Abstract

Objective

To investigate the relationship between cerebrospinal fluid (CSF) β -amyloid peptide (A β 42) and CSF Tau in a large population of patients referred to memory clinics for investigation of cognitive dysfunction.

Methods

We analyzed Alzheimer's disease (AD) biomarkers in CSF taken from 3565 patients referred to 18 French memory clinics. Patients were classified into four profiles according to levels of CSF biomarkers (A: amyloidosis, N: neurodegeneration). The association between CSF Tau and CSF A β 42 were analyzed using general linear regression models, in the overall population and stratified by biomarkers profiles. We compared linear and quadratic models using Akaike information criterion. We also assessed change in biomarker profiles in a subset of patients who had 2 assessments of biomarkers.

Results

CSF Tau was negatively associated with CSF A β 42 in the overall population, following a non-linear quadratic model. However, the nature of this association was different in the 4 profiles: positive association in A-N- profile, negative association in A-N+ and A+N+ profiles, lack of association in A+N- patients. When considering patients with longitudinal data on profiles, 36% of those initially classified as A-N+ evolved to an A+N+ profile.

Conclusions

The nature of the association between CSF A β 42 and CFS Tau depends on the A/N profiles of patients. These results suggest an increase in CSF A β 42 early in the disease before its decline while tau pathology progresses, this pattern is particularly observed in non-APOE4 subjects. This phenomenon may explain why some patients with neurodegeneration only markers convert to an AD profile (A+N+) over time.

Introduction

Alzheimer's disease (AD), the most common cause of dementia, is neuropathologically characterized by extracellular β -amyloid peptide (A β 42) deposits, neurofibrillary tangles composed of intraneuronal abnormally phosphorylated Tau, and neuronal and synaptic loss [1]. According to the "amyloid cascade" hypothesis [2], extracellular accumulation of A β is the first step, successively followed by deposits of neurofibrillary tangles, neuronal death and finally the clinical onset of symptoms [3]. A competing hypothesis is that neurofibrillary tangles appear first, particularly in sporadic AD [4, 5].

The development of AD biomarkers during the past decade allows new opportunities for studying the in-vivo kinetics of amyloid and tau lesions [6, 7]. Cerebrospinal fluid (CSF) measurement of A β 42 has been shown to be inversely correlated with total brain A β load [8], while CSF tau levels positively correlated with the presence of neocortical neurofibrillary tangles [9]. Based on the amyloid hypothesis, a temporal chronology of AD biomarkers has been proposed [10], and in 2011 the National Institute on Aging-Alzheimer's Association (NIA-AA) proposed biomarker based recommendations for the staging of preclinical AD [11]. Using evidence of amyloidosis (A) and neurodegeneration (N), Stage 1 corresponds to presence of A β deposits and the absence of neurodegeneration (A+N-), while stage 2/3 corresponds presence of both markers (A+N+), without or with subtle cognitive decline. One year after the publication of the NIA-AA recommendations, Jack et al. reported an additional category of subjects, characterized by positivity for only neurodegeneration markers (A-N+) and proposed the designation of SNAP, for Suspected Non-Alzheimer's disease Pathophysiology for these subjects [12].

The concept of SNAP (A-N+) remains the subject of debate [13]. Several studies have shown accelerated cognitive decline in these persons [14–17], with poorer clinical prognosis than A+N- subjects [18]. However, other studies found no differences between SNAP and A-N- subjects in cognitive decline, while the A+N- and A+N+ groups declined faster [19–21]. It is worth noting that the precise biomarkers used to define SNAP remains heterogeneous across studies, some use CSF Tau or phosphorylated Tau, or T1-weighted structural MRI, and/or FDG PET imaging data.

CSF allows assessment of both A β 42 and Tau, the hallmarks of AD, but their relationship remains poorly understood. A recent study based on data on 766 subjects from 3 independent cohorts found a non-linear quadratic association between CSF Tau and A β 42 [22]. In the present study, we aim to extend these analyses using data on 3,565 patients in order to cover a wide spectrum of AD pathology. We test the hypothesis that the nature of the association between these biomarkers depends on the AD "profile" of patients. In further analysis on patients who had 2 lumbar punctures we analyzed the longitudinal change in biomarkers profiles to test the hypothesis that persons initially classified as SNAP may evolve to an AD profile.

Methods

Subjects

Following national recommendations, CSF analyses are routinely undertaken in patients with cognitive signs referred to hospital-based memory centers in France [23, 24]. For the present study, CSF biomarkers from 18 hospitals in and around Paris, France, were aggregated in one biochemistry department. All patients seen between January 1st 2008 and January 1st 2018 for whom AD biomarkers from CSF were available were included in the analysis; methods and characteristics of the population have been previously reported elsewhere [25, 26]. The study was approved by the Ethical Committee of Paris University Hospitals. Patients under legal protection were excluded. Written consent was signed in priority by the patients, and in case of inability to sign, by their caregivers. The consent procedure was approved by the local ethical committee.

CSF analysis

Lumbar puncture was performed on patients in a fasting state, typically between 9 and 12 am. All centers used the same model of 10 mL polypropylene tube to collect CSF (January 2008 to November 2012: CML model TC10PCS; December 2012 to January 2018: Sarstedt catalog no. 62.610.201). CSF samples were centrifuged at 1,000 g for 10 minutes at 4°C within 4 hours of collection, and then aliquoted in 0.5 mL polypropylene tubes and stored at -80°C for further analysis. CSF levels of A β 42, total Tau, and pTau-181 were measured with the commercially available sandwich ELISA INNOTEST, using the manufacturer's procedures (Fujirebio Europe NV, formerly Innogenetics NV). The Alzheimer's Association quality control program for CSF biomarkers validated the quality of CSF evaluations of the hospital biochemistry department [27].

Profiles based on CSF biomarkers

The CSF biomarker profiles were used to determine the "profile" of every subject using the NIA-AA staging framework [11]. The amyloidosis profile (A+N-) was characterized by a low level of CSF A β 42 and normal levels of CSF Tau and CSF p-Tau 181. The amyloidosis combined with neurodegeneration profile (A+N+) was defined by a low level of CSF A β 42 and increased level of CSF Tau and/or CSF p-Tau 181. Subjects with high levels of CSF Tau and/or CSF p-Tau 181 but normal A β 42 were classified as SNAP (A-N+). Those with normal levels of all three biomarkers were classified as "normal" (A-N-).

In this study we chose not to use the recently proposed A/T/N classification [18, 28] as we have previously showed that some profiles (A-T+N-, A+T+N-) were quite rare, representing less than 1% of the sample [25]. Furthermore, in our data CSF Tau and CSF p-Tau 181 were highly correlated (Spearman coefficient correlation = 0.84, $P < 0.001$).

Abnormal values of CSF biomarkers were defined using thresholds used routinely in clinical practice based on higher Youden index in order to discriminate AD patients from non-AD patients (i.e. best compromise for sensitivity and specificity). The type of the polypropylene tube changed in November 2012, and the ELISA INNOTEST sandwich changed on May 1st 2016, requiring adjustment of thresholds at these 2 dates. The cut-offs for CSF A β 42, Tau and p-Tau 181 moved respectively from 500/300/65 pg/mL [29] to 730/300/58 pg/mL [25] after the change of tube.

Covariates

These included age, sex, and performance on the 30-item Mini Mental State Examination (MMSE) for an assessment of general cognitive status. APOE ϵ 4 status was known for a subsample of 1034 individuals.

Statistical analysis

Participant characteristics were presented overall and by profiles defined using NIA-AA CSF biomarkers (A-N-, A+N-, A+N+, A-N+). Proportions were calculated for categorical variables, while means and standard deviations were computed for continuous variables. Differences as a function of profiles were assessed using a χ^2 test or Student t-test as appropriate.

The association between CSF Tau and A β 42 was examined using general linear regression models with CSF A β 42 as the dependent variable (PROC GLM of SAS). The analysis was initially adjusted only for the type of collection tube (unadjusted model), and then further adjusted for age, sex, and APOE ϵ 4 status. Analysis were first undertaken in the total sample and then stratified by the 4 profiles (A-N-, A+N-, A+N+, A-N+). The difference in the association between CSF Tau and A β 42 in the 4 profiles was tested formally using interaction terms in the linear regression models.

We compared the linear model (A β 42 = α + β x Tau) to the quadratic model (A β 42 = α + β x Tau + γ x Tau²) following the Akaike information criterion (AIC), with lower AIC values designating better model fit [30]. Linear and quadratic models were compared in the overall population and then separately in each profile (A-N-, A+N-, A+N+, A-N+).

In the sub-sample with APOE ϵ 4 data (N = 1034) we examined the association between CSF A β 42 and CSF Tau by first plotting the mean values of CSF A β 42 as a function of deciles of CSF Tau in those with an APOE ϵ 4 allele versus none. These associations were also examined in linear regression analysis, adjusted for collection tube, age and sex, in two groups based on median CSF Tau.

Finally, in persons with 2 lumbar punctures with CSF AD biomarkers, we examined the evolution of their biomarkers profiles to assess conversion in stage of AD pathology.

The CSF biomarkers were not normally distributed and we followed the approach used by other teams by log-transforming CSF Tau and using CSF A β 42 without any transformation in the statistical models [22]. CSF Tau and CSF phosphorylated Tau were highly correlated in our sample leading us to use CSF Tau in the main analyses; use of CSF p-Tau 181 in place of CSF Tau led to similar findings and conclusions.

All p-values were two-tailed and $p \leq 0.05$ was considered statistically significant. Statistical analyses were performed using SAS version 9.3 (SAS Institute, Cary, NC, USA).

Results

CSF biomarker data were available on 3565 persons, assessed between January 1st, 2008 and January 1st, 2018 in one of the 18 memory clinics included in the study. Their characteristics are summarized in Table 1. The mean (SD) age was 69.8 (10.3) years, 50% were women, and the mean (SD) MMSE at the time of the lumbar puncture was 21.7 (6.0). Of the 3565 persons in the sample, 27% had a normal biomarker profile (A-N-), 36% had an AD profile (A+N+), 22% were positive only for amyloid (A+N-), and 15% had the SNAP profile—positive only for neurodegeneration (A-N+). Compared to the normal profile, patients with an AD profile were older, more often women, had a lower MMSE scores and were more likely to carry at least one APOE ϵ 4 allele.

There was an inverse association between CSF Tau and CSF A β 42 when the study population was considered together (β [SE] = -82.1[6.7], $p < 0.001$, Table 2). In analysis stratified by profiles, CSF Tau was positively associated with CSF A β 42 in A-N- subjects (β [SE] = 153.6 [17.7]), and negatively associated with CSF A β 42 among A+N+ (β [SE] = -19.7[7.2]) and A-N+ subjects (-125.2[22.9]), while no significant association was observed in A+N- patients. These associations were robust to adjustment for age, sex, and APOE4 status. The test for

Table 1. Characteristics of the study population, overall and as a function of profiles defined by CSF biomarkers. Profiles are based on CSF Aβ42, CSF Tau, and CSF p-Tau (NIA-AA classification): A-N-: normal levels of all three biomarkers; A+N-: low level of CSF Aβ42 and normal levels of CSF Tau and CSF p-Tau 181; A+N+: low level of CSF Aβ42 and increased level of CSF Tau and/or CSF p-Tau 181; A-N+: high CSF Tau and/or CSF p-Tau 181 but normal Aβ42.

Characteristics	Profiles defined by CSF biomarkers					P value

<https://doi.org/10.1371/journal.pone.0217026.t001>

interaction was highly significant (<0.001) suggesting that the association between CSF Aβ42 and CSF Tau differed in the four profile groups.

Comparisons of linear and quadratic models for the association between CSF Tau and CSF Aβ42 are presented in S1 Table. The quadratic model fitted the data better in the total study population (delta AIC = 43). However, this was not the case in all profile sub-groups as the quadratic model was inferior to the linear model for A-N-, A+N- and A+N+ profiles (delta AIC = -2), and was only better than the linear model in A-N+ patients (delta AIC = 8). The scatter plot of CSF Aβ42 and CSF Tau is presented in Fig 1, in the total study population and in the profiles defined by biomarkers.

Fig 2 shows the mean CSF Aβ42 value as a function of deciles of CSF Tau in APOE4 positive and negative participants. In APOE4 negative subjects, the mean value of CSF Aβ42 increased from the first to the 5th decile of CSF Tau (β[SE] = 49.9[9.9], p<0.001), and then decreased for subjects with higher CSF Tau levels (β[SE] = -83.3[12.5], p<0.001). For APOE4 positive subjects, there was no association between CSF Aβ42 and CSF Tau stable until the 5th decile (β[SE] = -10.6[17.4], p = 0.54), and then decreased for those with higher CSF Tau values (β [SE] = -16.6[8.5], p = 0.05).

Table 2. Association between CSF Tau (log transformed) and CSF Aβ42, linear regression analysis. Profiles are based on CSF Aβ42, CSF Tau, and CSF p-Tau (NIA-AA classification).

Finally, Table 3 presents the evolution of profiles among the 70 patients who had 2 lumbar punctures, over a median follow-up of 2.1 years. Of the 23 patients initially classified as A+N- profile, 61% of them remained A+N- at the 2^d assessment, and 13% of them evolved to A+N+ profile. For the 14 patients initially classified as A-N+ profile, 50% had the same profile and 36% evolved to an A+N+ profile.

Discussion

We report the following findings on the relationship between CSF Tau and CSF Aβ42 in a large, multicentric cohort of 3565 patients assessed for cognitive disorders:

- We confirmed the previously reported quadratic relationship [22] between these 2 biomarkers in the total population not stratified by biomarker profiles.
- Further analysis revealed that the association between CSF Tau and CSF Aβ42 is strongly dependant on biomarkers profiles. This association was positive in those with a normal profile, no association was found in amyloidosis only subjects, and an inverse association in those with SNAP and AD profiles. The association between CSF Tau and CSF Aβ42 was linear and not quadratic when examined separately in each profile group.

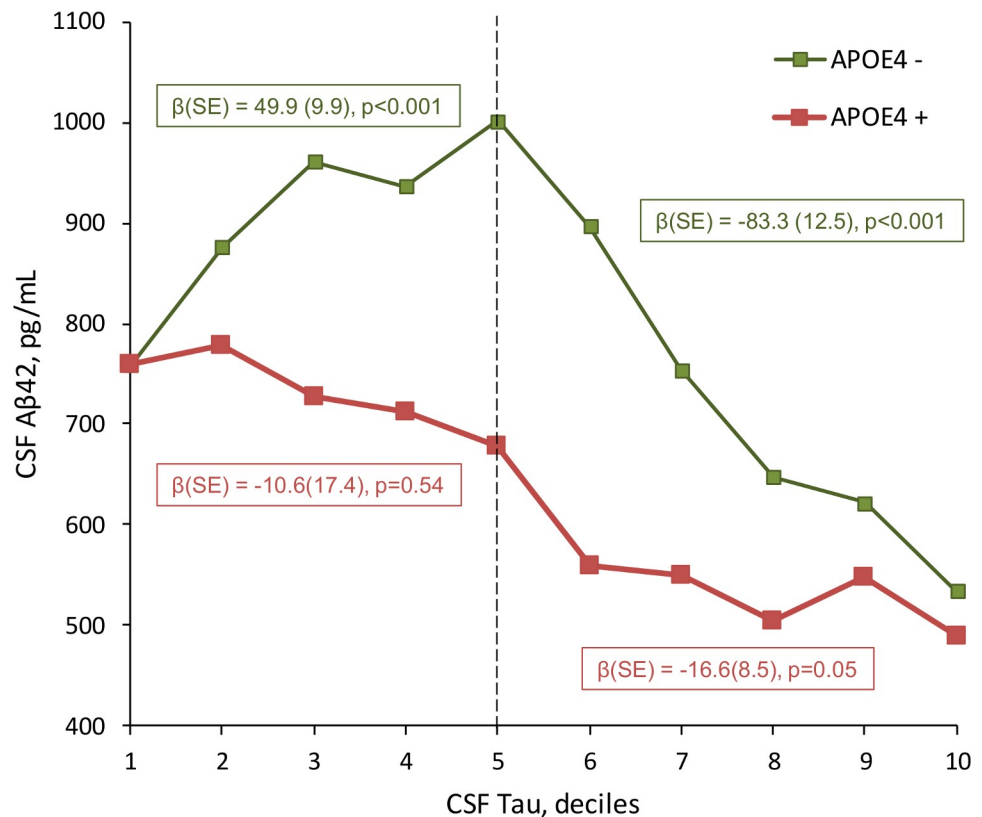

Fig 2. Mean CSF Aβ42 by deciles of CSF Tau, as a function of APOE4 status. Green line: No APOE ε4 allele. Red line: at least one APOE ε4 allele. The linear regression coefficients show analysis between CSF Aβ42 and deciles of CSF Tau are presented by APOE4 status, stratified by the median of CSF Tau.

Table 3. Change over time in profiles defined by CSF biomarkers profiles in 70 patients with 2 assessments of biomarkers. Profiles are based on CSF A β 42, CSF Tau, and CSF p-Tau (NIA-AA classification).

Profile at time 1	Profile at time 2				Total
	A-N-	A+N-	A+N+	A-N+	
A-N-	4 (30)	7 (54)	1 (8)	1 (8)	13
A+N-	5 (22)	14 (61)	3 (13)	1 (4)	23
A+N+	0 (0)	2 (10)	16 (80)	2 (10)	20
A-N+	1 (7)	1 (7)	5 (36)	7 (50)	14

<https://doi.org/10.1371/journal.pone.0217026.t003>

- Analysis of change in biomarkers showed that 36% of those who were initially classified as A-N+ evolved to an A+N+ profile, compared to 13% for those who were initially classified as A+N-.

We propose a theoretical framework to explain these results which suggest two distinct patterns, illustrated by Fig 3. The first pattern is characterized by biomarkers in normal range where level of A β 42 in the CSF increases with level of CSF Tau reflecting early stage of AD. This stage corresponds to an increase in production and/or decrease in degradation of A β 42 in the brain which is still being compensated by an increase in its clearance into the CSF. At some point in disease progression systems responsible for clearing A β 42 from the brain into the CSF become overwhelmed [31] and A β 42 accumulates in plaques in the brain and CSF A β 42 levels decrease while CSF Tau continues to increase to abnormal levels, reflecting the progression of tau pathology. Within this pattern, some A-N+ patients evolve to future AD profile as they are simply in the phase that follows the initial increase of CSF A β 42. This would explain why one third of our patients initially classified as A-N+ finally evolve to an A+N+ profile with biomarkers assessed at the second lumbar puncture. In the second pattern shown in Fig 3, level of CSF A β 42 remains low and stable during the initial progression of Tau pathology (A+N- patients) to the point where CSF A β 42 begins to decrease inversely with CSF Tau (A+N+). Interestingly, these two patterns of change in biomarkers reflect that we found in analyses stratified by APOE4 status; patients without APOE4 allele correspond to the first pattern: initial increase and then decrease of CSF A β 42 with progression of CSF tau, while patients with at least one APOE4 allele correspond to the second pattern: initial stability (A+N-) and then decrease of CSF A β 42 with progression of tau pathology.

The kinetics of CSF A β 42 in very early stages of sporadic AD remains largely unknown. Data from studies on carriers of autosomal-dominant AD mutations,[32, 33] as well as from experimental studies [34], suggest that CSF A β 42 levels increase before and during the early phase of brain amyloid deposition. In their study on biomarker changes in dominantly inherited Alzheimer's disease, Bateman et al. reported that CSF A β 42 levels were higher in persons with autosomal dominant AD 20 to 30 years before the clinical onset of the disease [32], the earliest observed phenomenon associated with AD.

In the recently proposed biological diagnosis of AD based on the A/T/N classification, A-T+ profiles are considered to be non-AD pathologic change [28]. Our findings suggest that this conclusion may need to be tempered in light of our findings that some of these subjects also evolve towards an AD profile. The neuropathological concept of "primary age-related tauopathy" (PART) has recently emerged to characterize the many patients with mainly neurofibrillary pathology and only few or none A β deposits [35, 36]. Whether this condition represents an independent disease remains the subject of debate; several authors have suggested that PART belongs to the AD spectrum, with some patients beginning their disease by an initial spreading of tau lesions that precedes A β accumulation [4, 37]. CSF biomarkers represents an

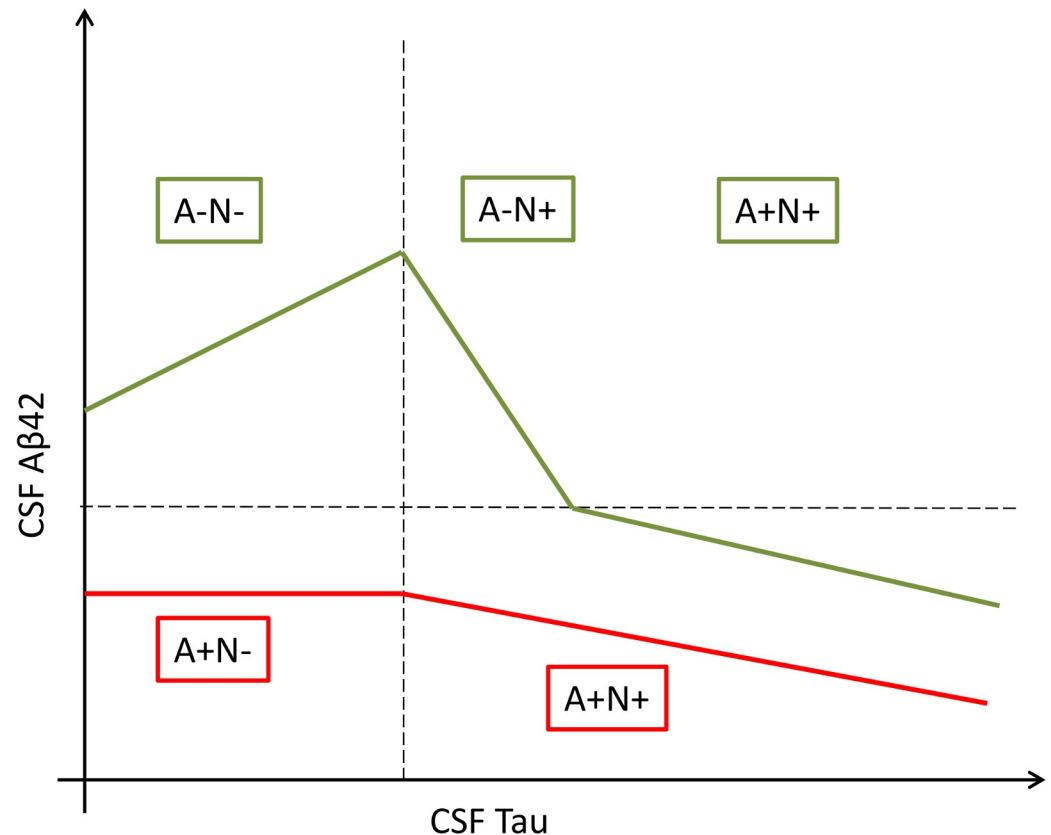

Fig 3. Two distinct patterns: Theoretical framework of the association between CSF A β 42 and CSF Tau. In green, patients with normal profiles have an increase of CSF A β 42 followed by a decrease after the progression of tau pathology. In red, patients with isolated low CSF A β 42 had a stable level before declining.

<https://doi.org/10.1371/journal.pone.0217026.g003>

opportunity to test in-vivo these hypothesis and the fact that one third of our patients initially classified as A-N+ evolved to an A+N+ profile supports this hypothesis. Furthermore, many neuropathological studies have reported that neurofibrillary tangles accumulation is a common feature of ageing [38–40]. Current methods lack sensitivity to detect minimal tangle presence in the entorhinal area and hippocampus, more sensitive methods for tau detection may in the future increase the proportion of A-N+ patients.

This study has several strengths, including its large size which allowed us to cover a wide spectrum of AD pathology, the inclusion of data from 18 memory clinics, and the fact that the analyses of CSF were performed in a single biochemistry department which prevents intersite variability [29]. One of the main limitations is that most of the patients had only one CSF biomarkers assessment, which allows only cross-sectional analysis. We however checked the evolution of biomarkers profiles in 70 patients who had 2 lumbar punctures. Future large scale studies with repeated CSF biomarkers assessments and large duration of follow-up will be helpful to better understand the kinetics of these biomarkers, especially at the early stage of the disease. Another limitation is that the four profiles were defined using CSF biomarkers rather than independent criteria (PET-imaging, neuropathology).

In conclusion, this report describes the relationship between CSF A β 42 and CSF Tau in a large and multicentric population of patients who were referred to memory clinics for further assessment of cognitive disorders. We found that the nature of the association between these biomarkers was dependent of the biomarker based profile of the patients: positive association

in normal profile, negative association in SNAP and AD profiles, lack of association in amyloidosis only subjects. These results plead for an increase of CSF A β 42 early in the disease, before its decline, especially among non-APOE4 subjects. This pattern may explain why some patients with neurodegeneration only markers convert to AD profiles only over time.
