Abstract

The growth of WSe_(2-x)Te_x alloys by molecular beam epitaxy has been demonstrated for the first time to investigate the phase transition from the semiconducting 2H phase to the semi-metallic 1T' phase as a function of Te concentration. Up to 14% Te incorporation, stable alloys in the semiconducting 2H phase are achieved while above 79% Te incorporation, stable alloys in the semi-metallic 1T' phase are obtained. Our results indicate the MBE-grown WSe_(2-x)Te_x alloys exhibit a miscibility gap from 14% to 79% Te concentrations at a growth temperature of 250 °C, a temperature compatible with direct vertical back-end-of-line integration. This miscibility gap results in phase separation of two different alloys, both with different composition and crystal structure. While the alloying of small Te concentrations does indeed result in a desired reduction of the semiconducting bandgap, the phase separation above 14% Te incorporation prohibits bandgap tuning for a wider range of applications. These results highlight the competing energies and kinetics associated with producing uniform WSe_(2-x)Te_x alloys.

Introduction

With the end of conventional silicon-based device innovation on the horizon and the explosion of research focusing on novel materials for next-generation memory and logic circuitry, two-dimensional transition metal dichalcogenides (TMDs) have emerged as viable candidates for the next-generation of low-power devices due to their wide range of electronic properties and monolayer scalability.¹⁻⁴ Until recently, the majority of research has focused on the fundamental investigation of the electronic properties and device applications using large-area bulk crystals grown at high temperature over a long growth period.⁵⁻⁸ These studies have provided valuable insight into the unique physical, electronic, and quantum properties of TMDs, which can be exploited for innovative sensors, transistors, and energy storage.⁹⁻¹³ As these materials are developed further, the semiconductor industry continues to search for new ways to tune the electronic properties for optimized performance. One method currently being investigated is the phase-engineering of TMDs, which permits control over the band structure and is therefore a critical engineering challenge to overcome before commercially viable novel device applications based on TMDs can be realized.¹⁴

TMDs with a bandgap below 1 eV are of interest for prospective applications, in particular, for tunnel-field-effect-transistors (TFETs), where a sub-60 mV/dec subthreshold swing can be achieved without the fundamental switching constraints of thermionic emission.¹⁵⁻¹⁶ However, low on-currents

1
2
3 remain a significant issue for TFET devices and bandgap engineering must be optimized to enhance the
4 on-state current. Of course, the probability of tunneling between source and drain regions can be
5 amplified by reducing the bandgap of the semiconducting TMD in the device,¹⁷⁻¹⁹ which can possibly be
6 achieved by strategically forming ternary alloys. Alloying for band gap tuning has been successfully
7 demonstrated in III-V materials such as $\text{In}_x\text{Ga}_{1-x}\text{As}$ and $\text{GaAs}_x\text{P}_{1-x}$ alloys, but interfacial defects and
8 alloy scattering have resulted in significant challenges.²⁰⁻²² In recent years, mixed-chalcogen or mixed-
9 metal TMDs have been synthesized using a number of deposition methods, usually at high growth
10 temperatures ($> 800\text{ }^\circ\text{C}$) where the Gibbs free energy of mixing ($\Delta G_{\text{mix}} = \Delta H_{\text{mix}} - T\Delta S_{\text{mix}}$) is dominated
11 by the entropy (ΔS) rather than the enthalpy (ΔH) of mixing. Specifically, wide bandgap semiconductors
12 based on group VIB transitional metals (Mo and W) have been the focus of many previous reports. Both
13 mixed-metal TMD alloys (i.e. $\text{Mo}_x\text{W}_{1-x}\text{S}_2$ or $\text{Mo}_x\text{W}_{1-x}\text{Se}_2$)²³⁻²⁵ and mixed-chalcogen TMD alloys (i.e.
14 $\text{MoS}_x\text{Se}_{1-x}$) have been investigated,²⁶⁻²⁸ where the bandgap varies by a few hundred meV over the stable
15 composition range of each alloy.

16
17
18
19
20
21 A recent study performed by Yu *et al.* demonstrated bandgap control of $2\text{H-WSe}_{(2-x)}\text{Te}_x$ monolayers
22 between 1.67 eV and 1.44 eV over the stable composition range up to 50% Te incorporation. However,
23 alloys with a Te concentration greater than 50% exhibited phase separation into a semi-metallic $1\text{T}'$
24 phase and a semiconducting 2H phase.³¹ These results are somewhat promising for bandgap engineering,
25 but a bandgap below 1 eV has not yet been achieved, limiting their applicability in TFET applications.
26 Furthermore, the chemical vapor transport (CVT) growth technique required extremely long growth
27 periods and high growth temperatures ($\sim 900\text{ }^\circ\text{C}$), which limits the range of potential applications due to
28 typical thermal restrictions of the substrate or back-end-of-line circuitry. Conversely, very few studies
29 investigating the crystal formation of thin-film TMD alloys have employed molecular beam epitaxy,
30 where the much lower growth temperatures potentially enable direct integration of these TMD alloys
31 into the back-end-of-line. MBE provides a number of advantages to closely investigate the growth of
32 $\text{WSe}_{(2-x)}\text{Te}_x$ alloys, including the ultra-high vacuum deposition environment, low growth temperatures,
33 high purity sources, and precise control of the elemental beam flux. These advantages allow for
34 controlled deposition that can enable layer-by-layer thickness control directly on the substrate, even
35 down to the monolayer.

36
37
38
39
40
41 2H-WSe_2 is a semiconductor that possesses trigonal prismatic coordination and a direct band gap of
42 2.4 eV in the monolayer form and an indirect bandgap of 1.4 eV in bulk. Although it has been well
43 established that WTe_2 stabilizes in the distorted octahedral ($1\text{T}'$) phase and possesses semi-metallic
44 properties,²⁹ a recent theoretical study has predicted a 0.63 eV bandgap in the monolayer form of WTe_2
45 in the metastable 2H phase.³⁰ These results suggest a potential route for obtaining a semiconducting
46 TMD with a sub-1 eV bandgap when alloying WTe_2 with Se. Figure 1(a,c) shows the chalcogen-metal
47 coordination and (010) side view of 2H-WSe_2 , respectively, where the uniform bond lengths result in a
48 middle layer with uniform W spacing. Figure 1(b,d) shows the $1\text{T}'$ phase of WTe_2 , where the distorted
49 structure results in W-W distances of 2.86 Å and 4.4 Å. This atomic coordination of WTe_2 produces an
50 electronic structure where the valence and conduction bands exhibit a 0.3 eV overlap, forming the semi-
51 metal.

Experimental details

The growth of WSe_(2-x)Te_x presented in this research was performed in a VG-Semicon V80H MBE system equipped with an *in-situ* reflection high-energy electron diffraction (RHEED) tool for real-time surface analysis.³² A single-filament Knudsen effusion cell (k-cell) was used for selenium evaporation, a dual-filament, thermal cracker was utilized for tellurium evaporation, and a vertical e-beam evaporator was used for tungsten deposition. The WSe_(2-x)Te_x films were grown directly on highly-oriented pyrolytic graphite (HOPG), CVT-grown MoS₂, and Bi₂Se₃ grown by MBE on sapphire (0001) at a growth temperature of 250 °C. A nude ion gauge positioned at the focal point of deposition measured the chalcogen fluxes, while the W beam flux was calculated using blanket depositions and thickness measurements. A systematic increase in Te concentration of the alloys was achieved by keeping the flux pressures of Te and W constant at 8×10^{-7} mbar and 4×10^{-9} mbar, respectively, while incrementally reducing the Se flux pressure from 1×10^{-8} mbar to 1×10^{-9} mbar. The pure WSe₂ and WTe₂ reference samples were also grown at 250 °C using only the primary chalcogen flux, which was maintained at flux pressures of 6×10^{-8} mbar and 8×10^{-7} mbar, respectively. Prior to deposition, the HOPG and MoS₂ substrates were exfoliated immediately before loading into the UHV system and annealed to 400 °C for one hour, providing a clean surface free of environmental contaminants and oxidation.³³⁻³⁴ The Bi₂Se₃ substrates were grown on sapphire (0001) using a two-step growth method at 320 °C (the growth details can be found in previous publications).³⁵⁻³⁶ All heaters (k-cell, e-beam, and substrate) were maintained at the growth temperature for two hours to allow ample time for outgassing and temperature stabilization. To initiate growth, the elemental source shutters were opened simultaneously, and throughout the duration of the deposition, a beam-interruption growth technique was utilized for the W flux, where the shutter was cycled between open and closed for 30 s and 90 s, respectively. Due to the slow growth rate of the beam interrupted films, a six hour growth period was needed to form a film ~3

1
2
3 nm thick (four monolayers). More information on the preparation of the substrates and the effectiveness
4 of beam-interrupted growth for WSe₂ and WTe₂ can be found in previous publications.³⁷⁻³⁸
5

6
7 X-ray photoelectron spectroscopy (XPS) measurements, including valence band spectra, were
8 carried out using a monochromated Al K α source and an Omicron EA125 hemispherical analyzer with a
9 spectral resolution of ± 0.05 eV. An analyzer acceptance angle of 8°, takeoff angle of 45°, and pass
10 energy of 15 eV were used in this study. Additional information about the XPS system can be found in
11 previously published literature.³⁹ The integrated intensities of relevant chemical states in the XPS core
12 level spectra were used to calculate the stoichiometry of the films using the appropriate relative
13 sensitivity factors for the W 4*f*, Te 4*d*, and Se 3*d* core levels (2.959, 1.388, 0.722, respectively). The
14 core levels were deconvoluted using version 1.36 of the curve-fitting software AAnalyzer.⁴⁰ An active
15 Shirley-Sherwood background was subtracted when fitting all spectra. Metallic chemical states were fit
16 using an asymmetric double-Lorentzian line shape, while non-metallic chemical states were fit with
17 Voigt (symmetric) line shapes.⁴¹ Low-energy electron diffraction (LEED) patterns and scanning
18 tunneling microscopy/spectroscopy (STM/S) were acquired in a separate Omicron tool from where the
19 XPS was measured. LEED and RHEED used bare MoS₂ and Bi₂Se₃ patterns for reference. Raman
20 spectra were acquired using an average of 20 sweeps where a Renishaw confocal Raman system was
21 employed with an excitation wavelength of 532 nm, laser power of 0.22 mW, and spot size of 500 nm.

26

27 Results and Discussion

28
29 Due to the relatively low growth temperature employed in MBE, both the kinetics of the atoms on
30 the substrate and thermodynamics of the crystal formation must be considered when optimizing a
31 deposition process. The sticking coefficient of elemental beam fluxes decreases and the desorption
32 coefficient increases with increasing substrate temperature.⁴² Generally speaking, this results in a
33 decreased nucleation rate at higher substrate temperatures. Furthermore, by raising the temperature of
34 the substrate, the probability of bond scission and forming more thermodynamically favorable crystals is
35 improved.
36
37

38
39 A previous report³⁷ showed the MBE growth of WTe₂ involves a dominant density of Te₂ dimers in
40 the deposition beam flux (~95%), which required the use of an extremely high Te:W flux pressure ratio
41 (200:1) along with a periodically interrupted W flux to produce stoichiometric WTe₂ films due to the
42 low flux density of atomic Te. Although the density of Te₂ dimers can be reduced with the use of a high-
43 temperature cracking region, they still present a significant kinetic challenge when growing Te-based
44 crystals at substrate temperatures below the thermal energy threshold needed to dissociate Te-Te dimers
45 on the surface (259.8 ± 5 kJ/mol).⁴³ Se₆ clusters are the dominant species in the Se vapor phase (~47%),
46 but they do not detrimentally dominate the atomic flux pressure like the Te₂ dimers.⁴⁴ This creates a
47 growth condition that only requires a Se:W flux pressure ratio of 20:1 to produce stoichiometric WSe₂ in
48 contrast with the extremely high Te:W flux pressure ratio required for stoichiometric WTe₂. This
49 introduces an imbalance when growing WSe_(2-x)Te_x alloys by saturating the substrate surface with Te₂
50 dimers that do not participate in the growth. Furthermore, the enthalpy of formation of W-Se is more
51 energetically favorable than W-Te (185.3 ± 5.5 kJ/mol compared to 38 ± 5 kJ/mol, respectively),⁴⁵⁻⁴⁶
52 which further exacerbates the challenge of incorporating Te into mixed chalcogen alloys.

To investigate the evolution of the physical and electronic properties of $\text{WSe}_{(2-x)}\text{Te}_x$ alloys, a series of samples were grown with the Te concentration varying from 0% to 100%. Shown in Figure 2, the valence band offset (VBO) for the WSe_2 reference film was determined to be ~ 0.66 eV and is consistent with a near-midgap Fermi level in multilayer WSe_2 (bandgap ≈ 1.4 eV).³⁸ Due the aforementioned vast differences in dissociation and formation energies, small amounts of Te were incorporated into the $\text{WSe}_{(2-x)}\text{Te}_x$ films only after significantly reducing the Se flux while maintaining a high Te flux. The VBO is concomitantly reduced to 0.61 eV and 0.58 eV in alloys containing 5% and 10% Te concentrations, respectively. However, the inset in Figure 2 shows an appreciable density of states are generated at the Fermi level when the Te concentration is 16% in addition to the density of states detected away from the Fermi level associated with the valence band edge of semiconducting WSe_2 . All Te concentrations higher than 16% (green region) exhibit DOS up to the Fermi energy consistent with a semi-metallic electronic structure. This indicates that $\text{WSe}_{(2-x)}\text{Te}_x$ alloys grown at 250 °C begin to phase separate at a Te concentration somewhere between 10% and 16%.

Figure 3(a) shows an STM image of sub-monolayer $\text{WSe}_{1.68}\text{Te}_{0.32}$, where the initial nucleation along the HOPG step edges results in small grains tens of nanometers across. STS data obtained from the same sample (Figure 3(b)) shows a DOS near the Fermi level, which is consistent with the XPS results (inset in Figure 2).

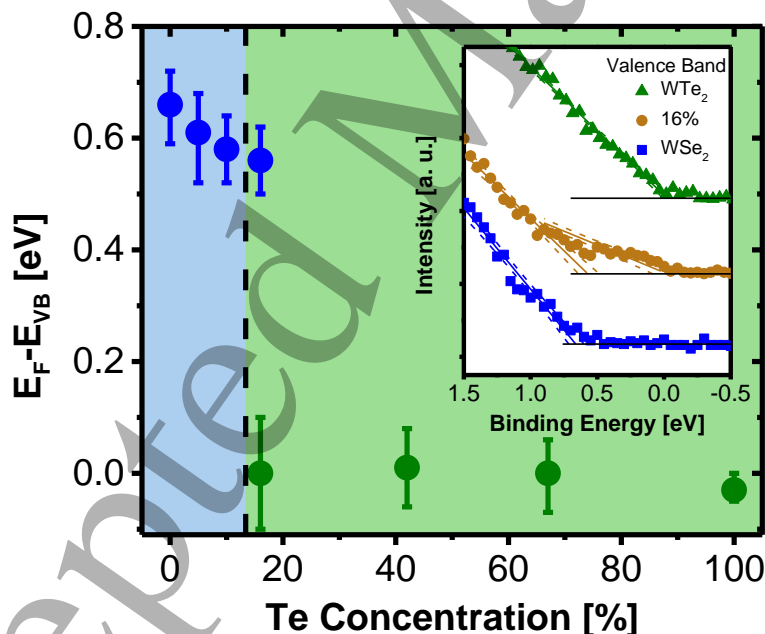

Figure 2: Plot of the valence band offset vs Te concentration over a wide range of $\text{WSe}_{(2-x)}\text{Te}_x$ alloys. The blue region represents alloys in the semiconducting 2H phase, and the green region represents alloys that exhibit metallic characteristics. The inset shows the valence band spectra of the two stoichiometric references along with the 16% Te alloy, where two stages of linear increase in intensity reflect both the semiconducting 2H alloy and the semi-metallic 1T' alloy. The valence band offset and the 95th percentile confidence intervals to the linear regression that provided the valence band offset for the WSe_2 , 16% Te film, and WTe_2 film, respectively, are (WSe_2 : 0.66 eV, 0.72 eV, 0.59 eV, 16%Te: 0.56 eV, 0.62 eV, 0.50 eV, WTe_2 : -0.03 eV, 0.00 eV, -0.05 eV). These were obtained from a linear regression to the data, as shown.

Figure 3:(a) Large-area STM image of sub-monolayer $\text{WSe}_{1.68}\text{Te}_{0.32}/\text{HOPG}$ showing the initial nucleation occurring at the step edges of the HOPG substrate. Select grains are outlined as a guide to the reader. (b) STS data obtained from the same sample showing a measurable density of states near the Fermi level indicating the presence of the semi-metallic $1\text{T}'$ phase. (c) Zoomed-in image where the star indicates the point the STS data was acquired.

Detailed XPS analysis of the Se $3d$, Te $3d$, and W $4f$ core level spectra was performed to investigate the evolution of the chemical states in the ternary alloys as a function of composition. In Figure 4(a), a broad peak was detected in the Te $3d$ core level spectra at ~ 573.2 eV from each of the ternary alloys. This chemical state exhibits a higher BE than the chemical state detected in the Te $3d$ core level in the WTe_2 reference (labelled 100%) and indicates the presence of an alloy in the semiconducting 2H phase. Furthermore, as the Te concentration is increased to 16%, a second, asymmetric feature at lower binding energy was deconvolved from the corresponding Te $3d$ spectra. The asymmetric double Lorentzian line shape and lower BE indicates the presence of a Te-rich, metallic-like state, which is consistent with the semi-metallic $1\text{T}'$ phase as also detected in the corresponding valence band spectra. Thus, we attribute this peak to the formation of a $1\text{T}'$ phase alloy.

The Te $3d$ core level can be used to calculate the miscibility gap of these films. Using the intensities of the $1\text{T}'$ and 2H chemical states from the 16%, 32%, and 67% Te concentration samples using a self-consistent fitting procedure, the binding energy of the $1\text{T}'$ and 2H phases are stable at 572.75 eV and 573.40 eV, respectively. The concentration of the two phases in the Te $3d$ core level were employed to determined that the $1\text{T}'$ phase is composed of 79% Te ($\text{WSe}_{0.42}\text{Te}_{1.58}$) and the 2H phase is composed of 14% Te ($\text{WSe}_{1.72}\text{Te}_{0.28}$). These stoichiometries represent the endpoints of the miscibility gap of these alloys at this growth temperature and indicates an energetically unfavorable enthalpy of mixing for $\text{WSe}_{(2-x)}\text{Te}_x$ alloys. Figure 4(b) shows the Se $3d$ core level spectra obtained from the range of alloys, where the emergence of an asymmetric feature at 16% Te indicates a small amount of Se is incorporated into the $1\text{T}'$ crystal structure. The chemical state associated with the 2H crystal structure exhibits an increasing shift to lower binding energy as the total Te concentration increases, which is consistent with an increase in Te concentration in the 2H crystal structure.

The evolution of the tungsten chemical states (W-Se and W-Te bonding) as a function of Te concentration was evaluated using the W 4f core level, which is shown in Figure 4(c). Two chemical states (W-Se and W-Te) were deconvolved from the '5%' and '10%' W 4f spectra, which were fit using symmetric Voigt line shapes indicating the chemical states correspond to semiconducting phases.⁴⁰ However, once the Te concentration reaches 16%, a chemical state with asymmetric line shape was detected indicating the presence of the semi-metallic, Te-rich 1T'-WSe_(2-x)Te_x phase. The intensity of the chemical state associated with the 1T' phase increases as the Te concentration is increased to 67%. The shift to higher binding energy from the WTe₂ reference exhibited by the W-Te chemical state in each of the W 4f core level spectra is likely due to final state electron density effects in metallic alloys.⁴¹ Furthermore, the increase in the high binding energy WO_x chemical state in samples containing more than 16% Te concentration is consistent with an increased oxidation rate of Te rich films and is likely enhanced by the increased number of defects and grain boundaries with increasing Te concentration in the alloy (see supplementary information for more discussion of oxidation and surface contaminants in Te-rich films). These results obtained through careful analysis of the XPS core levels further support the early onset of phase separation in these low-temperature MBE-grown alloys and highlights a major engineering challenge that must be solved before WSe_(2-x)Te_x alloys can be applied in novel device structures.

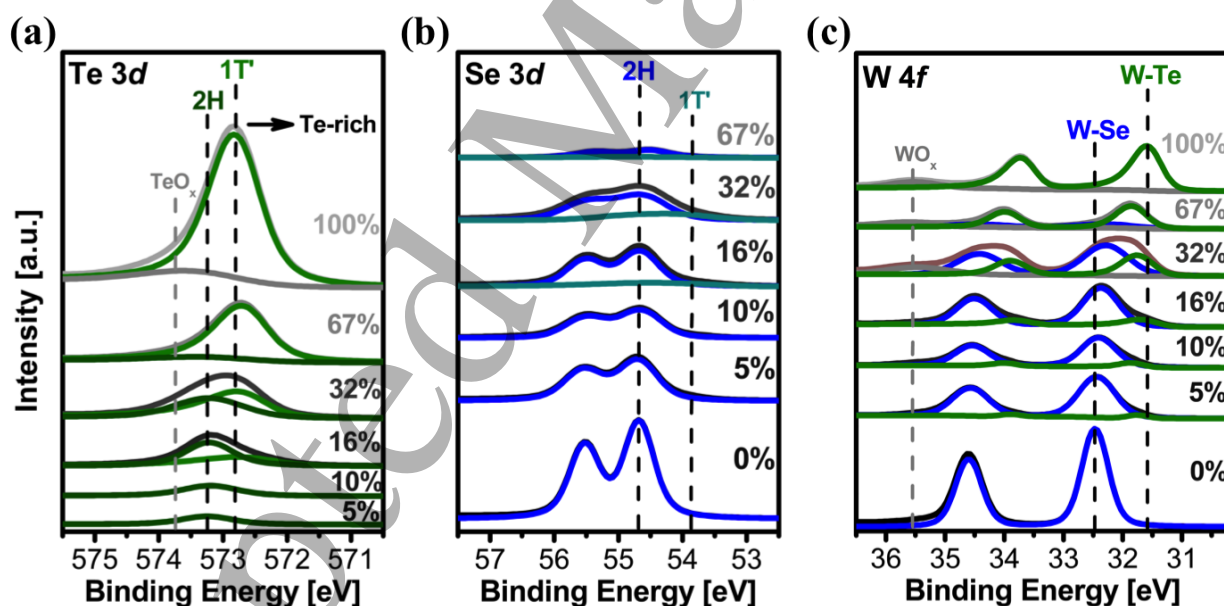

Figure 4: Deconvoluted XPS spectra of the WTe_xSe_{2-x} alloys for the (a) Te 3d, (b) Se 3d, and (c) W 4f core levels. At 16% Te concentration, phase separation is observed by the appearance of both metallic and non-metallic features in the Te 3d, Se 3d, and W 4f core levels. The phase separation persists at all compositions up to and including the 67% total composition.

Due to the rapid oxidation of WTe₂ thin films, *ex situ* structural characterization of the as-grown alloys must be performed immediately after removing from UHV, while still considering the non-uniform oxidation rates between the Te-rich 1T' phase and the Se-rich 2H phase. However, to avoid this issue, analysis of the surface using *in situ* RHEED can provide valuable insight into the phase separation

1
2
3 of the $\text{WSe}_{(2-x)}\text{Te}_x$ alloys. Figure 5(c) shows an out-of-plane view of the atomic arrangement of the top
4 layer of Se and W atoms in the 2H phase. The trigonal prismatic coordination results in a 60° rotational
5 symmetry along the surface where the two sets of evenly spaced Se atoms produce distinct RHEED
6 patterns. Figure 5(d) shows the out-of-plane view of the upper layer of Se atoms along with the
7 underlying W atoms of WTe_2 in the distorted 1T' phase. The octahedral coordination of the unevenly
8 spaced W atoms breaks the 60° surface symmetry of the 2H and 1T' phases and results in alternating
9 rows of Te atoms with out-of-plane displacements differing by 0.6 \AA (indicated by the different color
10 arrows in Figure 5(d)). Although this change in crystal structure is significant enough to produce a
11 distinctly different RHEED pattern (the additional streaks as highlighted with the red arrows in Figure
12 5(a)), the symmetry still yields thin films in the 1T' phase that are rotationally aligned to hexagonal
13 substrates. The sharp spots observed in LEED patterns and the sharp streaks in the RHEED from pure
14 WSe_2 fade to somewhat blurry spots and streaks in the 16% alloy and become even more blurry in those
15 obtained from the WTe_2 reference (Figure 5(b)). This is primarily due to the decrease in the average
16 grain size as the Te content is increased as judged from the STM (see supplemental information). In
17 fact, the grain size in the Te-rich films and pure WTe_2 is on the order of, or slightly larger than, the
18 LEED transfer length of 20 nm. Additionally, in the phase separated films, there are two sets of RHEED
19 patterns simultaneously with different, but close, reciprocal lattice spacing (the phase separated alloys
20 have relatively close lattice constants). This leads to an additional spread/blurriness in the RHEED
21 streaks (convolution of two patterns).
22
23
24
25
26
27
28

29 By applying the principles of RHEED analysis, a direct comparison of the lattice spacing of the
30 can be achieved though the relation $\frac{s_1}{s_2} = \frac{a_2}{a_1}$ when all other variables are kept constant. In this case, s_1
31 and s_2 represent the RHEED streak spacing and a_1 and a_2 represent the atomic spacing of WSe_2 and
32 WTe_2 respectively. Figure 5(a,b) shows a comparison of the RHEED and LEED patterns produced by
33 the $\text{Bi}_2\text{Se}_3/\text{sapphire}(0001)$ substrate, 2H- WSe_2 , 1T'- WTe_2 , and the phase-separated $\text{WSe}_{(2-x)}\text{Te}_x$ alloy
34 with 16% Te concentration. Using the method just described for directly comparing the diffraction
35 patterns, both the RHEED and LEED pattern ratios fall within 2% of the expected ratio for WSe_2 and
36 WTe_2 with lattice constants of $3.28 \pm 0.02 \text{ \AA}$ and $3.49 \pm 0.02 \text{ \AA}$, respectively. The additional set of
37 streaks (indicated by the red arrows) is again indicative of the 1T' phase. The faint appearance of this
38 additional set of streaks is further evidence of the emergence of the 1T' phase in the alloy with 16% Te
39 concentration.

Ball and stick models for (c) 2H-WSe₂ and (d) 1T'-WTe₂ where the green and red arrows indicate alternating rows of top-surface Te atoms with varying out-of-plane displacements.

Finally, to confirm the phase separation of the WSe_(2-x)Te_x alloys, Raman spectra were acquired from WSe_(2-x)Te_x samples with each of the Te concentrations (Figure 6). One broad feature was detected from stoichiometric WSe₂ at ~ 250 cm⁻¹ (overlapping in-plane E_{2g}¹ and out-of-plane A_{1g} modes) and a second peak was detected at ~ 260 cm⁻¹ (second order resonant Raman mode), which are consistent with previous reports of WSe₂ in the 2H phase.⁴⁷⁻⁴⁸ Incorporation of Te in the alloys resulted in a redshift of the E_{2g}¹ peak, which can be attributed to the high-frequency vibration caused by heavy Te atoms in the alloys. A significant reduction in peak signal to noise ratio was detected as the Te concentration was increased up to 32%, indicating a film with suppressed long-range order. Although the behavior of the WSe₂ Raman modes are consistent with the conclusions drawn from the XPS results, the rapid oxidation of W atoms bonded to Te along with the *ex-situ* exposure time needed to attain the Raman spectra (> 15 min) makes it difficult to draw absolute conclusions regarding the magnitude of the phase separation. Despite the uncertainty in the absolute magnitude of the phase separation, the broad features detected in the spectra obtained from the films with 16% and 32% Te concentration around 230 cm⁻¹ suggest the presence of a the A₁⁹ Raman mode exhibited by WTe₂. Two distinct peaks are detected at 170 cm⁻¹ and 220 cm⁻¹ in the Raman spectrum obtained from stoichiometric WTe₂ (corresponding to the A₁⁷ and A₁⁹

modes, respectively), which are consistent with a previous report and indicates the low density of defects in the stoichiometric film facilitates a greater oxidation resistance.⁴⁹

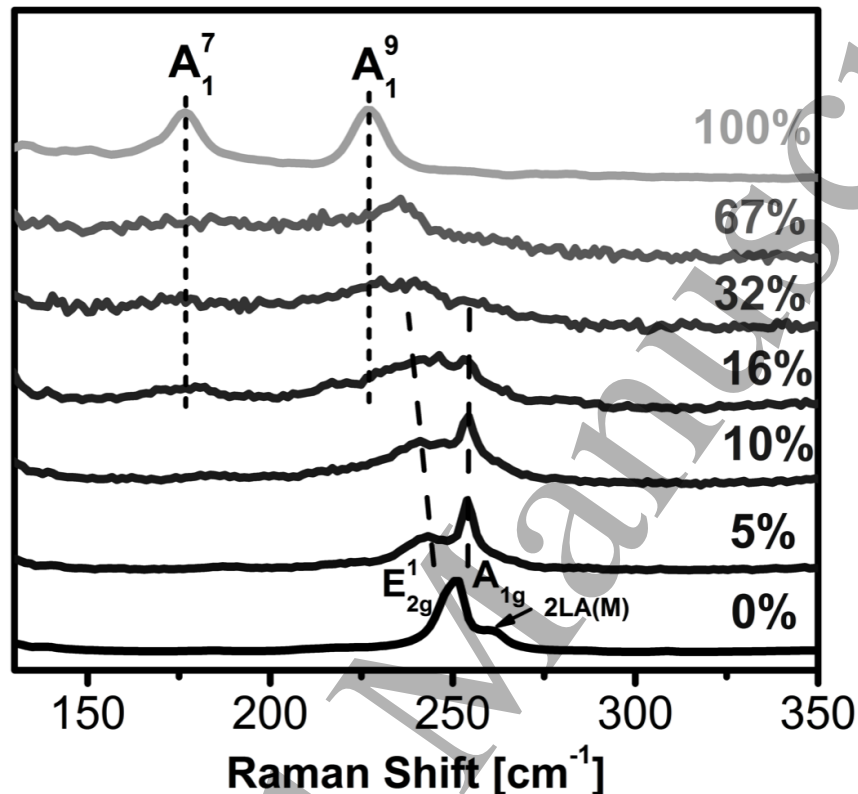

Figure 6: Raman spectra of the $\text{WSe}_{(2-x)}\text{Te}_x$ alloys showing a redshift of the 2H phase E_{2g}^1 peak as a function of increasing Te concentration, and the onset of the 1T' phase peaks.

Conclusion

In conclusion, we have demonstrated the growth of $\text{WSe}_{(2-x)}\text{Te}_x$ alloys on van der Waals substrates by MBE and observed crystalline phase separation at Te concentrations much lower than previously reported in bulk alloys grown at much higher temperatures by CVT. *In situ* RHEED analysis in conjunction with *ex situ* XPS and Raman measurements indicate $\text{WSe}_{(2-x)}\text{Te}_x$ alloys remain stable in the semiconducting 2H phase until a concentration of ~14% Te is reached, at which composition phase separation results in the coexistence of a semiconducting 2H alloy and a semi-metallic 1T' alloy. Alloys containing 79% Te are more stable in the 1T' phase only. The edge of the miscibility gap at 14% is supported by patches of semi-metallic behavior detected by STS in regions of a sub-monolayer film with 16% Te concentration. The results presented in this research highlight the challenges facing the direct synthesis of $\text{WSe}_{(2-x)}\text{Te}_x$ thin film alloys in growth conditions compatible with the strict requirements associated with back-end-of-line semiconductor device processing where these alloys would be most useful.
