ABSTRACT

La₂O₃ thin films were deposited by atomic layer deposition from a liquid heteroleptic La precursor, La(ⁱPrCp)₂(ⁱPr-amd), with either water, ozone, ethanol, or both water and ozone (separated by a purge) as the oxygen source. The effect of the oxygen source on the film growth rate and properties such as crystallinity and impurities was studied. Saturation of the growth rate was achieved at 225 °C with O₃ as the oxygen source. With water, very long purge times were used due to the hygroscopicity of La₂O₃ but saturation of the growth rate was not achieved. Interestingly, when an O₃ pulse was added after the water pulse with a purge in between, the growth rate decreased and the growth saturated at 200 °C. With ethanol lanthanum hydroxide was formed instead of La₂O₃ at 200–275 °C whereas hexagonal La₂O₃ films were obtained at 300 °C but the growth was not saturative. Using the separate pulses of water and ozone in the same deposition provided the best results from the four studied deposition processes. After annealing the films deposited with the La(ⁱPrCp)₂(ⁱPrAMD)/H₂O/O₃ process showed pure hexagonal phase in all the films regardless of the deposition temperature, whereas mixtures of cubic and hexagonal La₂O₃ were seen with the other processes.

1. Introduction

Lanthanum oxide La₂O₃ is an interesting material for microelectronic applications due to its high permittivity (~27 for hexagonal La₂O₃) [1] and wide band gap (~5.5 eV) [2]. It has been studied as a gate dielectric on several semiconductors on its own [3–5] or combined with other oxides such as hafnium or yttrium oxide [6, 7]. La₂O₃ has also been used as a capping layer on HF-based gate dielectric oxides [8–10]. Also, La₂O₃ and La containing ternary oxides have been studied as a passivation layer on Ge [11–13]. Another area of interest for La₂O₃ is optics because it is optically transparent over a wide wavelength range [14]. It can also be used as a dopant in thermoelectric oxide materials such as CaMnO₃ and SrTiO₃ to enhance electrical conductivity [15].

Although La₂O₃ is a technologically interesting material, it is somewhat problematic to process and study because of its hygroscopicity. When in contact with air, La₂O₃ absorbs water and forms lanthanum hydroxide, La(OH)₃, which has a low dielectric constant. In addition, the La(OH)₃ formation roughens the film surface which is a

disadvantage in many applications [16]. To combat the moisture absorbance issue, ternary lanthanum containing oxides have been studied for microelectronic applications. One of the most studied is lanthanum aluminum oxide LaAlO₃ because it is moisture resistant and has thermal stability comparable to La₂O₃ [17–19].

With atomic layer deposition (ALD) it is possible to deposit accurately thin and conformal films without pinholes and hence ALD has become an attractive method for industrial use, especially in microelectronics [20]. ALD is a chemical method, where precursor vapors are pulsed onto a substrate one at a time and the film growth occurs only on the surface of the substrate in a self-limiting manner, enabling excellent controllability of the thickness and film composition.

Lanthanum precursors used in ALD include the β-diketonate La(thd)₃ (thd = 2,2,6,6-tetramethyl-3,5-heptane-dione) [21], cyclopentadienyl-based precursors such as La(Cp)₃ (Cp = cyclopentadienyl) [22] and La(ⁱPrCp)₃ (ⁱPrCp = isopropylcyclopentadienyl) [3, 23], amidinates La(ⁱPrAMD)₃ (ⁱPrAMD = *N,N'*-diisopropylacetamidinato) [17] and La(ⁱPrfAMD)₃ (ⁱPrfAMD = *N,N'*-diisopropylformamidinato) [24] and silylamide La[N(SiMe₃)₂]₃ (N(SiMe₃)₂ = bis(trimethylsilyl) amide)

[25]. $\text{La}(\text{thd})_3$ with O_3 has a low growth rate of $0.36 \text{ \AA}/\text{cycle}$ at $225\text{--}275 \text{ }^\circ\text{C}$. The process is saturative at $250 \text{ }^\circ\text{C}$ but at this temperature the films contain high amounts of carbon. $\text{La}(\text{iPrCp})_3$ is not very stable thermally and decomposition of the precursor is observed at $250 \text{ }^\circ\text{C}$ [26]. With $\text{La}[\text{N}(\text{SiMe}_3)_2]_3/\text{H}_2\text{O}$ process saturation of the growth rate was not achieved and the films contained H and Si impurities. With the amidinate precursor $\text{La}(\text{iPrAMD})_3$ saturation of the growth rate has been achieved at $250 \text{ }^\circ\text{C}$ with O_3 as the oxygen source with a growth rate of $1.0 \text{ \AA}/\text{cycle}$. $\text{La}(\text{iPrAMD})_3$ has been used to deposit lanthanum aluminum oxide nanolaminates with trimethylaluminum and water.

The most studied oxygen sources in the deposition of La_2O_3 are H_2O and O_3 , but also O_2 plasma has been used [23]. In La_2O_3 deposition the choice of oxygen source is more important than in most oxide processes because both water and ozone cause problems. The hygroscopicity of La_2O_3 complicates the process when water is used and with O_3 high levels of carbon impurities have been detected in the films due to carbonate formation [21].

In this paper, we report a heteroleptic liquid cyclopentadienylamidinate precursor, lanthanum bisisopropylcyclopentadienyl- N,N' -diisopropylacetamidinate, ($\text{La}(\text{iPrCp})_2(\text{iPrAMD})$) (Fig. 1) to be used as an La source in the ALD of lanthanum oxide. The aim of using heteroleptic precursors is to combine the best properties of the different types of ligands in order to tailor precursors with higher reactivity and thermal stability. Previously, we have reported ALD of Y, Pr, Gd and Dy oxides from the $\text{RE}(\text{iPrCp})_2(\text{iPrAMD})$ (RE = rare earth) precursors with either water or ozone as the oxygen source [27]. In this study, we focus more on the effect of the oxygen source on the film properties. We tested the La precursor with H_2O and O_3 in separate deposition processes and both together in the same deposition process. Because of the problems assigned to water and ozone in the La_2O_3 deposition, ethanol was tested as an alternative oxygen source for comparison.

2. Experimental details

Films were deposited with an F-120 hot-wall flow-type ALD reactor (ASM Microchemistry, Ltd) using liquid $\text{La}(\text{iPrCp})_2(\text{iPrAMD})$ precursor (Air Liquide) with either ethanol, water, ozone or both water and ozone ($\text{H}_2\text{O}/\text{O}_3$) as the oxygen source. When both H_2O and O_3 were used in the same deposition, the pulsing sequence was La precursor-purge- H_2O -purge- O_3 -purge. Ethanol and water were kept at room temperature in containers outside the reactor and the vapor flow was controlled by needle valves. Pressure in the chamber was on the order of 5 mbar. Nitrogen (AGA, 99.999%, $\text{H}_2\text{O} \leq 3 \text{ ppm}$, $\text{O}_2 \leq 3 \text{ ppm}$) was used as the carrier and purging gas. Si(100) wafers were used as substrates. The $\text{La}(\text{iPrCp})_2(\text{iPrAMD})$ precursor was evaporated at a temperature of $126 \text{ }^\circ\text{C}$

and the deposition temperature was in the range of $200\text{--}325 \text{ }^\circ\text{C}$. Ozone with a concentration of $100 \text{ g}/\text{m}^3$ was generated from O_2 (AGA, 99.999%) in an ozone generator (Wedeco Modular 4 HC).

Films were characterized for thickness, crystallinity, morphology, and composition. Film thicknesses were determined by modeling [28] the reflectance spectra measured within wavelengths of $370\text{--}1100 \text{ nm}$ with a spectrophotometer (Hitachi U-2000). Some thicknesses were confirmed also with X-ray reflectivity measurement (PANalytical X'Pert Pro MPD X-ray diffractometer). Crystallinity and phase of the films were determined by grazing incidence X-ray diffraction (GIXRD) using the same instrument and an incident beam angle of 1° . In situ high temperature XRD (HTXRD) measurements were conducted using an Anton-Paar HTK1200N oven. PANalytical Highscore Plus v.4.5 was used for XRD phase identification using ICDD and ICSD databases. Because of the air sensitivity of the films, they were stored in a desiccator. Surface morphology of the films was studied with a Multimode V atomic force microscope (AFM) equipped with a NanoScope V controller (Veeco Instruments) operated in the tapping mode. Images ($500 \times 500 \text{ nm}^2$ and $2 \times 2 \text{ } \mu\text{m}^2$) were captured in air using silicon probes with a nominal tip radius of 8 nm and a nominal spring constant of $3 \text{ N}/\text{m}$ (VLFM or FESP from Bruker). Roughness was calculated as a root-mean-square value (RMS) from $2 \times 2 \text{ } \mu\text{m}^2$ images (512×512 pixels) obtained at $0.5\text{--}1.0 \text{ Hz}$ scan rate. Roughness calculations and image processing were done with a Bruker Nanoscope Analysis 1.5 program. Film compositions were measured with time-of-flight elastic recoil detection analysis (TOF-ERDA) with $40 \text{ MeV } ^{79}\text{Br}^{7+}$ beam obtained from a 5 MV tandem accelerator (EGP-10-II) at a detection angle of 40° . Some films were annealed at $700 \text{ }^\circ\text{C}$ in air or in N_2 atmosphere for 1 h. After the annealing the films were let to cool down slowly in the oven. XRD and TOF-ERDA were also measured from the annealed samples.

3. Results and discussion

In all four studied processes the growth rates increased with increasing deposition temperature. The highest growth rates were obtained with H_2O as the oxygen source (Fig. 2). Purge time had a clear effect on the growth rates when water was used. The growth rate varied from $1.2 \text{ \AA}/\text{cycle}$ at $200 \text{ }^\circ\text{C}$ to $3.0 \text{ \AA}/\text{cycle}$ at $300 \text{ }^\circ\text{C}$ when 0.8 s La precursor and H_2O pulses and 20 s purge after the water pulses were applied. With 10 s purge the growth rate was $4.4 \text{ \AA}/\text{cycle}$ already at $250 \text{ }^\circ\text{C}$. The hygroscopicity of La_2O_3 can explain the very high growth

Fig. 2. Growth rates of the La_2O_3 films at different temperatures deposited with $\text{La}(\text{iPrCp})_2(\text{iPrAMD})/\text{H}_2\text{O}$ (0.8 s precursor pulses, 20 s purge after H_2O), $\text{La}(\text{iPrCp})_2(\text{iPrAMD})/\text{O}_3$ (1.0 s pulses), $\text{La}(\text{iPrCp})_2(\text{iPrAMD})/\text{H}_2\text{O}/\text{O}_3$ (0.8 s La and H_2O pulses, 1.0 s O_3 pulse, 10 s purge after H_2O), and $\text{La}(\text{iPrCp})_2(\text{iPrAMD})/\text{EtOH}$ processes (0.7 s pulses).

rates of the films deposited with H₂O as the oxygen source: La(OH)₃ is formed during the water pulse and if the purging period is not long enough, water is desorbed during the following La precursor pulse and reacts with the lanthanum precursor. This results in CVD-type reactions that do not enable the self-limiting growth mode of ALD [17]. When long purges after the water pulses are used, La(OH)₃ dehydrates before the next pulse. Lee et al. have reported that because of the hydroxide formation, very long (60 s), purge time after the water pulse was needed to achieve almost saturated growth with La(ⁱPrfAMD)₃ at 250 °C [24]. In our previous work [27], similar behavior was seen with praseodymium oxide but to a lesser extent as La is the most hygroscopic of the rare earths and the tendency decreases along the series. The chemistry of the light lanthanides resembles that of alkaline earth metals and similar behavior has been reported in ALD of barium oxide with water [29].

With O₃, the growth rates varied between 0.6 and 2.1 Å/cycle depending on the deposition temperature (Fig. 2). The pulse lengths for the precursors were 1.0 s and purges 1.5 s. When both water (0.8 s pulse) and ozone (1.0 s pulse) were used, the growth rates were close to the growth rates obtained with ozone as the only oxygen source. With the H₂O/O₃ process, growth rates varied from 0.7 Å/cycle at 200 °C to 1.8 Å/cycle at 325 °C. Two purge times after the water pulse, 10 and 20 s, were tested but the growth rate was nearly the same with both purge times, in marked contrast with the growth rates with water as the only oxygen source. It seems that the ozone pulse decreases the absorption of water in the growing film. This might be related to the carbon content of the films deposited with ozone as explained later.

Ethanol was tested as an oxygen source to see if it would have a lower reactivity than water toward La(OH)₃ formation. With ethanol, the growth rate followed the growth rates of O₃ and H₂O/O₃ 200–275 °C. At 300 °C the growth rate was considerably higher compared to the lower deposition temperatures and was at the same level as with water at 300 °C (Fig. 2). Longer purge times after the ethanol pulse did not affect the growth rate of the films at 250 °C but at 300 °C the growth rate increased with increasing purge time. This is the opposite of what happens with water. Due to the abrupt change in the growth rate at 300 °C, we believe that water is formed during the deposition at 300 °C through dehydration of ethanol. Catalytic activity of metal oxide surfaces toward dehydration reactions of alcohols has been demonstrated for different metal oxides in various studies [30–33]. The formation of water is also supported by the hydrogen depth profiles measured by ERDA (not shown) since in the films deposited at 200 and 250 °C the hydrogen content is highest at the film surface and decreases deeper in the film whereas in the film deposited at 300 °C the hydrogen content is high through the whole film thickness.

Saturation of the growth rate was studied at 200 and 250 °C with water as the oxygen source but was not achieved even with the 20 s purge time after the H₂O pulse. With a 0.7 s La precursor pulse at 200 °C the growth rate was 1.2 Å/cycle and with a 2.5 s pulse already 3.2 Å/cycle. In the La(ⁱPrCp)₂(ⁱPrAMD)/O₃ process the saturation of the growth rate was confirmed at 225 °C with 1.0 Å/cycle (Fig. 3a) and in the La(ⁱPrCp)₂(ⁱPrAMD)/H₂O/O₃ process at 200 °C with 0.7 Å/cycle (Fig. 3b). With ethanol saturation was not achieved at any studied temperature: At 200 °C the growth rate varied between 0.90 Å/cycle with 0.7 s La precursor pulse and 2.8 Å/cycle with 3.0 s pulse.

The choice of the oxygen source affected the crystallinity of the films. The films deposited with ozone at 200 °C were amorphous and at 225–275 °C very weakly crystalline. Cubic, *c*, La₂O₃ (ICDD-022-0367) was obtained at 300 °C and a mixture of cubic and hexagonal, *h*, La₂O₃ (ICDD-005-0602) at 325 °C (Fig. 4a). Previously, with the La(thd)₃/O₃ process amorphous films were reported below 300 °C and cubic La₂O₃ at and above 300 °C [21]. The La(ⁱPrCp)₃/O₃ process produced amorphous films at 200 °C [3]. In the La(thd)₃/O₃ study, the amorphous films were identified by TOF-ERDA to contain large amounts of carbon and the elemental composition was close to La₂O₂CO₃ phase. Also in our work, high carbon contents were measured from the films deposited

with ozone at low temperatures, which can explain the amorphous nature of these films. The elemental compositions will be discussed later in the text.

With water, crystalline La₂O₃ films were deposited at 200 °C and above. The films deposited at 200–250 °C were mixtures of the cubic and hexagonal phases but the hexagonal phase became more dominant with increasing deposition temperature (Fig. 4b). At 300 °C the cubic phase was dominant again. It appears that the phase composition of La₂O₃ films may depend in a sensitive manner on both deposition temperature and impurity contents. In the previous studies with water as the oxygen source, amorphous films were deposited at all the studied temperatures from 150 to 250 °C in the La[N(SiMe₃)₂]₃/H₂O process, apparently because of the high amounts of Si impurities in the films [25]. The films deposited with the La(Cp)₃/H₂O process at 260 °C were reported to contain LaO(OH) according to Fourier transform infrared spectroscopy. The data was measured 5 min after the film was taken out of the reactor. XRD measurement was not reported [22].

The crystallinity of the films deposited with the H₂O/O₃ process resembled the films deposited with ozone at 200–275 °C (Fig. 4c). The films were amorphous at 200 °C and weak crystallinity was observed at 250 and 275 °C. Above that the films were cubic La₂O₃. At 300 °C the most intensive peak was (004) but at the higher deposition temperature of 325 °C (222) was clearly the strongest. Unlike with water or ozone alone, no mixtures of phases were formed at any deposition temperature.

The film deposited with ethanol at 250 °C showed very clear peaks from hexagonal La(OH)₃ (ICDD-036-1481) instead of La₂O₃ (Fig. 4d). There were also some weakly visible peaks that could be attributed to *c*-La₂O₃. Some of the hydroxide reflections were also visible at 200 °C but the peaks were very broad with low intensities. The presence of both the hydroxide and oxide phases is supported by the results of the compositional analysis discussed later. At 275 °C, a mixture of *h*-La₂O₃ and La(OH)₃ phases with low intensities and broad peaks was observed. At 300 °C the diffraction peaks match *h*-La₂O₃ but the two strongest ones are not fully separated indicating a small La(OH)₃ peak in between (Fig. 4d).

Differences in the crystal structures between the films deposited with different processes were visible also after annealing at 700 °C in air. In the case of O₃, the originally amorphous films deposited at 250 °C crystallized to the cubic La₂O₃ phase with a couple of very small peaks attributed to the hexagonal phase while the film deposited at 325 °C had the strongest peaks from the hexagonal phase but also a minor peak from the cubic phase was visible (Fig. 5a). Films deposited with H₂O above 200 °C were hexagonal La₂O₃ after the annealing while the film deposited at 200 °C was still a mixture of cubic and hexagonal phases (Fig. 5b). Films deposited with H₂O/O₃ above 250 °C were hexagonal La₂O₃ after the annealing (Fig. 5c). At 250 °C one very small peak attributed to cubic La₂O₃ was observed after the annealing. With ethanol, the La(OH)₃ containing films deposited at 200 and 250 °C were converted to mixtures of different phases (Fig. 5d). Hexagonal La₂O₃ was seen clearly with strong peaks but in addition there seemed to be LaO(OH) (ICDD-019-0656) and at least at 250 °C also cubic La₂O₃. Annealing at 700 °C in air atmosphere is thus not enough to remove all the hydroxide species from these films. In contrast, the film deposited at 300 °C was *h*-La₂O₃ after the annealing.

The films deposited with O₃ or H₂O/O₃ at the temperatures where the growth rates saturated had the highest carbon contents as deposited and after annealing at 700 °C in air there were some additional peaks that did not fit the La₂O₃ phases, although the compositional analysis showed low carbon content. These peaks were attributed to lanthanum silicate phases. HTXRD in air from room temperature to 900 °C confirmed that there is no such temperature where the oxide phase would be the only phase. When the peaks from the carbonate phase disappeared, new peaks from the silicate phases appeared. This behavior is very different from the films deposited at higher temperatures. However, annealing in nitrogen atmosphere was successful. Both the

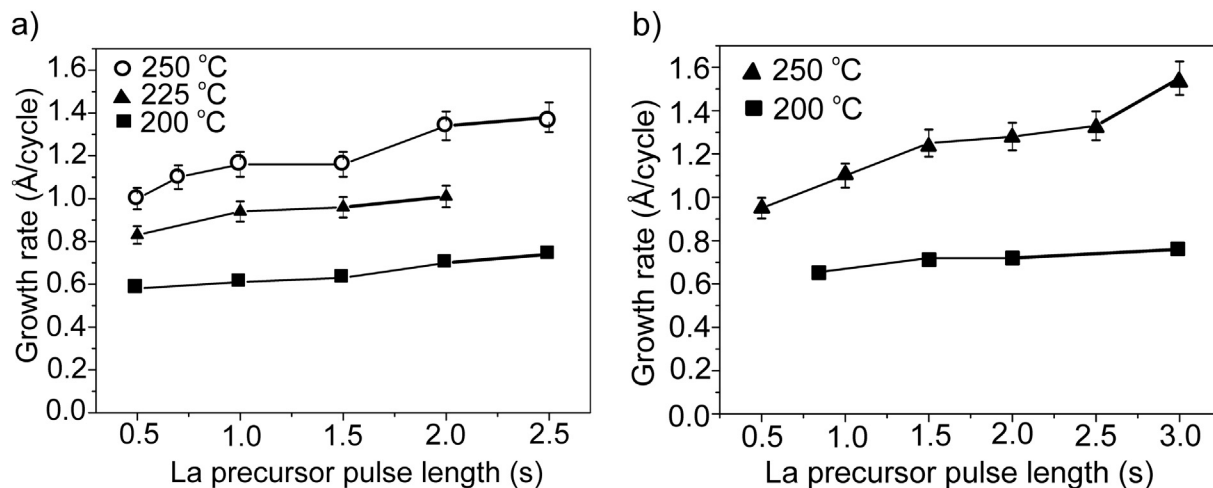

Fig. 3. La₂O₃ film growth rate as a function of La precursor pulse length in a) La(iPrCp)₂(iPrAMD)/O₃ and b) La(iPrCp)₂(iPrAMD)/H₂O/O₃ process. Pulse time for H₂O was 0.8 s and for O₃ 1.0 s.

film deposited with ozone and the film deposited with water and ozone at 200 °C crystallized to cubic La₂O₃ at 500 °C. At 600 °C the first sign of the hexagonal phase was seen and at 750 °C the film deposited with H₂O/O₃ was pure hexagonal La₂O₃ whereas the film deposited with O₃

was hexagonal La₂O₃ with one very small peak from the cubic phase. According to the HTXRD measurements, these films can be crystallized to either cubic or hexagonal La₂O₃ by carefully choosing the annealing temperature (Fig. 6).

Previously, it has been reported that the thickness of the films might affect the appearance of the pure hexagonal phase. For example, in the case of the La(Cp)₃/H₂O process, the pure hexagonal phase appeared in films thicker than 100 nm [1]. This thickness could be decreased by using ozone instead of water as the oxygen source [34]. In our study, a 110 nm thick film deposited with ozone as the oxygen source was a

mixture of cubic and hexagonal phases after annealing. With water, the deposition temperature affected the phase: > 100 nm thick film deposited at 200 °C was still a mixture of phases after annealing but > 100 nm thick films deposited at 225 and 250 °C were hexagonal La₂O₃ after annealing. The La(¹PrCp)₂(¹PrAMD)/H₂O/O₃ process was clearly different since the annealed films showing hexagonal phase at all

Fig. 7. AFM images of the films deposited at 250 °C with a) H₂O b) O₃, c) H₂O/O₃ and d) EtOH as the oxygen source. Film thicknesses were 47–65 nm.

deposition temperatures were only 47–72 nm thick. When exposed to air at room temperature, the annealed films started to convert to hydroxide faster than the as-deposited films indicating better film purity as discussed below.

The AFM images of the films deposited at 250 °C (Fig. 7) and 300 °C (Fig. 8) indicate that the films deposited with water are rough (RMS roughness values above 2 nm) compared to the films deposited with O₃ or H₂O/O₃. The high roughness values are likely due to the high growth rates and crystallinity of the films. The films deposited with ozone as the oxygen source were the smoothest with RMS values ranging from 0.61 nm at 200 °C to 0.91 nm at 300 °C. The roughness increases with increasing deposition temperature which can be explained by the

increasing crystallinity. For the H₂O/O₃ process the roughness values were around 1.5 nm for all the measured films. The films deposited with the La(¹PrCp)₂(¹PrAMD)/EtOH process at 200 and 250 °C were La(OH)₃ and the roughness values of these films were much higher than the values of the La₂O₃ films from the other processes. A 55 nm thick La(OH)₃ film deposited at 250 °C had RMS value of 3.8 nm. At 300 °C also the films deposited with EtOH were La₂O₃ and the roughness was 1.6 nm which is in the same range with the H₂O/O₃ process.

Elemental compositions of selected films were measured with TOF-ERDA. The main impurities were carbon and hydrogen. However, the hydrogen contents are not completely representative because the films react with moisture to form hydroxide during storage. A general trend

Fig. 8. AFM images of the films deposited at 300 °C with a) H₂O b) O₃, c) H₂O/O₃ and d) EtOH as the oxygen source. Film thicknesses were 36–72 nm.

Table 1
Representative samples from the depositions with different oxygen sources.

Oxygen source	Growth rate saturation	La:O	C (at. %)	H (at. %)	Crystalline phase
H ₂ O/O ₃ at 200 °C	Yes	0.45	8	3	Amorphous <i>h</i>
Annealed at 700 °C in N ₂		0.51	0.2	6	
O ₃ at 200 °C	Yes	0.31	19	3	Amorphous <i>h</i> , minor peaks <i>c</i>
Annealed at 700 °C in N ₂		0.53	0.2	7

h hexagonal La₂O₃, *c* cubic La₂O₃.

seemed to be that the higher the carbon content the lower the hydrogen content. The highest carbon levels were measured from the films deposited at low temperature with ozone (19 at.% of carbon at 200 °C and 10 at.% at 250 °C) and the second highest from the films deposited with H₂O/O₃ (around 8 at.% of carbon at 200–250 °C). All of these films contained around 3 at.% of hydrogen. When the deposition temperature was raised, the carbon content decreased and hydrogen content increased. For example with H₂O/O₃ at 325 °C the carbon content was < 4 at.% and the hydrogen content 6 at.%, and with ozone the numbers were 4 at.% of carbon and 15 at.% of hydrogen.

Previously, high carbon levels have been detected in the La(thd)₃/O₃ process with around 11 at.% of carbon at deposition temperatures of 225–300 °C [21]. Lanthanum oxide is known to be very hygroscopic but these results imply that carbonate impurities stabilize the films, i.e. the high carbon content inhibits the absorption of moisture and keeps the hydrogen content lower in the films deposited with ozone and H₂O/O₃ at 200 to 250 °C. Visually, the films with high carbon content maintained their original appearance when stored in air whereas the films deposited with water started to turn matt and eventually flaked off the substrate.

With the water and ethanol processes, the carbon levels in the films were clearly lower and hydrogen levels higher than with ozone and H₂O/O₃, between 1 and 2 at.% of carbon and 11 to 24 at.% of hydrogen at 200–250 °C. This can be explained by the strong oxidation ability of ozone which can cause bonds in the ligands to break, leaving carbon impurities in the film. The films deposited with EtOH at 250 °C showed mainly La(OH)₃ in the X-ray diffractograms and very small peaks that could be due to cubic La₂O₃. According to the compositional analysis, the hydrogen content of this film is 17 at.%. If the whole film would be La(OH)₃, the hydrogen content should be much higher, 43 at.%. This result confirms that the very small peaks seen in the XRD are La₂O₃. It is also possible that part of the film is amorphous. Even though the film deposited at 300 °C with EtOH shows *h*-La₂O₃ in XRD it contains 22 at.% of hydrogen according to TOF-ERDA.

All measured films had an excess of oxygen compared to the stoichiometric La:O ratio (0.67) in La₂O₃. The best La:O ratios in our study (~0.55) were measured from the films deposited with water and the worst with ozone as the oxygen source. With water the ratios did not change with the deposition temperature as much as they did with ozone (0.31 at 200 °C and 0.47 at 325 °C). The excess of oxygen is explained with the carbonate and hydroxyl species in the films.

Some films contained small amounts of fluorine (from 0.06 ± 0.3 to 0.75 ± 0.2 at.%) and nitrogen (max. 0.15 ± 0.1 at.%). Fluorine has been seen before in films deposited with ozone in the same type of ALD reactor and it is attributed to the fluorine containing gaskets and vacuum grease used in the reactor [35]. An obvious source for the nitrogen is the amidinate ligand.

Compositional analysis was performed for selected films also after annealing at 700 °C. To minimize the contamination caused by reactions with ambient air, the films were taken to the TOF-ERDA measurement right after the annealing. The carbon contents of the films annealed in air were in general < 1 at.% while the highest value was 2 at.% in a film deposited at 250 °C with H₂O/O₃. The hydrogen contents varied between 2 and 5 at.%. The films deposited with EtOH at 200 and 250 °C showed La(OH) phase in the XRD. According to the TOF-ERDA depth profiles, the La(OH) phase is probably the topmost layer since there is around 10 at.% of hydrogen close to the surface but only around 2 at.% deeper in the bulk of the films. Also chlorine (~0.5 at.%) was found from the annealed samples and it is most likely contamination from the oven used to anneal the samples.

The films deposited with O₃ or H₂O/O₃ at 200 °C and annealed at 700 °C in N₂ atmosphere contained only 0.2 at.% of carbon and 6–7 at.% of hydrogen according to the compositional analysis. The La:O ratios (0.53 for O₃ and 0.51 for H₂O/O₃) were closer to the stoichiometric value than after annealing in air atmosphere (0.41 for both processes) but still there was some additional oxygen, apparently in the form of hydroxide.

4. Conclusions

In this work, we studied atomic layer deposition of La₂O₃ from a heteroleptic La precursor La(ⁱPrCp)₂(ⁱPrAMD) with either H₂O, O₃, EtOH, or both H₂O and O₃ as the oxygen source. The choice of the oxygen source had a great effect on the growth rates, crystallinity, and impurity levels of the films. With water, the hygroscopicity of La₂O₃ caused problems and saturation of the growth rate was not achieved even when 20 s purge period after the water pulse was used. Interestingly and importantly, hygroscopicity was not a problem when ozone pulse was added after the water pulse since saturation of the growth rate was achieved with the La(ⁱPrCp)₂(ⁱPrAMD)/H₂O/O₃ process at 200 °C with a growth rate of 0.7 Å/cycle. Also the La(ⁱPrCp)₂(ⁱPrAMD)/O₃ process was saturative at 225 °C with a growth rate of ~1 Å/cycle. At 250 °C both of these processes were close to saturation. With ethanol, no saturation was achieved at any deposition temperature. Besides La₂O₃, lanthanum hydroxide La(OH)₃ was formed when ethanol was the oxygen source. Evidence of the hydroxide formation was not seen in the diffractograms of the other processes, although elemental analysis revealed that the films deposited with water had high hydrogen content. The La(ⁱPrCp)₂(ⁱPrAMD)/H₂O/O₃ process showed deviating crystallization behavior from the other processes after annealing as pure, high permittivity hexagonal phase was formed in all the films regardless of the deposition temperature, whereas the films deposited with the other processes had mostly mixtures of cubic and hexagonal La₂O₃. The most representative samples from each process are collected in Table 1.

Acknowledgment

Mr. Mikko Heikkilä is thanked for the help with the XRD measurements and Dr. Peter King for correcting the English in the manuscript. This work was funded by the Finnish Centre of Excellence in Atomic Layer Deposition (Academy of Finland), (284 623).
