## Abstract

In the circumpolar north (45-90°N), permafrost plays an important role in vegetation and carbon (C) dynamics. Permafrost thawing has been accelerated by the warming climate and exerts a positive feedback to climate through increasing soil C release to the atmosphere. To evaluate the influence of permafrost on C dynamics, changes in

27  soil temperature profiles should be considered in global C models. This study

28  incorporates a sophisticated soil thermal model (STM) into a dynamic global

29  vegetation model (LPJ-DGVM) to improve simulations of changes in soil temperature

30  profiles from the ground surface to 3 m depth, and its impacts on C pools and fluxes

31  during the 20th and 21st centuries. With cooler simulated soil temperatures during the

32  summer, LPJ-STM estimates ~0.4 Pg C yr$^{-1}$ lower present-day heterotrophic

33  respiration but ~0.5 Pg C yr$^{-1}$ higher net primary production than the original LPJ

34  model resulting in an additional 0.8 to 1.0 Pg C yr$^{-1}$ being sequestered in circumpolar

35  ecosystems. Under a suite of projected warming scenarios, we show that the

36  increasing active layer thickness results in the mobilization of permafrost C, which

37  contributes to a more rapid increase in heterotrophic respiration in LPJ-STM

38  compared to the stand-alone LPJ model. Except under the extreme warming

39  conditions, increases in plant production due to warming and rising $CO_2$, overwhelm

40  the enhanced ecosystem respiration so that both boreal forest and arctic tundra

41  ecosystems remain a net C sink over the 21st century. This study highlights the

42  importance of considering changes in the soil thermal regime when quantifying the C

43  budget in the circumpolar north.

44

## 1. Introduction

46      Permafrost is an important control on vegetation and soil carbon (C) dynamics by

47  affecting hydrological and soil thermal conditions in northern high-latitude

48  ecosystems (Wania et al., 2009a; Schaphoff et al., 2013), which account for a large

49    portion of the global C stocks (Hugelius et al., 2014). Recent climate warming has

50    caused significant thawing of the near-surface permafrost across the circumpolar

51    region (Romanovsky et al., 2015), including Alaska (Jorgenson et al., 2006;

52    Osterkamp, 2007), Canada (Camill, 2005), and Russia (Streletskiy et al., 2015).

53    Projected warming over the 21$^{st}$ century is expected to greatly reduce the areal extent

54    of permafrost and seasonally frozen ground (Lawrence et al., 2012). If permafrost

55    thaws, a fraction of soil organic C (SOC) in previously frozen layers will decompose

56    and be released as $CO_2$ and $CH_4$ (Hayes et al., 2014; Walter-Anthony et al., 2014;

57    Olefeldt et al., 2012; Johnston et al., 2014). Furthermore, organic matter

58    decomposition rates in unfrozen soils are sensitive to soil temperatures, which vary

59    non-linearly across the soil column. Therefore, careful consideration of soil thermal

60    regime changes (i.e. soil temperatures across the soil column from surface to deep soil

61    layers) are important when simulating the potential future C loss from soils.

62        In addition to soil C pools, vegetation C pools are also sensitive to changes in soil

63    thermal dynamics by permafrost thaw and rates of associated biogeochemical

64    processes (Euskirchen et al., 2006). Field studies have indicated that permafrost thaw

65    increases aboveground net primary production via increased nutrient availability (e.g.,

66    Schuur et al., 2007). While not explicitly testing the effects of thaw, other model

67    studies have indicated a net C gain in circumpolar ecosystems because increased

68    vegetation productivity more than compensated belowground C losses under a

69    warming climate (Hartley et al., 2012; Koven, 2013). However, this net C gain may

70    be optimistic as the effects of water stress and disturbances (e.g. insect infestations,

71  wildfires) on permafrost-region biomass are not adequately incorporated in current

72  models (Abbott et al., 2016). Thus, large uncertainties currently exist regarding the

73  magnitude and timing of this permafrost-C feedback to the climate system (Schuur et

74  al., 2013), due in part to the complexity of ecosystem C processes in areas of

75  degrading permafrost (e.g., thermokarst, thermal erosion) and their heterogeneity

76  across regions.

77      To date, a number of studies have used process-based land surface models to

78  estimate permafrost-C feedbacks under projected thaw scenarios (Koven et al., 2011;

79  Schaefer et al., 2011; Harden et al., 2012; MacDougall et al., 2012; Schneider von

80  Deimling et al., 2012). Soil thermal dynamics within these models vary in their

81  complexity, from calculations of the cumulative active layer thickness distribution

82  (e.g., Harden et al., 2012) to more sophisticated parameterizations of soil physics (e.g.,

83  MacDougall et al., 2012). Thaw dynamics are typically considered in a top-down

84  one-dimensional manner, and heat transfer via conduction is the primary mode

85  considered. However, the importance of soil water in non-conductive heat transfer

86  (e.g., latent heat exchange, convection) has long been recognized as an important

87  control on soil thermal dynamics (e.g., Romanovsky and Osterkamp, 2000). In this

88  regard, our recent modeling studies that incorporate interactions between heat and

89  water transport (Jiang et al., 2012a) have shown improvements in simulating the soil

90  thermal regime changes in both tundra and boreal forest ecosystems in the northern

91  high latitudes (Jiang et al., 2015).

92      To provide a better quantification of the ecosystem C budget in northern high

93    latitudes and how this budget may change in the future, we use the

94    Lund-Potsdam-Jena Dynamic Global Vegetation Model (LPJ-DGVM, Sitch et al.,

95    2003; Gerten et al., 2004) coupled with a sophisticated soil thermal model (STM) by

96    Jiang et al. (2012a) to conduct a set of simulations for both historical and future

97    periods. The standard version of LPJ-DGVM has been widely used to simulate the

98    global C budget and its response to climate change (e.g., Sitch et al., 2008). However,

99    the model has used simplified soil temperature parameterizations for high-latitude

100    regions (Sitch et al., 2003). Although later studies by Wania et al. (2009a, b) have

101    taken steps to improve soil thermal and hydrologic parameterizations for permafrost

102    conditions in northern peatlands, soil temperature and water dynamics are still

103    modeled separately. As a consequence, the modeled active layer thickness exhibits

104    poor agreement with observations (Wania et al., 2009b). Moreover, the effects of the

105    vertical soil C distribution on decomposition have not been considered. In an

106    extended LPJ, which includes managed land (LPJmL), Schaphoff et al. (2013) have

107    recently coupled the interactions of soil water and heat transport, and considered

108    vertically differentiated soil C stocks based on an organized soil C dataset in Jobbagy

109    and Jackson (2000). However, the discrete vertical differentiation of the soil

110    temperature profile in LPJmL is relatively coarse and the vertical distribution of SOC

111    down to 3 m is highly concentrated in the uppermost soil layers (e.g., 0-20 cm) and

112    does not consider long-term SOC accumulation in deep soil layers (Hugelius et al.,

113    2014).

114        In this study, we integrate STM into LPJ to improve simulations of soil

115    temperature dynamics from the ground surface to a depth of three meters, and the

116    consequent impact on soil organic C stabilization and release across the northern

117    permafrost region. Because the newly coupled version of the model, LPJ-STM,

118    considers a fine vertical differentiation of soil temperatures, interactions of soil water

119    with heat transport, and a vertical distribution of SOC with more C in deeper soil

120    layers, we expect LPJ-STM to provide a more accurate quantification of the C budget

121    for historical periods and to improve projections of carbon dynamics under future

122    scenarios. To examine if LPJ-STM improved estimates of soil temperatures and

123    associated carbon dynamics over LPJ, we compare estimates of both models to site

124    observations of soil temperatures and net ecosystem production (NEP). In addition,

125    simulated atmospheric carbon dioxide concentrations determined by using the model

126    NEP estimates with an atmospheric transport model are compared to atmospheric

127    flask measurements. To examine how improvements in simulated soil thermal regime

128    affect the estimates of the contemporary C budget of northern high latitude

129    ecosystems and its projection into the 21$^{st}$ century, we compare estimates of net

130    primary production (NPP), heterotrophic respiration ($R_H$), and net ecosystem

131    production (NEP) as well as vegetation and soil C stocks between LPJ and LPJ-STM.

132

## 2. Methods

**2.1. Model description**

135    LPJ model simulates large-scale vegetation structure and land-atmosphere C and

136    water fluxes in a modular framework (Sitch et al., 2003; Gerten et al., 2004). In the

137 standard LPJ soil model, two soil layers have a fixed depth (i.e. 0.5 m and 1.0 m). The

138 vertical distribution of soil C within these two soil layers is not explicitly considered.

139 For permafrost thermal dynamics, LPJ calculates soil temperature at a depth of 25 cm

140 in a very simplistic way based on the surface air temperature seasonal cycle with a

141 dampened oscillation about a common mean and with a temporal lag (Sitch et al.,

142 2003). The magnitude of the damping and temporal lag is related to soil texture, and

143 the applied function assumes a sinusoidal variation in seasonal temperatures

144 (Campbell and Norman, 1998). In this study, we replace the existing soil temperature

145 scheme in the original LPJ with STM (Jiang et al., 2012a) to produce the coupled

146 LPJ-STM model. Meanwhile, we modified the hydrology scheme following Wania et

147 al. (2009b) and the representation of soil carbon dynamics following Schaphoff et al.

148 (2013) in the LPJ-STM model.

149

150    2.1.1. Soil thermal dynamics in LPJ-STM

151    While the original LPJ only includes a temperature calculation at a depth of 25 cm,

152 LPJ-STM has a vertical differentiation of soil temperature profile and provides a more

153 complete depiction of soil thermal dynamics, including estimates of active layer

154 thickness (ALT). Here, we estimate ALT using the $0^{o}C$ isotherm line as in Wania et al.

155 (2009b). In LPJ-STM, the top three meters of soil is split into six layers with

156 thicknesses of 10, 10, 10, 20, 50, and 200 cm (Figure 1) that differ with respect to

157 physical and hydraulic properties of boreal forest and tundra sites (Jiang et al., 2012a).

158 These soil layer thicknesses are finer than the five soil layers used by Schaphoff et al.

159 (2013) for the top 3 meters: 20, 30, 50, 100, and 100 cm. In addition, unlike

160 Schaphoff et al. (2013), LPJ-STM divides each of the soil layers into a number of

161 depth-step increments to calculate soil temperatures. From the first to the sixth layer,

162 the number of depth-step increments is respectively 10, 10, 10, 10, 20, and 40. To

163 simulate perennially frozen ground, soil between 3 and 50 m is classified as the

164 seventh layer with soil temperature simulated at 0.5 m depth-step increments.

165      Soil temperature is simulated numerically at each depth step by solving a modified

166 Richards equation (Hansson et al., 2004; Saito et al., 2006). The governing equation

167 for heat transport is as follows:

168
$$\frac{\partial C_p T}{\partial t} - L_f \rho_i \frac{\partial \theta_i}{\partial t} + L_0(T) \frac{\partial \theta_v(T)}{\partial t}$$
$$= \frac{\partial}{\partial z}\left[\lambda \frac{\partial T}{\partial z}\right] - C_w \frac{\partial q_l T}{\partial z} - C_v \frac{\partial q_v T}{\partial z} - L_0(T) \frac{\partial q_v}{\partial z} - C_w S T \qquad (1)$$

169 where $C_p$ (J m$^{-3}$ K$^{-1}$) is the volumetric heat capacity of the soil, $C_w$ is the

170 volumetric heat capacity of liquid water ($4.18 \times 10^6$ J m$^{-3}$ K$^{-1}$), $C_v$ is the volumetric

171 heat capacity of water vapor ($1.2 \times 10^3$ J m$^{-3}$ K$^{-1}$), $\theta_i$ is the volumetric ice content

172 (%), $\theta_v$ is the volumetric unfrozen water content (%), $t$ is time (units), $z$ is depth (m),

173 $T$ is the absolute temperature (K), $\rho_i$ is the density of ice (931 kg m$^{-3}$), $L_0$ is the

174 volumetric latent heat of vaporization of liquid water (J m$^{-3}$), $L_f$ is the latent heat of

175 freezing ($3.34 \times 10^5$ J kg$^{-1}$), $\lambda$ is the apparent thermal conductivity of soil (J m$^{-1}$ s$^{-1}$

176 K$^{-1}$), $q_L$ is the flux density of liquid water, $q_v$ is the flux density of water vapor (m

177 s$^{-1}$), and S is a sink term accounting for root water uptake (s$^{-1}$). While soil

178 temperatures vary with depth step, the $\theta_i$ and $\theta_v$ used by LPJ-STM to calculate

179 these temperatures (see below) are assumed to be uniformly distributed in each soil

180     layer (i.e., do not vary with depth steps within a soil layer).

181

182     2.1.2. Hydrology in LPJ-STM

183     To match the layering scheme in STM, we simply modify the hydrology in LPJ

184 partly following the routine in Wania et al. (2009b). The original top 0.5 m layer in

185 LPJ now corresponds to the top four layers in LPJ-STM and the bottom layer (from

186 0.5 m to 1.5 m) in LPJ is extended to 3 m depth and corresponds to the fifth and sixth

187 layer in LPJ-STM. The actual water holding capacity (*AWHC*, mm/mm) in each layer

188 *i* is determined as the difference between the water hold capacity (*WHC*, mm/mm)

189 and the ice content (*icefr*, mm/mm, estimated in STM):

190     $AWHC_{(i)} = WHC_{(i)} - icefr_{(i)}$

191     Of the top four layers (or top 50 cm, Figure 1), the change in water content (mm)

192 in each layer is determined as a layer-weighted difference of liquid water input (i.e.

193 rainfall and melting water) and output (i.e. soil evaporation and transpiration),

194 estimated in the LPJ hydrology module. In the top four layers, water in the *i*th layer

195 exceeding $AWHC_{(i)}$ is available for percolation into the $5^{th}$ and $6^{th}$ layers (Figure 1).

196 All these water fluxes (i.e., rainfall, melt water, soil evaporation, transpiration and

197 percolation) are estimated from the LPJ hydrology module (Gerten et al., 2004). In the

198 $5^{th}$ and $6^{th}$ layer, the change in water content is calculated as the difference between

199 percolation and transpiration. Within the $7^{th}$ layer, the soil water content is assumed to

200 be constant. The soil water content is updated daily in the hydrology routine, and then

201 passed on to STM to calculate the soil temperature of each depth step in each layer. In

202     the model, LPJ-STM does not consider hydraulic conductivity of water contents

203     above field capacity. Roots can access water in all six layers as long as the layer is not

204     frozen.

205

206     2.1.3. Soil carbon dynamics in LPJ-STM

207     To provide a vertical distribution of the C pool across the soil column to 3 m deep

208     (six layers, Figure 1), we used a similar routine as that in Schaphoff et al. (2013):

209     $$SoilC_{(i)} = d_{(i)}^{K} SoilC_{total}$$

210     where $d$ (unitless) is the relative share of the $i$th layer in the entire soil pool and $K$

211     (unitless) is the slope parameter that characterizes the relative rate of decrease with

212     depth. In Schaphoff et al. (2013), $K$ is varied by different plant functional types (PFTs)

213     based on an optimized cumulative log-log equation from Jobbagy and Jackson (2000).

214     Here, we use a $K$ value of 0.7 for all PFTs to estimate SOC stock in each layer, based

215     on the information of vertical soil C distribution in the recent databases

216     (FAO/IIASA/ISRIC/ISSCAS/JRC, 2012; Hugelius et al., 2014).

217     Change in the total soil C stock, $SoilC_{total}$ (g C/m$^2$), is determined by the C input

218     to soil from litter (i.e. 30% of decomposed litter goes into the soil C pool) and the C

219     loss from soil by decomposition ($k_{mean}$). The value of $k_{mean}$ is determined as a layer

220     weighted sum of the mean decomposition rate $k_{mean_{(i)}}$ in each soil C layer:

221     $$k_{mean} = \sum_{i=1}^{nlayer} (k_{mean_{(i)}} \cdot d_{(i)}^{K})$$

222     Within each soil layer, we calculate the decomposition rate of each depth step using

223     the same soil temperature and moisture-dependent scheme as in Sitch et al. (2013).

224   Then we determine $k_{mean_{(i)}}$ as the mean decomposition rate of all depth steps within

225   the $i$th layer:

226   $$k_{mean_{(i)}} = \frac{1}{n_{depthsteps}} \sum_{j=1}^{n_{depthsteps}} k_j$$

227   For example, $k_{mean_{(i)}}$ of the 1$^{st}$ layer is the mean of decomposition rates of all 10

228   depth steps (each step is 1 cm thick). This is different from Schaphoff et al. (2013), in

229   which $k_{mean_{(i)}}$ is calculated using the mean soil temperature and soil moisture of

230   layer $i$.

231   To mechanistically simulate the C shift between layers, following Schaphoff et al.

232   (2013), the annual shift of C input $C_{shift_{(i)}}$ (unitless) for soil layer $i$ into the lower layer

233   due to cryoturbation and bioturbation is estimated by:

234   $$C_{shift_{(i)}} = \frac{d_{(i)}^{K} k_{mean_{(i)}}}{k_{mean}}$$

235

236   **2.2. Climate forcing**

237   In this study, monthly air temperature, cloud cover, precipitation, number of wet

238   days, atmospheric $CO_2$ concentrations and soil property data are used to drive both

239   LPJ and LPJ-STM. Historical climate data for 1901-2000 are obtained from the

240   Climate Research Unit (CRU; Mitchell and Jones, 2005). The historical atmospheric

241   $CO_2$ concentration datasets are from ice-core records and atmospheric observations

242   (Keeling and Whorf, 2005), and soil texture data is derived from the FAO soil datasets

243   (Zobler, 1986; FAO, 1991).

244   For the period 2001-2100, we use six climate scenarios produced with the MIT

245     Integrated Global System Model (IGSM; Sokolov et al., 2005) under two emission

246     scenarios (reference and level 1 stabilization cases, Table 1) in the Synthesis and

247     Assessment Product 2.1 of the U.S. Climate Change Science Program (Clarke et al.,

248     2007; Webster et al., 2012). The reference emission scenario (REF), which assumes

249     no climate policy, is very similar to the IPCC RCP8.5 scenario. The average $CO_2$

250     concentration over last decade of the $21^{st}$ century in the IGSM REF simulations, with

251     median settings for C cycle parameters and reference emission scenario, is 870 ppm

252     (Sokolov et al., 2009; Webster et al., 2012), compared to 890 ppm from the IPCC

253     RCP8.5 scenario. The corresponding total greenhouse gas forcing is an equivalent

254     $CO_2$ concentration of 1330 and 1250 ppm, respectively. In contrast, the level 1

255     stabilization scenario (POL) assumes a rather stringent climate policy with global

256     greenhouse gas emissions declining from year 2015 to year 2060 and staying fixed

257     thereafter. As a result, $CO_2$ concentrations increase by the end of $21^{st}$ century to only

258     480 ppm (560 ppm of $CO_2$-equivalent), which falls in between the values for the

259     IPCC RCP4.5 and RCP2.6. More detailed comparisons between the RCPs and the

260     scenarios used in this study can be found in Webster et al. (2012).

261       Climate simulations for the two emission scenarios are carried out using three

262     different sets of parameters defining the climate system responses to anthropogenic

263     emissions. These responses are dependent on climate sensitivity, the rate of heat

264     uptake by the deep ocean, and the strength of aerosol forcing for a given emissions

265     loading. Climate parameter sets corresponding to the $5^{th}$, $50^{th}$ and $95^{th}$ percentiles of

266     the probability distribution for the increase in surface air temperature in the last

267 decade of 21$^{st}$ century in the ensembles of simulations with REF and POL emissions

268 (Sokolov et al., 2009) are chosen to represent low (L), median (M) and high (H)

269 climate responses, respectively. The 90% probability ranges for the 21$^{st}$ century

270 surface warming relative to 1981-2000 are 3.7-7.4$^o$C and 1.1-2.5$^o$C for the REF and

271 POL scenarios respectively, with median values of 5.1$^o$C and 1.6$^o$C (Sokolov et al.,

272 2009; Webster et al., 2012). Thus results from six simulations used in this study

273 (REF_M, REF_L, REF_H and POL_M, POL_L, POL_H) cover a very wide range of

274 possible changes in future climate.

275

276 **2.3. Simulation Protocols**

277 Both the LPJ and LPJ-STM simulations are initially run for 2000 "spin-up" years

278 before 1901, using a cyclic replication of climate data from 1901 to 1930. Similar to

279 the strategy in Schaphoff et al. (2013), the first 990 years spin-up for LPJ-STM is run

280 to achieve an equilibrium state of vegetation cover and mean-annual litter input into

281 soils. The size of the slow soil C pool is analytically solved assuming a mean climate

282 condition, and then we run for a further 1010 years with climate variability to

283 initialize the soil C pool for each soil layer. From 1901 to 2100, the historical data

284 (CRU, 1901-2000), followed by each of the six projected IGSM climates and $CO_2$

285 concentrations, are used to drive the simulations for the study region, which is

286 represented by a total of 25,063 grid cells at a 0.5$^o$ latitude $\times$ 0.5$^o$ longitude resolution.

287

288 **2.4. Evaluation of model performance**

13

289    We compare the LPJ and LPJ-STM modeled soil temperatures with observations

290    from eight sites studied in Jiang et al. (2012a). To evaluate the model performance for

291    simulating C dynamics, we first compare the simulated C fluxes from both LPJ and

292    LPJ-STM to the measured NEP from FLUXNET sites (http://fluxnet.ornl.gov). We

293    also examine the ability of each model to reproduce seasonal fluctuations in

294    atmospheric $CO_2$ concentration by using the modeled NEP across the circumpolar

295    region to drive an atmospheric inversion and transport model TM2 (Kaminski et al.,

296    1999). The simulated $CO_2$ concentrations are then compared with the atmospheric

297    flask measurements from monitoring stations. As in Heimann et al. (1998), we

298    calculate the normalized mean-squared deviation (NMSD, equation is shown in Table

299    2) to evaluate the goodness of fit between the simulated and observed seasonal

300    atmospheric $CO_2$ concentration.

301

302    **3. Results**

303    **3.1. Model performance**

304    The LPJ-STM is able to well simulate the soil temperature profile for high latitude

305    sites (Figure 2). When compared with measured soil water content at 25 cm,

306    LPJ-STM shows clearly better agreement than LPJ (Figure 3). The LPJ-STM soil

307    temperature estimates have lower root mean square error (RMSE) values than the LPJ

308    estimates when compared against field measurements (Figure 4). By replacing the

309    LPJ soil temperature model with the STM, the seasonal temperature fluctuations are

310    dampened with a much cooler soil during the growing season (the duration of the

311 annual non-frozen period of the top 25 cm of soil) and a slightly warmer soil during

312 the cold period (September - May). As shown in Jiang et al. (2012a), the soil

313 temperature profile simulated by STM shows good agreement with observations at 11

314 sites, but the discrepancy between modeled and measured soil temperatures tends to

315 increase with profile depth. Our model shows a clear latitudinal gradient of ALT in the

316 circumpolar north (Figure 5). Compared with ALT observations from 172 sites in

317 GTN-P database (Biskaborn et al., 2015), a simple linear regression indicates a good

318 agreement in general trends between modeled historical ALT and site observations

319 (Figure 5). However, the model tends to overestimate ALT at sites where the observed

320 ALT is less than 100 cm and underestimate ALT at sites where the observed ALT is

321 greater than 100 cm.

322 Compared with measured NEP at FLUXNET sites, LPJ-STM performs better than

323 LPJ in reproducing monthly NEP (Figure 6), based on more accurate simulation of

324 NEP during the growing season. The larger amplitudes of the seasonal NEP cycles

325 produced by LPJ-STM are mainly due to the lower summer $R_H$ and higher winter $R_H$,

326 relative to LPJ estimates. When we use the NEP estimates from LPJ and LPJ-STM

327 separately as inputs for TM2, and we find that the NEP from LPJ-STM leads to a

328 larger amplitudes of the seasonal cycles of $CO_2$. This seasonal pattern is more

329 comparable with observations from not only the northern stations, but also stations in

330 the tropics ($30^{o}N – 30^{o}S$, e.g., Ascension Island) and Southern Hemisphere ($30^{o}S$

331 southward; e.g., Cape Grim, Tasmania), where the seasonal cycle is still largely

332 influenced by atmospheric transport of $CO_2$ from the northern biosphere. Compared

333 with NMSD values for models in Heimann et al. (1998), LPJ-STM performs better in

334 reproducing the seasonal cycle of atmospheric $CO_2$ (Table 2).

335

336 **3.2. Changes in permafrost extent**

337 The LPJ-STM projections indicate potential large changes in future soil thermal

338 dynamics of circumpolar ecosystems. The model results show a substantial decrease

339 in the extent of near-surface permafrost under the projected IGSM climates with the

340 changes in extent being largely dependent on the warming strength (Figure 7).

341 Throughout the 21$^{st}$ century, the modeled decrease in permafrost extent varies among

342 different climate scenarios, and the rate of permafrost loss increases during the second

343 half of the century. In particular, under the REF_H scenario, nearly 88% of

344 near-surface permafrost (i.e. in top 3 meters) will disappear by 2100, when there will

345 be only relict permafrost at depths untied to prevailing climatic conditions (Figure 7).

346 Under the POL_L scenario, only about 15% near-surface permafrost will disappear

347 throughout the same time period. In general, the REF emission scenarios correspond

348 to a larger loss of permafrost than the POL emission scenarios.

349

350 **3.3. Carbon budget**

351 **3.3.1. Present-day**

352 The two models achieve different initial equilibrium states in the year 1901, in

353 which LPJ-STM estimates a smaller area covered by boreal deciduous forests than

354 LPJ because LPJ-STM projects a shorter growing season and the photosynthesis of

355    boreal deciduous trees is concentrated during the growing season. Instead, LPJ-STM

356    estimates a larger area covered by evergreen forests than LPJ because the

357    mid-summer NPP of boreal needleleaved trees is highly influenced by summer root

358    respiration, which is lower in LPJ-STM because of the lower summer soil

359    temperatures than that estimated with LPJ. Consequently, LPJ-STM estimates larger

360    vegetation and soil C stocks (+13.7 Pg C or +8% and +430.2 Pg C or +50%,

361    respectively, Table 3), and approximately 1.1 Pg C yr$^{-1}$ higher NEP than LPJ during

362    the 1900s (Figure 8).

363        Throughout the 20$^{th}$ century, LPJ-STM consistently yields ~0.5 Pg C yr$^{-1}$ higher

364    NPP than LPJ, despite the shorter growing season. Compared with LPJ, the growing

365    season length as simulated by LPJ-STM is 14±8 days shorter at present, primarily due

366    to later spring thaw (~10±6 days), and to a lesser extent due to earlier refreezing in

367    autumn (~4±3 days). Unlike NPP, the difference in annual $R_H$ between LPJ-STM and

368    LPJ gradually decreases from -0.6 Pg C yr$^{-1}$ in 1900s to around -0.4 Pg C yr$^{-1}$ for

369    2000s (Figure 8). Larger NPP and smaller $R_H$ in LPJ-STM translates to 0.8 - 1.0 Pg C

370    yr$^{-1}$ higher NEP in the 2010s, relative to those in LPJ. Spatially, almost the whole area

371    underlain by permafrost (Figure 5) exhibits stronger C sequestration in LPJ-STM

372    relative to LPJ (Figure 9). In particular, the strongest enhancement in annual NEP

373    (+50 to +100 g C m$^{-2}$ yr$^{-1}$) occurs in the Canadian boreal forest, Eastern Siberia and

374    Mongolia, while the greatest reduction occurs in western Russia with up to a 90 g C

375    m$^{-2}$ yr$^{-1}$ decrease in annual NEP.

376        The larger NPP in LPJ-STM maintains a higher vegetation C pool at present (i.e.

17

227.7 – 229.4 Pg), which is about 17.2 - 18.1 Pg C higher than in LPJ (i.e. 210.1 –

211.8 Pg, Table 3). Generally, the additional vegetation C estimated by LPJ-STM

occurs mostly in boreal forest zones (e.g., the Alaskan and Canadian boreal forests)

with up to 1.1 kg C m$^{-2}$ increases in vegetation C density (Figure 9). Higher NPP also

leads to more litter C input into the soil, and together with the lower $R_H$ contributes an

~430 Pg larger soil C pool in LPJ-STM during the 2010s (i.e. ~1297 Pg C, Table 3).

The major differences in simulated soil C pool between the two models occur in the

boreal forest eco-regions (e.g., the Alaskan, Canadian and Siberian boreal forests),

where LPJ-STM produces up to 20 kg C m$^{-2}$ higher soil C stocks (Figure 9). The

LPJ-STM simulations indicate that the continuous permafrost in the far northern

regions and Mongolia store the largest soil C pools in the circumpolar north.

LPJ-STM permafrost better than LPJ in simulation SOC pool, when compared

with two major global soil C datasets. In particular, LPJ-STM estimates higher soil C

than the land-based Harmonized World Soil Database (HWSD,

FAO/IIASA/ISRIC/ISSCAS/JRC, 2012), but lower soil C in permafrost areas (~17.8

$\times 10^6$ km$^2$, Figure 10) defined by the Northern Circumpolar Soil Carbon Database

version 2 (NCSCDv2, Tarnocai et al., 2009; Hugelius et al., 2014). In particular,

LPJ-STM estimates 177 Pg C for the top 30 cm of the soil profile compared to 151 Pg

C by HWSD and 217 ± 12 Pg C by NCSCDv2. For the top 100 cm of the soil profile,

LPJ-STM estimates 389 Pg C compared to 288 Pg C by HWSD and 472 ± 27 Pg C by

NCSCDv2. The higher SOC stocks estimated by LPJ-STM relative to HWSD occur

in most areas underlain by permafrost (e.g., Siberia, Alaska, and Canadian boreal

399     forest and tundra, Figure 10). The lower SOC stocks estimated by LPJ-STM relative

400     to NCSCDv2 mainly occur in Siberia.

401

**3.3.2. Future carbon budgets**

403     Under the warming scenarios, both models predict significant increases in annual

404     NPP and $R_H$, where the magnitude is largely controlled by the level of climate change

405     (Table 4). In particular, the reference climate scenarios cause an approximate increase

406     of 47-59% in annual NPP by 2100, but only ~10% accrual under the policy climate

407     scenarios (Table 4). In parallel, the NPP difference between LPJ-STM and LPJ

408     increases from around 0.5 Pg C yr$^{-1}$ to 0.8-0.9 Pg C yr$^{-1}$ under the reference scenarios,

409     but exhibits only a slight increase (~0.1 Pg C yr$^{-1}$) under the policy scenarios (Figure

410     8). Changes in $R_H$ show similar patterns of response to the climate variability as those

411     of NPP (Table 4), while the difference in $R_H$ between the two models shows a clear

412     decreasing trend through all six warming scenarios (Figure 8).

413     As the difference of NPP and $R_H$, the NEP in both models is simulated to decrease

414     over the 21$^{st}$ century, because the annual $R_H$ increases faster than NPP, especially

415     under the severe warming scenarios (Table 4). For example, forced by the REF_M

416     and REF_H scenarios, the study region eventually shifts from a C sink to a source by

417     2090s. Meanwhile, the NEP difference between the two models exhibits a clear

418     decline (from ~0.9 to ~0.6 Pg C yr$^{-1}$) through the 21$^{st}$ century, despite the strong

419     inter-annual variability (Figure 8). However, the significant positive difference here

420     indicates that the introduction of STM into LPJ contributes to maintaining the

421    modeled capacity of C sequestration in the circumpolar north.

422        Given the enhanced plant productivity associated with warming and $CO_2$ increase,

423    both models predict a large increase in the vegetation C pool, which is 18.4 – 22.3 Pg

424    C larger in LPJ-STM (294.1 - 358.0 Pg C) than in LPJ (275.7 - 336.4 Pg C) by 2090s

425    (Table 3). Driven by six warming scenarios, LPJ projects substantive soil C loss

426    ( -26.5 to -58.8 Pg C), and LPJ-STM projects a 2.8 - 34.1 Pg C gain in soil C stock

427    over the period of 2000 – 2100 under four out of the six IGSM climates but 5.3 and

428    27.1 Pg soil C loss under REF_M and REF_H (Table 3).

429

430    **4. Discussion**

431        In this study, we examine how a more detailed representation of soil thermal

432    dynamics, soil hydrology, and soil C dynamics influences estimates of C fluxes and

433    pools of ecosystems in the circumpolar north. The detailed representation of these

434    ecosystem processes in LPJ-STM estimates higher NPP, but lower RH for current

435    circumpolar ecosystems than the more aggregated representation of these processes in

436    LPJ. As a result, more C (0.8 to 1.0 Pg C $yr^{-1}$) is estimated to be sequestered in these

437    ecosystems by LPJ-STM with almost all of the additional C (96%) being stored in

438    soils. With global warming, the LPJ-STM still estimates more C is sequestered in the

439    future than LPJ with most of the additional C being stored in soils, but the difference

440    between model estimates decrease over time. Below we focus our discussion on: 1)

441    how the LPJ-STM improved the quantification of present-day C budgets; 2) how

442    these improvements affect projections of future permafrost degradation and their

443 effects on C dynamics; and 3) sources of uncertainty in simulating C dynamics in the

444 circumpolar north region.

445

446 **4.1. Present-day soil C budgets**

447     The increase in annual $R_H$ as simulated in both models is mainly driven by the

448 warming soil temperatures. The addition of vertical differentiation of the soil

449 temperature profile and a depth distribution of soil C in LPJ-STM improves the

450 representation of soil physical and biogeochemical processes. This leads to a more

451 accurate simulation of thawing and refreezing processes as well as ALT estimates,

452 further reducing the model errors in soil C stock. The lower summer soil temperatures

453 produced by LPJ-STM largely stabilize soil C by reducing $R_H$, especially for the top

454 layers (e.g., the upper 30 cm, Figure 10). The impact of considering permafrost on $R_H$

455 in our simulation is different from Wania et al. (2009a), who shows that the

456 introduction of permafrost increases soil respiration by about 0.39 Pg C $yr^{-1}$ probably

457 because LPH-WHy simulates higher soil C stock (+39 Pg C) over 1991-2000.

458 However, LPJ-STM estimates lower (-0.6 Pg C $yr^{-1}$) $R_H$ than LPJ mainly because

459 LPJ-STM estimates significantly lower summer soil temperatures than LPJ, even

460 though LPJ-STM has a larger soil C pool than LPJ. As demonstrated in Schaphoff et

461 al. (2013), saturated hydraulic conductivity may also play an important role in the C

462 balance, as $R_H$ achieves peak rates around field capacity and decreases as water

463 saturation is approached because of decreasing soil oxygen content. Because we did

464 not consider water contents above field capacity in our analyses, $R_H$ may be

465     somewhat overestimated in our study. In addition, $R_H$ may also be overestimated at

466     sites where the model overestimates the size of the active layer (Figure 5).

467     Consequently, our estimates of soil C pool in the circumpolar north may be

468     conservative, especially in regions with high water content (e.g., wetland).

469       The slightly lower SOC from LPJ-STM relative to NCSCDv2 is probably due to

470     not considering the effects of some important processes in our model that influence

471     deep C storage in the northern permafrost region, such as peatland development

472     (Smith et al., 2004; Treat et al., 2016), syngenetic permafrost aggradation in areas of

473     loess deposition (i.e. Yedoma; Shur et al. 2004), and alluvial deposition (i.e. large

474     river deltas; Hugelius et al., 2014). Northern peatlands in particular store large

475     amounts of SOC, with approximately 184 and 94 Pg C in Histels (i.e. permafrost

476     peatlands) and Histosols (non-permafrost peatlands), respectively (Tarnocai et al.,

477     2009; Yu et al., 2010). Moreover, the model-data differences could be partly attributed

478     to the spatial heterogeneity caused by disturbances that have not been explicitly

479     simulated in the model, such as fire and thermokarst (Grosse et al., 2011). Similar to

480     our results, lower estimates of SOC relative to NCSCDv2 have been observed in other

481     earth system models (Todd-Brown et al., 2013). Compared with HWSD, LPJ-STM

482     estimates higher SOC stocks in most of the permafrost affected areas. It is difficult to

483     evaluate these differences, however, because HWSD has not included enough

484     information about how their estimates were derived.

485       We estimate that approximately 844 Pg C are stored within the top 3 m of soils,

486     which is slightly lower than the estimates of $1035 \pm 150$ Pg C in Hugelius et al.

487    (2014). We recognized that, in parts of the circumpolar north, soils might not extend

488    to a depth of 3 meters or even be present in areas with bedrock near or at the surface.

489    In other areas, there is widespread occurrence of massive ground ice (Schirrmeister et

490    al., 2011) as in regions with deep yedoma deposits (Kanevskiy et al., 2011). Because

491    these factors are not accounted for in LPJ-STM, our model may overestimate the SOC

492    stocks in the region. Meanwhile, some important soil forming processes (e.g., peat

493    formation, cryoturbation) that greatly influence the distribution of SOC in deep soil

494    layers (Bockheim, 2007; Hugelius et al., 2010) are not mechanistically modeled,

495    which may cause bias in SOC estimates, especially in the mineral soil layers.

496    Therefore, in ice-rich permafrost areas, model-data differences in deep layer SOC can

497    be substantial. However, due to the scarce field data (i.e. few sampled pedons) and

498    limited quantification of spatial variability in both ground ice content and soils, the

499    empirical SOC data in some remote areas (Mishra et al., 2013), and in regions of thin

500    sedimentary overburden (e.g., highlands and alpine terrain) have relatively high

501    uncertainty (Hugelius et al., 2014). Therefore, more field measurements in deep soil

502    layers and representation of spatial distribution of shallow soils and ground ice are

503    needed to better constrain the regional simulations of SOC in the permafrost zone.

504        LPJ-STM produces lower $R_H$ than LPJ mainly because of the lower summer soil

505    temperatures in the active layer and the freezing conditions below, where microbial

506    activity is limited. The higher NPP in LPJ-STM is a counter-balance between the

507    reduced summer below-ground autotrophic respiration due to cooler soil temperature,

508    and the decrease in water availability associated with the decreased rooting depth in

509      permafrost affected areas. The enhancement in $CO_2$ exchange through amplified plant

510      productivity in LPJ-STM is consistent with the finding in Forkel et al. (2016).

511      However, our simulation results are different from Wania et al. (2009a), who show

512      that integrating a simple permafrost model into LPJ slightly reduced circumpolar

513      (45-90$^o$N) NEP due to the decrease in NPP and increase in $R_H$.

514

515      **4.2. Permafrost degradation and its implications for future carbon budget**

516      Compared with the simulated permafrost extent in Lawrence et al. (2012), our

517      study estimates a slightly larger extent of the entire permafrost zone in the early 2000s.

518      Driven by the range of MIT IGSM climate scenarios, we estimate large variabilities in

519      permafrost extent by 2100 (Figure 7), which are comparable to the projections in

520      Slater and Lawrence (2013). The lower boundary of modeled permafrost retreat (i.e.

521      ~23% reduction in permafrost area under the coolest climate, POL_L), is similar to

522      the estimate in a conservative permafrost model (Anisimov and Reneva, 2006) that

523      predicts an approximate 19-24% reduction in near-surface permafrost area by 2080.

524      At the biome level, our simulated range of permafrost degradation also covered the

525      estimates from other model simulations. For example, our projected permafrost extent

526      under the IGSM policy scenarios in the Canadian boreal forest region is similar to

527      Zhang et al. (2008) who show a 15 - 19% reduction in the extent of permafrost

528      through the 21$^{st}$ century. Although the rate of permafrost retreat could potentially be

529      faster than the migration of boreal deciduous forests, the presence of permafrost still

530      constrains the northward expansion of boreal broadleaved summergreen trees, which

531     is consistent with the findings in Tchebakova et al. (2009). As the southern boundary

532     of permafrost moves northward, temperate forests are projected to migrate to the

533     north and gradually replace the boreal forests. This expansion is partly because

534     temperate trees are favored in the warming climate in our model.

535         The reduced difference in future NEP between LPJ-STM and LPJ (Figure 8) occur

536     for a number of reasons. The more positive effect of permafrost on the C sink by

537     LPJ-STM compared to LPJ will decrease as the permafrost degrades because more of

538     the newly thawed labile SOC pool will be exposed to decomposition in LPJ-STM.

539     The projected replacement of boreal evergreen conifer forests with herbaceous and

540     deciduous vegetation in the thawing permafrost area can influence the C inputs to

541     mineral soil, because of variations in productivity among these biomes (Jobbagy and

542     Jackson, 2000) and in the ability of roots to access the mineral substrate (O'Donnell et

543     al., 2011). As permafrost thaws, areas with a transition from boreal evergreen forest to

544     temperate deciduous forest exhibit a fast decline in annual NEP, although the NPP

545     increases rapidly due to a larger temperature range for temperate types (Sitch et al.,

546     2008). This implies that the enhancement in biomass productivity by vegetation

547     change in boreal zone could not offset the C loss through increased $R_H$ by warming

548     climate. Because both models predict a declining trend in annual NEP, the reduced

549     model difference implies a faster reduction in NEP by LPJ-STM. This indicates a high

550     sensitivity of C sequestration to permafrost degradation, especially under severe

551     warming scenarios (e.g., REF_H).

552         Unlike LPJ that projects a reduced SOC pool throughout the 21st century because

553     of the warming-stimulated SOC decomposition, LPJ-STM predicts a gain in the SOC

554     pool over the current century. In LPJ-STM, increased litter C inputs from the

555     stimulated plant growth are sufficient to compensate for the loss of SOC by

556     decomposition, which is greatly suppressed by the simulated cooler summer soil

557     temperature (Table 3). However, we also notice that as soil temperature increases,

558     litter decomposition becomes stronger and the amount of decomposed litter turning

559     into SOC becomes insufficient to compensate for the respiratory C loss from soil. As

560     a result, SOC accumulation slows down and even declines during the second half

561     century under severe warming scenarios (e.g., REF_H, Table 3).

562

563     **4.3. Sources of uncertainty**

564         Despite the improved simulation of soil temperatures, LPJ-STM still likely

565     overestimates NPP because nitrogen limitations to NPP have not been explicitly

566     considered as in other modeling studies (Sokolov et al., 2008; Xu and Prentice, 2008;

567     Smith et al., 2014) or shown in field studies (Nordin et al., 2004; Hobara et al., 2006).

568     However, increased nitrogen mineralization associated with enhanced decomposition

569     from permafrost degradation (Keuper et al., 2012; Koch et al., 2013, 2014;

570     Walter-Anthony et al., 2014; Hayes et al., 2014) may cause nitrogen to be more

571     available to NPP in permafrost environments than in other biomes under warming

572     conditions, especially in well-drained tundra ecosystems with deep rooting zones

573     (Shaver et al., 2001; Mack et al., 2004; Schuur et al., 2007).

574         Permafrost degradation can also cause a substantial change in surface hydrology,

which will further influence the vegetation dynamics and C balance in the region. For

example, in ice-rich and poorly-drained permafrost areas, permafrost degradation will

cause substantial ground-surface subsidence and ponding where the over-saturated

conditions may increase tree mortality in boreal forests (Osterkamp et al., 2000;

Jorgenson et al., 2001). Long-term permafrost degradation will eventually promote

subsurface water drainage and increase the dryness of soils (Yoshikawa and Hinzman,

2003). In peatlands, the warming-caused declines in water table may increase soil

decomposition, leading to a long-term C loss (Ise et al., 2008; Oechel et al., 1998;

Sulman et al., 2009; Olivas et al., 2010). In contrast, a low water table may cause a

long-term C gain in non-peat wetlands (Sulman et al., 2010). Given the importance of

hydrological change on C balance, future C models should be coupled with

climate-driven hydrological models (e.g., Wania et al., 2009a,b).

Another uncertainty source is fire disturbance. Future stimulated fire regimes in

both boreal forest (Turetsky et al., 2011), and tundra landscapes (Rocha et al., 2012)

will exacerbate the permafrost degradation rate relative to the change from warming

alone (Lawrence et al., 2012; Schuur et al., 2013; Jiang et al., 2015). Fires may

therefore play a more important role in C dynamics of the circumpolar north.

However, the fire-caused change in permafrost thaw has not been accounted in

current modeling work. A more mechanistic description for the relationships between

fire, permafrost and C dynamics is necessary for future modeling efforts.

## 5. Conclusions

597      This study examines the importance of the changes of soil thermal regime in

598    determining the C budget in the circumpolar north. With explicitly modeled

599    temperatures at different depths, the LPJ-STM model estimates larger soil organic C

600    stocks in the circumpolar north, which agrees well with empirical global data source.

601    Our model simulations indicate that, although most biogeochemical processes of C

602    storage and decomposition take place in top soil layers (i.e. top 30 cm), deep layers

603    also substantially influence the SOC dynamics, especially when these layers confront

604    a phase change. Some missing processes that affect the soil thermal regimes (e.g.,

605    formation of taliks, absence of snow dynamics) result in a significant uncertainty of

606    our estimates. Thus more field measurements of deep soil organic carbon are needed.

607    This study highlights the importance of more adequate representation of soil thermal

608    dynamics in dynamic global vegetation models, such as LPJ, for quantifying C

609    responses to climate change in northern high latitudes.

**Table 2** Normalized Mean Squared Deviation (NMSD) between simulated and observed seasonal cycle of $CO_2$; for comparison of the observed with the TM2 simulated seasonal cycles of $CO_2$, produced by coupling the monthly net ecosystem productivity by LPJ and LPJ-STM for northern, tropical and southern monitoring stations. The station data is from Heimann et al. (1998), for the period of 1983-1992.

| Station | Coordinate | LPJ | LPJ-STM | Average* |
|---|---|---|---|---|
| Alert, Northwest Territories | 82°27'N, 62°31'W | 17.8 | 14.3 | 28.4 |
| Point Barrow, Alaska | 71°19'N, 156°36'W | 12.3 | 11.5 | 13.2 |
| Cold Bay, Alaska | 55°12'N, 162°43'W | 10.5 | 5.8 | 11.1 |
| Cape Meares, Oregon | 45°29'N, 124°00'W | 6.7 | 4.3 | 18.6 |
| Azores (Terceira Island) | 38°45'N, 27°05'W | 1.7 | 1.1 | 4.0 |
| Niwot Ridge, Colorado | 40°03'N, 105°38'W | 6.1 | 3.0 | 5.9 |
| Sand Island, Midway | 28°13'N, 177°22'W | 9.4 | 4.5 | 8.8 |
| Key Biscayne, Florida | 24°40'N, 80°12'W | 6.4 | 3.7 | 9.7 |
| Cape Kumukahi, Hawaii | 19°31'N, 154°49'W | 29.4 | 16.8 | 14.7 |
| St. Croix, Virgin Islands | 17°45'N, 64°45'W | 9.2 | 6.3 | 6.2 |
| Seychelles (Mahe Island) | 4°40'S, 55°10'E | 2.2 | 1.9 | 1.0 |
| Ascension Island | 7°55'S, 14°25'W | 4.3 | 4.1 | 10.6 |
| American Samoa | 14°15'S, 170°34'W | 1.3 | 1.4 | 5.2 |
| Cape Grim, Tasmania | 40°41'S, 144°41'E | 1.6 | 1.1 | 17.4 |
| Amundsen Scott (South Pole) | 89°59'S, 24°48'W | 6.5 | 5.8 | 34.7 |

*The mean value of NMSDs from five prognostic models (BIOME2, FBM, SILVAN, and TEM)

883    used in Heimann et al. (1998).

884    $$NMSD = \frac{1}{12} \sum_{m=1}^{12} \left( \frac{C_{T,m} + C_{F,m} + C_{O,m} - C_{OBS,m}}{\sigma_m} \right)^2$$   NMSD is calculated as the normalized

885    square of difference between the sum of monthly $CO_2$ concentration from biospheric ($C_{T,m}$), fossil

886    fuel ($C_{F,m}$), ocean flux ($C_{O,m}$), and the 10-year mean of observed $CO_2$ flux values ($C_{OBS,m}$)

887    for the period 1983-1992. The factor used to normalized the difference is the standard deviation

888    ($\sigma_m$) of the observed value for each month (m = 1,…,12) of the year.

889

890 **Table 3** The average carbon stocks in the 1900s, 2010s and 2090s estimated with LPJ and LPJ-STM.

## Figure caption

**Fig. 1.** Diagram illustrating hydrologic modeling framework in relation to soil profile structure. Vertical soil structure is divided into seven distinct layers (3 organic horizons, 3 mineral horizons and a deep horizon) that vary with respect to hydraulic properties (k, porosity, etc.). The model tracks and quantifies different water fluxes including precipitation (Pr), interception by vegetation ($E_I$); snow melt water (M), evaporation ($E_s$) transpiration ($E_T$) runoff ($R_{surface}$),subsurface flow ($R_{subsurface}$), and percolation or infiltration ($R_{perc}$). The solid arrows ($\rightarrow$) reflect infiltration pathways of precipitation and snowmelt, which can be transferred from the ground surface to any of the top four layers. The dashed arrows (- - >) reflect vertical water loss pathways via $E_s$ and $E_T$, which can originate from the top three organic horizons or the uppermost mineral horizon. The dashed-dotted arrows ($- \cdot \rightarrow$) reflect downward migration of soil water (i.e. $R_{perc}$) which can occur across all soil horizons. The dotted arrows ($\cdot \cdot \cdot >$) indicate either pathways of $R_{surface}$ at the ground surface, or $R_{subsurface}$ from the B or C mineral horizons.

**Fig. 2.** LPJ-STM simulated (top) and observed (bottom) soil temperature profile at the Westdock site (using probe 2 data).

**Fig. 3.** Difference in soil moisture at 25 cm by LPJ and LPJ-STM relative to observations at three sites.

917 **Fig. 4.** Observed and simulated daily soil temperature at 25 cm with STM and the soil

918 temperature algorithm in LPJ at eight sites. RMSE represents the root mean square

919 error from the fit between observations and simulations. AT: Atqasuk (70.5$^{o}$, -157.5$^{o}$);

920 BP: Betty Pingo (70.5$^{o}$, -149$^{o}$); TL: Toolik (68.5$^{o}$, -149.5$^{o}$); WD: Westdock (70.5$^{o}$,

921 -148.5$^{o}$). BP-1 and BP-2 are two different sites, and WD-1, 2, 3, 4 are four different

922 sites.

923

924 **Fig. 5.** Modeled distribution of active layer thickness (ALT) in areas underlain by

925 permafrost in 2000 (left) and a comparison (right) between modeled and observed

926 ALT at 172 sites derived from the GTN-P database (Biskaborn et al., 2015). The dash

927 line represents the 1:1 line.

928

929 **Fig. 6.** Observed and simulated monthly NEP (g C m$^{-2}$, positive value means a C flux

930 to the biosphere, and negative value represents a C flux to the atmosphere) with LPJ

931 and LPJ-STM at nine sites (latitude and longitude shown in parentheses) located north

932 of latitude 45$^{o}$N. $R^2$ represents the coefficient of determination from simple linear

933 regressions. Observed NEP data were obtained via the FLUXNET database

934 (http://fluxnet.ornl.gov).

935

936 **Fig. 7.** Time series of near surface permafrost extent in the 45$^{o}$N northward region

937 simulated with LPJ-STM for the historical and projection periods. Near-surface

938 permafrost extent is the integrated area of 0.5$^{o}$ × 0.5$^{o}$ grid cells with the maximum

939 active layer shallower than 3 m.

940

**Fig. 8.** Difference (LPJ-STM minus LPJ) in modeled annual net primary production (NPP), heterotrophic respiration ($R_H$) and net ecosystem productivity (NEP) of the circumpolar north for the historical period and six future projections.

944

**Fig. 9.** Distribution of the differences (LPJ-STM minus LPJ) of modeled mean annual carbon fluxes ($\Delta$NEP, $\Delta$RH, $\Delta$NEP) and mean carbon standing stocks ($\Delta$vegetation C, $\Delta$soil C, $\Delta$ecosystem C stocks) during the 2000s for the circumpolar region north of $45^{o}$N.

949

**Fig. 10.** Carbon density (kg C $m^{-2}$) in the top 30 cm (a) and 100 cm (b) of soil estimated by LPJ-STM for the year 2000, the Northern Circumpolar Soil Carbon Database version 2 (NCSCDv2, Hugelius et al., 2014), and the Harmonized World Soil Database (HWSD, FAO/IIASA/ISRIC/ISSCAS/JRC, 2012).
