

## SOIL CONSERVATION THROUGH EXTENDED CROP ROTATIONS

### EFFECTIVE FERTILIZER APPLICATION

### INTRODUCTION

A reduced frequency of summerfallowing associated with extended rotations could be beneficial in terms of helping to arrest and possibly overcome the degree of soil degradation that has taken place. However, in the east central region of Saskatchewan, extended stubble cropping is frequently perceived as being impractical because of the high input costs that are involved. In most cases, the major input cost in recropping is fertilizer. Therefore, if extended recropping programs are to be accepted by more of the farming community, the benefits of effective fertilizer application need to be demonstrated under local conditions. The objective of this study is to help create an awareness of the importance of effective fertilizer application in making extended crop rotations practical and profitable. This report will review the results obtained during the growing season of 1987.

### MATERIALS AND METHODS

Table 1 outlines the experiments conducted in 1987.

A total of 59 fertility trials, representing 6 different experiments, were established at 21 separate sites in east central Saskatchewan.

Experiments were established in randomized complete block, split-plot or split-split plot designs replicated six times. Subplots were 9.1 x 1.5m separated by two rows of spring seeded winter wheat. Fertilizer applications were applied in October 1986 and/on May 1987, depending upon experimental design. Results of soil analyses obtained prior to fertilization are given in the Appendix.

All trials were treated with appropriate herbicides and maintained weed free. Yield of most sites was determined by machine harvesting a 7.5 m<sup>2</sup> area of each plot. Yield of heavy textured sites were determined by harvesting either a 2.5 m<sup>2</sup> or 4.0 m<sup>2</sup> centre area of each plot. Harvesting began during the third week of August and continued for approximately 3 weeks.

## RESULTS AND DISCUSSIONS

### a) Methods of N-P Placement; Fall vs Spring

The information in Table 1 is based upon data collected from 14 separate fall and spring trials. Individual site yields and statistical analysis are included in the appendix. Results in Table 1 are based upon 4 wheat and 10 barley trials that included fall and spring applied fertilizer treatments.

TABLE 1. AVERAGE YIELD RESPONSE (BASED ON 14 TRIALS) TO FALL & SPRING APPLICATIONS OF FERTILIZER

+ Indicates drill in P applied.

Rates: N as 46-0-0 at 70 kg N/ha  
P as 0-45-0 at 36 kg N/ha

Check Yield: Fall - 1,869 kg/ha  
Spring - 1,947 kg/ha

Highest grain yields were obtained when the nitrogen was banded rather than broadcast. For the two comparable treatments, banding resulted in a 45% and 38% yield advantage over broadcasting based on the yield response to

fertilizer. A significant yield difference between comparable band and broadcast treatments occurred at all locations. Phosphorus additions were beneficial in elevating grain yields, however, phosphate placement had a limited effect on grain yield. Yield for treatments where N was banded indicates a slight advantage to banding or splitting the phosphate as opposed to the conventional method of seed placing all the phosphate though the difference was small (approximately 1 bu/ac). Top average yields were achieved where the P application was split between the band and the seedrow. At one site (8724) the two split P treatments were significantly higher yielding than either the dual band or drill in P treatments while at another site (8711) the dual band application was significantly higher than the drill in P application. This is in agreement with results of 1986 where very little difference in yield occurred, on average, between methods of P application but where, at times, one method may have an advantage over another. The average results comparing response to phosphate based on the method of P placement is summarized in Figure 1.

**FIGURE 1**  
(AVERAGE OF 17 SITES)

On average, spring applications were 10% higher yielding than fall applications. However, this figure is somewhat misleading when comparing yield changes between the fall vs spring broadcast and fall vs spring band treatments. The average yield of the two spring broadcast applications was 33% higher than that of the fall applications. Spring band applications exceeded fall applications by only 5% as illustrated in Figure 2. It is apparent that yields are influenced less by over winter environmental conditions when fertilizer is banded than when broadcast. The overall benefit to spring applications is somewhat of a puzzle in view of the relatively dry spring. One might have expected the fall applications to favour those of the spring, such as occurred in 1986. It should also be stated that the advantage of spring applications as determined by test plots is somewhat biased in that the actual yield differences between times of application under field conditions is probably less than that observed. This suggestion is based on the manner of plot establishment since all fertilization, seedbed preparation and seeding is performed within hours. On a commercial scale these operations are often separated by at least several days which could contribute to increased seedbed moisture losses. Therefore any extra spring tillage operation (eg. fertilizer application) can significantly reduce soil moisture availability and therefore crop response.

A total of 3 trials compared spring applications only (8730, 8731, 8732-appendix). Results from these trials are in agreement with previously stated observations regarding methods of fertilizer applications.

**FIGURE 2**  
(AVERAGE OF 2 TREATMENTS OVER 14 SITES)

a) Response To Increasing N Rates

The effects of increasing rates of nitrogen was evaluated at a total of 12 sites (1 wheat, 11 barley). The yield of individual sites and their associated statistical analysis are shown in the appendix. All sites responded to at least one increment of supplemental N, three sites (8713, 8720B, 8720C) had significant yield responses to 140 kg N/ha. The average response to band applied N is summarized in Figure 3. On average, grain yields continued to increase to 140 kg N/ha exceeding the check yield (1596 kg grain/ha) by 87%.

Four of the trials were established in the fall, (ie. 8711, 8713, 8718, 8724) eight in the spring. All nitrogen treatments were evaluated with a standard rate of drill in P<sub>2</sub>O<sub>5</sub> (30 kg/ha).

c) Response to Increasing P<sub>2</sub>O<sub>5</sub> Rates

At a total of 12 sites (1 wheat, 11 barley) the response to increasing increments of P<sub>2</sub>O<sub>5</sub> was evaluated. All phosphate fertilizer was seed placed, at 4 (8711, 8713, 8718, 8724) sites nitrogen fertilizer and where appropriate the required phosphate was banded during the fall. In all cases the phosphate treatments were evaluated at a standard rate of pre-plant banded N (105 kg/ha). Individual site results and statistical analysis are outlined in the appendix. All but one site (8718 wheat) responded significantly to added phosphate. The lowest yield response to 60 kg P<sub>2</sub>O<sub>5</sub>/ha was 5% (8726) while the highest was 31% (8720). At no site did a significant yield response occur beyond the 45 kg P<sub>2</sub>O<sub>5</sub>/ha addition. Mean yield responses to increasing rates of drill in P<sub>2</sub>O<sub>5</sub> are shown in Figure 4. On average yields increased to 45 kg P<sub>2</sub>O<sub>5</sub>/ha and then levelled.

**FIGURE 3**  
(AVERAGE OF 12 SITES)

**FIGURE 4**  
( AVERAGE OF 12 SITES)

**D) Depth of Bands**

At 5 sites (2 wheat, 3 barley) the depth of banding (3", 6") in the fall and spring was evaluated, at 1 site (barley) the depth of banding was evaluated in the spring only. Results and accompanying statistics for each site are shown in the appendix. At all sites 3 methods of fertilization were also assessed, the rate of N and P<sub>2</sub>O<sub>5</sub> application was 70 and 30 kg/ha respectively.

The average check (unfertilized) yields for the 2 depths of bands are summarized in Table 2.

**TABLE 2. INFLUENCE OF DEPTH OF BANDING ON GRAIN YIELD  
OF UNFERTILIZED CHECK TREATMENTS (KG/HA)**

| <u>Depth</u> | <u>Grain Yield (kg/ha)</u> |               | <u>Average</u> |
|--------------|----------------------------|---------------|----------------|
|              | <u>Fall</u>                | <u>Spring</u> |                |
| 3"           | 1702                       | 1655          | 1679           |
| 6"           | <u>1627</u>                | <u>1622</u>   | <u>1625</u>    |
| Average      | 1665                       | 1639          | 1652           |

For both fall and spring operations increasing the depth of the band to 6" appeared to result in a yield reduction (tillage effect) in the unfertilized treatments. On average, the tillage effect of the banding operation resulted in slightly lower check yields when conducted in the spring compared to fall.

The average response to 3 methods of fertilizer application as influenced by depth and time of banding is summarized in Table 3.

TABLE 3. GRAIN YIELD RESPONSE (KG/HA) DUE TO TIME AND DEPTH OF BANDING\*

| <u>Depth</u> | <u>Grain Yield Increase (kg/ha)</u> |               |                |
|--------------|-------------------------------------|---------------|----------------|
|              | <u>Fall</u>                         | <u>Spring</u> | <u>Average</u> |

| 6"           | <u>1645</u>                         | <u>1845</u>   | <u>1745</u>    |
| Average      | 1534                                | 1814          | 1674           |

\* Based on average of 3 different fertilizer treatments

The average yield response to applied fertilizer was greater as the depth of banding was increased, however, this result was statistically significant at only one site (8721). Spring banding was superior to fall banding at all but 1 site (8725).

Table 4, 5 and 6 summarize the grain yield increases obtained for each of the 3 methods of fertilizer applications.

| 3"           | 1462                                | 1775          | 1619           |
| 6"           | <u>1652</u>                         | <u>1904</u>   | <u>1778</u>    |
| Average      | 1557                                | 1840          | 1699           |

In all cases of fall application increasing the depth of banding from 3" to 6" resulted in increased yields. This was also true for the spring treatments except in the case where the fertilizer treatment consisted of a dual N-P band (see Table 5) in which case placing the N and P at a shallower depth was slightly more effective. This data would suggest that the need for some starter P when dual N-P bands are placed at greater depths.

The difference in response to method of P application depending on the depth of N banding is graphically illustrated in Figure 5 (includes 1 spring trial). In these trials banded P was superior to drill in P at the shallow band depth but at the greater depth of banding, the reverse occurred. Similar results have been previously observed suggesting that the benefit of including some drill in P (ie. starter P) appears to be more important as the depth of banding increases.

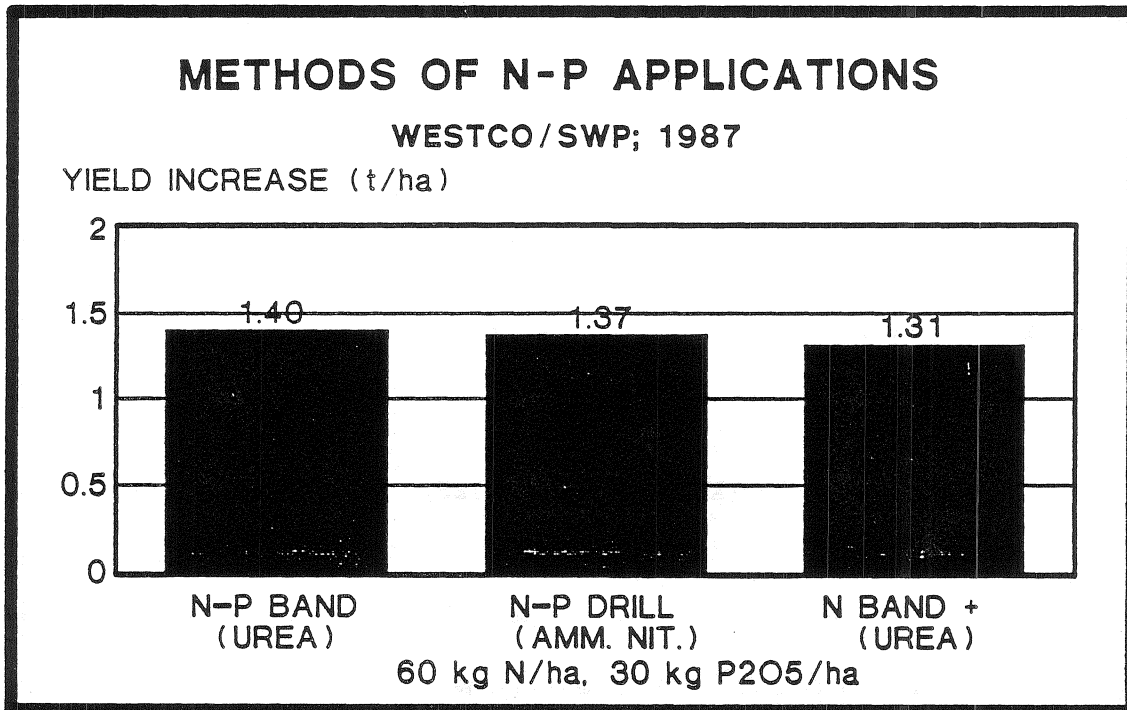

**FIGURE 5**  
(AVERAGE OF 5 SITES)

e) Drill in vs Banded N-P

Placing significantly higher amounts of N directly in the seedrow as an alternative to conducting a separate pre-plant banding operation was evaluated at 5 different sites (1 wheat, 4 barley). Three of the sites were established in the fall of the year. The rate of N and P application was 60 and 30 kg/ha respectively. The source of the band N was urea, while drill in N source was ammonium nitrate. Individual site results and associated statistics are reported in the appendix. A significant response in grain yield to fertilizer application occurred at all sites. A significant difference between fertilizer treatments occurred at only one location (8731). At this site the dual band application was more effective than the N band, P drill in application, the yield difference between these two treatments amounted to 9.3 bushels/acre of barley.

FIGURE 6  
(AVERAGE OF 5 SITES)

The average yield response to the three methods of fertilizer application is graphically shown in Figure 6. On average, the three methods of application performed equally well. Of some surprise is the effectiveness of the N-P drill in application. The total amount of ammonium nitrate fertilizer seed placed (60 kg N/ha) significantly exceeds the maximum amount of ammonium nitrate (ie. 45 kg N/ha) that is normally suggested as a safe limit for seedrow application with a press drill. Though sub soil moisture conditions were favorable at time of seeding the seedbed moisture conditions were less than ideal. Furthermore several sites experienced a period of moisture stress during the early portion of the growing season. This resulted in a significant reduction of the plant stand at several locations and a delay in maturity for the drill in N-P treatment. However, as moisture conditions improved, plants present appeared to compensate through tillering. The results of this application would suggest that further investigation is warrant. Based upon the results obtained in these trials there appeared to have been no benefit for the retention of seed placed (starter) phosphate as opposed to a dual N-P pre-plant application in 1987.

f) Potassium Source Study

At 9 different sites ( 1 wheat, 8 barley) the chloride and sulphate sources of potash were evaluated. Individual site results and associated statistics are reported in the appendix. At no site was there a statistical difference between potash sources nor was there a significant response in yield to potash additions. The effects of potash fertilization are graphically illustrated in Figure 7. On average no yield differences occurred with the addition of either potash source. Recent Canadian and U.S. studies have reported yield responses to potassium chloride fertilization. It is thought that in some situations the chloride ion can suppress the influence of several cereal grain diseases. In this trial cereal diseases were not deemed to have affected any site to any significant extent. Soil analyses revealed that all sites selected for this study contained adequate levels of soil chloride.

FIGURE 7  
(AVERAGE OF 9 SITES)

g) Banding in Heavy Textured Soils

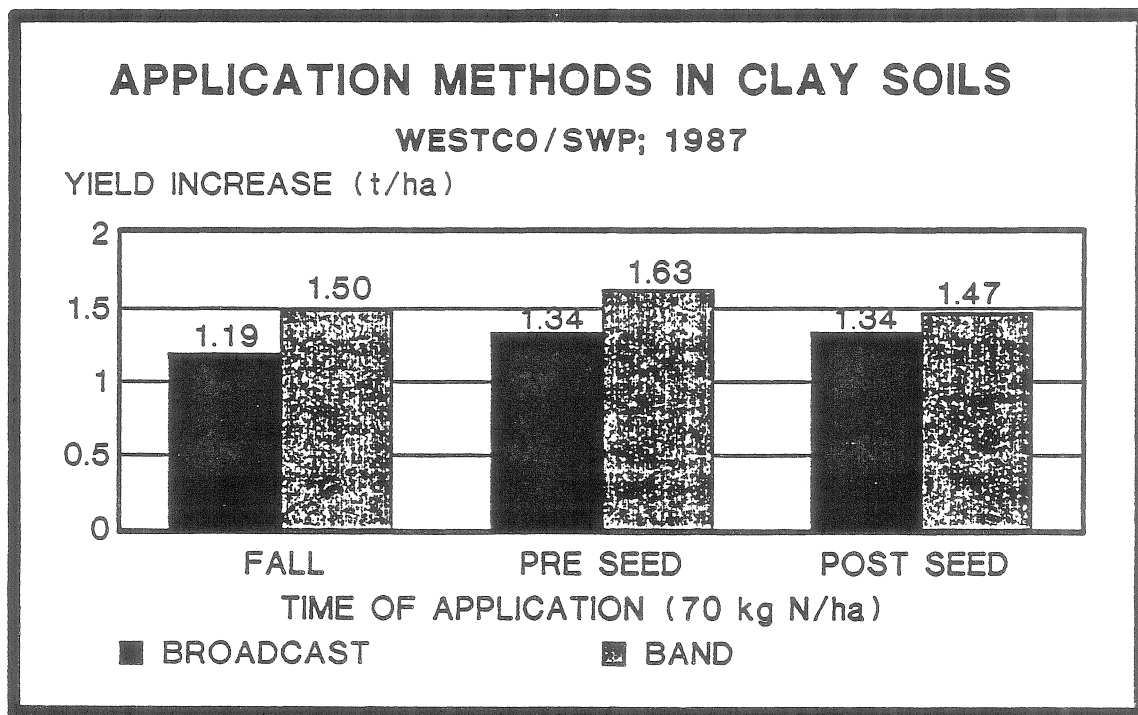

A total of 3 sites (2 wheat, 1 barley) were established to compare options of nitrogen application on heavy textured soils. Fall banding on these soils is often difficult to conduct if they are dry. Spring banding prior to seeding can result in serious compaction of clay soils which in turn has an adverse influence on seedbed quality. In this study an attempt was made to evaluate the time and method of N application, depth of post seeding bands and, at 1 location, the effect of speed on post seeding applications. It should be noted that the wheel tracts (ie. areas of potential soil compaction) were not included in the samples that were harvested for yield determinations. In other words, this study did not attempt to address the potential impact of compaction by application equipment at any of the application dates.

i) Time and Method of N Applications

Average yield data and associated statistics are given in the appendix. All fertilizer applications were made in a direction perpendicular to that of seeding. The rate of N application in these trials was 70 kg N/ha, P was seed placed by the co-operating producer at a rate of approximately 30 kg P<sub>2</sub>O<sub>5</sub>/ha. Trials were seeded using co-operators field equipment (discer seeder, air seeder, hoe-drill). Statistically, the time of N application did not affect grain yield at the three sites. At all locations N additions significantly increased grain yield and at 2 sites band N yields were significantly higher than broadcast N yields (4.6 and 5.9 bushels/acre increase of barley and wheat respectively).

The average results for the three trials are shown in Figure 8. On average, spring pre-seeding band applications were the most effective in terms of increasing yields. At all times of application broadcast N was less effective than banded N. These findings are in support of results obtained in 1986.

**FIGURE 8**  
(AVERAGE OF 3 SITES)

ii) Depth of Post Seeding Bands

Average yield data by site and associated statistics are given in the appendix. Average yield response to the three depths of post seeding bands is outlined in Table 7.

TABLE 7. GRAIN YIELD RESPONSE TO DEPTH OF POST SEEDING BANDS\*

| <u>Depth</u> | <u>Grain Yield kg/ha</u> |                   | <u>Grain Yield Response (kg/ha)</u> |

| Average      | 982                      | 2508              | 1526                                |

\* Average response of 3 sites. All N banded.

Band N applications significantly increased yield at all band depths. There was a trend for grain yield responses to N additions to decrease as band depth increased.

At 2 sites a broadcast application of N was included in the experiment. Average yield responses are shown in Table 8.

TABLE 8. GRAIN YIELD RESPONSE TO DEPTH  
OF POST SEEDED BANDS AND BROADCAST N\*

| <u>N Application</u> | <u>Depth</u> | <u>0 kg N/ha</u> | <u>70 kg N/ha</u> | <u>Grain Yield<br/>Response (kg/ha)</u> |
|----------------------|--------------|------------------|-------------------|---|
| Band                 | 0-1"         | 910              | 2213              | 1303                                    |
| Band                 | 2-3"         | 887              | 2208              | 1321                                    |
| Band                 | 4-5"         | 937              | 2161              | 1224                                    |
| Broadcast            | 0-1"         | <u>944</u>       | <u>2044</u>       | <u>1100</u>                             |
| Average              |              | 920              | 2157              | 1237                                    |

All band N applications were superior to the broadcast application.

iii) Speed of Post Seeding Band Applications

At one site the speed (2-3 vs 5-6 mph) of post seeding band operations was evaluated. Yield and statistical analysis is given in the appendix and in Table 9.

TABLE 9. GRAIN YIELD RESPONSE TO SPEED  
OF POST SEEDING BANDS\*

| <u>Speed of<br/>Banding (mph)</u> | <u>0 kg N/ha</u> | <u>70 kg N/ha</u> | <u>Grain Yield<br/>Response (kg/ha)</u> |
|-----------------------------------|------------------|-------------------|---|

| Average                           | 770              | 2233              | 1463                                    |

\* One site only.

Yield was not significantly influenced by the speed of the tillage operations in the unfertilized treatments (ie. 0 kg N/ha), this agree with field observations where no difference in soil disturbance was noted. When 70 kg N/ha was applied the yield of the faster operating speed was significantly higher than that of the slower speed. The reason for this yield difference is not readily apparent and warrants further investigation. It is possible that the higher speed resulted in less disturbance of the seedbed and the germinating seedlings. Some of the germinating seedlings were displaced onto the soil surface where their survival would be questionable.
