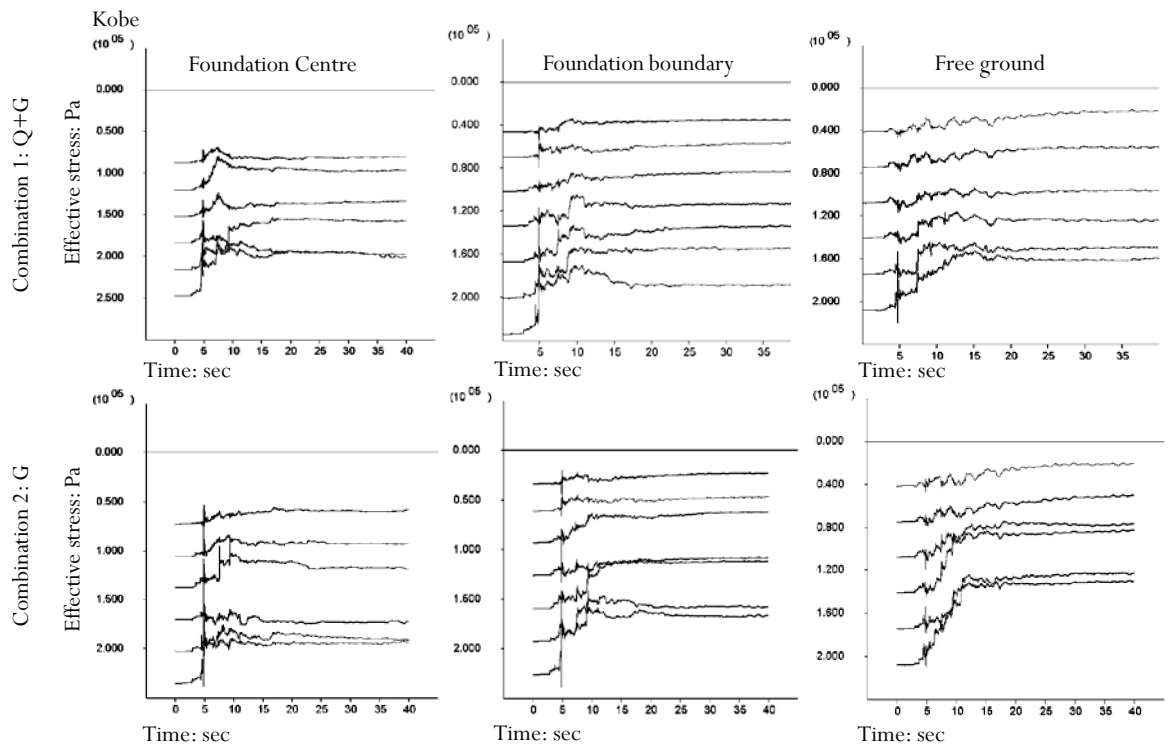

Fig. 5(b) Time history of effective stress – Kobe scenario

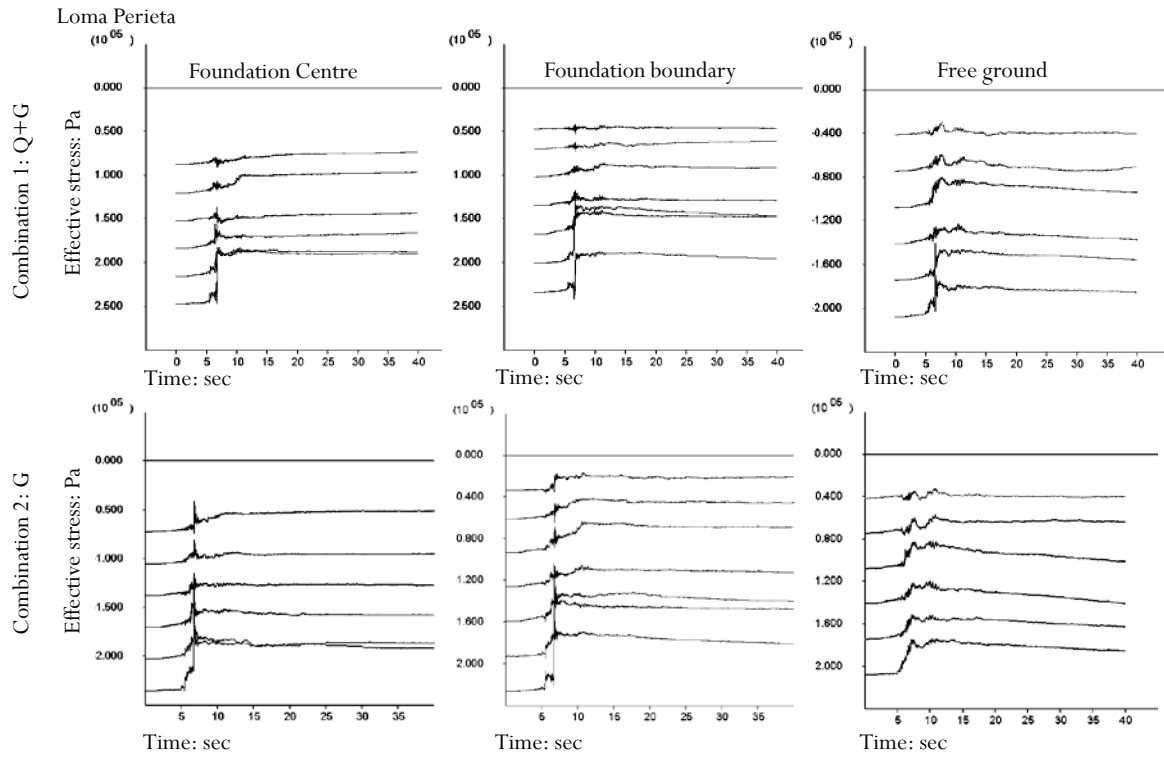

Fig. 5(c) Time history of effective stress – Loma Perietá scenario

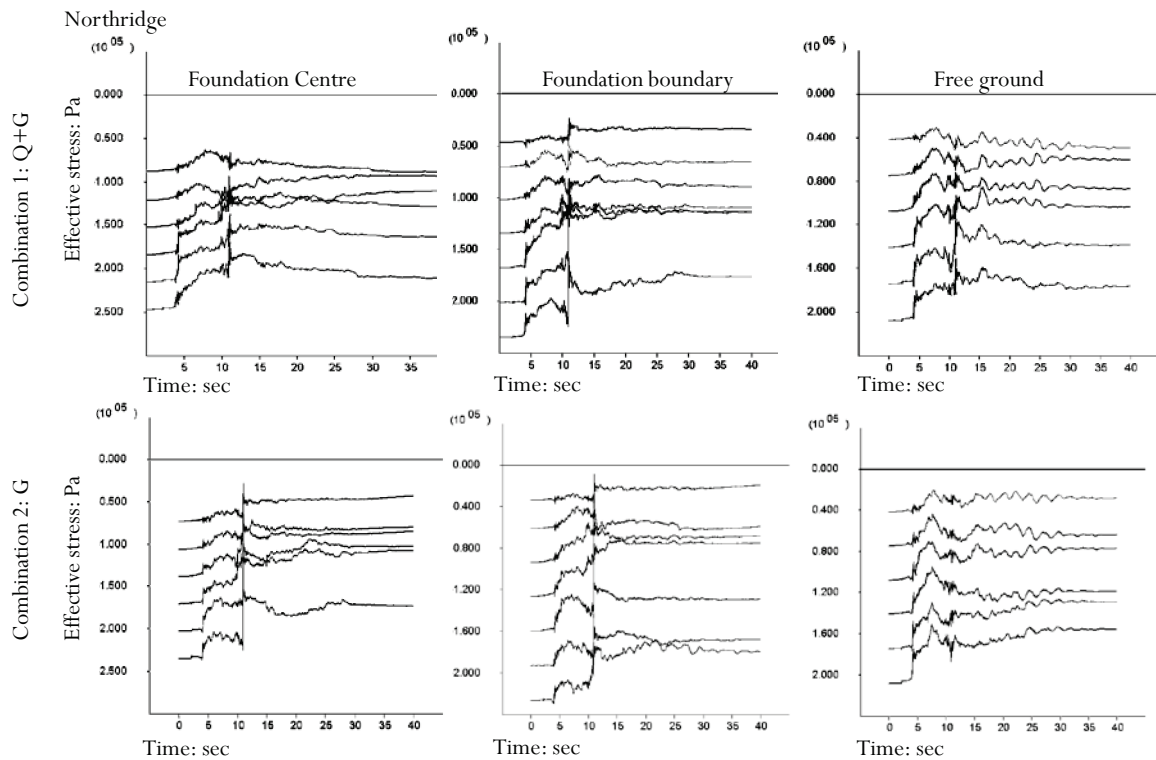

Fig. 5(d) Time history of effective stress – Northridge scenario

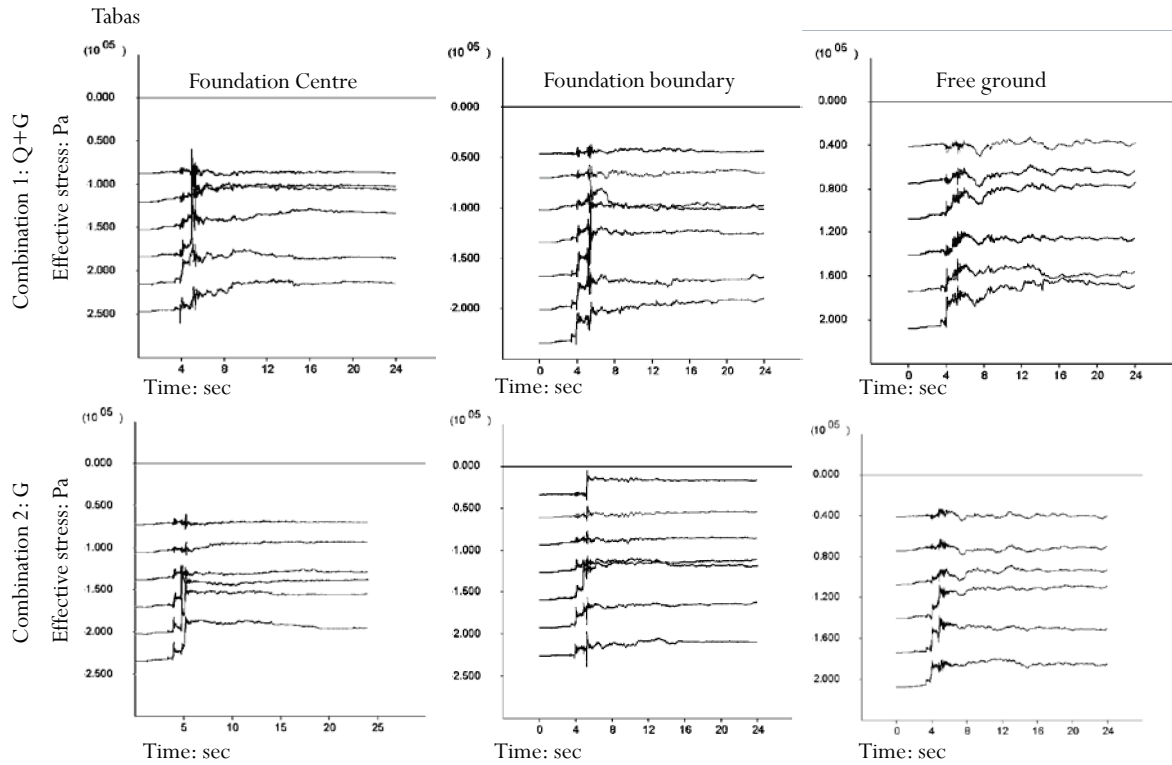

Fig. 5(e) Time history of effective stress – Tabas scenario

A suite of observations are made through examining the timed effective stress trends (Fig. 5) for the six input motions: Upon seismic excitation of shallow foundations, the likelihood of the loss in effective stress is found to be greater in deeper depths. For surcharged areas, the loss in effective stress terminates as the amplitude decreases from its early maximum order. For free field, however, the loss in effective stress continues irrespective of the magnitude of the motion amplitude.

In Fig. 6 and Fig 7, the pore pressure is plotted against the depth for both loading combinations. An $r_u = 0.7$ is set as the threshold for liquefaction. The relatively lower residual pore pressure ratio captured immediately beneath the foundation is in agreement with the work of Andrianopoulos et al. (2006). The analysis suggests a reduction in r_u for regions within the influence zone of bearing pressure. Risk of liquefaction decreased with an increase in surcharge pressure (combination 1 G+Q) and for points closer to the centreline of the foundation (Fig 4a comparing with Fig 3b). This is generally in agreement with recent findings of Bertalot *et al.* (2013), which was predominantly based on collated field data. Findings at this stage may suggest the use of spread foundations with a fairly good degree of certainty should the ultimate and serviceability limit states are satisfied.

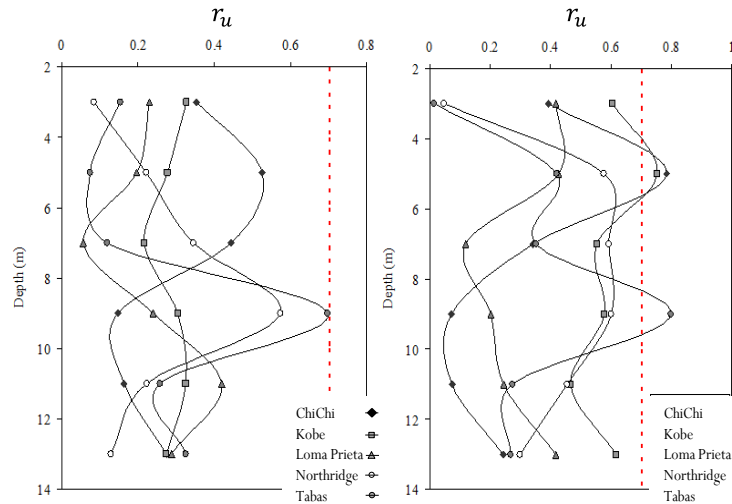

Fig. 6 Pore pressure ratio - Combination 1 G+Q: dashed line indicating liquefaction risk threshold (a-left) free ground (b-right) beneath foundation edge

Fig. 7 Pore pressure ratio - Beneath the centreline of foundation: dashed line indicating liquefaction risk threshold (a-left) Combination 1 G+Q (b-right) Combination 2 G+0

A total number of 41 ‘type A’ piles combined with 19 ‘type B’ piles were initially recommended to mitigate the risk of liquefaction. Piles were designed to act as single elements and were designed to be capped with an 80cm thick slab of c.840 m² area (Fig. 8). Through non-linear dynamic analysis, surcharge is deemed to reduce the liquefaction potential, whereby soil beneath the structure shows admissible levels of risk for amplitudes of horizontal input sine waves of 300 gal, $a_{max}=0.3g$ with a frequency of 5 Hz. Thereby, a 1m thick mat foundation with four layers of Fi20@20cm c/c could replace the designed piled system and satisfy state limits (predicted lateral and vertical displacements edging below 30mm).

The consequent reduction in carbon footprint is quantified using BS EN 15804 (2013), indicating that the alteration could contribute to embodied carbon emission limitation at a rate of 0.91 KgCO₂ e/kg for reinforcing steel combined with 0.17 kgCO₂ e/kg for C50 concrete.

Fig 8. Layout of piled foundation: dark hatched circles represent type 'B' piles while blue hatched circles represent type 'A' piles

For a reduced workforce (and bus roundtrips), material (rebar, concrete, etc), energy (Diesel, network electricity), machines, and for similar freight distance, road type, mobilization and demobilization ratio (0.3%) and waste ratio (0.3%), the European Federation of Foundation Contractor (EFFC) and Deep Foundation Institute (DFI) methodology is used to compare the carbon footprint of the benchmark problem for piled and spread mat foundation types.

Fig. 9(a) and Fig. 9(b) show the carbon footprint of piled and spread foundations, respectively. The significant reduction in GHG from 1,400 to 460 tCO₂e is mainly associated with materials (a reduction from 1,157 to 392 tCO₂e) and freight (from 161 to 46 tCO₂e).

Materials	1,200 tCO₂e
Concrete / Slurry / Grout	910 tCO ₂ e
Steel	180 tCO ₂ e

5. Conclusions

Results of a seismic vulnerability survey of a benchmark 4-storey building on a liquefiable soil have been presented and critically discussed. The Finn strain-hardening plasticity model with non-associated flow rule is adopted to take into account the excess pore water pressure build-up on seismic excitation. Excess pore pressure measurements from a series of models suggested that, upon seismic excitation of shallow foundations, the likelihood of the loss of effective stress is greater in deeper depths and across free field. In addition, the likelihood of reaching a state of liquefaction is inversely proportional to foundation contact pressure. Beneath shallow foundations, the loss of effective stress terminates as the amplitude decreases from its early maximum order. For the surveyed benchmark problem, the commonly practiced risk assessment showed a moderate-to-high potential of liquefaction and the necessity for implementation of 900m of drilling to cast 15m long 1.5-2.0m in diameter reinforced concrete piles. However, through taking into account the impact of dead surcharge in analysis and the Finn constitutive model, the original scheme was altered to a 1-m thick mat foundation. That alteration in design benefitted in a 75% drop in the emission rate, a marked proportion of which was on reduced materials and haulage carbon cost.

List of Notations

R_u	Excess pore water pressure ratio
K_G^E	Elastic shear modulus
B^E	Elastic bulk modulus
P_a	Atmospheric pressure
ne	Coefficient between 0.4 to 0.6
ϕ_{cv}	Constant volume angle of friction
N_{160}	Modified blow SPT number
G_i^p	Plastic modulus at stress ratio η tending to zero

η_f	Stress ratio at failure
R_f	Coefficient between 0.7 to 0.98, inversely proportional with relative density
W	Water content
E_d	Dynamic modulus of Elasticity
E_s	Static modulus of Elasticity
D	Diameter of grains
e	Void ratio
ϕ'	Peak drained angle of friction
C'	Effective cohesion
γ	Unit weight
ν	Poisson's ratio
ε_v	Volumetric strain
τ	Shear stress
σ'	Effective normal stress
mbgl	Metre below ground level
mAOD	Metre above ordnance datum
