ABSTRACT

We observed three massive subhalos in the Coma cluster with *Suzaku*. These subhalos, labeled “ID 1,” “ID 2,” and “ID 32,” were detected with a weak-lensing survey using Subaru/Suprime-Cam, and are located at the projected distances of $1.4 r_{500}$, $1.2 r_{500}$, and $1.6 r_{500}$ from the center of the Coma cluster, respectively. The subhalo “ID 1” has a compact X-ray excess emission close to the center of the weak-lensing mass contour, and the gas mass to weak-lensing mass ratio is about 0.001. The temperature of the emission is about 3 keV, which is slightly lower than that of the surrounding intracluster medium (ICM) and that expected for the temperature versus mass relation of clusters of galaxies. The subhalo “ID 32” shows an excess emission whose peak is shifted toward the opposite direction from the center of the Coma cluster. The gas mass to weak-lensing mass ratio is also about 0.001, which is significantly smaller than regular galaxy groups. The temperature of the excess is about 0.5 keV and significantly lower than that of the surrounding ICM and far from the temperature versus mass relation of clusters. However, there is no significant excess X-ray emission in the “ID 2” subhalo. Assuming an infall velocity of about 2000 km s^{-1} , at the border of the excess X-ray emission, the ram pressures for “ID 1” and “ID 32” are comparable to the gravitational restoring force per area. We also studied the effect of the Kelvin–Helmholtz instability to strip the gas. Although we found X-ray clumps associated with the weak-lensing subhalos, their X-ray luminosities are much lower than the total ICM luminosity in the cluster outskirts.

Key words: galaxies: clusters: individual (Coma Cluster) – X-rays: galaxies: clusters

1. INTRODUCTION

Galaxy clusters are the largest self-gravitating bound systems in the universe and are composed of thousands of galaxies, the intracluster medium (ICM), and dark matter. The ICM covers a total mass range of roughly $10^{13-14} M_{\odot}$ and is bound to the potential of the dark matter halo, which covers that of $10^{14-15} M_{\odot}$. Therefore, the gravity of the dark matter halo plays the most important role in cluster evolution and structure formation. Numerical simulations with the cold dark matter (CDM) model predict that the galaxy clusters form through the merger or accretion of a smaller system like galaxy groups. Since the dynamical timescale of galaxy clusters is comparable to the Hubble time, the outskirts of the galaxy clusters still maintain the evolution effects via the accretion of the substructures. The central region of these accreting objects is expected to have survived until recently as subhalos in the cluster host halo.

The mass distribution of subhalos provides us with information on the mass assembly of the galaxy cluster. Okabe et al. (2014a) surveyed and measured the mass of subhalos in the Coma cluster using weak-lensing observations with Subaru/Suprime-Cam. Thanks to the large apparent size, they detected 32 cluster subhalos whose mass range is $\sim 2-50 \times 10^{12} h^{-1} M_{\odot}$. They first confirmed that the subhalo mass function, $d n/d \ln M_{\text{sub}}$, is well represented with a single power law or a Schechter function. The best-fit indexes of each model are ~ 1 , which agree well with the CDM model prediction on the sub-scale of the cluster. Stacked signals of subhalos were well represented with a sharply truncated Navarro–Frenk–White (NFW) mass model (Navarro et al. 1995) as expected from a tidal destruction model. For the three most massive subhalos

whose mass are higher than $\sim 1 \times 10^{13} h^{-1} M_{\odot}$, they measured the mass and truncation radius of each subhalo. One of them is a famous substructure of the Coma cluster around the NGC 4839 group.

If subhalos in the cluster outskirts still possess some amount of their hot gas and are not excluded in X-ray analysis, the derived ICM density would be overestimated. The recent *Suzaku* observations reported that the entropy of the ICM, which is a useful parameter for the thermodynamical history, shows flatter profiles beyond r_{500} than expectations from pure gravitational heating (Bautz et al. 2009; George et al. 2009; Reiprich et al. 2009; Hoshino et al. 2010; Kawaharada et al. 2010; Akamatsu et al. 2011, 2012; Simionescu et al. 2011, 2013; Urban et al. 2011, 2014; Sato et al. 2012, 2014; Walker et al. 2012a, 2012b, 2013; Ichikawa et al. 2013; Okabe et al. 2014b). Since the gas fraction in the Perseus cluster assuming hydrostatic equilibrium exceeds the cosmic baryon fraction, Simionescu et al. (2011) claimed the effect of gas clumpiness, although a *Chandra* observation showed no significant excess X-ray sources in the outskirts (Urban et al. 2014).

The weak-lensing mass estimation of cluster main halos is complementary to X-ray observations. In the cluster outskirts, the hydrostatic mass with *Suzaku* is significantly lower than the weak-lensing mass with the Subaru telescope (Kawaharada et al. 2010; Ichikawa et al. 2013; Okabe et al. 2014b; Mochizuki et al. 2015). Okabe et al. (2014b) discussed how the bivariate scaling functions of the electron density and temperature indicate that entropy flattening of the outskirts of the galaxy clusters is caused by the steepening of temperature profiles. Deviations from hydrostatic equilibrium have been discussed in Kawaharada et al. (2010), Ichikawa et al. (2013),

^a The name of subhalos (Okabe et al. 2014a).

^b The projected weak-lens mass of the subhalos (Okabe et al. 2014a).

^c The best-fit mass with truncated NFW model (Okabe et al. 2014a).

^d The truncation radius derived from Okabe et al. (2014a).

^e For “ID 1” and “ID 2,” the center of the subhalos determined from the mass contour. The center of “ID 32,” however, is derived from the weak-lensing signal peak since the difference between the weak-lensing signal peak and the mass contour is significantly smaller than the *Suzaku* point-spread function.

^f The Galactic hydrogen column density (Kalberla et al. 2005).

^g The distance from the X-ray peak of the Coma cluster center ($12^{\text{h}}59^{\text{m}}44^{\text{s}}.81, 27^{\circ}56'49''92$).

Okabe et al. (2014b), and Mochizuki et al. (2015). Hoshino et al. (2010) proposed another idea in which electron temperature is lower than the ion temperature in these regions, since heating the electrons takes a longer time than that of the ion after accretion shocks and mergers.

With weak-lensing mass measurements of subhalos, we can search X-ray clumps associated with these subhalos efficiently with X-ray observations. In this paper, we describe the X-ray properties of three massive subhalos whose mass is greater than $\sim 9 \times 10^{12} h^{-1} M_{\odot}$, detected by Subaru weak-lensing observations of the Coma cluster (Okabe et al. 2014a). Excluding the NGC 4839 subgroup, we observed two of the most massive subhalos with *Suzaku*. We also observed a smaller subhalo, whose total mass is $\sim 9 \times 10^{12} h^{-1} M_{\odot}$. We summarize the observations and data preparation in Section 2. Section 3.1 shows the X-ray images and surface profiles of each subhalo. In Section 3.2, we summarize the spectral fitting and the results. We compare the X-ray properties with those of other galaxy groups and discuss the effect of ram pressure and gas clumpiness in Section 4.

We use $\Omega_{m,0} = 0.27$, $\Omega_{\Lambda} = 0.73$, and $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$ in this paper. At the redshift of the cluster, $z = 0.0231$ (Struble & Rood 1999), $1'$ corresponds to 28.9 kpc. The solar abundance table is given by Lodders (2003). The errors are in the 68% confidence region for the single parameter of interest.

2. OBSERVATION AND DATA REDUCTION

In the Coma cluster, Okabe et al. (2014a) detected three massive subhalos whose masses are higher than $10^{13} M_{\odot} h^{-1}$, which are labeled as “ID 1,” “ID 9,” and “ID 32.” The weak-lensing signals of these three subhalos were well represented by a truncated NFW model. Since “ID 9” is associated with a halo of the famous subgroup around NGC 4839, which has already been observed with *Suzaku* and reported by Akamatsu et al. (2013), we observed “ID 1,” “ID 32,” and a southern offset region of “ID 32” as a background (hereafter “ID 32 BGD”) with *Suzaku*. We also observed the “ID 2” subhalo, which is associated with the NGC 4816 group and whose total mass reaches $9 \times 10^{12} M_{\odot} h^{-1}$, with *Suzaku*. The mass, truncation radius (hereafter r_t), and coordinates of each subhalo are summarized in Table 1 and the observational logs with *Suzaku* are shown in Table 2. The three subhalos, “ID 1,” “ID 2,” and “ID 32,” are located at the projected distances of $1.4 r_{500}$, $1.2 r_{500}$, and $1.6 r_{500}$ from the X-ray peak of the Coma cluster,

respectively. In Figure 1, we overlaid the fields of view (FOVs) of the *Suzaku* pointings and the contours of the mass map derived from weak-lensing (Okabe et al. 2014a) on the X-ray image with *ROSAT*. We also used four *Suzaku* pointings beyond $2.5 r_{500}$ of the Coma cluster to study the X-ray background emission. The details are described in the Appendix.

In this study, we used only XIS data. The XIS instrument consists of three sets of X-ray CCDs (XIS 0, 1, and 3). XIS 1 is a back-illuminated (BI) sensor, while XIS 0 and 3 are front-illuminated (FI). The instruments were operated in the normal clocking mode (8 s exposure per frame). The data were reprocessed the standard screening criteria⁴ using HEASoft 6.15. We also performed event screening with the cosmic-ray cut-off rigidity $\text{COR} > 6 \text{ GV}$, and the Earth rim $\text{ELEVATION} > 10^{\circ}$. We generated ancillary response files by “xissimarfgen” Ftools task (Ishisaki et al. 2007), assumed a uniform sky of $20'$ radius. The effect of degrading energy resolution by radiation damage was included in the redistribution matrix files by “xismfgen” Ftools task. We employed the night earth database generated by the “xisnxbgen” Ftools task for the same detector area to subtract the non-X-ray background (NXB).

3. ANALYSIS AND RESULTS

3.1. X-ray Images and Surface Brightness Profiles

In Figure 2, we present combined XIS images of subhalos in a 0.5–2.0 keV energy band. Here, the difference in the exposure times is corrected with the exposure map generated by the “xisexpmapgen” Ftools task. In addition, we also corrected the vignetting effect using a flat image at 1 keV.⁵ We created surface brightness profiles from these images of individual subhalos along the direction to the center of the Coma cluster, (R.A., decl.) = ($12^{\text{h}}59^{\text{m}}44^{\text{s}}.81, 27^{\circ}56'49''92$). The resultant surface brightness profiles are shown in Figure 3.

As shown in Figures 2(a) and 3(a), an excess emission is seen around the center of the “ID 1” mass contour. The surface brightness profile shows that most of the excess emission is confined within $\sim 2'$ ($0.6 r_t$) from the mass center. In contrast, the “ID 2” subhalo does not show any excess emission: the brightness profile gradually increases toward the Coma cluster center as shown in Figure 3(b).

Figure 1. Weak-lensing mass contour map in linear scale from Subaru overlaid on the X-ray image taken by the *ROSAT* All Sky Survey in the 0.1–2.4 keV band. Here, the exposure time was corrected and instrumental backgrounds were subtracted. The X-ray image was smoothed by a Gaussian of $\sigma \approx 2'$. The color bar is in units of counts s^{-1} pixel $^{-1}$. The FOVs of the *Suzaku* pointings are plotted with boxes (yellow). The solid (white) circles indicate r_{500} ($\sim 44'$) and $r_{vir} \sim r_{98}$ ($\sim 97'$), respectively, which were derived with weak-lensing observations by Okabe et al. (2010). The dashed (magenta) box shows the field of the Subaru weak-lensing survey (Okabe et al. 2014a) and the mass distribution derived from this survey was overlaid in contours. The crosses (green) show the positions of representative galaxies, NGC 4807, the NGC 4816 group, and IC 4088, for the subhalos “ID 1,” “ID 2,” and “ID 32,” respectively.

In Figure 3(c), the “ID 32” subhalo shows an excess emission whose peak is not located on the center of the mass contour, but shifts about $3'$ ($0.3 r_t$) away from the subhalo center toward the northern part or the opposite direction from the Coma cluster center. The excess emission is extended to at least $5'$ ($0.6 r_t$) from the mass center. Because of the asymmetrical profile for “ID 32,” we also made projections of the surface brightness of the northern and southern parts from the mass center of the subhalo along the perpendicular direction in Figure 3(c). The resultant projections of the surface brightness are shown in Figure 3(d). The excess emission at the northern direction extends out to 5 – $6'$ ($0.6 r_t$) toward the east and west directions. The peak of the X-ray emission is

located in the northern part and shifts about $3'$ ($0.3 r_t$) away from the subhalo center toward the west. In contrast, the brightness of most of the southern part is consistent with that of the background region, although there are two peaks at $\sim 6'$ offsets to the east and the west. We extracted spectra around these two excesses. Since their spectra are relatively hard and fitted with a power-law model, the southern peaks are possibly caused by background point sources.

3.2. Spectral Fitting

We extracted spectra over subhalo regions and background regions as shown in Figure 4. The regions around point sources brighter than 1×10^{13} erg s^{-1} cm^{-2} in 2.0–10.0 keV were excluded from the spectral analysis. Since the mass contours of the subhalo “ID 1” in linear scale are elongated, we extracted spectra over an elliptical region whose semiminor and semimajor axes are 1.0 and 1.6 r_t , respectively. Here, we excluded a circular region around a background galaxy group (Okabe et al. 2014a), plotted as a dashed circle in Figure 4. To study background emissions including the ICM contribution, we extracted spectra over an square region (hereafter “ID 1 BGD”), excluding the elliptical region. For the “ID 32” subhalo, we extracted spectra over two semicircular regions (hereafter “south” or “north” regions) of the subhalo out to the truncation radius. The background spectra for “ID 32” were extracted from the FOV of the “ID 32 BGD” observation.

The spectral fitting was carried out using XSPEC 12.8.1g and the extended C-statistic estimator. The spectra were binned to have at least one count per channel. We used the energy ranges of 0.5–7.0 keV and 0.7–7.0 keV for the BI and FI detectors, respectively. We excluded the energy band around the Si-K edge (1.82–1.84 keV) because its response was not modeled correctly.

We assumed that the X-ray emissions from “ID 1 BGD” and “ID 32 BGD” consist of the Galactic emissions from the Local Hot Bubble (LHB) and the Milky Way Halo (MWH), the cosmic X-ray background (CXB), and the ICM of the Coma cluster. The LHB and MWH were modeled with a thermal plasma model (apec model; Smith et al. 2001) without and with Galactic absorption, $apec_{LHB}$ and $phabs_{GAL} \times apec_{MWH}$, respectively. Here, $phabs_{GAL}$ indicates the Galactic absorption using $phabs$ model in the XSPEC package, and the column density of each subhalo direction is summarized in Table 1. The temperature of the $apec_{LHB}$ was fixed at 0.1 keV, while its normalization was a free parameter. We also allowed the temperature and normalization of the $apec_{MWH}$ to vary. For the LHB and MWH, the redshift and abundance were fixed to be 0 and 1 solar, respectively. The CXB emission was described by an absorbed power-law model with a photon of index $\Gamma = 1.4$,

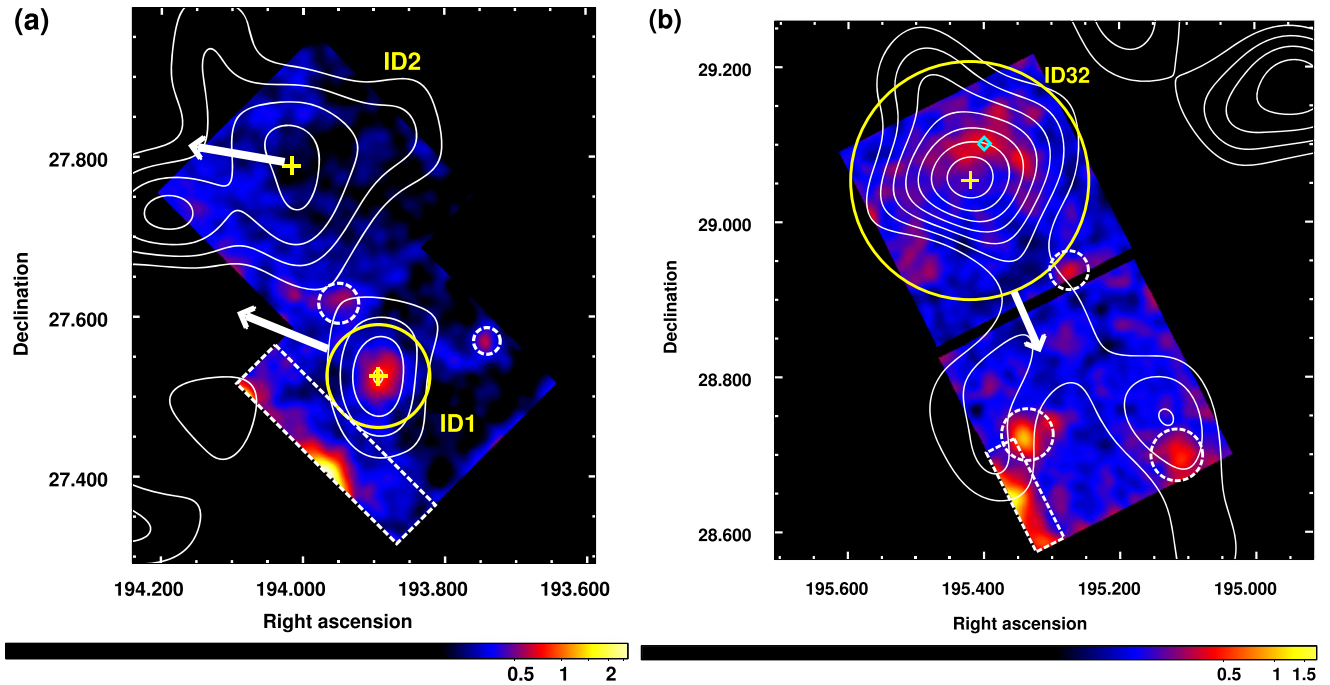

Figure 2. Weak-lensing mass contour map in linear scale overlaid on the NXB subtracted XIS images in 0.5–2.0 keV. (a) around “ID 1” and “ID 2,” and (b) around “ID 32” in the 0.5–2.0 keV energy band. Here, the difference in the exposure times and the vignetting effect at 1 keV were corrected. The images were smoothed by a Gaussian of $\sigma = 24$ pixels $\approx 25''$. The numbers below the color bars have units of counts $\text{Ms}^{-1} \text{pixel}^{-1}$. The contours (white) show the mass map derived from weak-lensing by Okabe et al. (2014a). The direction of the Coma cluster center from the center of each subhalo is shown by the arrow. The crosses are the center of each subhalo as summarized in Table 1. For “ID 1” and “ID 32,” the solid (yellow) circles show the truncation radii. The diamond (cyan) mark in the “ID 32” subhalo corresponds to the X-ray peak of the excess emission. When creating the surface brightness profiles, the regions in the dashed (white) circles and boxes were excluded.

$\text{phabs}_{\text{GAL}} \times \text{power} - \text{law}_{\text{CXB}}$. The normalization of $\text{power} - \text{law}_{\text{CXB}}$ was estimated beyond the virial radius of the Coma cluster as described in the Appendix.

The ICM emission was modeled with a thermal plasma model with the Galactic absorption, $\text{phabs}_{\text{GAL}} \times \text{apec}_{\text{ICM}}$. The temperature, normalization, and abundance were allowed to vary, except for the abundance for “ID 32 BGD” which was fixed at 0.2 solar. The redshift of the ICM component was fixed at the value of the Coma cluster, $z = 0.0231$. Thus, we used the following model formula for the spectra for “ID 1 BGD” and “ID 32 BGD”: $\text{constant} \times (\text{apec}_{\text{LHB}} + \text{phabs}_{\text{GAL}} \times (\text{apec}_{\text{MWH}} + \text{apec}_{\text{ICM}} + \text{power} - \text{law}_{\text{CXB}}))$. Here, the constant is a normalization parameter for the difference in relative normalizations among XIS detectors.

For the subhalo regions, we added an extra thermal plasma model, $\text{phabs}_{\text{GAL}} \times \text{apec}_{\text{subhalo}}$. We allowed the temperature and normalization of the $\text{apec}_{\text{subhalo}}$ of “ID 1” and “ID 32” to vary. The abundance for “ID 1” was a free parameter but that for “ID 32” was fixed at 0.2 solar, since we can not constrain the abundance. Even if the abundance was fixed to be 0.1 or 0.3 solar, the results did not change.

The redshift of the $\text{apec}_{\text{subhalo}}$ was also fixed at the value of the Coma cluster. Thus, we modeled the spectra extracted from subhalo regions as the following formula: $\text{constant} \times (\text{apec}_{\text{LHB}} + \text{phabs}_{\text{GAL}} \times (\text{apec}_{\text{MWH}} + \text{apec}_{\text{ICM}} + \text{apec}_{\text{subhalo}} + \text{power} - \text{law}_{\text{CXB}}))$. We finally fitted the spectra extracted for each subhalo region and the corresponding background region simultaneously, assuming that the X-ray background components have the same surface brightness, temperature, and abundances. Here, relative normalizations of the three XIS detectors were allowed to vary.

The fitting results are summarized in Table 3. Figure 5 shows the best-fit spectra of the background regions. The ICM temperatures for the “ID 1” and “ID 32” regions, $4.33_{-0.37}^{+0.60}$ and $5.19_{-0.83}^{+1.04}$ keV, respectively, are consistent with previous results of the southwest and northwest directions (Simionescu et al. 2013) at similar distances from the cluster center, respectively. Although the error range is fairly large, the ICM abundance of “ID 1” was also consistent with that in Simionescu et al. (2013).

The temperatures and normalizations of the Galactic components are consistent between “ID 1” and “ID 32.” The normalization of the LHB derived from the “ID 1” and “ID 32” spectral fits is consistent with that for the region at 110’–130’ (Appendix). However, the temperature and normalization of MWH are significantly different from those derived for the 110’–130’ region. When we use the temperature and normalizations of the Galactic components obtained from 110’–130’ region, and fitted the spectra of the subhalo regions, the temperature and normalization of “ID 1” and the “north” region of “ID 32” did not change within statistical errors, although the temperature of the “south” region of “ID 32” decreased to about 0.1 keV. Considering the possible spatial variation of the Galactic components, we adopted the results of the simultaneous fits using “ID 1 BGD” and “ID 32 BGD.”

3.3. Fitting Results of the Subhalo Components

Figure 5 also shows the best-fit spectra of the subhalo regions. The fitting results of the subhalo components are summarized in Table 3. The spectra for the subhalo and background regions were well represented with our model

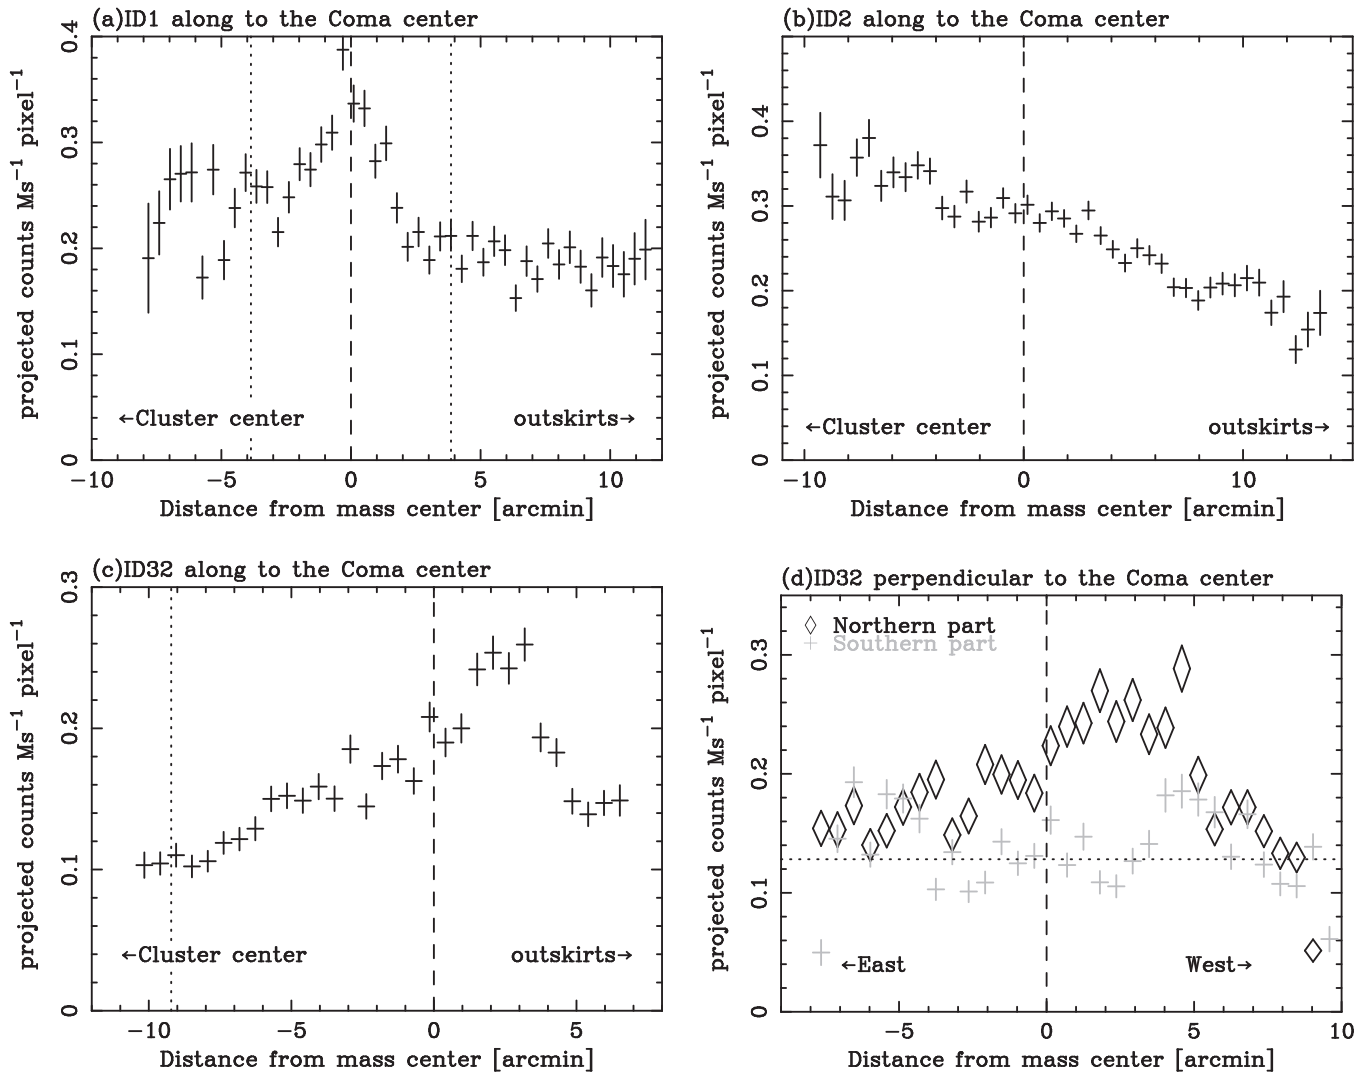

Figure 3. Projected surface brightness profiles of (a) “ID 1” subhalo, (b) “ID 2” subhalo, and (c) “ID 32” subhalo along the direction to the outskirts from the Coma cluster center extracted from the combined XIS FOV images in the 0.5–2.0 keV energy band. The side of the negative numbers corresponds to the direction to the center of the Coma cluster. Here, the NXB was subtracted and the effect of the exposure time and vignetting were corrected. The minus X -axis corresponds to the direction of the Coma cluster center. The dashed vertical lines indicate the center of each subhalo and the dotted vertical lines show the truncation radius of the subhalo “ID 1” and “ID 32.” (d) The projection direction is perpendicular to (c). The sides of the negative and positive numbers correspond to the directions east and west.

formula. Without the subhalo components, the data-to-model ratios show significant excess.

The temperatures of each subhalo component are lower than that of the surrounding ICM. For “ID 1,” the temperature is $2.71^{+0.99}_{-0.59}$ keV and is cooler than the ICM component, $4.33^{+0.60}_{-0.37}$ keV. The temperatures “north” and “south” of “ID 32” are about $0.55^{+0.07}_{-0.13}$ and $0.29^{+0.13}_{-0.07}$ keV, respectively. These values are significantly lower than the surrounding ICM temperature, $5.19^{+1.04}_{-0.83}$ keV. The abundance of the subhalo “ID 1” component is consistent with that of the surrounding ICM. The luminosity of the “ID 1” component is about 2×10^{41} erg s⁻¹ at 0.5–2.0 keV energy range and those of the “north” and “south” regions of “ID 32” are $\sim 2 \times 10^{41}$ erg s⁻¹ and $\sim 7 \times 10^{40}$ erg s⁻¹ at the same energy range, respectively.

3.4. The Representative Background Structure Fitting

Background galaxy groups are located within the “ID 1” and “ID 32” subhalo regions at $z = 0.418$ (Wen et al. 2009) and $z = 0.189$ (Hao et al. 2010), respectively (Okabe et al. 2014a).

If the weak-lensing signals were mostly caused by the corresponding background galaxy groups, the virial mass, M_{vir} would be $1\text{--}3 \times 10^{15} M_{\odot}$ for “ID 1” and several times $10^{14} M_{\odot}$ for “ID 32” (Okabe et al. 2014a). For such massive clusters, we expect that the ICM temperatures and ICM luminosities exceed 10 keV and 10^{45} erg s⁻¹ for “ID 1,” respectively, and several keV and several times 10^{44} erg s⁻¹ for “ID 32,” respectively. Therefore, we refitted the *Suzaku* spectra using redshifts of the background galaxy groups. As a result, the temperature increased to ~ 4 and 0.8 keV for “ID 1” and the “north” region of “ID 32,” respectively, and the X-ray luminosity became $\sim 10^{44}$ erg s⁻¹ and 2×10^{43} erg s⁻¹ in the 0.5–2.0 keV range, respectively. These temperatures and X-ray luminosities are far below the expected values assuming that the weak-lensing signals come from the background galaxy groups. Thus, it is unlikely that the excess emissions and weak-lensing signals come from the background galaxy groups, and are fairly associated with the Coma cluster.

Figure 4. Same images as Figure 2. The elliptical region (yellow) in the left panel and semicircular regions (yellow) in the right panel are used in spectral extraction for the “ID 1” subhalo, and “south” and “north” regions of the “ID 32” subhalo, respectively. The solid box (yellow) in the left panel excluding the elliptical region and that in the right panel are used in the background analysis (“ID 1 BGD” and “ID 32 BGD,” respectively). The regions within the dashed box and circles (white) are excluded from these spectral analyses.

3.5. The Gas Mass Estimation

To estimate the gas mass of each subhalo, we first approximated the spherical symmetry and assumed constant density up to $2r_5$ and $6r_5$ for “ID 1” and “ID 32,” respectively, which correspond to $\sim 0.6 r_t$ for each subhalo, since beyond these radii the excess emission was not detected. The best-fit normalization in the spectral fitting leads us to derive average electron density within the extracted region of each subhalo.

The resultant average electron densities of “ID 1,” and the “south” and “north” regions of “ID 32” are $(5.3 \pm 0.6) \times 10^{-4} \text{ cm}^{-3}$, $(2.0 \pm 0.8) \times 10^{-4} \text{ cm}^{-3}$, and $(2.4 \pm 0.4) \times 10^{-4} \text{ cm}^{-3}$, respectively. Integrating the electron densities out to $0.6 r_t$, the derived gas mass are $(2.1 \pm 0.2) \times 10^{10} M_\odot$, $(6.8 \pm 1.2) \times 10^{10} M_\odot$, and $(5.8 \pm 2.2) \times 10^{10} M_\odot$ for “ID 1” and the “north” and “south” regions of “ID 32,” respectively.

We also estimated the electron density profiles by deprojecting radial profiles of the surface brightness centered on the center of the mass contour and the X-ray peak of “ID 1” and “ID 32” subhalos, respectively. We integrated the electron density profiles out to $0.6 r_t$, within which the X-ray emissions of each subhalo are detected. Then, the derived gas mass of “ID 1” and “ID 32” are $(1.5 \pm 0.1) \times 10^{10} M_\odot$ and $(9.5 \pm 0.5) \times 10^{10} M_\odot$, respectively. Comparing these values with those assuming constant electron density, the systematic uncertainties in the gas mass would be about a factor of two to three.

Using the radial profiles of the electron density profile and the temperatures of “ID 1” and the “north” region of “ID 32” derived from the spectral fits, radial profiles of the thermal gas pressure, $P = n_e kT$ out to $\sim 0.6 r_t$, were estimated and plotted in Figure 6. Since the surface brightness and temperature of the ICM component surrounding “ID 1” and “ID 32” are close to those of the southwest direction and the azimuthal averages excluding the southwest direction derived by Simionescu et al. (2013),

we compared our pressure profiles with those derived by Simionescu et al. (2013). The thermal pressure at $0.5 r_t$ of “ID 1” is slightly higher than that of the southwest direction. That in $0.3\text{--}0.5 r_t$ of “ID 32” is slightly below the ICM pressure.

We also estimated the gas mass assuming that the excess emission comes from background galaxy groups located within the “ID 1” and “ID 32” subhalo regions. The calculation methods are the same as mentioned in the previous paragraphs. Assuming flat density profiles, the total gas mass for “ID 1” and “ID 32” are $(1.8 \pm 0.2) \times 10^{13} M_\odot$ and $(1.3 \pm 0.8) \times 10^{13} M_\odot$, respectively. By deprojecting the surface profiles, we estimated the gas mass by integrating the calculated density profiles. The resultant gas masses are $(1.3 \pm 0.1) \times 10^{13} M_\odot$ and $(1.3 \pm 0.1) \times 10^{13} M_\odot$ for “ID 1” and “ID 32,” respectively.

4. DISCUSSION

We observed three massive subhalos detected by the weak-lensing survey with Subaru, “ID 1,” “ID 2,” and “ID 32,” which are located at the *Suzaku* projected distances of $1.4 r_{500}$, $1.2 r_{500}$, and $1.6 r_{500}$ from the center of the Coma cluster, respectively. Excess X-ray emission has been detected from “ID 1” and “ID 32,” while “ID 2” has no significant excess emission. Temperatures of these subhalos were lower than that of the surrounding ICM. In Section 4.1, we compare the $M_{\text{gas}}\text{--}M_{\text{total}}$ and $kT\text{--}M_{\text{total}}$ relations between subhalos and regular galaxy groups. We estimate the ram pressure and mass-loss rate caused by the Kelvin–Helmholtz instability in Section 4.2. As discussed in Simionescu et al. (2011), the clumping in the galaxy clusters leads us to overestimate the electron density. In Section 4.3, we study the effect of the subhalos on the density and temperature measurements.

^b The energy range is 0.5–2.0 keV.

4.1. Comparison of the Gas Mass Fraction and Temperature with Other Clusters

The gas mass and weak-lensing mass of “ID 1” and “ID 32” are plotted in Figure 7(a). The gas mass fraction, or the gas mass to weak-lensing mass ratio, of these two subhalos is about 0.001. Here, we used the gas mass derived from integrating the radial profiles of the electron density. We compared these gas mass fractions of the subhalos with the gas mass to hydrostatic mass ratios of clusters and groups of galaxies. Since the mean density within the truncation radius of subhalos “ID 1” and “ID 32” is about 6600 times and 27,000 times higher than the critical density of the universe, respectively, we calculated the gas mass and hydrostatic mass at a radius within which each average density is the same as each subhalo’s overdensity, using *Chandra* results by Vikhlinin et al. (2006). The gas mass fractions of these clusters correlate well with the hydrostatic mass, and are about 0.02–0.1, which are about one to two orders of magnitude higher than those of the subhalos. If these subhalos had been regular groups before infalling onto the Coma cluster, they should have lost most of their gas.

In Figure 7(b), we also compared the relation of the temperature and total mass (kT – M_{total} relation) of the subhalos and clusters. Here, we also calculated the temperature and hydrostatic mass of the *Chandra* clusters in Vikhlinin et al. (2006) at the radius of the same overdensities, or r_{6600} for “ID 1” and r_{27000} for “ID 32.” The temperature of “ID 1” is slightly lower than expected by the kT – M_{total} relation of the clusters. For “ID 32,” the temperature of the subhalo is several times lower than those of the kT – M_{total} relation of the clusters.

4.2. The Effect of Ram Pressure Stripping

The observed very low gas mass fraction and morphologies of the excess emission indicate that the gas in the infalling subhalos has been stripped via the ram pressure of the surrounding ICM. The subhalo would be unable to hold the interstellar materials when the ram pressure exceeds the

gravitational restoring force per area. At the truncation radius, the fraction of the ram pressure to the gravitational restoring force per area (Takizawa 2006)

$$\text{Ratio} = \frac{P_{\text{ram}}}{F_{\text{grav}}/\text{Area}} = 1.3 \left(\frac{r_t}{100 \text{ kpc}} \right)^4 \left(\frac{n_{e,\text{ICM}}}{10^{-5} \text{ cm}^{-3}} \right) \times \left(\frac{M_{\text{subhalo}}}{10^{13} M_{\odot}} \right)^{-1} \left(\frac{M_{\text{gas,subhalo}}}{10^{10} M_{\odot}} \right)^{-1} \left(\frac{v_{\text{gal}}}{2500 \text{ km s}^{-1}} \right)^2 \quad (1)$$

is a useful parameter to investigate the present stripping effect. Here, the $n_{e,\text{ICM}}$, v_{gal} , r_t , M_{subhalo} , and $M_{\text{gas,subhalo}}$ are the electron density of the ICM, velocity of the subhalo, truncation radius, mass of the subhalo, and gas mass of the subhalo, respectively. By adopting those parameters of the subhalos and ICM, we calculated the ram pressure to the gravitational force per area ratio as a function of the subhalo moving velocity and plotted it in Figure 8. We also estimated the ratio at the $0.6 r_t$, which corresponds to the border of the excess X-ray emission. The ram pressure should have been lower than the present value when infalling on the outer regions, since the ICM density decreases with the distance from the cluster center.

Since NGC 4807 and IC 4088 are located near the center of the mass contours of “ID 1” and “ID 32” (see Figure 1), respectively, these galaxies are likely representative galaxies of these subhalos. The recession velocities of NGC 4087 and IC 4088 are 6989 and 7095 km s⁻¹ (NASA/IPAC Extragalactic Database),⁶ respectively. Considering that of the Coma cluster, 6925 km s⁻¹, the velocities in line of the sight of these galaxies are 64 and 170 km s⁻¹, respectively. As shown in Figure 8, if these subhalos are moving toward the line of sight, the ratio of the ram pressure to the gravitational force in a unit area is orders of magnitudes lower than the unity. Even if

Figure 6. Thermal pressure profile of “ID 1” centered on the mass center (open circles) and that of “ID 32” centered on the X-ray peak (open stars). The dotted (magenta) and dashed (green) lines indicate the ICM pressure range of the southwest direction and azimuthal average excluding the southwest direction derived by Simionescu et al. (2013).

these subhalos are moving with an inclination angle of 45° , the ram pressure is still not effective to remove the gas of the subhalos.

On the other hand, the infall velocities for “ID 1” and “ID 32” are about 2000 km s^{-1} , which is estimated using the best-fit NFW profile derived from the weak-lensing for the main halo (Okabe et al. 2010). This value is comparable with the infall velocity of the subcluster, NGC 4839 group, whose infall velocity is $1700^{+350}_{-500} \text{ km s}^{-1}$ (Colless & Dunn 1996). Adopting the infall velocity, at $1.0 r_t$, the ram pressure is higher than the gravitational force per area and enough to remove the gas, and at $0.6 r_t$, or at the border of the excess X-ray emission, the ram pressure is comparable to the gravitational force per area. These subhalos are located beyond r_{500} on the sky, and if

they are moving perpendicular to the line of sight with the infall velocity, their gas beyond $0.6 r_t$ can be stripped via ram pressure stripping.

We also estimated the mass-loss rate caused by Kelvin–Helmholtz instabilities since the gas in the center of “ID 32” seems to be removed. Nulsen (1982) estimated the mass-loss rate caused by viscous stripping via Kelvin–Helmholtz instabilities, $\dot{M}_{\text{KH}} \approx \pi r_D^2 \rho_{\text{ICM}} v$. Here, r_D and ρ_{ICM} are the disk radius and gas density of the ICM, respectively. The mass-loss rate can convert

$$\dot{M}_{\text{KH}} \approx 25 \left(\frac{n_e}{10^{-5} \text{ cm}^{-3}} \right) \left(\frac{r_D}{100 \text{ kpc}} \right)^2 \times \left(\frac{v_{\text{gal}}}{2500 \text{ km s}^{-1}} \right) \left[M_\odot \text{ yr}^{-1} \right]. \quad (2)$$

We assumed that r_D is same as the truncation radius. Using the velocity of line of sight of each subhalo, the results of the mass-loss rate were $\dot{M}_{\text{HK}} \approx 6 M_\odot \text{ yr}^{-1}$ for “ID 1” and $\approx 60 M_\odot \text{ yr}^{-1}$ for “ID 32.” In contrast, adopting the infall velocity, the mass-loss rates of “ID 1” and “ID 32” are 180 and $680 M_\odot \text{ yr}^{-1}$, respectively. Considering the timescales for the mass-loss of 520 and 390 Myr for “ID 1” and “ID 32,” respectively, infalling from the virial radius of the Coma cluster, the total mass-loss rates from adopting the infall velocity the subhalo are about 9×10^{10} and $3 \times 10^{11} M_\odot$ for “ID 1” and “ID 32,” respectively. These values of mass are more massive than current gas mass of the both subhalos. Therefore, the destruction of gas by the Kelvin–Helmholtz instability explains the very low gas fraction of the “ID 1” and “ID 32” subhalos. However, the mass-loss rate would be smaller with magnetic fields that suppress the destruction by Kelvin–Helmholtz instability.

4.3. The Contribution of the X-ray Emission of Subhalos to the ICM

Suzaku enables us to measure the entropy profiles of the galaxy clusters out to the virial radius (Bautz et al. 2009; George et al. 2009; Reiprich et al. 2009; Hoshino et al. 2010; Kawaharada et al. 2010; Akamatsu et al. 2011, 2012; Simionescu et al. 2011, 2013; Urban et al. 2011, 2014; Humphrey et al. 2012; Walker et al. 2012a, 2012b, 2013; Sato et al. 2012, 2014; Ichikawa et al. 2013; Okabe et al. 2014b; Mochizuki et al. 2015). Contrary to the prediction of the accretion shock heating model prediction, the entropy of galaxy clusters shows flat profiles beyond r_{500} . Simionescu et al. (2011) interpreted gas density in the outskirts to be overestimated due to gas clumping and the entropy is

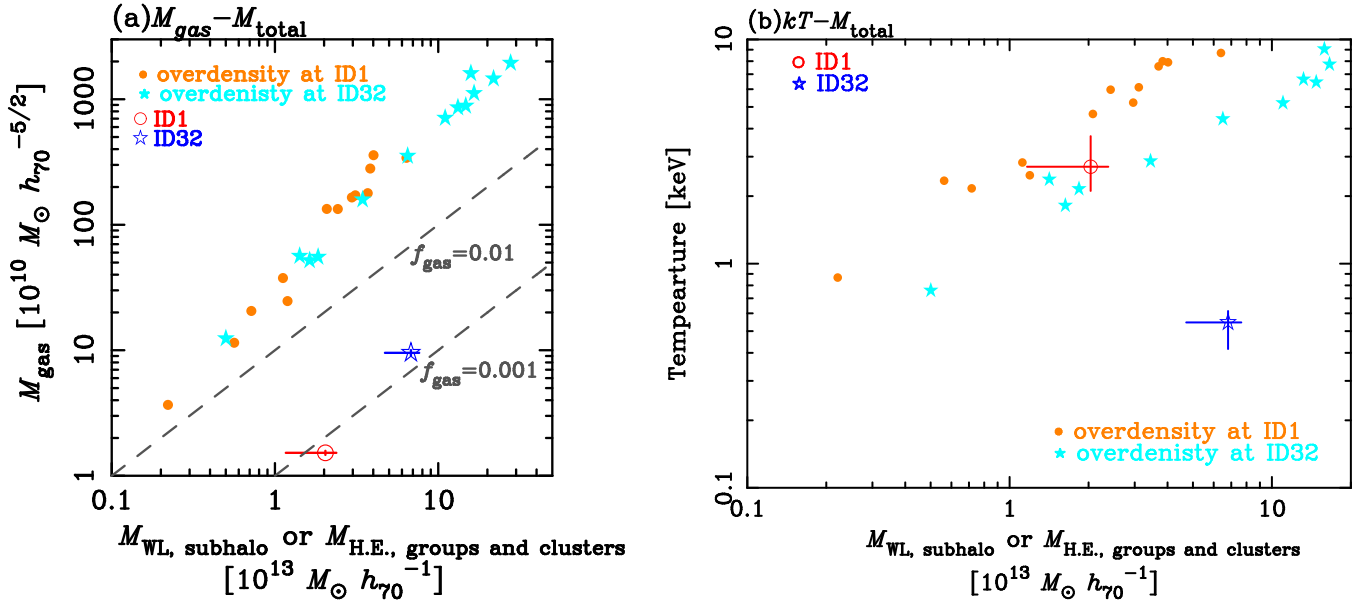

Figure 7. (a) The subhalo gas mass against weak-lensing mass or hydrostatic mass. The open (red) circles and (blue) stars indicate “ID 1” and “ID 32,” respectively. The error bars of the weak-lensing masses of the subhalos include the systematic errors. The filled (orange) circles and (cyan) stars are the gas mass vs. hydrostatic mass at the radius within which the mean density of the groups and clusters are the same overdensity as “ID 1” and “ID 32,” respectively. The gas mass and hydrostatic mass of the groups and clusters were calculated from *Chandra*’s results (Vikhlinin et al. 2006). (b) The same as the left panel but for temperature vs. weak-lensing mass or hydrostatic mass.

Figure 8. Ratio of the ram pressure to gravitational force per area against the velocity of each subhalo. The solid and dashed lines are the ratio calculated at $1.0 r_t$ and $0.6 r_t$, respectively. The red and blue lines correspond to “ID 1” and “ID 32,” respectively. The vertical solid and dotted lines correspond to velocities of each subhalo assuming the 0° and 45° inclination angle, respectively. The infall velocities are plotted with the red and blue dot-dashed lines for “ID 1” and “ID 32,” respectively. The horizontal solid line corresponds to unity.

underestimated. However, observing the Perseus cluster outskirts with *Chandra*, the number of detected sources is consistent with the background sources (Urban et al. 2014). With X-ray and weak-lensing joint analysis, Okabe et al. (2014b) discussed that entropy flattening of the outskirts of the galaxy clusters caused by the steepening of the temperature profiles, rather than the flattening of the gas density.

We studied the effect of subhalo luminosities on the estimation of electron densities when these subhalos are not excluded from spectral analysis. The observed X-ray flux of the excess emissions of “ID 1” and “ID 32” are $(1-2) \times$

$10^{-13} \text{ erg s}^{-1} \text{ cm}^{-2}$ in the 0.5–2.0 keV energy band. Considering that the threshold of the detection of point sources with a 10 ks *Suzaku* exposure is about $10^{-13} \text{ erg s}^{-1} \text{ cm}^{-2}$ in the 2.0–10.0 keV range, if similar subhalos are located in other clusters, most of them would be below the detection threshold flux of *Suzaku*. We note that regions around subhalos like “ID 9,” or the southwest subcluster around NGC 4839, can be easily excluded from spectral analysis of clusters observed with *Suzaku* because of their very high X-ray luminosities.

Within the projected distance of $1.2-1.6 r_{500}$ where the two subhalos are located, the ICM gas mass would be several times $10^{13} M_{\odot}$, which is estimated using the weighted average of the radial profiles of electron density observed with *Suzaku* by Simionescu et al. (2011), excluding the southwest direction, where the X-ray luminous subhalo “ID 9” is located. Thus, the ICM gas mass is two orders of magnitude higher than the gas mass of excess emission of “ID 1” and “ID 32.” The 0.5–2.0 keV luminosities of these two subhalos are a few times $10^{41} \text{ erg s}^{-1}$ and are negligible when compared to the X-ray luminosity of the Coma cluster within $1.2-1.6 r_{500}$, $\sim 10^{43} \text{ erg s}^{-1}$, which is also estimated using the average of ICM temperature and normalization observed with *Suzaku* (Simionescu et al. 2013) excluding the southwest direction. Although Okabe et al. (2014a) detected 32 subhalos with weak-lensing observations, most of them are less massive and located within r_{500} . As a result, we can conclude that the X-ray emission of the subhalos does not affect the overestimation of the gas mass of the Coma cluster.

In order to evaluate the bias in the ICM temperature measurements, we extracted spectra again from FOVs observed around each subhalo, and fitted the spectra with the ICM and background model. The temperature of the ICM did not change within the statistic error range, since the total flux of the subhalos is one to two orders of magnitude lower than that of the ICM. If the number of subhalos is much higher, they may affect on the temperature and density measurements. Therefore, we created mock spectra, assuming two thermal components

for clumps and surrounding ICM emission, by changing the flux ratio of two components. When we simulated a sum of mock spectra of 2 and 1 keV emissions for the ICM and subhalo whose flux is half that of the ICM, respectively, the derived temperature with a single temperature model became 1.2 keV, which is 40% lower than the original ICM temperature, and the electron density was also overestimated by 30%. This indicates the entropy to be low biased by 50%. Thus, if there are many clumps enough to increase the normalization of the ICM for changing the entropy profiles, the temperature bias is more significant.

Simionescu et al. (2013) derived the entropy of the Coma cluster beyond r_{500} ($\sim 47' \pm 1'$) derived from Planck Collaboration et al. (2013), and the entropy profile is consistent with the accretion shock heating model (Pratt et al. 2010). Here, the r_{500} derived from weak-lensing analysis (Okabe et al. 2010) is well consistent with that from the Planck Collaboration et al. (2013). Since there is no evidence for entropy flattening like other clusters and pressure excesses, they suggested that the gas clumps are easily destroyed in a dynamical active cluster. Therefore, their discussion is consistent with our study that a gas clump does not affect the gas density estimation of the Coma cluster.

5. SUMMARY AND CONCLUSIONS

We observed the three massive subhalos, “ID 1,” “ID 2,” and “ID 32,” which are detected from a Subaru weak-lensing analysis (Okabe et al. 2014a), with *Suzaku*. The weak-lensing survey of subhalos in the outskirts of the galaxy cluster enables us to efficiently carry out follow-up X-ray observations of gas subhalo candidates associated with weak-lensing-detected subhalos.

While the excess emission is seen around the center of the “ID 1” mass contour, the “ID 32” subhalo shows that the emission peak is shifted in the northern part or outer side of the Coma cluster center. In contrast to above two subhalos, the “ID 2” subhalo does not show any excess emission. The spectral analysis indicated that the temperature of the subhalo gas is significantly lower than the surrounding ICM. By deprojecting the surface brightness profiles, we derived the gas mass of each subhalo. The total gas mass of “ID 1” and “ID 32” is 2×10^{10} and $1 \times 10^{11} M_{\odot}$, respectively. Compared to the $kT-M_{\text{total}}$ and $M_{\text{gas}}-M_{\text{total}}$ relation of regular galaxy groups, the gas fractions of the subhalos are much lower than regular galaxy groups. Adopting the infall velocity estimated from the best-fit NFW profile derived by weak-lensing analysis of the Coma cluster (Okabe et al. 2010), beyond 0.6 times the truncation radius of the subhalos, or at the border of the excess X-ray emission, the ram pressure is effective in removing the gas. With the infall velocity, the total amount of the removed gas mass from the subhalos via Kelvin–Helmholtz instabilities is about 9×10^{10} and $3 \times 10^{11} M_{\odot}$ for “ID 1” and “ID 32,” respectively. The luminosities of the subhalos are about two orders of magnitude lower than that of the Coma cluster outskirts and do not affect the gas mass estimate of the ICM.

We thank the anonymous referee for carefully reading the manuscript and providing valuable comments. We also thank all members of the *Suzaku* operation team and the XIS calibration team. We acknowledge the support of a Grant-in-Aid for Scientific Research from the MEXT, No. 25400235 (K.M.), 25800112 (K.S.), and 26800097 (N.O.). This work

was supported by “World Premier International Research Center Initiative (WPI Initiative)” and the Funds for the Development of Human Resources in Science and Technology under MEXT, Japan.

APPENDIX THE CXB ESTIMATION

For estimations of the CXB level, we extracted the spectra beyond 110" offset observations, which corresponds to $2.5 r_{500}$ (Okabe et al. 2010), excluding the south region from the Coma cluster, whose observation logs are shown in Table 4. We searched for point-like sources with the “wavdetect” tool in CIAO⁷ in the 0.5–2.0 and 2.0–5.0 keV images. We also excluded the area around the hot pixels.⁸ The flux level of the faintest source was about $1 \times 10^{-13} \text{ erg s}^{-1} \text{ cm}^{-2}$ in 2.0–10.0 keV with a power-law model of a fixed photon index, $\Gamma = 1.7$. We assumed that the background emission was composed of two thermal Galactic emissions, the LHB and the MWH, and the CXB. The LHB and MWH were modeled by non-absorbed and absorbed thermal plasma models (apec; Smith et al. 2001). The CXB was modeled by an absorbed power-law model. We also convolved the Galactic absorption with photoelectric absorption model, phabs. The column density was fixed to be $8.5 \times 10^{19} \text{ cm}^2$ (Kalberla et al. 2005). Therefore, we modeled the spectra by the following formula, constant \times (apec_{LHB} + phabs \times (apec_{MWH} + power – law)). Although the temperature of the LHB was fixed at 0.1 keV, the normalization was allowed to vary. The temperature and normalization of the MWH were free parameters. The photon index of the CXB was fixed at 1.4, and the normalization was allowed to vary. The fitting results are summarized in Table 5. The derived CXB normalization was consistent with Kushino et al. (2002). The parameters of the LHB and MWH are comparable with previous results (Simionescu et al. 2013).
