**ABSTRACT:** Energy-transducing respiratory complex I (NADH:ubiquinone oxidoreductase) is one of the largest and most complicated enzymes in mammalian cells. Here, we used hyperfine electron paramagnetic resonance (EPR) spectroscopic methods, combined with site-directed mutagenesis, to determine the mechanism of a single proton-coupled electron transfer reaction at one of eight iron–sulfur clusters in complex I, [4Fe-4S] cluster N2. N2 is the terminal cluster of the enzyme's intramolecular electron-transfer chain and the electron donor to ubiquinone. Because of its position and pH-dependent reduction potential, N2 has long been considered a candidate for the elusive “energy-coupling” site in complex I at which energy generated by the redox reaction is used to initiate proton translocation. Here, we used hyperfine sublevel correlation (HYSCORE) spectroscopy, including relaxation-filtered hyperfine and single-matched resonance transfer (SMART) HYSCORE, to detect two weakly coupled exchangeable protons near N2. We assign the larger coupling with  $A(^1\text{H}) = [-3.0, -3.0, 8.7]$  MHz to the exchangeable proton of a conserved histidine and conclude that the histidine is hydrogen-bonded to N2, tuning its reduction potential. The histidine protonation state responds to the cluster oxidation state, but the two are not coupled sufficiently strongly to catalyze a stoichiometric and efficient energy transduction reaction. We thus exclude cluster N2, despite its proton-coupled electron transfer chemistry, as the energy-coupling site in complex I. Our work demonstrates the capability of pulse EPR methods for providing detailed information on the properties of individual protons in even the most challenging of energy-converting enzymes.

**■ INTRODUCTION**

Mitochondrial complex I (NADH:ubiquinone oxidoreductase) is a redox-coupled proton pumping enzyme that is essential for respiration. By catalyzing NADH oxidation and quinone reduction, it contributes to the proton motive force across the mitochondrial inner membrane that drives the synthesis of ATP. Knowledge of the mechanism of complex I is not only of fundamental importance for understanding proton-coupled electron transfer (PCET) reactions but also required to unravel the molecular origins of a diverse range of neuromuscular and neurodegenerative diseases.<sup>1,2</sup> Complex I is the most enigmatic of the proton-translocating respiratory enzymes, and the mechanism of its redox-coupled proton transfer chemistry is currently unknown.<sup>3</sup>

Recently, much progress has been made in structural knowledge of complex I. The structure of the entire *Thermus thermophilus* complex<sup>4</sup> was followed by structures of its yeast and mammalian homologues, which are almost twice the size of the bacterial enzyme.<sup>5–8</sup> The structures of the catalytically active core subunits are closely conserved in all cases, consistent

with a conserved mechanism of catalysis. They show that the two substrate-binding sites in complex I, the flavin-containing NADH binding site and the quinone binding site, are separated by almost 70 Å and connected by an electron-transfer relay of seven Fe–S clusters to shuttle electrons between them (Figure 1). Near-linear Fe–S relays of this kind are common in metalloenzymes,<sup>9–12</sup> but the relay in complex I is exceptionally long and its pattern of alternating high and low potential centers<sup>13</sup> likely contributes to intramolecular electron transfer being at least an order of magnitude faster than enzyme turnover.<sup>14,15</sup> Intriguingly, Fe–S cluster relays are increasingly being found to have important roles beyond electron transfer. The cluster furthest from the active site in [NiFe]-hydrogenases exerts a strong influence on the kinetics of catalysis,<sup>16,17</sup> whereas the cluster adjacent to the active site plays a crucial role in protecting it against O<sub>2</sub>.<sup>18,19</sup> The unusual [4Fe-3S] hydrogenase cluster is evolutionarily related to [4Fe-4S] cluster

PDB ID: SLDW (bovine complex I).

N2,<sup>20</sup> the terminal cluster in complex I's intramolecular electron transfer chain (Figure 1), which has been suggested to synchronize electron and proton transfer events.<sup>15</sup>

As the immediate electron donor to ubiquinone, cluster N2 has long been considered a candidate “energy-coupling” site in complex I, i.e., the site at which redox catalysis initiates proton translocation across the membrane.<sup>21,22</sup> As there is no evidence to suggest that any upstream electron transfers (from NADH toward N2) are coupled to proton pumping, the alternative candidate is the quinone/quinol-binding site. N2 and the bound quinone headgroup are known to be in close proximity: densities observed in cocrystallization experiments with a short-chain analogue suggested that the quinone headgroup binds within 12 Å of cluster N2<sup>4</sup> (within electron-transfer distance), consistent with earlier data from electron paramagnetic resonance (EPR) spectroscopy.<sup>23</sup>

The reduction potential of N2 has long been known to be pH dependent<sup>22</sup> suggesting it may carry out a crucial PCET reaction during complex I catalysis (we use the term PCET to describe reactions in which the occupancy of a protonatable site changes in response to cluster reduction). However, a lack of consensus on the extent of the pH dependence, particularly for the well-studied mammalian complex,<sup>3</sup> has hindered mechanistic interpretations. Importantly, a strongly coupled PCET reaction, as required for an energy-coupling site, would exhibit a pH dependence of  $-60$  mV per pH unit with a substantial separation of the pK values for the oxidized and reduced states to ensure stoichiometric proton uptake upon reduction. A  $-60$  mV dependence was reported for the mammalian (*Bos taurus*) complex, but in complex I from the aerobic yeast *Yarrowia lipolytica*, it was found to be substantially less ( $-36$  mV/pH) and to be abolished by a single point mutation (H226M in the 49 kDa subunit).<sup>24</sup> Density for His226 was not observed in the structure of *Y. lipolytica* complex I,<sup>7</sup> but its homologous residue in the bovine enzyme His190 was observed in close proximity of cluster N2 (Figure 1).

Investigating the role of protons in large metalloenzymes such as complex I by observing them *directly* (rather than indirectly through pH-dependent potentiometric titrations) is a

challenging task. For complex I, available structures lack the resolution required to define the protonation states of amino acids, or the presence of water molecules, in the vicinity of cluster N2. By examining the hyperfine interactions between the electron spin on the cluster and nearby nuclear spins (e.g., <sup>1</sup>H), pulse EPR spectroscopy is ideally suited to provide this missing information. However, although numerous continuous-wave EPR spectroscopic studies have determined the nature and redox properties of the EPR-visible clusters in complex I,<sup>22,25–29</sup> few pulse EPR studies have been reported. Relaxation-filtered hyperfine (REFINE) spectroscopy predicted the absence of a nitrogen nucleus in the primary coordination sphere of N2,<sup>30,31</sup> as later confirmed structurally (Figure 1), and double electron–electron resonance spectroscopy enabled a definitive assignment of the spectroscopically observed clusters to the structurally defined clusters through distance measurements.<sup>13</sup>

Here, we investigate the existence of exchangeable protons in the environment of N2 both indirectly, using pH-dependent reduction potential measurements, and directly and selectively using pulse EPR spectroscopy. First, we define the pH-dependent reduction potential of N2 in the mammalian complex using small-volume potentiometric titrations<sup>32</sup> under tightly defined conditions: we develop a widely applicable buffer system over a wide pH range that accounts for temperature-dependent changes in pH during sample preparation that could otherwise lead to misleading results.<sup>32,33</sup> Then, we apply pulse EPR measurements to detect exchangeable protons in the vicinity of the reduced N2 cluster. We reveal the presence of a hydrogen bond to a conserved histidine in the second coordination sphere of the cluster and confirm the protonation state of the histidine as the origin of the pH-dependent reduction potential. By defining the PCET reaction of cluster N2, we show that its behavior is not consistent with it being the energy-coupling reaction in complex I, directing the focus of future work to the coupled chemistry of quinone reduction. Thus, we demonstrate the capability of pulse EPR methods for interrogating mechanistic hypotheses involving the properties of individual protons in large and experimentally challenging energy-transducing complexes.

## RESULTS AND DISCUSSION

**pH Dependence of the N2 Reduction Potential.** To establish unambiguously the pH dependence of the reduction potential of N2 in mammalian complex I, we carried out a series of EPR-monitored small-volume redox titrations, at pH values from 5 to 9, on the bovine enzyme (Supplementary Figure 1). The data are summarized in Figure 2. Temperature-independent pH buffer systems, the pH values of which are unchanged from room to cryogenic temperatures (Supplementary Figure 2), were used to obtain the data points at pH 6.0, 7.0, 8.0, and 9.0. We note that substantial temperature-dependent pH changes of commonly used buffers have been known for four decades,<sup>33</sup> but their impact on measurements such as these is often ignored; the systems devised here (Supplementary Table 1) are suitable for wider applications. Furthermore, because bovine complex I proved to be unstable at pH < 6 for the  $\sim 3$  h required for a titration, we obtained the data point at pH 5.0 by exploiting the dramatic pH change that occurs in certain buffers upon freezing and could thus obtain a reliable measurement under this challenging condition (see Experimental Section). A data point recorded at pH 7.4 (see

**Figure 2.** pH-dependent reduction potential of Fe–S cluster N2 in bovine complex I. Data points resulting from EPR-monitored potentiometric titrations (see [Experimental Methods](#) and [Supplementary Figure 1](#)) were fitted with a single proton with  $pK_{\text{ox}} = 5.6 \pm 0.2$ ,  $pK_{\text{red}} = 7.4 \pm 0.2$ ,  $E_{\text{acid}} = -75 \pm 5$  mV, and  $E_{\text{alk}} = -175 \pm 5$  mV (solid line).

([Figure 2](#)) using the same approach confirmed the validity of this alternative strategy.

The solid line in [Figure 2](#) represents the best fit to the data for a single protonated group and has a maximum slope of  $-40$  mV per pH unit. The  $pK$  values for the protonable group are  $pK_{\text{ox}} = 5.6 \pm 0.2$  and  $pK_{\text{red}} = 7.4 \pm 0.2$ , and the reduction potentials of N2 are  $E_{\text{acid}} = -75 \pm 5$  mV and  $E_{\text{alk}} = -175 \pm 5$  mV in the protonated and deprotonated forms, respectively. In principle, multiple more weakly coupled protons could also give rise to the same pH dependence, as was found to be case for *Escherichia coli* cytochrome *b*-562.<sup>34</sup> However, the transfer of a single proton together with *two* electrons (to give a pH dependence of  $-30$  mV/pH) can be excluded because N2 exhibits only two oxidation states ( $[4\text{Fe-4S}]^{2+/+}$ ).<sup>3</sup>

The pH dependence determined does not match the data reported previously for bovine complex I in submitochondrial particles or mitochondria, which exhibited slopes of  $-60$  mV/pH unit, from approximately pH 6.2 to 8.7.<sup>22</sup> However, our data are consistent with data on complex I in mitochondrial membranes from *Y. lipolytica* conducted over a wider pH range (pH 5.0–9.0).<sup>24</sup> Uncertainties in the buffer pH values in earlier studies offer a possible explanation for the disagreement in the pH dependencies obtained. The moderate pH dependence of the N2 reduction potential, observed now in both species, suggests that the PCET reaction occurring at N2 is only weakly coupled and thus argues against it being the mechanistic coupling point in complex I. However, titration data can only provide indirect information on the existence of exchangeable proton(s). Thus, to investigate the proton environment of cluster N2 directly and its interactions with exchangeable protons in detail, we turned to hyperfine spectroscopic techniques.

**The Exchangeable Proton Environment of N2 (Bovine Complex I).** To enable selective investigation of the proton environment of cluster N2 without interference from the many other Fe–S clusters ([Figure 1](#)), we chose samples set at reduction potentials at which N2 is the sole paramagnetic species present (see [Experimental Methods](#) and [Supplementary Figure 3](#)). Structural data on bovine complex I<sup>6</sup> suggests that there are approximately 40 protons within 5 Å of N2, so assignment of all the proton couplings observed by hyperfine spectroscopy is unrealistic, especially given the limited resolution of available structures. We thus focused on the

exchangeable protons, using deuterium exchange, and by investigating the pH dependence of hyperfine couplings.

In agreement with the data in [Figure 2](#), only weakly coupled protons were observed in hyperfine sublevel correlation (HYSCORE) spectra. To observe differences in the weakly coupled protons clearly (see [Supplementary Figures 4 and 5](#) for primary data), we employed previously described HYSCORE subtraction procedures.<sup>35,36</sup> The HYSCORE difference spectra obtained for pH 6.0 vs. pD 6.0 (H vs. D) and for pH 6.0 vs. pH 9.0 (low pH vs. high pH) are shown in [Figure 3A and B](#) (where

**Figure 3.** HYSCORE spectra showing the exchangeable protons in the vicinity of N2 in bovine complex I. (A) [pH 6.0–pH 9.0] and (B) [pH 6.0–pD 6.0] difference spectra. (C) HYSCORE spectrum showing the deuterium coupling only present in the deuterated samples (pD 6.0). Spectra were recorded at 10 K at  $g_{\perp}$ , time increment 16 ns,  $\tau = 116$  ns (A and B), or time increment 24 ns,  $\tau = 420$  ns (C). See [Experimental Methods](#) for sample preparation, further measurement conditions, and HYSCORE subtraction procedures.

pH 6.0 is 1.4 pH units below  $pK_{\text{red}}$ ). Both spectra reveal two sets of cross peaks centered at approximately [17.8, 12.5] and [16.4, 13.4] MHz. HYSCORE difference spectra at additional field positions, required because the microwave pulses cannot excite the entire broad Fe–S cluster EPR spectrum (resulting in orientation selection), also exhibit two sets of cross peaks ([Supplementary Figure 6](#)). As expected from the exchangeable proton couplings revealed in the difference spectra (labeled 1 and 2), the pD 6.0 sample gave rise to small additional couplings ( $<2$  MHz) in the  $^2\text{H}$  region ([Figure 3C](#)). We could not detect significant differences in the nitrogen region in low pH vs high pH spectra ([Supplementary Figure 4A and B](#)) nor in the  $^{14}\text{N}$  difference spectra (not shown). A comparison of the nitrogen region in the H vs D spectra is not feasible because the cross-peaks resulting from  $^{14}\text{N}$  and  $^2\text{H}$  (both quadrupolar nuclei with  $I = 1$ ) overlap. The unaltered  $^{14}\text{N}$  region suggests that there are no substantial changes in the protonation/bonding state of any  $^{14}\text{N}$  nucleus in the immediate vicinity of N2.

Using the method developed by Dikanov and co-workers to analyze orientation-selected HYSCORE spectra<sup>36,37</sup> as a starting point to determine the hyperfine coupling parameters ([Supplementary Table 2](#)), we found that our data are well described by two weakly coupled protons, H1 and H2 ([Supplementary Figures 8 and 9A–C](#)) with the parameters in [Table 1](#) (see also [Supplementary Table 3](#)). The deuterium coupling ([Figure 3C](#)) could be simulated well ([Supplementary Figure 9D](#)) using the parameters for H1 and accounting for the smaller gyromagnetic ratio of deuterium and including a quadrupole coupling ([Supplementary Table 3](#)). The S...H hydrogen bond was estimated from the quadrupole coupling to be  $1.77 \pm 0.29$  Å, which compares favorably with donor–acceptor distances from structural data (see [Table 1](#) and [Supplementary Table 4](#)). The hyperfine coupling of D2 is

expected to be very small (<0.5 MHz) and, with the  $\tau$  value of the experiment chosen to place a blind spot on the deuterium Larmor frequency (2.3 MHz at 349.5 mT), is not clearly visible (Figure 3C).

Figure 4 shows that exchangeable proton couplings can also be detected directly at pH 6.0 using single-matched resonance

Figure 4. SMART-HYSCORE spectra of N2 in bovine complex I at pH 6.0 (A), pH 9.0 (B), and pD 6.0 (C). Spectra were recorded at 10 K at  $g_{\perp}$ , time increment of 8 ns,  $\tau = 96$  ns. See Supplementary Figure 7 for full spectrum of (A) and Experimental Methods for sample preparation and measurement conditions.

transfer (SMART) HYSCORE. In this experiment,<sup>41</sup> which unlike the HYSCORE experiment does not suffer from blind spots, well-resolved double-quantum cross-peaks that correlate two different protons are visible (Figure 4A) along the antidiagonal at twice the proton Larmor frequency ( $\sim 30$  MHz). These peaks are not visible in the pD 6.0 or pH 9.0 samples (Figure 4B and C). The SMART HYSCORE pH 6.0 spectrum is described well by the hyperfine coupling parameters for H1 and H2 given in Table 1 (Supplementary Figure 9E). One of the two protons giving rise to the combination peaks along  $2\nu_{1\text{H}}$  in Figure 4A must be H1 to give rise to the significant splitting observed. A nonexchangeable proton with similar parameters to H1 can be excluded because the combination peaks should then also be present in the pD 6.0 and pH 9.0 spectra. However, the origin of the second proton giving rise to the combination peak in Figure 4A is less clear because reasonable fits to the experimental data could also be obtained using alternative (weak-coupling) parameters for H2. Given that nonexchangeable protons with similar-sized couplings to H1 are present in the HYSCORE spectra (Supplementary Figure 5), it is remarkable that these do not give rise to combination peaks centered around  $(2\nu_{1\text{H}}^1, 2\nu_{1\text{H}}^1)$ . We found that the combination peaks observed in the pH 6.0 SMART HYSCORE spectrum are highly sensitive to the angle between the hyperfine tensors of H1 and H2 (Supplementary

Figure 10). We therefore conclude that it is the orientation of the H1 hyperfine tensor that enabled us to observe the combination peak resulting from the H1 and H2 transitions directly using SMART HYSCORE. We also attempted Q-band Mims electron nuclear double resonance (ENDOR) measurements (data not shown) but found differences in the proton couplings were better resolved using HYSCORE techniques given the relatively low concentrations of our samples and the small sample sizes.

Thus, the couplings from two exchangeable protons, H1 and H2, are present at pH 6.0 ( $< pK_{\text{red}}$ ) but absent at pH 9.0 ( $> pK_{\text{red}}$ ) or following deuterium exchange: the protonable groups that produce these couplings must have  $pK_{\text{a}}$  values between 6 and 9. Previously, the pH dependence of the reduction potential of cluster N2 in *Y. lipolytica* was found to be ablated by the mutation of a nearby highly conserved histidine residue (His226 in *Y. lipolytica*, corresponding to His190 in *B. taurus*, see Figure 1). Thus, it is likely that either H1 or H2 arise from His190. To assist with the assignment of H1 and H2, we thus compared the proton environment of cluster N2 in the wild-type and H226M variant of complex I from *Y. lipolytica*.

**Assignment of Exchangeable Proton H1 Using *Y. lipolytica* Complex I.** When His226 in *Y. lipolytica* complex I was mutated to methionine, a residue with no exchangeable protons, the reduction potential of N2 decreased to a pH-independent value of  $-216$  mV.<sup>24</sup> If His226 gives rise to either H1 or H2, then one of the proton couplings described above will be absent in the H226M variant. In H226M, selective reduction of N2 is not possible as its reduction potential is close to that of the other EPR-visible Fe–S clusters. We thus took advantage of the different relaxation times of N2, relative to that of the [2Fe-2S] cluster N1b, which is also visible at the maximum acceptable measurement temperature for HYSCORE spectra with good signal-to-noise (14 K). We thus employed relaxation filters (REFINE spectroscopy)<sup>30</sup> to measure the proton hyperfine couplings to N2 selectively (Supplementary Figure 11). The resulting REFINE-HYSCORE difference spectra are shown in Figure 5.

The [wild-type – H226M] difference spectrum (pH 6.5) clearly reveals a single set of proton cross-peaks (Figure 5A) with hyperfine coupling parameters that match H1 (Table 1). In contrast, the [pH 6.5 – pD 6.5] difference spectrum of the wild-type shows two sets of cross peaks (Figure 5B) that are essentially identical to bovine H1 and H2 (Figure 3B). Therefore, we conclude that H1 arises from the exchangeable proton of His226 in *Y. lipolytica* complex I and His190 in bovine complex I. As for bovine complex I, we could not detect

**Figure 5.** HYSORE spectra showing the exchangeable protons in the vicinity of N2 in wild-type and H226M *Y. lipolytica* complex I. (A) [Wild-type – H226M] symmetrized difference spectrum (pH 6.5) and (B) wild-type [pH 6.0 – pD 6.0] symmetrized difference spectrum. Spectra were recorded at 14 K at  $g_{\perp}$ , time increment 16 ns,  $\tau = 116$  ns, and filtering time  $T_f = 62 \mu\text{s}$ . See [Experimental Methods](#) for sample preparation, further measurement conditions, and HYSORE subtraction and symmetrization procedures.

significant differences in the  $^{14}\text{N}$  couplings in *Y. lipolytica* complex I difference spectra.

**H1 is Hydrogen-Bonded to Cluster N2.** The isotropic hyperfine coupling ( $A_{\text{iso}}$ ) of H1 shows that a substantial amount of electron spin density is present on the exchangeable proton of His190/226 (Table 1). It was not possible to fit the data satisfactorily with  $A_{\text{iso}}$  set to zero. His190/226 is present in the second coordination sphere of N2, so there are no through-bond interactions to explain the nonzero  $A_{\text{iso}}$ . However, the anisotropic through-space interaction ( $T = 3.9$  MHz) is also relatively large, suggesting a close association between the proton and the reduced cluster. We thus propose that His190/226 forms a hydrogen bond to the reduced [4Fe-4S] N2 cluster. Hydrogen bonds have long been known to play an important role in modulating the reduction potentials of Fe–S clusters, and a recent ultrahigh resolution (0.48 Å) structure of a high-potential iron–sulfur protein from *Thermochromatium tepidum* has revealed the extensive hydrogen-bonding network around the [4Fe-4S] cluster.<sup>42,43</sup> However, to the best of our knowledge, only one set of hyperfine parameters for a proton hydrogen-bonded to a Fe–S cluster (the [2Fe-2S] cluster in a Rieske protein, Table 1) has been reported.<sup>36</sup>  $|A_{\text{iso}}|$  and  $|T|$  for this leucine proton are comparable to the hyperfine coupling parameters for H1. The anisotropy of H1 also compares favorably with values reported for His residues hydrogen bonded to semiquinones (Table 1). For cluster N2, hydrogen bonding could involve either the bridging sulfides of the Fe–S cubane or the sulfurs of the ligating cysteines.<sup>43</sup> Current structural data on the *Y. lipolytica* or *B. taurus* enzymes cannot confirm or distinguish either possibility, but a hydrogen bond between the histidine and one of the cysteine ligands was modeled in the structure of (oxidized) *T. thermophilus* complex I.<sup>4,44</sup> The observed anisotropy can be satisfactorily reproduced using a homology model for the bovine enzyme created from *T. thermophilus* structural data together with the N2 spin projection factors (describing the magnetic coupling of the four Fe-subsite spins to form an  $S = 1/2$  ground state) we determined previously<sup>13</sup> (see [Supplementary Table 4](#)).

The H1 hydrogen bond to N2 explains the large drop in reduction potential (76 mV at pH 7)<sup>24</sup> observed in the H226M variant. Similarly, the reduction potential of the [3Fe-4S] cluster in succinate:ubiquinone oxidoreductase dropped by 68 mV (pH 8) upon substitution of a second-coordination sphere His thought to be hydrogen-bonded to the cluster with Thr.<sup>45</sup> Birrell and co-workers<sup>46</sup> systematically studied the effects of

hydrogen bonding on the reduction potential of the all Cys-ligated [2Fe-2S] cluster in HydC from *Thermotoga maritima* and observed a difference of 58 mV in the reduction potentials of the V131H and V131M variants (at pH 7). In all cases the hydrogen bond withdraws electron density from the cluster, increasing the stability of the reduced cluster and hence increasing its reduction potential.

**The Exchangeable Proton H2.** Besides the conserved histidine, there are no other amino acids in the vicinity of N2 with canonical  $\text{p}K_{\text{a}}$  values between 6 and 9. Therefore, H2 may originate from a bound water molecule located close to N2. Recent molecular dynamics simulations have suggested that many water molecules infiltrate the protein around the quinone-binding channel and the Fe–S clusters,<sup>47</sup> and indeed, they are likely required for proton transfer to and from the histidine. Identification of candidate water molecules may be possible using higher resolution structural data in the future. The substantial anisotropy of H2 (Table 1) suggests that the  $\text{H}_2\text{O}$  molecule may be in a preferred orientation with respect to the cluster (albeit free to rotate), but the lack of isotropic interaction and lower magnitude of the anisotropic interaction both imply that it interacts more weakly than H1. It is thus likely that the  $\text{p}K$  of H2 responds only weakly to the cluster oxidation state, such that its  $\text{p}K_{\text{ox}}$  and  $\text{p}K_{\text{red}}$  are close together, and H1 dominates the pH dependence of the N2 reduction potential (Figure 2).

**Effects of His190/226 on Catalysis.** To assess the catalytic importance of protonating the conserved histidine, we compared how the activities of wild-type and variant *Y. lipolytica* complex I vary with pH. Using NADH and decylubiquinone (a soluble analogue of the native ubiquinone), the activity of H226M was  $\sim 80\%$  that of the wild-type enzyme, and it displayed the same pH-dependent activity with a maximum at pH  $\sim 7.5$  regardless of the presence of the histidine (Supplementary Figure 12). Similarly, in activity assays conducted using ubiquinone-10 in an artificial membrane system comprising complex I and the alternative oxidase to enable  $\text{Q}_{10}$  cycling,<sup>48</sup> the H226M variant displayed  $\sim 65\%$  of the wild-type activity at pH 7.5. Previously, it was demonstrated that the H226M variant is capable of proton pumping as well as of redox catalysis.<sup>24</sup> Therefore, neither the redox reaction or proton translocation is severely impaired by the absence of His190/226, and we conclude that proton-coupled electron transfer at cluster N2 is not required for complex I catalysis.

## CONCLUSIONS

The question whether the terminal Fe–S cluster N2 in complex I is involved in proton pumping was first raised in the 1970s and has remained subject to debate ever since. Here, we have shown that the characteristics of the PCET reaction at N2 are not consistent with it being the coupling reaction that initiates proton translocation. The following lines of evidence led to this conclusion: (1) The limited pH dependence of the N2 reduction potential (less than  $-60$  mV per pH unit) shows that proton transfer is not strongly coupled to electron transfer. At pH 7.4, the complete reduction of cluster N2 results in only 50% of the enzyme molecules taking up a coupled proton, insufficient to support the efficient and stoichiometric proton translocation mechanism that is exhibited by complex I.<sup>49</sup> Data on the pH dependence of the N2 reduction potential are now consistent for complex I from both mammalian and yeast species. (2) Consistent with (1), no strongly coupled exchangeable protons (as would be required for efficient

energy conversion) could be detected in the vicinity of N2. Instead, two weakly coupled exchangeable protons are present. The more strongly coupled of these belongs to a conserved histidine in the second coordination sphere of N2 that we conclude is hydrogen-bonded to the reduced cluster. (3) Despite the profound effect of the conserved histidine residue on the reduction potential and pH dependence of N2, enzyme activity is not substantially compromised upon its substitution.

We cannot exclude that protonation at cluster N2 plays an indirect role in complex I catalysis, perhaps by supporting proton uptake for ubiquinone reduction. How protons are supplied to the ubiquinone headgroup is unknown, and clues may result from re-examining the proton environment of the cluster in the presence of a bound substrate analogue or under a membrane potential. The mechanisms of the binding, reduction, and dissociation of ubiquinone/ubiquinol, possibly involving semiquinone<sup>3</sup> or doubly anionic intermediates,<sup>50,51</sup> must now be investigated as candidates for the catalytic step that couples proton transfer to electron transfer in this reversible energy-transducing enzyme.

Many essential enzymes such as hydrogenases, nitrogenases, fumarate reductase, carbon-monoxide dehydrogenase, and nitrate reductase contain a multitude of buried iron–sulfur clusters. In this paper, we have pinpointed the properties of a single proton in a giant 1 MDa enzyme that contains a multitude of Fe–S clusters, demonstrating how pulse EPR methods can be used to isolate and examine the behavior of single redox-active centers in highly complicated systems.

## ■ EXPERIMENTAL SECTION

**Protein Preparations.** Bovine complex I was prepared using the protocol of Sharpley et al.<sup>52</sup> implemented as described previously,<sup>32</sup> except that the buffer for the Superose 6 Increase column contained 20 mM Tris, 150 mM NaCl, 10% (v/v) glycerol, and 0.05% (w/v) *n*-dodecyl  $\beta$ -D-maltoside (DDM, Glycon). Complex I from *Y. lipolytica* was prepared as described previously<sup>53</sup> except that cells were grown at 30 °C.

Complex I catalytic activities were measured using 200  $\mu$ M NADH and 200  $\mu$ M decylubiquinone in 20 mM Tris-HCl, 0.15% asolectin (Avanti Polar Lipids), 0.15% 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonate (CHAPS, CalBioChem), pH 7.5 at 32 °C. Activities for the bovine enzyme were between 10 and 20  $\mu$ mol NADH min<sup>-1</sup> mg<sup>-1</sup>, and the midpoint potential of N2 was independent of the activity. The buffer for pH-dependent activity measurements contained 100 mM of each of MES, MOPS, and Tris pH corrected with KOH or H<sub>2</sub>SO<sub>4</sub>.

All complex I EPR samples were supplemented with glycerol to a final concentration of 30% (v/v).

**EPR Sample Buffers.** Temperature-independent pH buffers were used to set pH values between 6.0 and 9.0 (see Supporting Information text and Supplementary Table 1 for details). The buffer used to obtain the pH 5.0 data point in Figure 1 (see also Supplementary Figure 1) contained 100 mM citric acid, 150 mM NaCl, and 30% (v/v) glycerol and was adjusted to pH 6.0 at room temperature. Using pH indicators (see Supporting Information), we established that its pH drops by 1.0  $\pm$  0.2 units from 298 to 77 K. The pH 7.4 data point in Figure 2 was prepared in 100 mM MES, 150 mM NaCl, and 30% (v/v) glycerol and adjusted to pH 6.0 at room temperature to give a final pH of 7.4  $\pm$  0.2 at 77 K.

**Preparation of EPR Samples.** Prior to all titrations, bovine complex I was exchanged into the desired buffer and pH using an Amicon Ultra 0.5 centrifugal filter with an Ultracel-100 membrane (Vivaspin). The protein concentration was typically 10  $\mu$ M except for two titrations at pH 6.0 and 9.0 at 30  $\mu$ M. Reduction potential titrations were carried out as described previously.<sup>32</sup> Briefly, 140  $\mu$ L of sample was stirred in an electrochemical cell inside an anaerobic

glovebox (Braun UniLab-plus, O<sub>2</sub> < 0.5 ppm) for 10 min at 6 °C to remove O<sub>2</sub>. Redox mediators (anthraquinone-2-sulfonate, benzyl viologen, indigodisulfonate, indigotrisulfonate, and methylene blue) were each added to the same final molar concentration as the protein. Then, the reduction potential of the solution (at 6 °C) was set by successive substoichiometric submicroliter additions of sodium dithionite (in 10 mM Tris buffer, pH 8) and monitored by open-circuit potentiometry using an EmStat3<sup>+</sup> (PalmSens). Once the desired potential was attained, 9  $\mu$ L of solution was transferred to an EPR tube, flash-frozen inside the glovebox, and stored in liquid nitrogen. Pulse EPR measurements (Figures 3 and 4) were conducted on samples selected from those described above on the basis of the maximum reduction of N2 with all other EPR-visible clusters fully oxidized (−167 mV at pH 6.0, see Supplementary Figure 1A, and −145 mV at pH 9.0). The bovine pD 6.0 sample (protein concentration 30  $\mu$ M, −160 mV) was made using the same procedure as for a full titration except that D<sub>2</sub>O and deuterated glycerol-*d*<sub>3</sub> (Sigma-Aldrich) were used. The pD was adjusted using pD = pH meter reading + 0.41.

NADH-reduced samples of native and H226M *Y. lipolytica* complex I (final concentration 30  $\mu$ M) were prepared in the glovebox by the addition of 1  $\mu$ L of 40–50 mM NADH to 15  $\mu$ L of complex I solution at pH 6.5 or pD 6.5 (see Supplementary Table 1 for buffer composition). The pH of 6.5 is slightly higher than for the equivalent bovine complex I samples due to the instability of concentrated *Y. lipolytica* complex I at pH 6.0, but His226 is still 92% protonated. Solutions were transferred to EPR tubes and flash-frozen inside the glovebox.

All reduction potentials are reported relative to the potential of the standard hydrogen electrode (SHE). The offset of the reference electrode (DRI-REF-2, World Precision Instruments), +200 mV, was determined using quinhydrone as a standard.

**EPR Spectroscopy.** EPR measurements were performed using an X/Q-band Bruker Elexsys E500 spectrometer equipped with a closed-cycle cryostat (Cryogenic Ltd., UK). All X-band measurements were carried out in an ER 4118X-MS2 resonator (Bruker), operated in either continuous wave (CW) or pulse mode. CW spectra were baseline subtracted using a buffer-only sample measured under the same conditions. CW measurements of titration samples were carried out at 25 K, 2 mW microwave power, modulation amplitude 0.7 mT at 100 kHz modulation frequency.

Two-pulse echo-detected field sweeps (EDFS) were acquired with the pulse sequence  $\pi/2$ - $\tau$ - $\pi$ - $\tau$ -echo ( $\pi/2 = 16$  ns,  $\pi = 32$ , and  $\tau = 200$  ns). HYSCORE spectra were recorded with the 4-pulse sequence  $\pi/2$ - $\tau$ - $\pi/2$ - $t_1$ - $\pi$ - $t_2$ - $\pi/2$ - $\tau$ -echo;  $\pi/2 = 16$  ns,  $\pi = 16$  ns at twice the power of the  $\pi/2$  pulses (i.e., in a second channel),  $t_1 = t_2 = 80$  ns,  $\tau$  given in figure legends, 4-step phase cycle [0,0,0,0] - [0,0,180°] + [0,0,180°,0] - [0,0,180°,180°]. SMART HYSCORE spectra were recorded with the 4-pulse sequence HTA- $t_1$ - $\pi$ - $t_2$ -HTA- $\tau$ - $\pi$ - $\tau$ -echo (4-step phase cycle [0,0,0,0] - [0,0,180°,0] + [0,0,0,180°] - [0,0,180°,180°]) with  $\pi = 32$  ns, high turning angle (HTA) pulse = 40 ns, and  $t_1 = t_2 = 96$  ns. Because of the spectral asymmetry about the diagonal (typical for SMART-HYSCORE spectra), the SMART HYSCORE spectra were symmetrized.<sup>54</sup>

REFINE experiments were carried out with a  $T_1$  filter ( $T_f$ ) of 62  $\mu$ s and  $\pi = 32$  ns initial inversion pulse prior to the EDFS pulse sequence ( $\pi$ - $T_f$ - $\pi/2$ - $\tau$ - $\pi$ - $\tau$ -echo, single channel) or HYSCORE pulse sequence ( $\pi$ - $T_f$ - $\pi/2$ - $\tau$ - $\pi/2$ - $t_1$ - $\pi$ - $t_2$ - $\pi/2$ - $\tau$ -echo), where  $t_1 = t_2 = 80$  ns and  $\tau$  is specified in the figure legends. As for standard HYSCORE experiments, the fourth pulse in REFINE HYSCORE experiments ( $\pi = 16$  ns) was placed in a different channel to all other pulses. Pulse EPR measurements of bovine complex I samples (with N2 as the sole paramagnetic species) were carried out at 10 K to maximize the signal-to-noise ratio. Pulse EPR experiments of NADH-reduced *Y. lipolytica* complex I were carried out at 14 K to eliminate contributions from N3 and N4 (N1b could be filtered out using the relaxation filter). The HYSCORE spectra obtained from *Y. lipolytica* were symmetrized<sup>55,56</sup> (Figure 5) due to their lower signal-to-noise compared to their bovine counterparts measured at 10 K. Additional (variable) experimental parameters are provided in the figure legends.

Typical acquisition times were 14 h for HYSORE, 24 h for REFINE HYSORE, and 60 h for SMART HYSORE experiments.

**Analyses of EPR Data.** The reduction potentials of N<sub>2</sub> at each pH were determined by plotting the integrals of the simulated N<sub>2</sub> spectra as a function of potential and by fitting the resulting data to the one-electron Nernst equation (see [Supplementary Figure 1](#) and ref 32). The data points shown in [Figure 2](#) were fitted with the equation

$$E_m([H^+]) = E_{\text{alk}} + \frac{2.3RT}{nF} \log_{10} \left( \frac{1 + \frac{[H^+]}{K_{\text{red}}}}{1 + \frac{[H^+]}{K_{\text{ox}}}} \right)$$

where  $T = 282$  K (temperature at which the titrations were carried out),  $n = 1$ ,  $E_{\text{alk}} = -175$  mV,  $K_{\text{ox}} = 10^{-5.6}$ , and  $K_{\text{red}} = 10^{-7.4}$ . Errors in the values were estimated from the error in the pH value of the buffer at cryogenic temperatures ( $\pm 0.2$  pH units) and the error in the fit of the experimental data to the Nernst equation ( $\pm 10$  mV).

HYSORE difference spectra ([Figures 3A and B and 5](#)) were obtained by normalizing the nitrogen cross peaks in the (−,+) quadrant ([Supplementary Figure 4](#)) to the same intensity using spectra recorded under the same experimental conditions (microwave frequency, magnetic field position, and  $\tau$ ). To obtain the hyperfine coupling parameters of the exchangeable proton couplings revealed by the subtractions, we performed contour line shape analysis (a plot of  $\nu_{\alpha}^2$  versus  $\nu_{\beta}^2$ , [Supplementary Figure 8](#)) of the cross peaks as a first approximation and as previously described.<sup>36</sup> The hyperfine coupling parameters of H1 and H2 ([Supplementary Table 2](#)) were then further refined through simulations of all pulse EPR data as described in the [Supporting Information](#).

## ■ ACKNOWLEDGMENTS

We thank Prof. Conrad Mullineaux (QMUL) for use of his fluorescence spectrometer and Camille Galateau (QMUL) for carrying out some of the pH indicator and fluorescence measurements. Prof. Ulrich Brandt (Radboud Center for Mitochondrial Medicine, The Netherlands) is gratefully acknowledged for providing the *Y. lipolytica* H226M strain. We are grateful to Prof. Jeffrey Harmer (The University of Queensland) and to the reviewers for helpful comments on the manuscript. This research was funded by the EPSRC (First Grant EP/M024393/1 to M.M.R. and studentship EP/M506394/1 to J.J.W.) and by The Medical Research Council (U105663141 to J.H.).
