Preface

Annual catch quotas and other regulations of the Barents Sea fisheries are set through negotiations between Norway and Russia. Assessment of the state of the stocks and quota advices are given by the International Council for the Exploration of the Sea (ICES). Their work is based on survey results and international landings statistics. The results from the demersal fish winter surveys in the Barents Sea are an important source of information for the annual stock assessment.

The development of the survey started in the early 1970s and focused on acoustic measurements of cod and haddock. Since 1981 it has been designed to produce both acoustic and swept area estimates of fish abundance. Some development has taken place since then, both in area coverage and in methodology. The development is described in detail by Jakobsen *et al.* (1997), Johannesen *et al.* (2009) and Appendix 2. At present the survey provides the main data input for a number of projects at the Institute of Marine Research, Bergen:

- monitoring abundance of the Barents Sea demersal fish stocks
- mapping fish distribution in relation to climate and main prey abundance
- monitoring food consumption and estimating predation mortality caused by cod

This report presents the main results from the surveys in January-March 2015. The surveys were performed with the Norwegian research vessels “Johan Hjørt” and “Helmer Hanssen” and the Russian research vessel “Fridtjof Nansen”. Annual survey reports since 1981 are listed in Appendix 1, and names of scientific participants are given in Appendix 3.

1 Introduction

The Institute of Marine Research (IMR), Bergen, has performed acoustic measurements of demersal fish in the Barents Sea since 1976. Since 1981 a bottom trawl survey has been combined with the acoustic survey. Typical effort of the combined survey has been 10-14 vessel-weeks, and about 350 bottom trawl hauls have been made each year. Most years three vessels have participated from about 1 February to 15 March.

The purpose of the investigations is:

- Obtain acoustic abundance indices by length and age for cod, haddock and redfish
- Obtain swept area abundance indices by length (and age) for cod, haddock, redfish and Greenland halibut
- Map the geographical distribution of those fish stocks
- Estimate length, weight and maturity at age for those stocks
- Collect and analyse stomach samples from cod, for estimating predation by cod
- Map the distribution of maturing/prespawning capelin

Data and results from the survey are used both in the ICES stock assessments and by several research projects at IMR and PINRO.

From 1981 to 1992 the survey area was fixed (strata 1-12, main areas ABCD in Fig. 2.1, red lines in the distribution maps, e.g. Fig 5.1). Due to warmer climate and increasing stock size in the early 1990s, the cod distribution area increased. Consequently, in 1993 the survey area was extended to the north and east (strata 1-23, main areas D'ES in Fig. 2.1, black lines in the distribution maps, e.g. Fig 5.1) in order to obtain a more complete coverage of the younger age groups of cod, and since then the survey has aimed at covering the whole cod distribution area in open water. For the same reason the survey area was extended further northwards in the western part in 2014 and 2015 (strata 24-26 in Fig. 2.1, blue lines in the distribution maps, e.g. Fig 5.1). In most years in the period 1997-2007 Norwegian research vessels had limited access to the Russian EEZ, and in 1997, 1998 and 2007 the vessels were not allowed to work in the Russian EEZ. In 1999 the coverage was partly limited by a rather unusually wide ice-extension. Since 2001, except in 2006 and 2007, Russian research vessels have participated in the survey and the coverage has been better, but for various reasons not complete in most years. In 2008-2015 Norwegian vessels had access to major parts of the Russian EEZ. The coverage was more complete in these years, especially in 2008, 2011 and 2014. In 2009, 2010, 2012, 2013 and 2015 the coverage in eastern areas was more limited due to strict rules regarding handling of the catch, bad weather or vessel problems. Table 3.6 summarizes degree of coverage and main reasons for incomplete coverage in the Barents Sea winter 1981-2015.

2 Methods

2.1 Acoustic measurements

The method is explained by Dalen and Smedstad (1979, 1983), Dalen and Nakken (1983), MacLennan and Simmonds (1991) and Jakobsen et al. (1997). The acoustic equipment has been continuously improved. Since the early 1990s Simrad EK500 echo sounder and Bergen Echo Integrator (BEI, Knudsen 1990) have been used. The Simrad ER60 echo sounder and the Large Scale Survey System (LSSS, Korneliussen *et al.* 2006) has replaced the EK500 and BEI; on R/V “Johan Hjort” since the 2005 survey and on R/V “Helmer Hanssen” since the 2008 survey. On the Russian vessels EK 500 was used from 2000 to 2004 and ER60 since 2005.

In the mid 1990s the echo sounder transducers were moved from the hull to a retractable centreboard, on R/V “Johan Hjort” since the 1994 survey and on R/V “Helmer Hanssen” since the 2008 survey. This latter change has largely reduced the signal loss due to air bubbles in the close to surface layer. None of the Russian vessels have retractable centreboards.

On the Norwegian vessels acoustic backscattering values (s_A) are stored at high resolution in LSSS. After scrutinizing and allocating the values to species or species groups, the values are stored with 10 m vertical resolution and 1 nautical mile (NM) horizontal resolution. The procedure for allocation by species is based on:

- composition in trawl catches (pelagic and demersal hauls)
- the appearance of the echo recordings
- inspection of target strength distributions
- inspection of target frequency responses

For each trawl catch the relative s_A -contribution from each species is calculated (Korsbrekke 1996) and used as a guideline for the allocation. In these calculations the fish length dependent catching efficiency of cod and haddock in the bottom trawl (Aglen and Nakken 1997) is taken into account. If the trawl catch gives the true composition of the species contributing to the observed s_A value, those catch-based s_A - proportions could be used directly for the allocation. In the scrutinizing process the scientists have to evaluate to what extent these catch-based s_A - proportions are reasonable, or if they should be modified on the basis of knowledge about the fish behaviour and the catching performance of the gear.

Estimation procedures

The area is divided into rectangles of 1/2° latitude and 1° longitude. For each rectangle and each species an arithmetic mean s_A is calculated for the demersal zone (less than 10 m above bottom) and the pelagic zone (more than 10 m above bottom). Each of those acoustic densities by rectangle are then converted to fish densities by the equation:

$$\bar{\rho}_A = \frac{\bar{s}_A}{\bar{\sigma}_A}$$

$\bar{\rho}_A$ is average fish density (number of fish / square NM) by rectangle

\bar{s}_A is average acoustic density (square m / square NM) by rectangle

$\bar{\sigma}_A$ is average backscattering cross-section (square NM) by rectangle

For cod, haddock and redfish the backscattering cross-section (σ), target strength (TS) and fish length (L cm) is related by the equation (Foote, 1987):

$$TS = 10 \cdot \log\left(\frac{\sigma}{4\pi}\right) = 20 \cdot \log(L) - 68$$

Indices for the period 1981-1992 have been recalculated (Aglen and Nakken 1997) taking account of:

- changed target strength function
- changed bottom trawl gear (Godø and Sunnanå 1992)
- size dependant catching efficiency for cod and haddock (Dickson 1993a,b)

In 1999 the indices for cod and haddock were revised and some errors in the time series were discovered and corrected (Bogstad *et al.* 1999).

Combining equations 1 and 2 gives

$$\bar{\rho}_A = 5.021 \cdot 10^5 \cdot \bar{s}_A / \bar{L}^2 \quad (3)$$

\bar{L}^2 is average squared fish length by rectangle and by depth channels (i.e., pelagic and bottom).

As a basis for estimating \bar{L}^2 trawl catches considered to be representative for each rectangle and depth zone are selected. This is a partly subjective process, and in some cases catches from neighbouring rectangles are used. Only bottom trawl catches are used for the demersal zone, while both pelagic and bottom trawl catches are applied to the pelagic zone. Length frequency distributions by 1 cm length groups form the basis for calculating mean squared length. The bottom trawl catches are normalised to 1 NM towing distance and adjusted for length dependant fishing efficiency (Aglen and Nakken 1997, see below). Length distributions from pelagic catches are applied unmodified. Since 2001 the post processing program BEAM has been used for working out the acoustic estimates. This program provides an automatic allocation of trawl samples to strata (rectangles). The automatic allocation is modified by the user when considered necessary.

Let f_i be the (adjusted) catch by length group i and let L_i be the midpoint (cm) of the length interval i . Then:

$$\bar{L}^2 = \frac{\sum_{i=i_{\min}}^{i_{\max}} f_i \cdot L_i^2}{\sum_{i=i_{\min}}^{i_{\max}} f_i} \quad (4)$$

For each species the total density ($\bar{\rho}_A$) by rectangle and depth zone is now calculated by equation (3). This total density is then split on length groups according to the estimated length distribution. Next, these densities are converted to abundance by multiplying with the area of the rectangle. The abundance by rectangle is then summed for defined main areas (Figure 2.1). Estimates by length are converted to estimates by age using an age length key for each main area. The total biomass is estimated by multiplying the numbers at age by weight at age from the swept area estimates (see section 2.3).

2.2 Swept area measurements

All vessels were equipped with the standard research bottom trawl Campelen 1800 shrimp trawl with 80 mm (stretched) mesh size in the front. Prior to 1994 a cod-end with 35-40 mm (stretched) mesh size and a cover net with 70 mm mesh size were used. Since this mesh size may lead to considerable escapement of 1 year old cod, the cod-ends were in 1994 replaced by cod-ends with 22 mm mesh size. At present a cover net with 116 mm meshes is mostly used.

The trawl is now equipped with a rockhopper ground gear (Engås and Godø 1989). Until and including 1988 a bobbins gear was used, and the cod and haddock indices from the time period 1981-1988 have since been recalculated to ‘rockhopper indices’ and adjusted for length dependent fishing efficiency and/or sweep width (Godø and Sunnanå 1992, Aglen and Nakken 1997). The sweep wire length is 40 m, plus 12 m wire for connection to the doors.

In the Norwegian shrimp survey (Aschan and Sunnanå 1997) the Campelen trawl has been rigged with some extra floats (45 along the ground rope and 18 along the under belly and trunk, all with 20 mm diameter) to reduce problems on very soft bottom. This rigging has been referred to as “Tromsø rigging”. When the shrimp survey was terminated in 2004 and later merged with the Ecosystem survey in 2005, shrimp data were also requested from the winter survey. “Tromsø rigging” was used in parts of the shrimp areas in 2004 (11 stations) and 2005 (9 stations), while in 2006-2014 “Tromsø rigging” was used for nearly all bottom trawl stations taken by Norwegian vessels in the winter survey. In 2015 “Tromsø rigging” was not applied due to less problems on soft bottom with the lighter Thyborøn trawl doors (see below) and indications of reduced bottom contact with this rigging.

Vaco doors (6 m², 1500kg), were previously standard trawl doors on board the Norwegian research vessels. On the Russian vessels and hired vessels V-type doors (ca 7 m²) have been

used. In 2004, R/V “Johan Hjort” changed to a V-type door (Steinshamn W-9, 7.1m², 2050 kg), the same type as used on the Russian research vessels. In 2010 the V-doors were replaced by 125” Thyborøn trawl doors (7.4m², 1720 kg). R/V “Helmer Hanssen” has used Thyborøn trawl doors since the 2008 survey. In order to achieve constant sampling width of a trawl haul independent of e.g. depth and wire length, a 10-14 m rope “locks” the distance between the trawl wires 80-150 m in front of the trawl doors on the Norwegian vessels. This is called “strapping”. The distance between the trawl doors is then in most hauls restricted to the range 48-52 m regardless of depth (Engås and Ona 1993, Engås 1995). Strapping was first attempted in the 1993 survey on board one vessel, in 1994 it was used on every third haul and in 1995-1997 on every second haul on all vessels. Since 1998 it has been used on all hauls when weather conditions permitted. Strapping is not applied on the Russians vessels, but the normal distance between the doors is about 50 m (D. Prozorkevich, pers. comm.).

Standard tow duration is now 15 minutes (until 1985 the tow duration was 60 min. and from 1986 to 2010 30 min.). Trawl performance is constantly monitored by Scanmar trawl sensors, i.e., distance between the doors, vertical opening of the trawl and bottom contact control. In 2005-2008 sensors monitoring the roll and pitch angle of the doors were used due to problems with the Steinshamn W-9 doors. The data is logged on files, but have so far not been used for further evaluation of the quality of the trawl hauls.

The positions of the trawl stations are pre-defined. When the swept area investigations started in 1981 the survey area was divided into four main areas (A, B, C and D, Fig 2.1) and 35 strata.

Figure 2.1. Strata (1-23) and main areas (A,B,C,D,D',E and S) used for swept area estimations. The main areas are also used for acoustic estimation. Additional strata (24-26, main area N) covered in 2014 and 2015, but not included in the estimations.

During the first years the number of trawl stations in each stratum was set based on expected fish distribution in order to reduce the variance, i.e., more hauls in strata where high and variable fish densities were expected to occur. During the 1990s trawl stations have been spread out more evenly, yet the distance between stations in the most important cod strata is shorter (16 or 20 NM) compared to the less important strata (24, 30 or 32 NM). During the 1990s considerable amounts of young cod were distributed outside the initial four main areas, and in 1993 the investigated area was therefore enlarged by areas D', E, and the ice-free part of Svalbard (S) (Fig. 2.1 and Table 3.5), 28 strata altogether. In the 1993-1995 survey reports, the Svalbard area was included in A' and the western (west of 30°E) part of area E. Since 1996 a revised strata system with 23 strata has been used (Figure 2.1). The main reason for reducing the number of strata was the need for a sufficient number of trawl stations in each stratum to get reliable estimates of density and variance. In later years a few pre-defined trawl stations have been performed north of the strata system due to increased abundance of cod in these areas, and in 2014 and 2015 the investigated area was extended by three new strata in northwest, 24-26 (main area N, Fig. 2.1, blue lines in the distribution maps, e.g. Fig 5.1). However, the results from these additional strata are so far not included in the estimation of standard abundance indices.

Swept area fish density estimation

Swept area fish density estimates ($\rho_{s,l}$) by species (s) and length (l) were estimated for each bottom trawl haul by the equation:

$$\rho_{s,l} = \frac{f_{s,l}}{a_{s,l}}$$

$\rho_{s,l}$ number of fish of length l per n.m.² observed on trawl station s

$f_{s,l}$ estimated frequency of length l

$a_{s,l}$ swept area:

$$a_{s,l} = \frac{d_s \cdot EW_l}{1852}$$

d_s towed distance (nm)

EW_l length dependent effective fishing width:

$$EW_l = \alpha \cdot l^\beta \text{ for } l_{\min} < l < l_{\max}$$

$$EW_l = EW_{l_{\min}} = \alpha \cdot l_{\min}^\beta \text{ for } l \leq l_{\min}$$

$$EW_l = EW_{l_{\max}} = \alpha \cdot l_{\max}^\beta \text{ for } l \geq l_{\max}$$

The parameters are given in the text table below:

Species	α	β	l_{\min}	l_{\max}
Cod	5.91	0.43	15 cm	62 cm
Haddock	2.08	0.75	15 cm	48 cm

The fishing width was previously fixed to 25 m = 0.0135 nm. Based on Dickson (1993a,b), length dependent effective fishing width for cod and haddock was included in the calculations in 1995 (Korsbrekke *et al.*, 1995). Aglen and Nakken (1997) have adjusted both the acoustic and swept area time series back to 1981 for this length dependency based on mean-length-at-age information. In 1999, the swept area 1983-1995 time series was recalculated for cod and haddock using the new area and strata divisions (Bogstad *et al.* 1999).

For redfish, Greenland halibut and other species, a fishing width of 25 m was applied, independent of fish length.

For each station, s , observations of fish density by length ($\rho_{s,l}$) is summed in 5 cm length-groups. Stratified indices by length-group and stratum will then be:

$$L_{p,l} = \frac{A_p}{S_p} \cdot \sum_{s \text{ in stratum } p} \rho_{s,l}$$

$L_{p,l}$ index, stratum p , length-group l

A_p area (n.m.²) of stratum p (or the part of the stratum covered by the survey)

S_p number of trawl stations in stratum p

The coverage of the most northern and most eastern strata differs from year to year. The areas of these strata are therefore calculated according to the coverage each year (Table 3.5). Indices are estimated for each stratum within the main areas A, B, C, D, D', E and S. Total number of fish in each 5 cm length group in each main area is estimated by adding the indices of all strata within the area. Total number of fish at age is estimated by using an age-length key constructed for each main area. Total indices on length and age are estimated adding the values for all main areas.

2.3 Sampling of catch and age-length keys.

Sorting, weighing, measuring and sampling of the catch are done according to instructions given in Mjanger *et al.* (2014). Since 1999 all data except age are recorded electronically by Scantrol Fishmeter measuring board, connected to stabilized scales. The whole catch or a representative sub sample of most species was length measured on each station.

At each trawl station age (otoliths) and stomach were sampled from one cod per 5 cm length-group. In 2007-2009, all cod above 80 cm were sampled, and in 2010 all above 90 cm, limited to 10 per station. The stomach samples were frozen and analysed after the survey. Haddock otoliths were sampled from one specimen per 5 cm length-group. Regarding the redfish species, *Sebastes norvegicus* and *S. mentella*, otoliths for age determination were sampled from two fish in every 5 cm length-group on every station. Greenland halibut were sorted by sex before length measurement. From this species no otoliths were collected. Table 3.4 gives an account of the sampled material.

An age-length key is constructed for each main area. All age samples are included and weighted according to:

$$w_{p,l} = \frac{L_{p,l}}{n_{p,l}}$$

$w_{p,l}$ - weighting factor

$L_{p,l}$ - swept area index of number fish in length-group l in stratum p

$n_{p,l}$ - number of age samples in length-group l and stratum p

Fractions are estimated according to:

$$P_a^{(l)} = \frac{\sum_p n_{p,a,l} \cdot w_{p,l}}{\sum_p n_{p,l} \cdot w_{p,l}}$$

$P_a^{(l)}$ - weighted fraction of age a in length-group l and stratum p

$n_{p,a,l}$ - number of age samples of age a in length-group l and stratum p

Number of fish by age is then estimated following the equation:

$$N_a = \sum_p \sum_l L_{p,l} \cdot P_a^{(l)}$$

Mean length and –weight by age is then estimated according to (only shown for weight):

$$W_a = \frac{\sum_p \sum_l \sum_j W_{a,p,l,j} \cdot w_{p,l}}{\sum_p \sum_l \sum_j w_{p,l}}$$

$W_{a,p,l,j}$ - weight of sample j in length-group l , stratum p and age a

3 Survey operation and material

Table 3.1 presents the vessels participating in the survey in 2015 and IMR trawl station series numbers. Catch data and biological samples from the Russian vessels were converted to the IMR SPD-format. The acoustic data from the Russian vessels was reported to IMR as allocated values by species at 5 nm intervals, split on a bottom layer (<10m from bottom) and a pelagic layer (>10m above bottom).

Table 3.1. Norwegian and Russian vessel participation by time period and Norwegian trawl station series numbers by vessel for the winter survey in 2015.

	Period	Series no.
Johan Hjort	28.01-12.03	70001-70221
Helmer Hanssen	21.01-15.02	70301-70431
Fridtjof Nansen	03.02-02.03	70501-70538

Table 3.2 presents the number of swept area trawl stations, other bottom trawl stations and pelagic trawl stations taken in the different main areas. For the calculation of swept area indices, only the successful pre-defined bottom trawl stations within the strata system were used. The number of stations in the new strata 24-26 is also given. Table 3.3 gives an account of the sampled length- and age material from bottom hauls and pelagic hauls. Figure 3.1 shows survey tracks and trawl stations in 2015. Due to bad weather and limited vessel time the coverage was somewhat skewed in several strata, as illustrated in the distribution maps (e.g Fig 5.1).

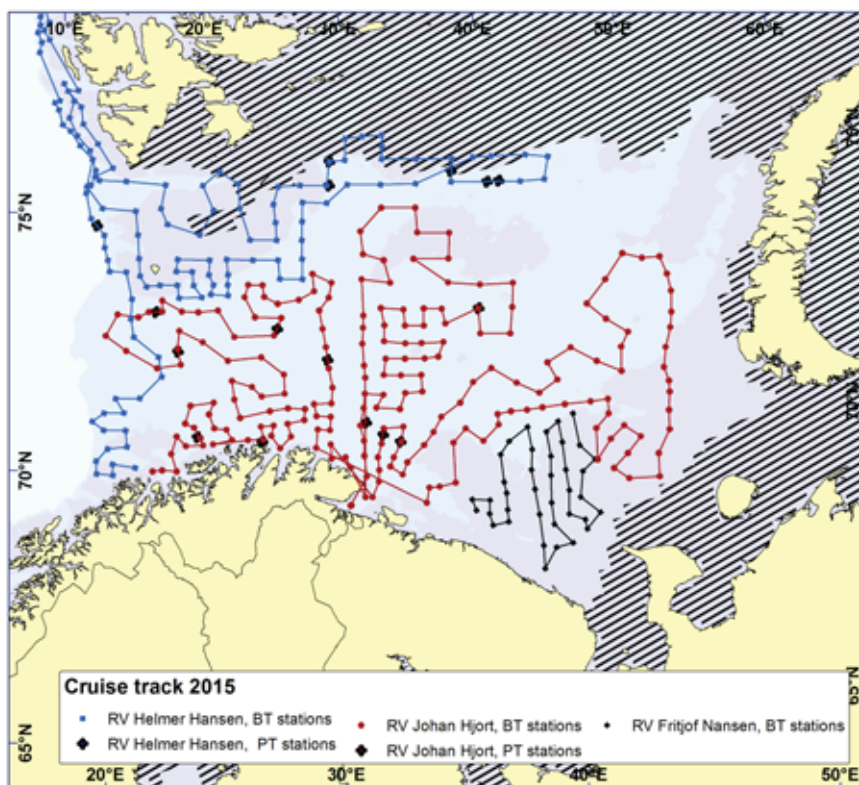

Figure 3.1. Survey tracks and all trawl stations in the winter survey 2015. Data source for the monthly ice cover: <ftp://sidads.colorado.edu/DATASETS/NOAA/G02135/shapefiles/>

¹REZ not covered, ²REZ (Murman coast and Area D' in 2006 and Area D' in 2012) not completely covered

³Additional northern areas (N) covered, not included in standard survey index calculations

Table 3.5. Degree of coverage and main reasons for incomplete coverage in the Barents Sea winter 1981-2015.

Year	Coverage	Comments
1981-1992	ABCD	
1993-1996	ABCDD'ES	
1997	Norwegian EEZ (NEZ), S	Not allowed access to Russian EEZ (REZ)
1998	NEZ, S, minor part of REZ	Not allowed access to most of REZ
1999	ABCDD'ES	Partly limited coverage due to westerly ice extension
2000	ABCDD'ES	
2001-2005	ABCDD'ES	Russian vessel covered where Norwegians had no access
2006	ABCDD'ES	Not access to Murman coast, no Russian vessel
2007	NEZ, S	Not allowed access to REZ, no Russian vessel
2008	ABCDD'ES	Russian vessel covered where Norwegians had no access
2009	ABCDD'ES	Reduced Norwegian coverage of REZ due to catch handling
2010	ABCDD'ES	Reduced Norwegian coverage of REZ due to bad weather
2011	ABCDD'ES	Russian vessel covered where Norwegians had no access
2012	ABCDD'ES	No Norwegian coverage of REZ due to vessel problems
2013	ABCDD'ES	No Norwegian coverage of REZ due to vessel shortage
2014	ABCDD'ESN	Strata 24-26 (N) covered for the first time
2015	ABCDD'ESN	Slightly reduced/more open coverage due to bad weather

4 Total echo abundance of cod and haddock

Table 4.1 presents the time series of total echo abundance (echo density multiplied by area) of cod and haddock in the investigated areas. Since 1993 the acoustic values have been split between the two species during the scrutinizing. The values for cod have showed an increasing trend since the mid 2000s, with a peak in 2013. The values for haddock increased gradually from the end of the 1990s to 2009, and have decreased somewhat in the later years. The fraction of the total echo abundance recorded in the bottom layer has been somewhat lower in later years for cod compared to the mid 2000s. For haddock this fraction is lower than for cod and more stable over the time series.

Table 4.1. Cod and haddock. Total echo abundance and echo abundance in the 10 m layer above the bottom in the Barents Sea winter 1981-2015 (m^2 reflecting surface $\cdot 10^{-3}$). 1981 - 1992 includes only mainly areas A, B, C and D.

Figure 4.2. HADDOCK. Distribution of total echo abundance winter 2015. Unit is s_A per square nautical mile ($m^2/n.mile^2$). Swept area strata and main areas (thick line) in red.

5 Distribution and abundance of cod

5.1 Acoustic estimation

Surveys in the Barents Sea at this time of the year mainly cover the immature part of the cod stock. Most of the mature cod (age 7 and older) have started on their spawning migration southwards out of the investigated area, and are therefore to a lesser extent covered. There are indications that a higher proportion than normal spawned along Finnmark in some of the previous years, e.g. 2004-2006. Thereby a higher proportion of the spawners might have been covered by the survey these years.

Table 5.1 shows the acoustic indices for each age group by main areas in 2015. The time series (1981-2015) is presented in Table 5.2. The estimates have been variable and increasing in later years, with a peak in 2013, and this may partly be explained by variable and not complete coverage of the distribution area towards north and east in several years. As cod grow older it get a more south-westerly distribution during winter, it so to say “grows” into the incomplete survey. This is especially evident for the strong 2004 and 2005 year-classes, which as 6-10 year olds stand out as the strongest in the time series. Of more recent year-classes the 2011 and 2014 year-classes seems to be strong.

¹Indices raised to also represent the Russian EEZ. ²Indices raised to also represent uncovered parts of the Russian EEZ’.

5.2 Swept area estimation

Figures 5.1 - 5.4 shows the geographic distribution of bottom trawl catch rates (number of fish per NM^2 , for cod size groups ≤ 19 cm, 20-34 cm, 35-49 cm and ≥ 50 cm. As in previous years, a high proportion of the smallest cod (less than 35 cm) were found in the eastern part of the survey area within the Russian EEZ and near the northern borders of the standard strata system (strata 1-23). In 2014 a higher proportion of cod ≤ 19 cm were found in the extended survey area (strata 24-26) than in the rest of the survey area, while in 2015 only 30 % of the number of cod ≤ 19 cm found in the standard survey area were found in the extended area (Table 6.3). Mehl *et al.* (2013, 2014) found that since 2009 more of the largest cod had been found in the north-western part of the survey area (main area S), and this trend is confirmed by the 2015 estimates.

Table 5.3 presents the distribution of the indices by main areas and age and the whole time series (1981-2015) is shown in Table 5.4. Also the bottom trawl indices have fluctuated somewhat due to the same reasons as for the acoustic indices, and the 2004 and 2005 year-classes at the moment stand out as the strongest in the time series. The 2009, 2011 and 2014 year-classes seemed to be strong as 1-year olds, but the 2009 year-class was reduced to below average level and the 2011 year-class to about average level at age 3. A considerable amount of cod was found in the extended survey area (Table 5.3), especially 2- and 4-year olds, and on average over all age groups about 32 % of the amount found in the standard survey area by numbers and about 17 % by biomass.

5.3 Growth and survey mortalities

Tables 5.5 and 5.6 present the time series for mean length (1981-2015) and mean weight (1983-2015) at age for the entire standard area. Weights and lengths at age were fairly low in the period 1995-2000, but increased somewhat in 2001. In later years there has been moderate fluctuations, but with a slight decreasing trend for older fish (7+). The same pattern is reflected in the annual weight increments (Table 5.7).

Table 5.8 gives the time series of survey based mortalities (log ratios between survey indices of the same year class in two successive years) since 1993. These mortalities are influenced by natural and fishing mortality, age reading errors, and the catchability and availability (coverage) at age for the survey. In the period 1993-1999 there was an increasing trend in the survey mortalities. The trend appears most consistent for the age groups 3-7 in the swept area estimates. Later surveys show lower mortalities, but there are some fluctuations for the same reasons as mentioned for the acoustic and swept area indices. Presumably the mortality of the youngest age groups (ages 1-3) is mainly caused by predation, while for the older age groups it is mainly caused by the fishery. Before 2001 the survey mortalities for age 4 and older were well above the mortalities estimated in the ICES assessment. Decreasing survey catchability at increasing age could be one reason for this. Another possible reason could be that the assessment does not include all sources of mortality, like discards, unreported catches, or poorly quantified predation. The low survey mortalities in the most recent years, even with “impossible” negative values, could partly be caused by fish gradually “growing into” the covered area at increasing age. The observed mortality rates in the acoustic investigations have been more variable. This might be caused by changes in fish behaviour and how available the fish is for acoustic registration.

6 Distribution and abundance of haddock

6.1 Acoustic estimation

Like for cod it is expected that the survey best covers the immature part of the stock. At this time of the year a large proportion of the mature haddock (age 6 and older) are on its spawning migration south-westwards out of the investigated area. In some earlier years, e.g. 2004 and 2005, concentrations of mature haddock have been observed pelagic rather far above bottom along the shelf edge. These concentrations are poorly covered by the bottom trawl sampling.

There are indications that the distribution of age groups 1 and 2 in some years are concentrated in coastal areas not well covered by the survey. This occurred in the late 1990s and will have strongest effect on poor year-classes. In the later surveys small haddock has been widely distributed, and the strong year-classes have been found unusually far to the north. This might be caused by favourably hydrographic conditions and/or density-dependent mechanisms. However, it is difficult to separate the two factors. Favourable hydrographic conditions may lead to better distribution of larvae and thus better survival. On the other hand, high densities of juveniles may cause delayed settlement and more active movement in search of prey.

Table 6.1 shows the acoustic abundance indices by age within the main areas. As in most of the previous years the highest abundance was observed in main area D. The time series (1981-2015) are presented in Table 6.2. The strong 2004-2006 year-classes can be followed through the time series and still have a strong contribution to the total abundance. In later years, the 2009, 2011, 2013 and 2014 year-classes seem to be fairly strong. However, the 2009 year-class show an unexpectedly low index for 2015.

Table 6.1. HADDOCK. Acoustic abundance indices for the main areas of the Barents Sea winter 2015 (numbers in millions).

Area	Age group										Total	Biomass ('000 t)

6.2 Swept area estimation

Figures 6.1 - 6.4 show the geographic distribution of bottom trawl catch rates (number of fish per NM^2) for haddock size groups ≤ 19 cm, 20-34 cm, 35-49 cm and ≥ 50 cm. Like in previous years (Mehl *et al.* 2013, 2014), the distribution extends further to the north and to the east than what was usual in the 1990s. To a certain degree, one can follow the high densities through the size groups, especially the northern and eastern distributions. This indicates that the distribution is more cohort-dependent than age-dependent, and it may be more appropriate to use cohort as scaling covariate rather than age, when indices are adjusted for poor coverage. Due to bad weather, some stations in the southeast were dropped this year. This is an area where one would expect to find mature haddock and it is reasonable to expect that this have influenced our estimates of mature haddock.

Table 6.3 presents the indices for each age group by main areas. The time series (1981-2015) are shown in Table 6.4. As with the acoustic indices, the strong 2004-2006 year-classes dominates bottom trawl indices. Overall, this survey tracks both strong and poor year-classes fairly well. In later years, the 2009, 2011, 2013 and 2014 year-classes are stronger than the 2007, 2008, 2010 and 2012 year-classes. The 2009 year-class index was unexpectedly low this year. Compared to cod a much lower proportion of haddock was found in the extended survey area (Table 6.3), on average over all age groups about 7 % of the amount found in the standard survey area by numbers and about 9 % by biomass.

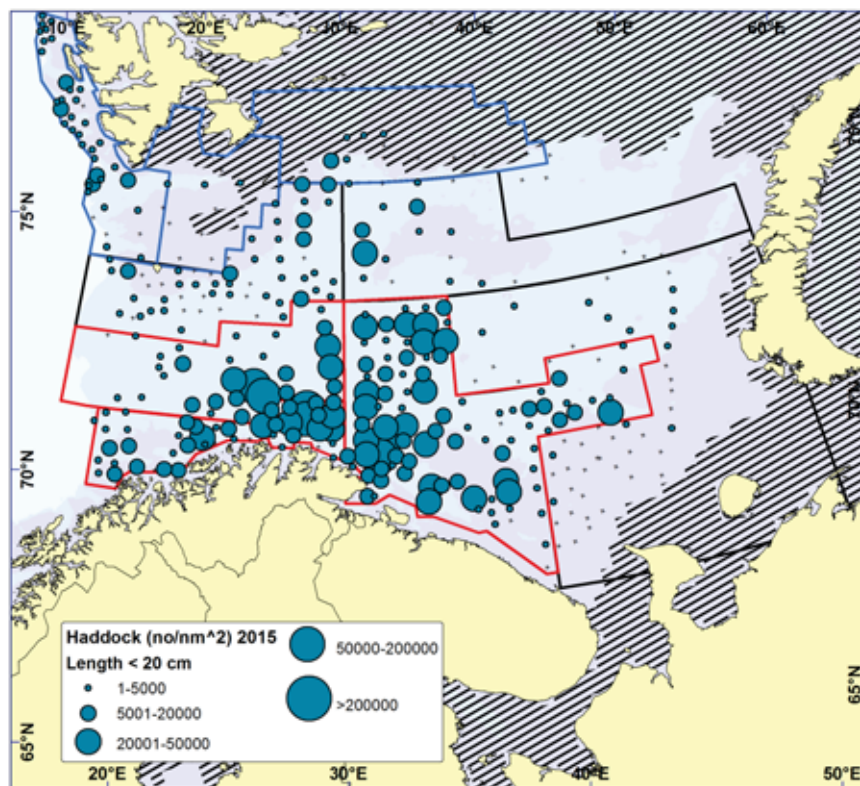

Figure 6.1. HADDOCK ≤ 19 cm. Distribution in valid bottom trawl catches winter 2015 (number per nm^2). Zero catches are indicated by black points.

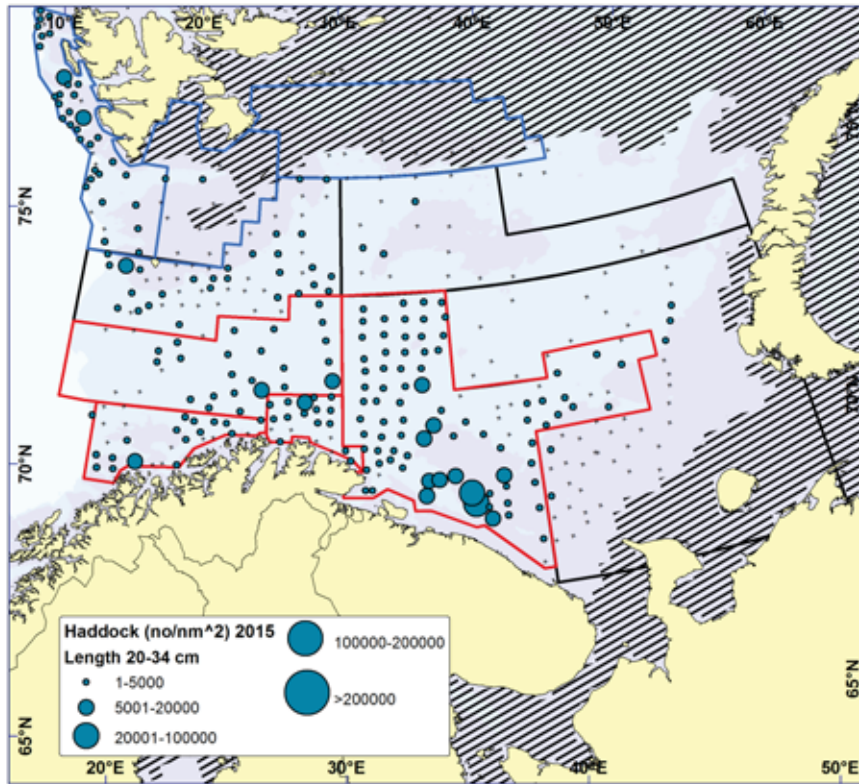

Figure 6.2. HADDOCK 20-34 cm. Distribution in valid bottom trawl catches winter 2015 (number per nm^2). Zero catches are indicated by black points.

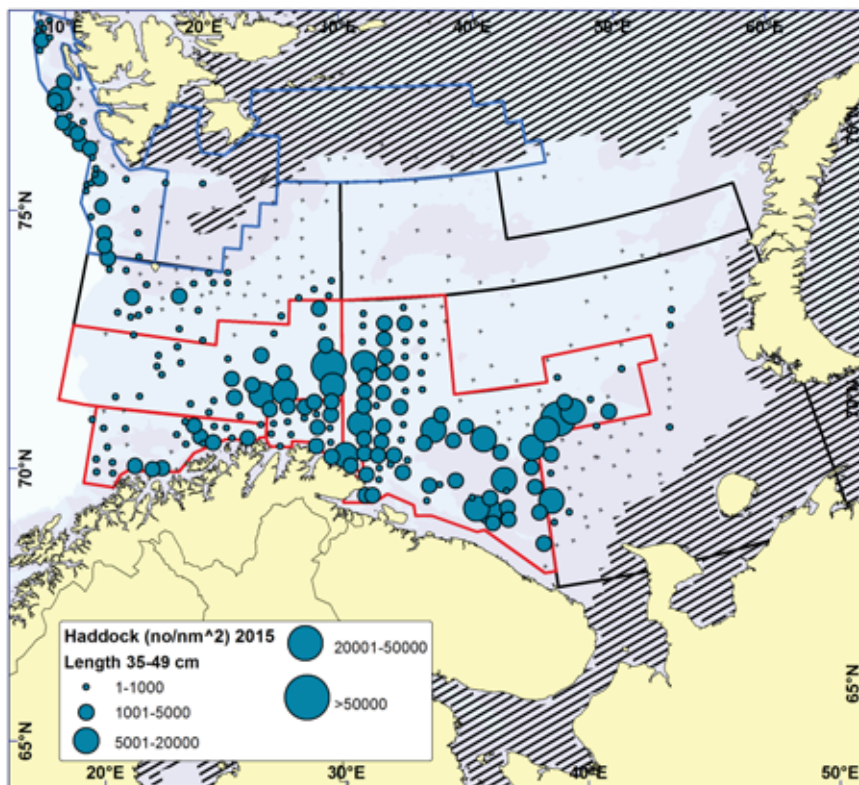

Figure 6.3. HADDOCK 35-49 cm. Distribution in valid bottom trawl catches winter 2015 (number per nm^2). Zero catches are indicated by black points.

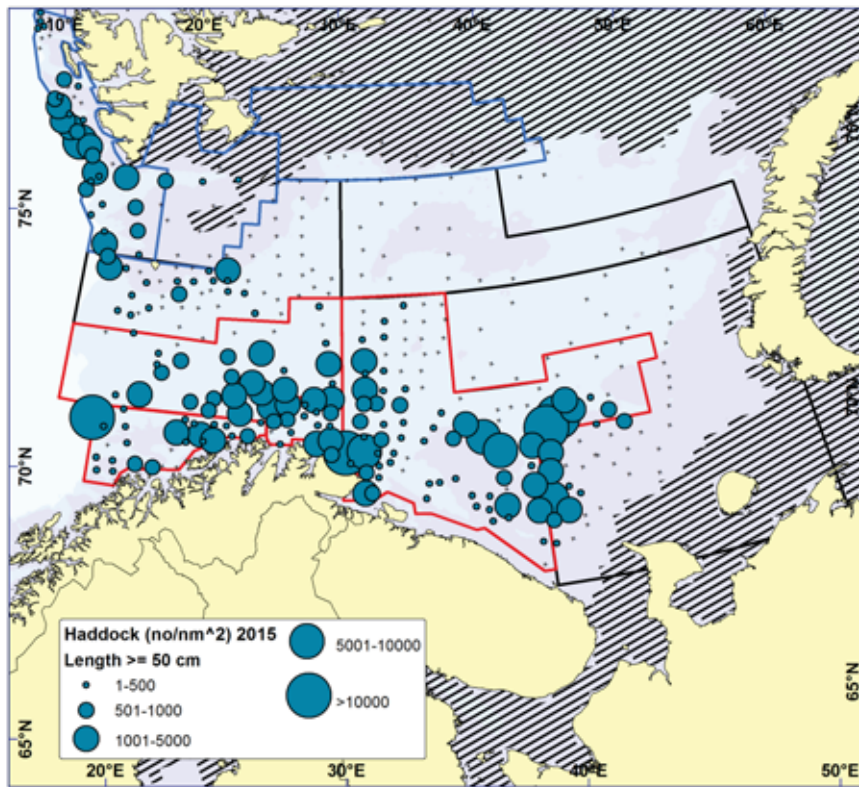

Figure 6.4. HADDOCK ≥ 50 cm. Distribution in valid bottom trawl catches winter 2015 (number per nm^2). Zero catches are indicated by black points.

6.3 Growth and survey mortalities

Tables 6.5 and 6.6 present the time series for mean length (1983-2015) and mean weight (1983-2015) at age for the entire standard area. Length estimates have been variable with no specific trends in the latest years. However, the variation is less than what it has been in earlier periods. Weight estimates also show less variation in later years, however there is a slight trend of decreasing weights of 4 years and older haddock for the last decade. Annual weight increments are shown in Table 6.7, and these are highly variable and show no trends.

Table 6.5. HADDOCK. Length (cm) at age in the Barents Sea from the investigations winter 1983 – 2015. Observations outside main areas A-S not included.

2014-15	55	133	296	406	402	222	400	262	143

Survey mortalities based on the acoustic indices (Table 6.8) have varied between years, and for most age groups there are no obvious trends. However, there are signs of co-variability within years. The 2009 year-class survey mortality (2014-2015) was high in both acoustic and swept area indices, and much higher than surrounding year-classes. The 2010 year-class had low survey mortality.

7 Distribution and abundance of redfish

7.1 Acoustic estimation

Earlier reports from this survey has presented distribution maps and abundance indices based on acoustic observations of redfish. In recent years blue whiting has dominated the acoustic records in some of the main redfish areas. Due to incomplete pelagic trawl sampling the splitting of acoustic records between blue whiting and redfish has been very uncertain. The uncertainty relates mainly to the redfish, since it only make up a minor proportion of the total value. This has been the case since the 2003 survey, and the acoustic results for redfish are therefore not included in the report.

7.2 Swept area estimation

The swept area time series for redfish (Tables 7.1 - 7.3) are based on catch data from trawls with bobbins gear until 1988 inclusive, and rockhopper gear since 1989. The time series has not been adjusted for this change. Figure 7.1 shows the geographical distribution of *Sebastes norvegicus* (Golden redfish) based on the catch rates in bottom trawl. It is mainly distributed south of the Bear Island. In most years the distribution is completely covered except towards northwest. *S. norvegicus* was found in the extended survey area in 2014 and 2015, mainly west of Spitsbergen (strata 24). On average over all size groups about 27 % of the amount found in the standard survey area by numbers was found in the extended area (Table 7.1), which is slightly less than in 2014 (34 %). Table 7.1 presents the time series (1986-2015) of swept area indices by 5 cm length groups. The indices have remained low since 1999 for all length groups. This indicates that about the twenty last year classes are very weak.

Also the coverage of *S. mentella* (Beaked redfish) (Figure 7.2) was not complete west and north of Spitsbergen. However, compared to *S. norvegicus* a smaller proportion was found in the extended survey area in 2015, about 14 % of the amount found in the standard survey area by numbers, which is somewhat higher than in 2014 (7 %). Table 7.2 presents the time series (1986-2015) of swept area indices for *S. mentella* by 5 cm length groups. A few good year classes were born in 1988-1990 before the recruitment collapse in 1991 and the stock decreased to low levels for about fifteen years. However, these few year classes got enough protection to survive to maturity and since 2007-2008 both recruitment and the number of larger *S. mentella* has been at a fairly high level. In 2015 the estimated indices for 20-39 cm *S. mentella* were considerable higher than what was found in the most recent years.

Figure 7.3 shows the geographical distribution of *S. viviparus* (Norway redfish) and Table 7.3 presents the time series (1986-2015) of swept area indices by 5 cm length groups. Almost all *S. viviparus* are found in area ABCD, and mainly in main area B. The indices are often driven by a few large catches, and since the mid 1990s the indices has in most years been below the average level in the time series 1986-2015. There was a large and unexplained increase in the indices for most length groups from 2013 to 2014, and the 2015 estimate is more similar to the one from 2014. The two estimates are the highest in the time series back to 1986.

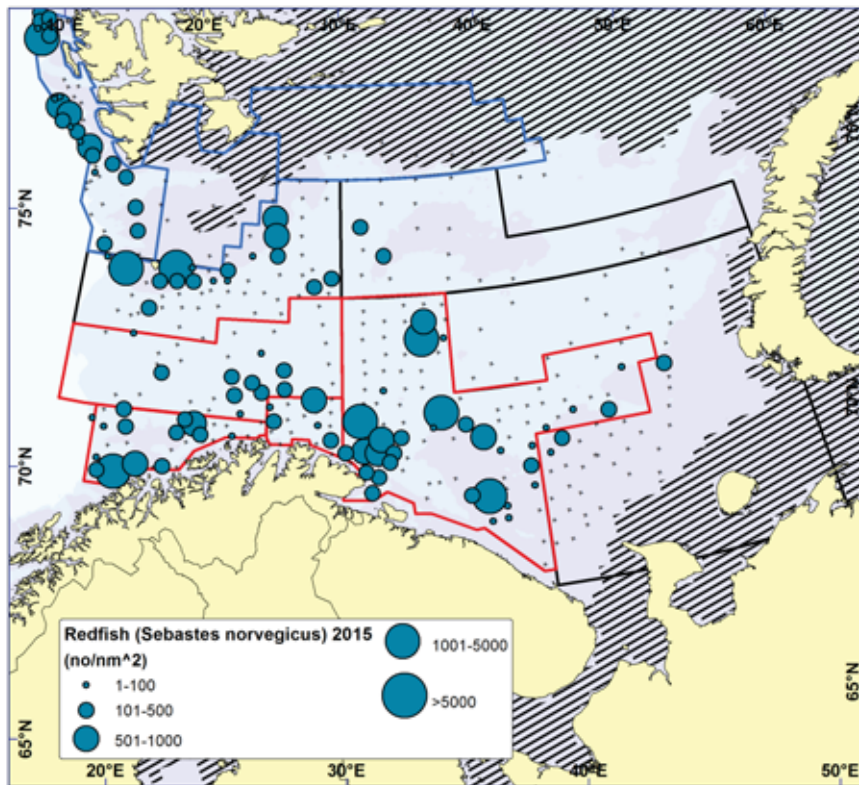

Figure 7.1. *Sebastes norvegicus*. Distribution in the trawl catches winter 2015 (number per nm^2). Zero catches are indicated by black points.

¹not scaled for uncovered areas, mainly found in NEZ

8. Distribution and abundance of Greenland halibut

Figure 8.1 shows the distribution of bottom trawl catch rates of Greenland halibut. The most important distribution areas for the adult fish (depths between 500 and 1000 m along the western slope), are not covered by the survey. Greenland halibut was found in the extended survey area in 2014 (Table 8.1), on average over all size groups about 27 % of the amount found in the standard survey area by numbers, which is almost the same proportion found in 2014 (24 %). The observed distribution pattern in 2015 was similar to those observed in previous years' surveys, i.e., mainly in the Bear Island channel towards the Hopen Deep, with some registrations in deep and cold water further east.

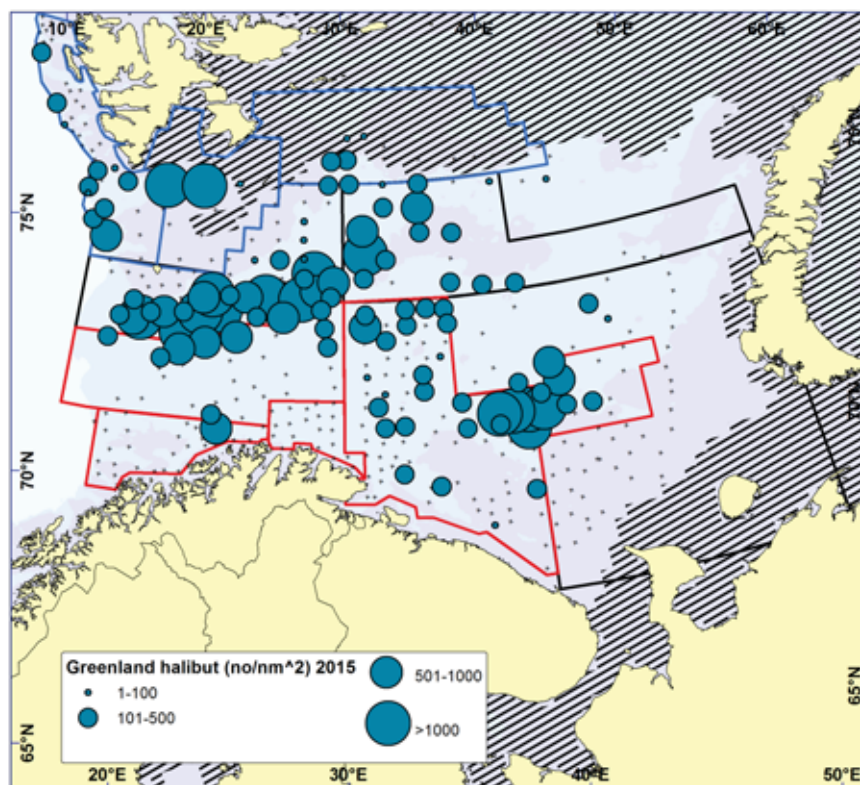

Figure 8.1 GREENLAND HALIBUT. Distribution in the trawl catches winter 2015 (number per nm^2). Zero catches are indicated by black points.

The time series of swept area indices by 5 cm length groups for 1990-2015 is presented in Table 8.1. Abundance indices have been low in the whole period, with few signs of improved recruitment in the covered area. However, recruitment from more northern areas has led to an increase in abundance indices of length groups above 30 cm since about 2005. There was a large increase in the indices for most length groups between 30 and 79 cm from 2014 to 2015, and the total index is the highest in the time series back to 1990.

Table 8.1. GREENLAND HALIBUT. Abundance indices from the bottom trawl surveys in the Barents Sea winter 1990-2015 (numbers in thousands). 1990-1992 includes only main areas A, B, C and D. Observations outside main areas A-S not included.

9 Distribution and abundance of capelin, polar cod and blue whiting

9.1 Capelin

Although capelin is primarily a pelagic species, small amounts of capelin are normally caught in the bottom trawl throughout most of the investigated area. In Figure 9.1 catch rates of capelin smaller and larger than 14 cm are shown for each of the winter survey in 2015. During this period capelin smaller than 14 cm will mainly comprise the immature stock component, while the larger capelin constitutes the prespawning capelin stock. Some few trawl hauls show large capelin catches (numbers exceeding 100 000 individuals) and these can probably not be considered representative for the density in the area, because such hauls will either result from hitting a capelin school at the bottom or up in the water column. For this reason, we chose not to present swept-area based indices for capelin in this report.

At this time of the year, mature capelin have started their approach to the spawning areas along the coast of Troms, Finnmark and the Kola peninsula, while immature capelin will normally be found further north and east, in the wintering areas. This is reflected on the map of capelin distribution, even though some large capelin are always found north of 75°N, and smaller capelin are found sporadically in near-coastal areas. The geographical coverage of the total capelin stock is incomplete, but the maturing component is probably more completely covered.

It has been noted during several surveys that when sampling capelin from demersal and pelagic trawls, the individuals from demersal trawls are normally larger (and older) than those sampled pelagically. This has led to formation of a hypothesis saying that larger individuals tend to stay deeper than smaller individuals and some even to take up a demersal life. This hypothesis has not been tested, and during the winter surveys there are probably too few pelagic hauls to study the vertical distribution of capelin in a systematic way.

9.2 Polar cod

Polar cod are not well represented in the trawl hauls conducted during the winter surveys (Figure 9.2). This reflects the more northern and eastern distribution area of this endemic arctic species. During this time of the year, the polar cod is known to be spawning under the ice-covered areas of the Pechora Sea and close to Novaya Semlya. It is not clear whether the concentrations found in open water these years are mature fish either on their way to spawning or from the spawning areas, or this is immature fish.

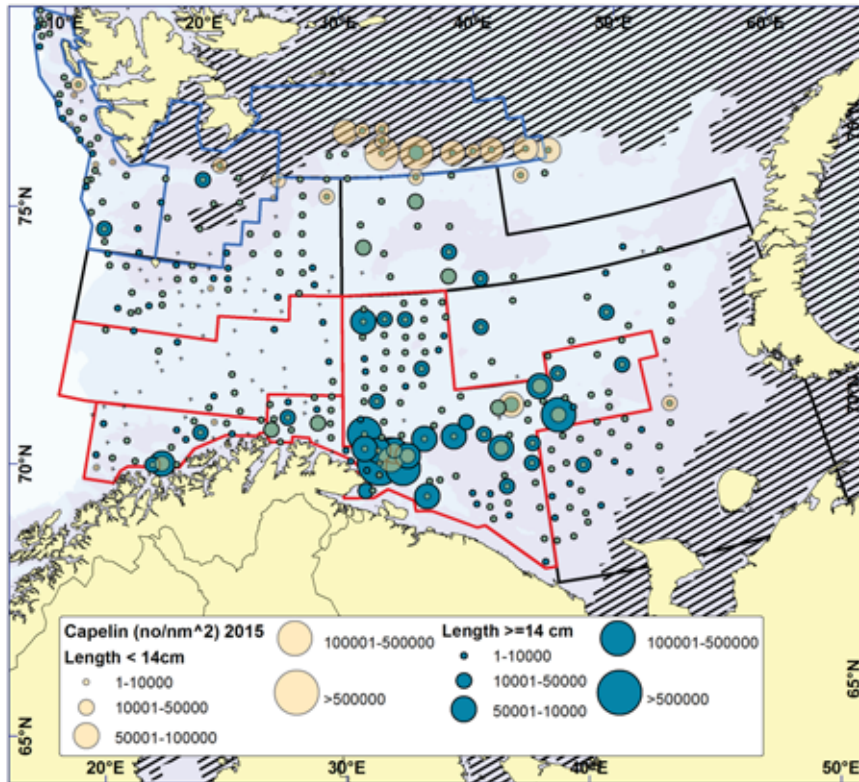

Figure 9.1. CAPELIN. Distribution in the trawl catches winter 2015 (number per nm^2). Zero catches are indicated by black points.

Figure 9.2 POLAR COD. Distribution in the trawl catches winter 2015 (number per nm^2). Zero catches are indicated by black points.

9.3 Blue whiting

Since 2000 the blue whiting has shown a wider distribution than usual. The echo recordings in 2001 and 2002 indicated unusual high abundance in the Barents Sea, while in 2003 it had decreased somewhat. In the 2004 survey the echo abundance increased again and peaked in 2006. Since then it has decreased considerably. Figure 9.3 shows the geographical distribution of the bottom trawl catch rates of blue whiting in 2015. Since the fish was mainly found pelagic the bottom trawl do not reflect the real density distribution, but gives some indication of the distribution limits. Acoustic observations would better reflect the relative density distribution. The number of pelagic hauls has, however, been too low to properly separate the pelagic recordings. During the years with high abundance of blue whiting, recordings of pelagic redfish, haddock and small cod might have been masked by dense concentrations of blue whiting.

Table 9.3 shows the bottom trawl swept area estimates by 5 cm length groups for the years 2001-2015. High abundance of fish below 20 cm in 2001, 2002, 2004, 2005, 2012 and 2015 reflects abundant recruiting (age 1) year classes. These recruits are observed in the survey as larger fish in the following years. As for some of the other target species in the survey, there was a large increase in the indices for most length groups from 2014 to 2015.

10 Registrations of other species

During the 2007-2015 surveys a total of 95 fish taxa were recorded, including 93 species, 4 genera and one family belonging to 35 families (Table 10.1). 50 species were recorded all years. Distribution maps of all species caught at the winter survey 2007-2012 were presented as a separate report (Wienerroither *et al.* 2013) similar to the Atlas of the Barents Sea fishes (Wienerroither *et al.* 2011, based on data from the ecosystem survey). Since the start of the winter survey (1981) the number of fish taxa recorded at the survey has increased due to expansion of the surveyed area, better taxonomic skills and identification keys (Johannesen *et al.* 2009), as well as routines for freezing difficult specimens for later identification on land by taxonomists. Still there are some groups which represent taxonomic challenges, mainly liparids and eelpouts.

Table 10.1. Fish species recorded at the winter survey 2007-2015, all gears included. The number of years each species was recorded is shown and for species not caught every year the capture history (1 = caught and 0 = not caught) is shown in parenthesis for consecutive years 2007-2015. Some clear misidentifications have been left out and some may be uncertain (see comment).

11 SUMMARY

In later years it has again become obvious that not all species and age groups are properly covered in the standard survey area, e.g. young age groups of the strong 2004 and 2005 year-classes of cod. This will have strong implications on both the consistency of the time series and the quality and uncertainty of the whole assessment and management advice. Good coverage of the whole available distribution area is therefore essential. In 2014 and 2015 the investigated area was enlarged by three new strata in northwest, 24-26 (Fig. 2.1). However, the data from additional areas are so far not included in the estimation of abundance indices.

Within the standard area there was a rather large increase from 2014 to 2015 in the indices of most age and length groups, both for cod, Greenland halibut and *Sebastes mentella*. For blue whiting the 2014 year class led to an increase of fish less than 20 cm. For haddock most ages decreased, while for *Sebastes norvegicus* and *Sebastes viviparus* the indices were similar to last year. It is not known to what extent the 2015 results are influenced by the shift from Tromsø-rigged to standard rigged bottom trawl. This should be further studied by analysing years when both riggings were used in nearby areas.

Cod

The estimates have been variable and increasing in later years, and this may partly be explained by variable and not complete coverage of the distribution area towards north and east in several years. In 2014 a 2015 a rather large amount of cod was found in the extended survey area, about 32 % of the amount found in the standard survey area by numbers and about 17 % by biomass in 2015. Since 2009 more of the largest cod have been found in the north-western part of the survey area, and this trend is confirmed by the 2015 estimates. The 2004 and 2005 year-classes at the moment stand out as the strongest in the time series. Both the 2009, 2011 and 2014 year-classes seemed to be strong as 1-year olds, but the 2009 year-class was reduced to below average level at age 3.

Haddock

Overall, the survey tracks both strong and poor year-classes fairly well. In later years, the 2009, 2011, 2013 and 2014 year-classes are stronger than the 2007, 2008, 2010 and 2012 year-classes. The 2009 year-class index was unexpectedly low this year. The strong 2004-2006 year-classes have dominated in both the acoustic and bottom trawl indices. Compared to cod a much lower proportion of haddock was found in the extended survey area, about 7 % of the amount found in the standard survey area by numbers and about 9 % by biomass.

Redfish

Also *S. norvegicus* was found in the extended survey area in 2015, about 27 % of the amount found in the standard survey area by numbers. The indices have remained low since 1999 for all length groups. This indicates that the last twenty year classes are very weak. A smaller proportion of *S. mentella* was found in the extended survey area in 2014, about 14 % of the amount found in the standard survey area by numbers. Since 2007-2008 both recruitment and the number of larger *S. mentella* has been at a fairly high level. There was a large and

unexplained increase in the indices for most size groups of *S. viviparus* from 2013 to 2014, when the total index reached the highest in the time series back to 1986. The 2015 indices for *S. viviparus* are similar to those in 2014.

Appendix 2. Changes in survey design, methods, gear etc.

Year	Change from	To
1984	Representative age sample, 100 per station	Stratified age sample, 5 per 5-cm length group
1986	1 research vessel, 2 commercial trawlers	2 research vessels, 1 commercial trawler
1987	60 min. tow duration	30 min. tow duration
1989	Bobbins gear	Rock-hopper gear (time series adjusted for cod and haddock)
1990	Random stratified bottom trawl stations Simrad EK400 echo sounder	Fixed station grid, 20 nm distance Simrad EK500 echo sounder and BEI post processing
1993	TS = 21.8 log L – 74.9 for cod and haddock Fixed survey area (A,B,C,D), 1 strata system, 35 strata Fixed station grid, 20 nm distance No constraint technique (strapping) on bottom trawl doors 5 age samples per 5-cm group, 2 per stratum	TS = 20 log L – 68 for all demersal species (time series corrected) Extended, variable survey area (A,B,C,D,D',E,S) 2 strata systems, 53 + 10 strata Fixed station grid, 20/30/40 nm distance Constraint technique on some bottom trawl hauls 2 age samples per 5-cm group, 4 per stratum (cod and haddock)
1994	Weighting of age-length keys by total catch 35-40 mm mesh size in cod-end Strapping on some hauls Hull mounted transducers	Weighting of ALK by swept area estimate 22 mm mesh size in cod-end Strapping on every 3. haul Keel mounted transducers Johan Hjort
1995	Variable use of trawl sensors Constant effective fishing width of the trawl	Trawl manual specifying use of sensors Fish size dependent effective fishing width (time series corrected) Strapping on every 2. haul
1996	Strapping on every 3. haul 2 research vessels, 1 commercial trawler 2 strata systems and 63 strata, 20/30/40 nm distance 2 age samples per 5-cm group, 4 per stratum	3 research vessels 1 strata system and 23 strata, 16/24/32 nm distance 1 age sample per 5-cm group, all stations with > 10 specimens (cod and haddock)
1997	16/24/32 nm distance Hull mounted transducers	20 nm distance Keel mounted transducers G.O. Sars (Sarsen)
1998	Strapping on every 2. haul 20 nm distance	Strapping on every haul 20/30 nm distance
2000	3 Norwegian research vessels	2 Norwegian and 1 Russian research vessel
2002	20/30 nm distance station grid	16/20/24/32 nm distance station grid
2003	Height trawl sensor for opening and bottom contact	Trawl eye for opening and bottom contact
2004	Vaco trawl doors EK 500 and BEI Sarsen	V- doors G.O. Sars and Johan Hjort ER60 and LSSS G.O. Sars
2005	EK 500 and BEI EK 500	ER60 and LSSS Johan Hjort ER60 Russian vessels
2006	Standard Campelen rigging	“Tromsø rigging” on Norwegian vessels
2008	V trawl doors	Thyborøn doors Jan Mayen/Helmer Hanssen
2010	V trawl doors	Thyborøn doors G.O. Sars and Johan Hjort
2011	30 min. tow duration	15 min. tow duration
2015	“Tromsø rigging” on Norwegian vessels	Standard Campelen rigging
