10 **ABSTRACT**

11 Hydrothermal circulation at mid-ocean ridge volcanic segments extracts heat from
12 crustal magma bodies. However, the heat source driving hydrothermal circulation in
13 ultramafic outcrops, where mantle rocks are exhumed in low-magma supply
14 environments, has remained enigmatic. Here we use a three-dimensional *P*-wave velocity
15 model derived from active-source wide-angle refraction/reflection ocean bottom
16 seismometer data and pre-stack depth-migrated images derived from multichannel
17 seismic reflection data to investigate the internal structure of the Rainbow ultramafic
18 massif, which is located in a non-transform discontinuity of the Mid-Atlantic Ridge.
19 Seismic imaging reveals that the ultramafic rocks composing the Rainbow massif have
20 been intruded by a large number of magmatic sills, distributed throughout the massif at
21 depths of ~2–10 km. These sills, which appear to be at varying stages of crystallization,
22 can supply the heat needed to drive high-temperature hydrothermal circulation, and thus

23 provide an explanation for the hydrothermal discharge observed in this ultramafic setting.
24 Our results demonstrate that high-temperature hydrothermal systems can be driven by
25 heat from deep-sourced magma even in exhumed ultramafic lithosphere with very low
26 magma supply.

27 INTRODUCTION

28 Exposures of mantle rocks are common along mid-ocean ridges spreading at slow
29 to ultraslow rates (<55 mm/yr), especially in magma poor regions (e.g., Tucholke and
30 Lin, 1994). Hydrothermal circulation at these sites produces serpentine via the reaction of
31 seawater with ultramafic rocks (e.g., Allen and Seyfried, 2004), resulting in fluids
32 enriched in H₂, CH₄, and other abiogenic hydrocarbons (e.g., Holm and Charlou, 2001).
33 Where exit-fluid temperatures are low (<100 °C), hydrothermal circulation can be
34 sustained by a combination of exothermic serpentinization and heat mined from hot
35 lithosphere (e.g., Allen and Seyfried, 2004). However, a magmatic heat source is required
36 to explain hydrothermal circulation at ultramafic sites where fluids exit the seafloor at
37 high flow rates and elevated temperatures (>340 °C) and are enriched in CO₂ (Allen and
38 Seyfried, 2004), despite these systems being located in settings away from neo-volcanic
39 zones such as ridge-axis discontinuities (German et al., 1996), rift valley walls (e.g.,
40 Ondreas et al., 2012), and inside-corner highs (Okino et al., 2015). While magma systems
41 beneath volcanic-hosted hydrothermal sites are well characterized (e.g., Singh et al.,
42 1999), the heat sources that drive high-temperature hydrothermal systems in ultramafic
43 settings have yet to be imaged. As a result, we have no *in situ* constraints on the geometry
44 of the sub-surface circulation system, and an incomplete understanding of the relationship

45 between lithospheric accretion, extension and hydrothermal processes in ultramafic
46 environments.

47 **GEOLOGICAL SETTING**

48 The Rainbow ultramafic massif is thought to be an oceanic core complex (OCC)
49 formed by detachment faulting (Andreani et al., 2014) within a non-transform
50 discontinuity (NTD) of the Mid-Atlantic Ridge (MAR, Fig. 1). The massif hosts the
51 Rainbow hydrothermal field (RHF) (German et al., 1996), which vents fluids enriched in
52 CH₄, H₂ and Fe (diagnostic of serpentinization (Holm and Charlou, 2001)) at high
53 temperatures and flow rates (German et al., 2010), indicating that a magmatic heat source
54 is present (Allen and Seyfried, 2004). However, the tectonized setting of the NTD lacks
55 significant volcanic features (Andreani et al., 2014; Eason et al., 2016; Paulatto et al.,
56 2015). The massif is largely covered by pelagic sediments, but basement outcrops expose
57 predominately serpentinites, with sparse occurrence of plutonic rocks and basalts
58 (Andreani et al., 2014). The presence of two inactive hydrothermal sites (Ghost City and
59 Clamstone, Fig. 1B) is inferred from fossil evidence (Lartaud et al., 2010; Lartaud et al.,
60 2011), but neither of them shows evidence of past high-temperature activity (Andreani et
61 al., 2014).

62 **NEW GEOPHYSICAL DATA AND METHODS**

63 To understand how magmatic and tectonic processes give rise to high-temperature
64 hydrothermal activity in an ultramafic setting we conducted a geophysical investigation
65 of the Rainbow NTD and neighboring segments using shipboard acoustic and potential
66 fields (Paulatto et al., 2015; Eason et al., 2016), and active-source seismic imaging. We
67 used travel times of *P*-waves recorded by 43 ocean bottom seismometers (OBSs) (Fig.

68 1A) using an iterative technique to compute the three-dimensional (3-D) P -wave velocity
69 (V_p) structure (Dunn et al., 2005). The 3D tomography model was used to depth-migrate
70 2-D multichannel seismic (MCS) reflection data collected with an 8-km-long hydrophone
71 streamer along 21 profiles (Fig. 1). Details about the seismic modeling and processing are
72 given in the GSA Data Repository¹.

73 **RESULTS AND DISCUSSION**

74 ***P*-wave Velocity Structure**

75 The 3D tomography model shows large V_p variations within the study area (Fig.
76 2A, B). The Rainbow massif is underlain by a cone-shaped core of high- V_p mantle
77 material that is elongated in the northeast-southwest direction (Fig. 2A, C). Above this
78 core, the flanks of the massif and adjacent nodal basins are characterized by layers of
79 low-to-moderately-low V_p (Fig. 2A, B) consistent with serpentinite or high-porosity
80 basalts. The lower velocities on the flanks of the massif are most likely associated with
81 highly serpentinized peridotites based on seafloor samples (Andreani et al., 2014).

82 **Pre-Stack Depth-Migrated Images**

83 Seismic reflection images reveal two primary types of events within the massif:
84 reflectors beneath both flanks of the massif that dip at 35–45° away from the area where
85 hydrothermal venting is clustered near the summit of the massif (Fig. 2D), and short, sub-
86 horizontal reflectors broadly distributed throughout the massif confined between the
87 northwest- and southeast-dipping reflectors (Fig. 2C, 3, 4A).

88 ***Nature of Dipping Reflectors***

89 The dipping reflectors are associated with the boundaries between the high- V_p
90 core of the massif and the overlaying lower velocity layers (Fig. 2D). This indicates that

91 the high- V_p core is separated from the overlaying layers by sharp impedance contrasts
92 that may be produced by faulting, alteration, or lithological contacts. In cross-section the
93 dipping reflectors resemble normal faults (Fig. 2D), but their depth extent (~5 km below
94 seafloor, bsf below the adjacent nodal basin in some instances, Fig. 2D) would require
95 the presence of exposed faults scarps on both flanks of the massif with kilometer-scale
96 vertical throws. Because such scarps are not observed (Andreani et al., 2014; Paulatto et
97 al., 2015), the dipping reflectors most likely represent lithological contacts,
98 serpentinization fronts, or a combination of both. The cone-shaped high- V_p core forms an
99 inverted funnel that shoals beneath the southwest flank near the summit of the massif
100 where hydrothermal activity is clustered (Fig. 2A), indicating that hydrothermal outflow
101 zones may be to some extent controlled by the sub-seafloor lithological and alteration
102 structure.

103 *Magma Sills Driving Ultramafic-Hosted Hydrothermal Circulation*

104 The sub-horizontal reflectors occupy an area of ~4.6 km x 8 km (Fig. 1B, 4A), and are
105 distributed within a depth range from ~2–10 km bsf (the majority being at 3–6 km bsf,
106 Fig. 4B). Their appearance and geometry are very similar to that of melt lenses imaged in
107 young crust at other spreading centers (e.g., Marjanović et al., 2014; Nedimović et al.,
108 2005), leading to the conclusion that they represent magmatic sills. The majority of them
109 intrude material with $V_p > 7.5$ km/s; this implies an ultramafic nature with little or no
110 alteration due to serpentinization (<15%, Fig. 4C). Only a few sills are imaged within
111 material with $V_p = 6.8$ – 7.3 km/s, which could either correspond to 20–40% serpentine,
112 gabbros, or a mixture of both (Fig. 4C).

113 Our 3D V_p model does not have the resolution to resolve the small-scale structure
114 of individual sills. However, the sills located closer to the RHF are, in general, of larger
115 dimensions and have larger reflection amplitudes (relative to surrounding reflectivity)
116 than those located farther away (Fig. 3). This, and the high temperature of the RHF
117 fluids, thus suggests that the sills located beneath the vent field are most likely partially
118 molten intrusions that provide the heat to drive hydrothermal circulation, while the rest of
119 the sills are likely solidified. Our MCS data can image both partially molten and
120 solidified intrusions because they are emplaced within a high V_p matrix, and thus
121 generate a negative impedance contrast with their host rock (Fig. 2C, 4A, D). The
122 presence of low- V_p sills may result in underestimation of the tomographically derived
123 background V_p , but we quantify this effect to be no more than 0.2 km/s (see the GSA
124 Data Repository¹).

125 Using previous estimates of heat flux and duration of hydrothermal activity at the
126 RHF (see the GSA Data Repository¹), we find that the heat delivered by solidification of
127 the imaged sills could cumulatively support high-temperature hydrothermal circulation
128 for a period of ~1,600-3,000 years, which is ~7–30% of the total hydrothermal system
129 lifespan (Cave et al., 2002; Kuznetsov et al., 2006). These estimates approximately
130 double if additional heat released by crystallization of melt impregnating peridotites that
131 is not accounted for in the seismically imaged sills is factored in (Table DR3). By
132 comparison, high-temperature discharge at the longer-lived, volcanic-hosted TAG active
133 hydrothermal field has been estimated to occur during only 1–2% of the system lifespan
134 (Humphris and Cann, 2000). Our results thus suggest that the RHF has a greater time-
135 averaged rate of hydrothermal discharge than the TAG field, which may explain why the

136 massive sulfide deposits at the RHF have structural and mineralogical characteristics
137 comparable to those of the TAG field (Marques et al., 2007) despite being a younger
138 system.

139 *Sill Intrusions in the Upper Mantle at NTDs*

140 The lateral dimensions of the sills (a few hundred meters up to ~1,400 m in
141 length, with the majority being 200–400 m long, Fig. 4C) and the ultramafic nature of the
142 host rock that they intrude presents a scenario similar to the Moho transition zone in
143 ophiolites, where gabbroic sills that are tens to hundreds of meters long and 0.1-100 m
144 thick intrude ultramafic host rock (Boudier et al., 1996; Kelemen and Aharonov, 1998).
145 Small gabbroic bodies intruding ultramafic outcrops are also observed along other
146 portions of the MAR (e.g., Dick et al., 2008), and if emplacement is rapid enough and
147 sustained over sufficiently long periods of time then thick gabbroic crustal sections may
148 be accreted (Grimes et al., 2008). At the Rainbow massif, however, the sills we image
149 occupy 4.8-9.2 km³ (assuming a sill thickness of 80-150 m), which is only 1-2% of the
150 volume of the exhumed ultramafic material (defined as material at depths less than 8 km
151 bsf and with $V_p > 7.3$ km/s). This suggests that sill emplacement at the Rainbow massif is
152 slow compared to OCCs with large gabbroic cores (e.g., Grimes et al., 2008), perhaps
153 because of its location within an axial discontinuity.

154 Exhumation of OCCs involves flexural rotation of the detachment footwall
155 (Garcés and Gee, 2007). Our observation of sub-horizontal sills at the Rainbow massif
156 thus implies that if the massif was exhumed along a detachment fault in a manner similar
157 to that of other OCCs (Andreani et al., 2014), then the sills must have been emplaced
158 after, or at the very end of, footwall rotation and exhumation. This interpretation is

159 consistent with the idea that exhumation of an OCC is terminated by magma
160 emplacement into the footwall (MacLeod et al., 2009). Alternatively, if sill emplacement
161 has occurred throughout the formation of the Rainbow massif, our observations indicate
162 that the massif has not been significantly rotated during exhumation. This scenario could
163 be possible if the massif was exhumed due to buoyancy forces resulting from the volume
164 increase associated with serpentinitization (O'Hanley, 1992). The tectonic setting of the
165 Rainbow massif, being located within a NTD, could result in different deformation and
166 exhumation mechanisms compared to OCCs formed at segment centers or inside corners,
167 but we do not currently have enough information to address this hypothesis.

168 Our experiment did not resolve a potential low- V_p source region for the magmatic
169 sills that intrude the massif, a region that is commonly observed beneath volcanic
170 spreading segments (Dunn et al., 2000). The source region for the sills must thus either
171 lie deeper than the region that our seismic tomography experiment can resolve (>8 km
172 bsf), or be located within the neighboring spreading segments (German and Parson,
173 1998), thus requiring lateral magma propagation. The lack of a volcanic magnetization
174 signature on the massif (Paulatto et al., 2015) argues against lateral emplacement of the
175 sills, as do the sill depths (~ 3 - 6 km bsf), because dikes propagating laterally from a
176 segment center into a NTD are predicted to shoal towards the segment end and breach the
177 seafloor (Behn et al., 2006). The high-magnetization volcanic cones and ridges located at
178 the ends of the neighboring segments (Paulatto et al., 2015) (Fig. 1B) probably mark the
179 loci of maximum dike propagation along these segments. The most plausible magma
180 source region is thus directly beneath the massif, with melt migrating vertically through
181 the upper mantle into the NTD. Our results thus provide compelling evidence that deep-

182 sourced magma can intrude exhumed ultramafic lithosphere to drive hydrothermal
183 circulation even in highly-tectonized regions with low, long-term magma supply.

184 **ACKNOWLEDGMENTS**

185 This research was funded by National Science Foundation (NSF) grants OCE-
186 0961680 and OCE-0961151. We thank the RV *M.G. Langseth*'s Captain, crew, and
187 technical staff, and the NSF-funded Ocean Bottom Seismograph Instrument Pool
188 (OBSIP, <http://www.obsip.org>) managers and technical staff for their efforts, which made
189 possible the success of cruise MGL1305. OBSIP data are archived at the IRIS Data
190 Management Center (Incorporated Research Institutions for Seismology;
191 <http://www.iris.edu>).

311 Figure 1. A: Regional bathymetry (Paulatto et al., 2015) and layout of the seismic
312 experiment across the Rainbow non-transform discontinuity (NTD) and neighboring
313 segments. Dashed white box shows location of maps shown in B and Figure 2A. White
314 dots—ocean bottom seismometers (OBS); MCS—multichannel seismic. Inset shows
315 location. B: Bathymetry of the Rainbow NTD. Labeled white lines are MCS profiles,
316 black segments show locations where sills have been imaged. Triangles indicate

317 hydrothermal sites. Closed white contours locate areas of elevated seafloor magnetization
318 (Paulatto et al., 2015).

319

320 Figure 2. A: Shaded topography of the Rainbow non-transform discontinuity (NTD)
321 colored according to P-wave velocity variations relative to average of the study area
322 (black line in B) at 1 km below seafloor. Circled numbers locate the one-dimensional P-
323 wave velocity (V_p) profiles shown in B. Other symbols as in Figure 1B. B: V_p plotted
324 against depth. C: Perspective views of the Rainbow massif and sub-seafloor seismic
325 structure. Fence diagram shows sill reflectors beneath both the active Rainbow
326 hydrothermal field (line 112) and the inactive Clamstone and Ghost City sites (line 114),
327 highlighted in the zoomed-in panel. D: Line 110 shows prominent west- and east-dipping
328 reflectors coincident with large lateral variations in seismic velocity. All seismic images
329 show reflectivity overlaid on V_p relative to average (red-blue color scale as in A). White
330 lines show the 7.3 (~20% serpentinization) and 7.9 km/s (fresh peridotite) iso-velocity
331 contours. V.E.—vertical exaggeration.

332

333 Figure 3. Close-up views of sub-horizontal reflectors interpreted as sills across the
334 southwest flank (line 108), center (112), and the northeast flank of the Rainbow massif
335 (116). Dashed line locates the Rainbow hydrothermal field (RHF). V.E.—vertical
336 exaggeration.

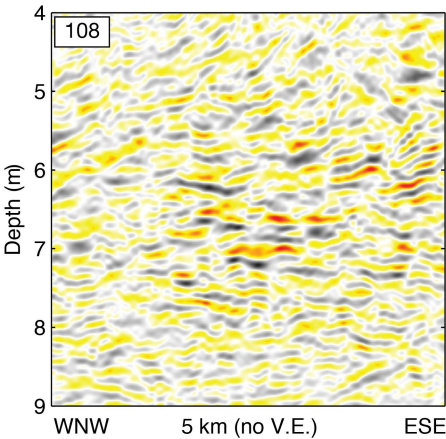

337

338 Figure 4. Distribution and characteristics of sills. A: Three-dimensional distribution of
339 sills within the Rainbow massif shown against the relative P-wave velocity (V_p) along

340 profiles 106 and 119. Inverted triangle locates the Rainbow hydrothermal field (RHF).
341 V.E.—vertical exaggeration. B: Histogram shows the distribution of sill depth (bsf—
342 below seafloor). C: Histogram shows the distribution of sill length. D: V_p and inferred
343 degree of serpentinization at the locations of the imaged sills. Values <7.3 km/s may
344 correspond to gabbro matrix or $>20\%$ serpentinized peridotite. Values >7.3 km/s
345 correspond to ultramafic rocks that are $<20\%$ serpentinized.

10 **OVERVIEW**

11 This supplementary document contains additional information and images about
12 the geophysical dataset, tomography modeling and checkerboard tests, MCS processing
13 and interpretation, and details about calculations of the energy balance of the Rainbow
14 hydrothermal field.

15 **METHODS**

16 **Geophysical Dataset**

17 The geophysical data were collected in April-May 2013 during the MARINER
18 (Mid-Atlantic Ridge INtegrated Experiments at Rainbow) expedition onboard the *R/V*
19 *Marcus G. Langseth* (cruise MGL1305). The experiment is centered on the Rainbow
20 massif and extends 80 km in the ridge-parallel direction and 32 km across the ridge
21 (Canales et al., 2013). The geophysical survey of the Rainbow area consisted of: (1) A
22 large-scale 3D active-source seismic tomography experiment using 46 ocean bottom

23 seismometers (OBSs) and airgun sources. (2) Twenty-one 2D multichannel seismic
24 (MCS) reflection profiles using one 8-km-long hydrophone streamer and airgun sources.
25 (3) An ~8-month-long deployment of a network of 15 OBSs for long-term monitoring of
26 the microseismicity of the Rainbow Massif and NTD. Analysis of this dataset is
27 underway (Horning et al., 2015) and will be reported somewhere else. (4) Multibeam
28 bathymetry and backscatter echosounding data, and underway potential fields (gravity
29 and magnetics). These data and results from their analysis are reported in (Eason et al.,
30 2016; Paulatto et al., 2015).

31 **Three-Dimensional Traveltime Tomography From Wide-Angle Seismic Data**

32 For three-dimensional (3D) refraction tomography, OBSs were placed within the
33 study area with an average spacing of 7 km, but with increasing density toward the
34 Rainbow massif (Fig. 1). A total of 46 OBSs were deployed and 43 provided full data
35 sets. Each OBS contained a hydrophone and a 1- or 3-component geophone, and recorded
36 at a sampling rate of 200 Hz. Approximately 3,800 airgun pulses were recorded by the
37 OBS that were spaced every ~450 m along 26 seismic lines (Fig. 1). In addition, the
38 airgun pulses of 21 MCS seismic lines (nominal source spacing of 37.5 m) were recorded
39 by the inner 20 OBSs of the array. Seismic tomographic imaging was carried out using
40 P-wave travel time data (~152,000 measurements) from both sets of seismic lines and an
41 iterative technique that computes 3D velocity structure (Dunn, 2015; Dunn et al., 2005).
42 Model parameters for isotropic velocity were spaced 0.5 km apart laterally, and vertically
43 increased from 0.25 km at the seafloor to 1 km at 10 km depth; model parameters for
44 azimuthal anisotropy were spaced 1 km laterally and increased from 0.5 km to 1 km from
45 seafloor to 10 km depth. We constructed a 1D depth-varying starting model of P wave

46 velocities by laterally averaging the V_p model of (Dunn et al., 2005) for a nearby segment
47 of the MAR. Then to obtain a stable 1-D starting model for the Rainbow area, we
48 inverted all of the data using this starting model and solved for a 3D solution. The 3D
49 anisotropic solution was then laterally averaged to create a new anisotropic 1D model,
50 which was used as a starting model for a new 3D calculation. Several iterations were
51 performed until the change in the 1D model from iteration-to-iteration was not
52 significant. A grid search was performed by varying the strength of separate horizontal
53 and vertical smoothness constraints on the tomographic image, to determine an
54 acceptable range of 3D solutions that fit the data. Solutions with large smoothing values
55 fit the data poorly. Very rough solutions also exhibit large data misfits and their velocity
56 structures are too rough to be constrained by the data on the basis of the Fresnel zone of
57 the seismic waves and checkerboard resolution tests. Models that best fit the data (chi-
58 squared misfit ~ 1.0) occur over a small range of smoothness values and are very similar
59 in appearance. Figure DR1 shows results of checkerboard resolution tests for vertical
60 tomographic slices that pass through the Rainbow massif.

61 **Two-Dimensional Multichannel Seismic Reflection Imaging.**

62 Two-dimensional multichannel seismic (MCS) reflection data were collected
63 across and along the Rainbow NTD and neighboring segments, comprising: seven NE-
64 SW-oriented profiles ~ 82 - 97 km in length (Lines 101-107), six WNW-ESE-oriented
65 profiles ~ 42 - 57 km in length (Lines 108, 110, 112, 114, 116, 118), six NW-SE-oriented
66 profiles ~ 42 km in length (Lines 109, 111, 113, 115, 117, 119), and two auxiliary short
67 profiles (Lines 122, 123) (Figs. 1, 2).

68 Acquisition parameters are given in Table DR1. MCS data processing consisted
69 of 3 main stages: (1) processing of shot gathers to prepare the data for depth imaging, (2)
70 pre-stack depth migration (PSDM) using as velocity model the long-wavelength V_p
71 structure from the regional 3D tomography volume described above; and (3) post-
72 migration image filtering and enhancement of low-frequency, laterally continuous
73 reflectors for interpretation and display purposes. Detailed processing steps are listed in
74 Table DR2. Figures DR2 and DR3 show the velocity model and pre- and post-
75 enhancement PSDM images for two representative profiles (110 and 112, respectively).

76 **Sill Identification, Picking, and Influence on Background V_p**

77 Sill identification was done visually on each of the reflection sections. Reflectors
78 within the Rainbow massif that have higher amplitudes than the background reflectivity,
79 have waveforms characterized by a single or multiple peak-trough pairs, and are sub-
80 horizontal or dip at low angle were interpreted as sills. We avoided interpreting as sills
81 pronounced “smiles” that could be artifacts due to migration of off-plane seafloor
82 scattering. Some of our interpreted sills have a moderate “smile” shape, which could be
83 due to overmigration because of uncertainties in the velocity model, or a true geological
84 shape, as concave-up or saucer-shaped magmatic sills are common in a variety of
85 geological settings (e.g., Schofield et al., 2010; Thomson, 2007).

86 Picking of the sills was done using an automatic event-tracking algorithm
87 following the negative (trough) amplitude of the waveform. Complex waveforms with
88 multiple peak-trough pairs were interpreted as arising from multiple, closely stacked sills
89 (e.g., Arnulf et al., 2014), and consequently stacked troughs were picked and assigned to

90 different sills. Figure DR4 shows an example of the interpretation and picking of sills
91 along Line 112.

92 The presence of low-velocity sills should decrease the background V_p of the
93 medium derived from the OBS data. We quantify this effect by using effective medium
94 theory (Kuster and Toksöz, 1974). If the background medium is unaltered peridotite
95 ($V_p=8$ km/s, $V_s=4.5$ km/s, density= 3300 kg/m³), and the sills are fully molten basalt
96 ($V_p=3.4$ km/s, $V_s=0$ km/s, density= 2.7 kg/m³), 2% porosity (volume of sills relative to
97 volume of material with $V_p>7.3$ km/s beneath the massif and above 8 km bsf) with aspect
98 ratio (thickness/length) of 0.1 (as gabbroic sills in the Oman ophiolite Moho transition
99 zone (Kelemen and Aharonov, 1998; Korenaga and Kelemen, 1997)) would produce an
100 effective background V_p of 7.8 km/s. In the end-member case in which all of the sills are
101 fully solidified gabbroic material ($V_p=7$ km/s, $V_s=3.9$ km/s, density= 2900 kg/m³), the
102 effective background V_p is 7.98 km/s, basically indistinguishable from unaltered
103 peridotite.

104 Therefore, if all of the sills were completely molten, some of the velocities in the
105 core of the massif where the sills are emplaced ($V_p=7.5-8.0$ km/s) could be due to the
106 effect of the low-velocity sills and not serpentinization, as indicated in Fig. 4D. In this
107 case, the sills would be intruding even less altered peridotite (<10% serpentinized),
108 strengthening our conclusion that the vast majority of the sills are emplaced in mantle
109 material. We find the scenario in which all of the imaged sills are completely molten
110 unlikely because of the minor presence of basalts on the surface of the massif (Andreani
111 et al., 2014), and because even in magmatically robust mid-ocean ridges like the East

112 Pacific Rise, only small portions of the axial melt lens contain large amounts of melts
113 (Marjanović et al., 2015; Singh et al., 1998; Xu et al., 2014).

114 **Energy Calculations**

115 Parameters for the following calculations are given in Table DR3. The energy per
116 unit volume released by full crystallization of magma sills as they cool from the liquidus
117 (T_L) to the solidus temperature (T_S) is (Lowell, 2010):

$$118 \quad U_m = \rho_m c_m (T_L - T_S) + \rho_m L$$

119 By computing the integrated volume of melt that all of the imaged sills could have stored
120 ($V_m=4.9-9.2 \times 10^9 \text{ m}^3$, for a range of sill thicknesses of 80-150 m (Benn et al., 1988;
121 Boudier et al., 1996; Kelemen and Aharonov, 1998; Korenaga and Kelemen, 1997; Xu et
122 al., 2014) and a circular plan-view geometry), we calculate the total energy released by
123 crystallization of the sills $E_m = 1.52-2.86 \times 10^{19} \text{ J}$.

124 We consider that the heat flux of the Rainbow hydrothermal system $H=0.5 \text{ GW}$
125 (German et al., 2010) consists of three primary components (Lowell, 2010): heat
126 transported by mantle upwelling (H_M), heat produced by serpentinization (H_{serp}), and heat
127 released by cooling of magmatic intrusions (H_m). The heat flux per unit area transported
128 by mantle upwelling at a slow-spreading ridge is estimated to be 1.8 MW km^{-2} (Lowell,
129 2010), which for Rainbow yields a mantle heat flux $H_M=0.186 \text{ GW}$, or 37% of the
130 estimated total heat flux H . To calculate H_{serp} we first make an estimation of the volume
131 and mass of serpentinite in the Rainbow massif based on the 3D Vp model. For velocity
132 values between 5.0 and 7.9 km/s, we convert Vp to serpentine fraction (ϕ_{serp}) using the
133 relation (Miller and Christensen, 1997):

134
$$\phi_{serp} = \frac{7.95 - Vp[km / s]}{2.88}$$

135 Vp values >7.9 km/s are assumed to correspond to no serpentinization ($\phi_{serp}=0$), while Vp
136 values <5.1 km/s are assumed to correspond to fully serpentinized material ($\phi_{serp}=1$) in
137 which Vp is further decreased due to large-scale porosity and fracturing. This yields a
138 volume of serpentine of 277.2-281.5 km³, corresponding to a mass of serpentine of 6.96-
139 7.07×10^{14} kg. The energy released by serpentinization is $2.5 \times 10^5 J kg^{-1}$ (Fyfe and
140 Lonsdale, 1981; Lowell, 2010), which yields an energy from serpentinization at Rainbow
141 of $E_{serp}=1.74-1.77 \times 10^{20} J$, about 1.5 times of that estimated for the serpentinized Atlantis
142 Massif (Früh-Green et al., 2003). Assuming that the massif has been being uplifted and
143 serpentinized during the last 390,000 years, based on its location relative to the Brunhes-
144 Matuyama magnetic reversal (Paulatto et al., 2015), we estimate a heat flux due to
145 serpentinization of $H_{serp}=0.014 GW$, or 3% of the estimated total heat flux H . From H_{serp}
146 and H_M we then estimate that ~60% of the total heat flux H , or $H_m=0.3 GW$, at Rainbow
147 has a magmatic origin. From E_m and H_m we then estimate that the cumulative duration of
148 magmatic intrusions at Rainbow capable of sustaining high-temperature hydrothermal
149 activity is 1,613-3,022 years (Table DR3). This duration represents ~7–30% of the total
150 span of hydrothermal activity at Rainbow, which has been estimated to be between
151 10,000–23,000 years (Cave et al., 2002; Kuznetsov et al., 2006).

152 The above calculation does not account for the possibility of additional heat
153 provided by crystallization of melt impregnating peridotites, which is observed in mantle
154 rock samples from the MAR (Cannat et al., 1997; Takazawa et al., 2007). We repeat the
155 above calculations taking into account the heat released by crystallization of melt
156 impregnating peridotites. We assume that the proportion of this additional melt is 1-3%

157 of the volume of the massif because 1-3% is the proportion of seismically imaged sills
 158 relative to the volume of fresh-to-slightly altered mantle material ($V_p > 7.3$ km/s).
 159 Factoring this additional melt, we find that magmatism at Rainbow could sustain high-
 160 temperature hydrothermal activity during 3,176-5,951 years (Table DR3), which is ~14-
 161 60% of system life.

Fig. DR1. Checkerboard reconstructions illustrating the resolving power of the tomography experiment. The reconstructions used the same ray paths, matrix of partial derivatives (weighted by data uncertainties), and regularization constraints as for the solution shown in the main text. The result is shown for the first iteration of the forward and inverse problem; subsequent iterations improve the magnitudes of the checkers, but not their form. Vertical cross sections are shown for locations along the centerline of the long-axis of the experiment (SW-NEW direction, Fig. 1) for **(A)**, $2 \times 2 \times 2 \text{ km}^3$ and **(B)**, $4 \times 4 \times 4 \text{ km}^3$ size anomalies. Overall, the best resolution occurs within the station bounds and above 8 km depth. Target checkerboard tests with the depth range of 8-10 km (not shown), where only ~ 2000 rays sample in total, found only large scale features can be detected ($>10 \text{ km}$), but not without significant smearing and distortion. The Rainbow hydrothermal field is located at 0 km distance along the horizontal axis.
