Abstract— Following on from the successful operation of a broadband, high-power gyrotron traveling wave amplifier (gyro-TWA) in W-band, experiments were carried out to demonstrate the versatility of the gyro-TWA and investigate its tuning characteristics. When operating at a lower voltage of 40 kV, 30 dB gain was achieved for a 1 GHz bandwidth frequency-swept input signal.

Keywords— gyrotron traveling wave amplifier, broadband amplification, helically corrugated waveguide, frequency-swept

I. INTRODUCTION

Gyrotron devices based on the cyclotron resonance maser instability have superior power capability over the slow-wave vacuum electron devices. The gyrotron traveling wave amplifier (gyro-TWA) is one of the members of the gyro-device family and it is able to produce high power coherent microwave radiation at mm-wave and sub-mm-wave frequencies. As an amplifier, the amplitude and phase of the gyro-TWA can be precisely controlled therefore it is attractive in applications such as communications, radar and electron spin resonance spectroscopy.

A W-band gyro-TWA using a helically corrugated waveguide (HCW) as the interaction region has been developed at the University of Strathclyde [1]. The HCW has both azimuthal and axial periodicities which allow to couple two different modes in the circular waveguide to generate new dispersion curves. By carefully choosing the geometry parameters, an ideal dispersion curve that has a nearly constant group velocity at small wavenumber values crossing a large frequency bandwidth can be achieved. The gyro-TWA was driven by an axial encircling large orbit electron beam which was generated by a cusp electron gun. It was able to operate at the 2nd cyclotron harmonic therefore only half of the magnetic field strength as compared to fundamental harmonic interaction was required.

The experiment setup of the gyro-TWA is shown in Fig. 1. The gyro-TWA itself contained key components including cusp electron gun [2, 3], pillbox window [4], input coupler [5], elliptical polarizer, input and output windows [6, 7], HCW, and the solenoid systems. The experiment also required a high-voltage power supply to drive the electron beam.

In previous gyro-TWA experiments, the gain curve was measured at discrete frequency points. Further improvement was achieved by building an integrated signal generation

and measurement system using advanced equipment from Keysight Ltd, as shown in Fig. 2. It includes a Keysight arbitrary waveform generator (AWG, model M8190A) to generate arbitrary waveform up to 5 GHz analog bandwidth. The signal was then modulated onto a ~15.5 GHz carrier signal by a Keysight vector signal generator. Then the RF signal was used to drive a low-power solid state source to generate the seed microwave signal for the gyro-TWA. To measure the amplified microwave signal and to determine the power level, a waveguide harmonic mixer (Keysight M1970W), a signal analyzer (Keysight PXA N9030A) and a real-time digitizing oscilloscope (Keysight MSOS804A) were used. All the equipment was remotely controlled.

II. SIMULATION AND MEASUREMENT RESULTS

The optimal operating voltage of the gyro-TWA is 55kV. In this experiment, to demonstrate the versatility in

operating the gyro-TWA the operating beam voltage was lowered to 40 kV. In this case, the other parameters, such as the beam alpha value and the magnetic field strength were needed to be adjusted accordingly. Fig. 3 shows the particle-in-cell (PIC) simulations with the new parameter sets using the 3D PIC code MAGIC. As compared with higher operating voltage, the gain dropped about 7 dB and the bandwidth becomes smaller. However, the radiated microwave power level was still more than 1 kW.

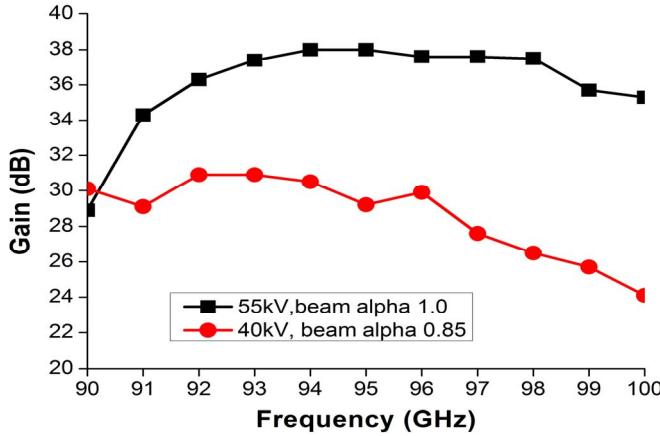

Fig. 3. Comparison of the gain at different parameter sets.

In the experiment, it was found that it is difficult to achieve a desired input signal beyond the bandwidth of 1 GHz. Therefore the frequency-swept signal was set to a bandwidth of 1.0 GHz at the central frequency of 93.5 GHz. From Fig. 4(a), the noise of the frequency-swept signal generated from the solid-state source was relatively large due to the nonlinear behavior of the frequency multipliers. The amplified signal in Fig. 4(a) showed clear frequency sweeping that aligned well with the input signal. The correlated mm-wave signal and the beam voltage is shown in Fig. 4(b). The spectrum of the amplified mm-wave signal in Fig. 4(c) showed a bandwidth close but smaller than 1 GHz. The phase information after post-processing shows good agreement between the input and amplified signals [8].

III. CONCLUSION

Frequency-swept experiments were carried out on a W-band gyro-TWA to investigate its characteristics on broadband amplification and its gains at different operating voltages. A 30 dB gain was achieved when it was driven by a 40 kV, 1.5 A electron beam. The measured results were in excellent agreement with the simulation prediction. The verification of the frequency agility of the W-band gyro-TWA enabled the possibility to carry out experiments for applications in the area of radar, communications and electron spin resonance spectroscopy.

The wider bandwidth experiment was limited by the nonlinear behavior from the frequency multipliers in the solid-state source. The future improvements of the gyro-TWA include sourcing a wider bandwidth solid-state source as well as a more stable high-voltage power supply to drive the electron beam.
