(Running title.) Multi-locus analysis of trichomonads

Abstract

In Europe, *Trichomonas gallinae* recently emerged as a cause of epidemic disease in songbirds. A highly virulent and clonal strain of the parasite, first found in the UK, has become the predominant strain there and spread to continental Europe. Discriminating this epidemic strain of *T. gallinae* from other strains necessitated development of multi-locus sequence typing (MLST). Development of the MLST was facilitated by the assembly and annotation of a 54.7 Mb draft genome of a cloned stabilate of the A1 European finch epidemic strain (isolated from Greenfinch, *Carduelis chloris*, XT-1081/07 in 2007) containing 21,924 protein coding genes. This enabled construction of a robust 19 locus MLST based on existing typing loci for *Trichomonas vaginalis* and *T. gallinae*. Our MLST has the sensitivity to discriminate strains within existing genotypes confidently, and resolves the American finch A1 genotype from the epidemic European finch A1 genotype. Interestingly, one isolate we obtained from a captive black-naped fruit dove *Ptilinopus melanospilus*, was not truly *T. gallinae* but a hybrid of *T. gallinae* with a distant trichomonad lineage. Phylogenetic analysis of the individual loci in this fruit dove provides evidence of gene flow between distant trichomonad lineages at two of the 19 loci examined and may provide precedence for the emergence of other hybrid trichomonad genomes including *T. vaginalis*.

Key words:

Trichomonosis, Trichomoniasis, genome, molecular epidemiology, emerging infectious disease, wild bird, MLST, hybrid

Introduction

A clonal strain of *Trichomonas gallinae* has recently emerged as a cause of epidemic disease in passerines in Europe: whilst this strain also causes trichomonosis in columbids and birds of prey, it is a minority strain in healthy columbids (Chi, et al. 2013; Lawson, et al. 2011a). This epidemic was first reported in finches in the UK (Pennycott, et al. 2005). Since when there has been unprecedented large-scale mortality of greenfinches, *Chloris chloris*, which has led to a 66% reduction in the British breeding population; from a peak of circa 4.3 million when the disease first emerged, to circa 1.5 million individuals in 2016 (Lawson, et al. 2018). Lethal spillover to other British passerines has also been observed (Lawson, et al. 2011b; Robinson, et al. 2010). Since some British raptors feed on passerine species (Cotgreave 1995), concern has been raised regarding the potential for an increase in raptor morbidity and mortality due to trichomonosis as a result of the finch epidemic (Chi et al. 2013). Since 2008, finch trichomonosis has been reported in southern Fennoscandia and continental Europe (Forzan, et al. 2010; Ganas, et al. 2014; Gourlay, et al. 2014; Neimanis, et al. 2010; Peters, et al. 2009), with chaffinch migration believed to be the primary vector of spread.

Sequence data from the 5.8S ribosomal RNA (rRNA) and surrounding internal transcribed spacer regions 1 and 2 (ITS1, ITS2) have been increasingly used to detect *T. gallinae* infection (Gaspar da Silva, et al. 2007) and to identify genetic heterogeneities in the parasite (Anderson, et al. 2009a; Felleisen 1997; Gerhold, et al. 2008; Grabensteiner, et al. 2010). Sequence analyses of the ITS1/5.8S/ITS2 region (hereafter called ITS region) have identified marked variation amongst isolates obtained from a wide geographical region and from different host taxa, with some 15 distinct ITS region sequences identified

as discrete ITS ribotypes (Anderson, et al. 2009a; Gerhold, et al. 2008; Grabensteiner, et al. 2010; Sansano-Maestre, et al. 2009).

ITS ribotypes of *T. gallinae* parasites obtained from 11 species of affected British passerines showed that they had 100% identity to each other and to ITS ribotype A isolates from the USA (Anderson, et al. 2009a; Gerhold, et al. 2008), Brazil (Kleina, et al. 2004), Spain (Sansano-Maestre, et al. 2009), and Austria (Grabensteiner, et al. 2010). Using the (hydrogenosomal) iron hydrogenase (Fe-hydrogenase) gene as a second genotyping marker (one which is particularly useful for amitochondrial protists which lack widely used mitochondrial house-keeping protein encoding genes (Voncken, et al. 2002)), we detected finer-scale genetic variation between *T. gallinae* sequences (Lawson, et al. 2011a). Although we found no variation amongst British passerine samples at this locus, when we compared columbid and bird of prey isolates collected from the UK and elsewhere, marked sequence diversity at the Fe-hydrogenase gene was observed which was not detected from the ITS region alone (Chi, et al. 2013). Thus we proposed a simple alphanumeric genotype with the letter being drawn from the ITS ribotype and the number from the Fe-hydrogenase subtype and in which A1 was the genotype of the European finch epidemic strain (Chi, et al. 2013).

Recently the A1 genotype has also been reported as an emerging cause of trichomonosis outbreaks in wild finches in the Canadian Maritimes (McBurney, et al. 2015) and as an infection of wild columbids in the USA (Girard, et al. 2014). It is possible, therefore, that there are multiple strains of *T. gallinae* within the A1 genotype worldwide. In order to determine the transmission pathways of this parasite between bird species and the spread of the recently emerged strains causing finch trichomonosis outbreaks in Europe and Canada, tools to further discriminate between parasites strains are required.

Multi-locus sequence typing (MLST) is a nucleotide sequence based method that is used to characterise the genetic relationships between microbial species. It has been successfully applied to study populations of bacterial and eukaryotic organisms (Hanage, et al. 2005; Maiden, et al. 1998; Tibayrenc 2009). Selected loci are normally single copy housekeeping genes so that the variation within these genes is nearly neutral but less prone to homoplasy than using an alternative approach such as multi-locus microsatellite typing, and thus they are better able to serve as robust markers of ancient and modern ancestry.

Since the draft genome of the closely related *Trichomonas vaginalis* was completed, two overlapping sets of MLST loci have been proposed (Conrad, et al. 2011; Cornelius, et al. 2012). We have sought to extend these analyses by applying them to *T. gallinae* and have therefore produced a draft annotated genome of the European finch epidemic strain of *T. gallinae* and used it initially to identify the loci involved. Primers were then produced to enable a parallel 19 locus MLST analysis from nine isolates of *T. gallinae* from captive and wild birds for comparison with a *T. vaginalis* reference strain.

Materials and Methods

Isolation and cloning of the genome clonal stabilate GF1c

For the genome stabilate, *T. gallinae* was isolated from a greenfinch found dead with oesophageal thickening, consistent with trichomonosis, in Norfolk in October 2007 (isolate XT1081-07) (Table 1). A sample was taken from the infected bird during post-mortem examination at the time of initial presentation and inoculated into Trichomonas Medium No. 2 (Oxoid, UK), incubated at 30°C and screened for motile trichomonads at days 1, 2 and 5 (Robinson, et al. 2010). The initial stabilate for the isolate was obtained and cryopreserved in liquid nitrogen with 5% dimethyl sulfoxide (DMSO) at -196°C until further processing. This stabilate was subsequently revived and cultured axenically in pH 7.2 Trypticase-yeast extract-maltose (TYM) supplemented with 10% heat inactivated horse serum at 37°C (Diamond 1954), parasites were subcultured three times prior to cloning. Cultures were diluted to 50 parasites per ml, so that one parasite could be found on average in every 2 (10 µl) wells of Terasaki plates (Greiner Bio-One™, Kremsmünster, Austria). The parasites were allowed to settle to the bottom of the wells, the plates were then scanned using an inverted microscope, the positions of wells containing only a single motile parasite were recorded. Wells containing no parasites or more than one were noted and ignored for cloning purposes. The plates were incubated for 24 hours at 37 °C in an atmosphere containing 5% carbon dioxide (CO₂) at 80% relative humidity before wells where the parasites had replicated were used to inoculate larger cultures. Clones were sub-cultured three times in TYM and in one case, for the genome clonal stabilate GF1c, the cloning procedure repeated. Finally, clones were re-cultured and adjusted to a final concentration of 5×10^6 living organisms per ml in TYM before cryopreservation. When in the logarithmic phase of growth, all cloned trichomonads exhibited normal

morphology and more than 95% motility. GF1c was cryopreserved in liquid nitrogen with 5% dimethyl sulfoxide (DMSO) at -196°C. A clonal stabilate of the captive black-naped fruit dove isolate (BND1c) was subsequently produced by the same method as described for GF1c.

Preparing DNA extraction for whole genome (Illumina) sequencing

Extraction of *T. gallinae* genomic DNA (gDNA) from parasite cultures was performed using DNAzol® (Invitrogen, UK) essentially as described in the manufacturer's instructions. A TruSeq PCR-Free kit was used with the gDNA to generate an Illumina shotgun library (insert size 200-300bp). Paired-end sequencing (2 × 150bp) was performed at the Centre for Genomic Research, University of Liverpool, on an Illumina HighSeq 2500 platform. The draft genome sequence was assembled de novo using Velvet (Zerbino and Birney 2008). The theoretical size of the genome was estimated from k-mer frequencies calculated in kAT (Mapleson, et al. 2017) and shown in Fig S1B. Genome size was calculated as the total number of k-mers (area under the curve) divided by the coverage (mean coverage/curve peak), using the R statistical package. The peak was also compared to a poisson distribution (Fig S1C). Genome assembly quality was assessed using a k-mer spectra plot generated in kAT by comparing the k-mer content between the final assembly and the trimmed paired end reads using a k-mer size of 27 (Fig S1A).

A new draft trichomonad genome.

A total of 32,936,526 paired-end reads were generated from sequencing, which were adapted and quality trimmed using cutadapt (version 1.2.1). The draft genome sequence

was assembled *de novo* using version of SPAdes. We used a homology-based approach with the aim of annotating the draft genome of *T. gallinae* using the OrthoMCL software (version 1.4)(Li, et al. 2003) via shared gene cluster membership after including genomic data from closely related organisms. Initially we downloaded 541 coding sequences (CDS) of *T. vaginalis* genes from RefSeq to prepare a model for use with the GlimmerHMM software (Majoros, et al. 2004). Using this model, we predicted 22,348 open reading frames (ORF) in the contigs of the *T. gallinae* genomic sequence. Finally, we performed an OrthoMCL analysis of these ORF's against the *T. vaginalis* proteome downloaded from RefSeq (Carlton, et al. 2007). Annotations for 16,651 ORFs (74.51%) were transferred from *T. vaginalis*, with 10,444 genes (46.73%) being annotated as hypothetical genes. It should be noted, that while the *T. vaginalis* draft genome contains 59,681 predicted genes, only about 26,000 are supported by experimental evidence (which is corroborated by the number of genes found in our study); the same study suggesting that the *T. vaginalis* genome contains large gene families and many repetitions (Carlton, et al. 2007). This situation would make overcompression of the draft genome, by grouping repeated reads in the same contig, more likely, hence decreasing the apparent size of the genome.

To assess the completeness of our draft genome and annotation BUSCO analysis was used to assess the number of Benchmarking Universal Single-Copy Orthologs. The results shown in Table 2 show that the draft genome and annotation are high quality and comparable. Overall the *T. gallinae* annotation has fewer fragmented BUSCOs than the *T. vaginalis* annotation despite the large difference in predicted proteome sizes. The difference between the genome and annotation scores stems from the protein coding prediction method employed by BUSCO, which is not trained for specific genomes. The fact that not all of the BUSCOs are present may be attributed to the BUSCOs that were searched for being generic eukaryote BUSCOs rather than specific for Trichomonads. Colinearity between *T. vaginalis* and *T. gallinae* was

determined for contigs and predicted CDS's using the MUMmer programmes NUCmer and PROmer respectively. Results were visualised and plotted using mummerplot (Delcher, et al. 2003).

Parasite strains and DNA extraction for MLST

Eight additional reference strains (Table 1) of *T. gallinae* from captive and wild birds from the UK and USA, collected between 2007 and 2015, were analysed using MLST in addition to the GF1c isolate. Most of these strains have been widely used in previous studies (Chi, et al. 2013; Gerhold, et al. 2008; Lawson, et al. 2011a). Cryopreserved isolates were revived and cultured in modified TYM medium at 37 °C and gDNA was extracted as per GF1c (above).

Choice of loci for MLST typing

Using the whole genome sequence of GF1c, genes were verified as single copy by performing an all-against-all, basic local alignment search tool (BLAST) comparison of nucleotide sequences. Based on their diversity and their ability to be readily amplified and sequenced on both DNA strands, 19 housekeeping loci were identified for the final MLST scheme. Each of the 19 loci was on a different contig of the sequenced genome. Primers were designed for each of the 19 loci using Primer-BLAST at the GenBank website (<http://www.ncbi.nlm.nih.gov/tools/primer-blast/>). All primers were designed from common sequence for the *T. gallinae* genes and *T. vaginalis* orthologs, using our new draft genome and the published draft genome sequence of *T. vaginalis* (version 1.2, <http://trichdb.org>).

PCR amplification for MLST

Primers for the sequencing of MLST loci were designed to amplify gene fragments of 655–966 base pairs in length. Details of primers and reaction conditions are provided in Table S1. All genes were amplified as follows: 30µL PCR reactions containing 20µL of HotStarTaq Master Mix Kit (Qiagen Inc., UK), 2µL of distilled water, 3µL of forward primer, 3µL of reverse primer, and 2µL of template of DNA. We used the same thermocycler program parameters for all loci as follows: initial denaturation of template DNA at 95°C for 3 minutes. 40 cycles of: 95°C for 45 seconds, 55-57 °C for 1 minute, 72 °C for 2 minutes with a five-second extension after each cycle, followed by the final extension at 72°C for seven minutes. Samples were visualized on 1% agarose gels to verify amplification. Bidirectional Sanger sequencing was conducted by Source BioScience (Nottingham, UK). Sequence alignments were carried out using MEGA software version 6.06.

Sequence analysis of MLST and phylogenetic trees

The nucleotide sequence of each of the selected housekeeping genes from *T. gallinae* was aligned with its respective gene sequence from the nine *T. gallinae* isolates using maximum likelihood (ML) trees generated using Molecular Evolutionary Genetics Analysis (MEGA) software version 6.06 (Tamura, et al. 2011), both for individual genes and for the concatenated gene sequences. Felsenstein's bootstrap test was used to evaluate the support for tree topologies and clustering of taxa (2,000 times) (Felsenstein 1985).

For the phylogenetic tree based on the housekeeping genes, ML tree evolutionary distances were computed using the Tamura-Nei method in units of the number of base substitutions per site (Tamura and Nei 1993). Bootstrap values of the ML tree with the highest log likelihood were obtained. For all trees, all positions containing gaps and missing data were eliminated. Constrained and unconstrained ML trees were used to test topological significance (Fig S3, Table S3). Trees were built using GTR model and Gamma correction in iqtree (Nguyen, et al. 2015). Evolutionary analyses were conducted using MEGA 6.06 (Tamura, et al. 2011) and network analyses were performed using Splitstree (Huson and Bryant 2006) to construct a Neighbor-Net analysis of loci MLST fragment and concatenated sequence of some loci of MLST after which a final consensus network, obtained from the combination of the individual ML tree for each gene, was constructed. These networks were also used to test for evidence of recombination using the Pairwise Homoplasy Index (PHI), which is included in the Splitstree package.

Results

Isolates used

For this study, we investigated the potential for increased resolution offered by MLST. Nine isolates of *T. gallinae* of known genotype were selected for the study; seven of the isolates were obtained in the UK (five wild birds and two captive), and two from wild birds in the USA (Table 1). Three isolates were ribotype A, one subtype A2, two subtype A1; one A1 was isolated from a UK greenfinch and the other from a USA house finch (*Haemorrhous mexicanus*). Five of the isolates, from captive and wild columbids in the UK, were ribotype C. One isolate was a highly divergent ribotype M, which was isolated in the UK from a captive-bred black-naped fruit dove.

Genome sequence data

MLST genes were selected based on the previously validated MLST of *T. vaginalis* proposed by (Conrad, et al. 2011). Initially, we attempted amplification and sequencing using the published *T. vaginalis* primers, however, few of the loci amplified using template DNA from *T. gallinae* isolates (data not shown). To engineer our own primers for *T. gallinae* orthologs, we produced a draft genome sequence of *T. gallinae* which we present here, the draft genome sequence and annotation of a clone from an isolate of the European finch epidemic strain of *T. gallinae* (A1) GF1c (GenBank accession number MRSU000000000).

The final assembly of the *T. gallinae* draft genome sequence was determined to consist of 11,704 contigs and an N50 contig size of 20,741. The assembly size was 54,799,485 bp with a coverage of 90 × and a G + C content of 33.77 %. The BUSCO analysis

suggested a completeness comparable to the published *T. vaginalis* draft genome (Table 2). The annotation results revealed 22,251 predicted genes, and 21,924 protein-coding sequences were identified, including three pseudogenes and four rRNAs. There were also 319 transfer RNAs (tRNAs) including predicted tRNAs for all amino acids (Table 3).

To test for collinearity between the *T. vaginalis* and *T. gallinae* assemblies, the contigs were plotted against each other in MUMmer (Fig 1A). This analysis revealed collinearity between 667 unique *T. vaginalis* contigs and 1,487 unique *T. gallinae* contigs representing 1% and 12% of the total number of contigs respectively. Given this low proportion of collinearity between contigs, the predicted coding sequences of *T. vaginalis* and *T. gallinae* were tested as well (Fig 1B). This showed 1,585 coding sequences in *T. vaginalis* are colinear with 13,551 coding sequences in *T. gallinae* representing 2.7% and 61% of the total number of coding sequences respectively.

MLST improves strain resolution and discriminates the American A1 strains from the European finch A1 epidemic strain.

The whole genome data were successfully mined for the *T. gallinae* MLST orthologous genes. Primers were then designed to amplify a long internal fragment of each gene. All 19 housekeeping gene fragments were successfully amplified using PCR and were sequenced for each of the *T. gallinae* isolates (Table 4, Table S1) affording comparison of 14,770 bp, and yielding 2,043 discriminating characters of 19 concatenated sequences for all 9 isolates of *T. gallinae* and the single *T. vaginalis* isolate.

The size of the fragments analysed for the selected housekeeping genes ranged between 655 bp (TGA-000730800) and 966 bp (TGA-000731500) (cf Table 4). For each

T. gallinae isolate, the sequence obtained for each of the 19 loci was compared with that of every other isolate, and single nucleotide polymorphisms (SNPs) were numbered consecutively. In total 773 *T. gallinae* SNPs were detected across these loci from 14,770 nucleotides analysed, corresponding to an average of 1 SNP every 19 bp. The number of SNPs varied for each gene, ranging from 1 SNP every 9 bp for TGA-000478600 to 1 SNP every 202bp for TGA-000149300.

We have used our panel of nine isolates and *T. vaginalis* as the out-group to demonstrate that strains of *T. gallinae* are only partially resolved into three groups by ribotyping (Fig 2A) or seven groups using genotyping with Fe-hydrogenase (Fig 2B). However, our MLST sequences yields a tree with enough resolution to discriminate all nine of the isolates while providing for reduced variance in distance estimates. Our ML tree (Fig 2C) was based on 14,770 bp of concatenated sequence comprising all 19 loci. The tree was rooted with the *T. vaginalis* as the out-group. On this tree two groups of *T. gallinae* are evident. All of the ribotype C isolates cluster together, although it is notable the C4 subtype is significantly divergent from the other ribotype C isolates. The ribotype A isolates cluster with the ribotype M isolate. Notably the UK and US A1 subtype isolates are resolved by the MLST and, importantly, the US A1 genotype appears to be more closely related to the US A2 genotype in the panel than to the European finch epidemic strain A1 genotype, supporting different origins for these strains.

Investigation of the M isolate

The M isolate was cloned to ensure that the results obtained were not the result of a mixed infection. Both isolate and clone were found to be identical to the European finch epidemic strain at several loci, including the Fe-hydrogenase subtyping locus

suggesting recent divergence from a common ancestor. The isolate is resolved in the concatenated tree because of the considerable divergence of a few loci. This incongruence is indicative of a hybrid origin and caused us to consider each of the MLST loci for evidence of introgressed genes.

Phylogenetic trees of individual genes were constructed using the ML and neighbour joining (NJ) methods. The tree topologies generated these two methods were found to entirely congruent. Individual phylogenetic trees for each of the 19 genes are presented in Fig S2 (A – S). Most of the coding genes (16/19) produced trees which were congruent with each other and with the Fe-hydrogenase subtyping gene, however four loci (A, D, I and the ITS region) produced incongruent trees. These four loci fell into two congruent groups: first, the D and I alleles were congruent with each other, showing greater similarity to alleles from ribotype C isolates than to other ribotype A isolates. Second, the trees produced from the ITS region and from A were congruent with each other but the M isolate gene sequences diverged substantially from those of the other isolates, suggesting that they had a non-*T. gallinae* origin.

We used trees and networks to further investigate the incongruent phylogenetic signals. Across all of our *T. gallinae* isolates, we compared (1) concatenated MLST, ITS region and Fe-hydrogenase sequences (Fig 2), (2) with those from the congruent group of 16 loci (Fig 3), from D and I (Fig 4) and from A and the ITS region (Fig 5). We plotted the phylogenetic relationships using Neighbour-Net split network with the EqualAngle algorithm, which takes recombination (as evidenced for 6 of the MLST loci in Table S2) into account in formulating the network depictions. As evidenced in Fig 3, the M1 isolate possesses alleles that segregate it with ribotype A isolates. Indeed, at most loci, it is indistinguishable from the A1 European finch epidemic strain. By contrast, the ITS

ribotype and Arp2/3 gene locus are so divergent that they do not group the isolate with any of the other isolates examined. Notably though, at two loci the alleles group most closely with C ribotype isolates C8 and C9 on the Neighbour-Net, but show some association with isolates of ribotype A - suggestive of gene flow between these groups.

Discussion

Improved genotyping and distinct origins for UK and US lineages of A1 subtype

The 19 locus test described in this study demonstrated excellent consistency and discriminatory ability for assessing phylogenetic relationships for the *T. gallinae* isolates examined. These findings suggest that this MLST will be a valuable alternative to established genotyping and subtyping targets for *T. gallinae*. However, the test's stability should be further assessed against a larger collection of isolates from different subtype strains and geographical locations to validate their discriminatory power.

Finch trichomonosis in the USA has been previously reported (Anderson, et al. 2010) and identification of genotype A1 has also been reported from the USA in band-tailed doves - *Patagioenas fasciata* (Girard, et al. 2014). Here we are able to differentiate the American A1 strain from a house finch, from the A1 strain causing the European finch epidemic. It is of interest that the American A1 strain actually appears to be more closely related to the American A2 strain, than the European A1 strain, suggesting some modest homoplasmy may occur in Fe-hydrogenase alleles.

Evidence for new strain emergence from trans-species, introgressed hybrids.

Our phylogeny based on the ITS region (Fig 2A) shows that isolate from a black-naped fruit dove possessed a distinct M ribotype which was highly divergent from the *T.*

gallinae complex. This suggested that the black-naped fruit dove parasite is a novel trichomonad species. Surprisingly, when subtyped with the Fe-hydrogenase gene the result was incongruent and the sequences obtained were identical to the A1 genotype of the European finch epidemic strain.

An obvious possibility to reconcile the results was that DNA had been extracted from a mixed infection, hence one of the black-naped fruit dove isolates was cloned. Despite being derived from a single parasite, the initial sequencing results were reproduced, namely a novel and highly divergent M ribotype with an A1 genotype sequence for the Fe-hydrogenase locus.

Using all MLST markers together, a close relationship between the M ribotype and the European finch epidemic A1 genotype is clear. Considered individually, however, the markers used fell into three groups, each giving a discrete tree topology. Within each group for each single marker the tree topologies were congruent. The majority of loci (17 of 21) were identical or nearly identical to the sequence to the European finch epidemic A1 genotype and hence produced a tree which suggested that the majority of the genome could be considered to be A1. Two markers were clearly still *T. gallinae* alleles, but appeared to be more akin to isolates with C ribotypes, suggesting a recent cross between the European finch epidemic A1 strain with an as yet uncharacterized C type followed by introgression. Most intriguingly, two alleles appeared to be from a non-*T. gallinae* trichomonad: the ITS 5.8S ribosomal locus, as previously noted, and the locus encoding an actin related protein – two well conserved house-keeping genes. The implication of this result is that the parasite was not an entirely newly discovered diverged species, but rather a recent chimaera or hybrid between *T. gallinae* and a hitherto uncharacterized trichomonad species arising either by fusion of two distant lineages or by some manner

of gene transfer. The black-naped fruit dove originates from Indonesia, Malaysia and the Philippines: it is possible that the loci from a divergent trichomonad species originated from the species' native range. Indeed, it is noteworthy that other authors have identified evidence of a divergent trichomonad species in another frugivorous columbid from Australia, the Pied Imperial pigeon (*Ducula bicolor*). The black-naped fruit dove from which the clonal isolate was derived was a captive bird from a UK zoological collection, whose parents were captive bred in a zoological collection in mainland Europe. It is therefore plausible that co-infection with multiple trichomonad parasite lineages, perhaps from different regions, occurred and led to hybrid formation.

Trichomonas vaginalis is morphologically indistinguishable from *T. gallinae* and it has been observed that some avian *Trichomonas* at least show high levels of sequence identity at some loci to *T. vaginalis* (Gerhold et al., 2008) prompting speculation as to the relationship of human and avian trichomonads (Maritz, et al. 2014). It is therefore somewhat surprising to discover such little collinearity between the two draft genomes of these trichomonads. However, this does inform the results from the MLST analysis, not least by suggesting that the *T. gallinae* genome appears to be congruent with *T. vaginalis* over only a part of the total genome. We also show that there are small-scale repeats in the *T. vaginalis* draft genome that appear only once in the *T. gallinae* draft genome, coupled with the difference between the contig collinearity and the coding sequences this suggests that the majority of the genome where there is no collinearity is non-coding.

Our results indicate that the black-naped fruit dove isolate of the M strain shows evidence of introgression from two crosses one of which was likely to have been recent. On this basis, we speculate that occasional hybrid formation and introgression may be an important factor in allowing rapid colonization of new hosts as may have happened in the

natural history of *T. vaginalis*. Future work utilizing high quality genomes and bespoke bioinformatic methods should help discriminate introgression from the possibility of lateral gene transfer, identify how and when and between what lineages genomic exchanges have occurred and elucidate the frequency of type of genetic exchange, particularly between more closely related lineages.

Missing	104	87	102	78
Completeness	65.67%	71.28%	66.33%	74.25%

Table 3 Summary of the *Trichomonas gallinae* genome European finch epidemic strain of *T. gallinae* A1 genotype, GF1c cloned stabilate (GenBank accession number MRSU000000000).

Feature	Value
Genome	
Size of assembly (bp)	54,799,485
Gene G + C content (%)	38.77
No. of scaffolds	11,704
N50 scaffold size (bp)	20,741
Protein-Coding Genes	
No. of predicted genes	21,924
Mean gene length (bp)	1,392
Gene G + C content (%)	38.25
Gene density (genes/Mb)	400.08
Non-Protein-Coding Genes	
No. of non-protein-coding genes	327
Predicted transfer RNA genes	319
Ribosomal RNA (rRNA)	4
Predicted snRNAs	4

Table 4. Multi-locus sequence typing (MLST) loci employed

<i>T. gallinae</i> Gene ID	<i>T. vaginalis</i>	Locus (Fig S2)	Gene Name	Length	SNPs	Nucleotides per SNP

Figure 1. MUMmer plot showing collinearity between *T. gallinae* and *T. vaginalis*. Red points denote collinearity matches >75% sequence identity and blue matches are inverted for both the contigs (A) and the coding sequences (B) for *T. gallinae* and *T. vaginalis*.

Figure 2. A concatenated phylogeny of *Trichomonas gallinae* based on 19 housekeeping genes of MLST created by using maximum likelihood provides resolution for all strains tested. *T. vaginalis* is included as an out-group. Numbers on branches indicate bootstrap values based on 2000 replicates. A) ITS ribotypes alone resolve only 3 groups of avian trichomonads A, C and M. B) Fe-hydrogenase is able to resolve 8 genotypes from the 10 avian trichomonads strains tested. C) MLST based on 19 loci (listed in Table 3) provides confident resolution of all the avian trichomonad strains tested.

Figure 3. Most markers group the M1 isolate with the A1 (finch strain). Phylogenetic trees and split network tree based on concatenated sequence analysis of *Trichomonas gallinae* strains, with 16 loci of MLST (all except loci A, D, and I), and the Fe-hyg gene

Figure 4. Introgression of *Trichomonas gallinae* genes. The phylogenetic (A) and split network (B) trees based on concatenated sequence of Loci D and I are incongruous with other loci grouping the M1 isolate with C8 and C9 strains.

Figure 5. Introgression of non-*T. gallinae* Trichomonad genes. The phylogenetic (A) and split network (B) trees based on concatenated sequence of Locus A and the ITS region are incongruous with other loci placing the M1 isolate outside of the *T. gallinae* group and thus suggesting a divergent trichomonad as the origin of these two loci.
