Running head: Long-term Social Stability

Analysis of the phenotypic link between behavioural traits at mixing and increased long-term social stability in group-housed pigs

1 Abstract

2 Mixing of growing pigs results in aggressive contests between group members. As 3 aggression serves to establish dominance relationships, it is possible that increased initial 4 aggression may facilitate the formation of social hierarchies. The objective of the study was to 5 investigate whether there is a phenotypic link between behavioural traits of aggression at 6 mixing and increased long-term group social stability. Aggressive behavioural traits were 7 recorded for 24 hours after mixing, whereas the numbers of skin lesions (anterior, central and 8 posterior) were obtained 24 hours (SL24h) and 3 weeks post-mixing (SL3wk) for 1,166 pigs. At 9 the group level, aggressive behavioural traits were positively correlated with anterior SL24h 10 (0.34 to 0.67; *P* < 0.01) at mixing, and negatively with central SL3wk (-0.28 to -0.38; *P* < 0.01) in 11 the stable group. At the individual animal level, most behavioural traits of aggressiveness 12 correlated positively with SL24h (0.09 to 0.53; P < 0.001), whereas the opposite associations 13 were found for SL3wk (-0.06 to -0.14; *P* < 0.05). Within aggressive cohorts, animals with a high 14 fight success rate received slightly fewer SL24h than equally aggressive, but unsuccessful pen 15 mates, while animals that avoided aggression received the fewest SL24h. Corresponding 16 associations were reversed in the stable group. These results provide evidence that increased 17 aggression at mixing may aid stable hierarchy formation. This raises an ethical dilemma in pigs 18 production, but potentially also in other species, that increased acute aggression during mixing 19 may actually decrease chronic aggression in groups and thus benefit the long term welfare of 20 the group. 21 22 23 24 25

30 **1. Introduction**

31 Repeated mixing of livestock species that adopt social systems characterised by 32 dominance hierarchies disrupts social relationships and results in aggressive contests between 33 group members. This kind of aggressive behaviour serves to establish dominance hierarchies 34 (Meese & Ewbank, 1973) but may be associated with high stress and injury levels, especially in 35 pigs, where the costs of aggression can be particularly significant. These effects make social 36 aggression a known welfare and economic concern in pig production, affecting growth, 37 reproduction, and carcase quality (Faucitano, 2001; Marchant et al., 1995; Stookey & Gonyou, 38 1994). As well as the physical and metabolic demands of prolonged fighting, an uncertain 39 hierarchy position may be stressful to individuals (DeVries et al., 2003). In pigs, individuals that were involved in aggression upon mixing but only achieved moderate fight success have been 40 41 shown to have higher baseline salivary cortisol levels than bottom and top ranking group 42 members (Coutellier et al., 2007; Mendl et al., 1992) implying that these animals may feel more 43 stressed than their subordinates. Methods of reducing aggression have been studied for over 30 44 years (Fraser 1984); however to date no practical, socially acceptable, low cost, high impact 45 solution has been found.

46

Physical aggression between pigs can cause injuries in the form of skin lesions. Lesions
to the anterior and central regions of the body have been shown to correspond with the
duration of reciprocal fighting, while lesions to the posterior region of the body are associated
with the receipt of non-reciprocal bullying (Turner et al., 2006^a). The number of lesions has
been found to moderately correlate with the duration of time spent engaged in aggression, and
combining the location and number of skin lesions has been shown to be a useful proxy
measure of aggression (Turner et al., 2006^a).

54

In commercial farming, once pigs are mixed for growing they will usually remain in
these groups for several months until regrouped again or marketed. As aggression serves to

establish dominance hierarchies, it is possible that increased aggression upon first mixing may
actually lead to more stable dominance relationships in the long-term. Indeed, there is some
evidence that initial increased aggression at mixing results in lower aggression and improved
productivity over the entire growing-finishing period (Canario et al., 2012; D'Eath, 2005; Turner
et al., 2009). If this is the case, aggressiveness at mixing would be essential to improved long
term welfare and production.

63

64 Efforts to reduce aggression in commercial pigs either through different management 65 strategies, environmental manipulations, or via genetic improvement are on-going. If reduced 66 aggression in new social groups is found to be detrimental to long-term group stability, then it 67 will be important to quantify any continual welfare or production concerns that arise as a 68 consequence of reducing mixing aggression. Although this study focuses on pigs due to the costs 69 of aggression in this species, the existence of a trade-off between acute aggression at mixing and 70 subsequent chronic aggression may have implications for other species reliant upon dominance 71 relationships.

72

73 Many pig aggression studies use information taken from small group sizes or staged 74 interactions between individuals. Often they focus on one aspect of aggression, for example the 75 effects of body weight or previous fight success (Andersen et al., 2000; Francis, Christisonl, & 76 Cymbaluk, 1996). This study utilises a dataset comprised of extremely detailed behavioural 77 observations taken from more than 1,100 animals under commercially relevant conditions after 78 24 hours post mixing. This has provided an opportunity to study the behavioural repertoire of 79 the pig when placed in an unstable social environment, with no human interference. These 80 behavioural traits were compared to skin lesions at mixing (SL24h) and in the social stable 81 group (SL3wk).

82

83	This study investigated whether there is a phenotypic link between aggression at mixing
84	and increased long-term group stability in the form of reduced skin lesions, and if so, to identify
85	mixing behaviours that improve long-term social behaviour. In particular it was of interest to
86	identify specific behaviours associated with skin lesions at mixing and three weeks post mixing.
87	

88 2. Methods

89 2.1. Animals and housing

90 The study comprised 1,166 pigs on a commercial farm in Ransta, Sweden, between 91 October 2005 and January 2007. Information gathered on all individuals included pen identity, 92 sex, breed, litter identity, and unique pig identification (ear tag or notch number). Single sex 93 (intact males, castrated males, and females) and single breed (703 purebred Yorkshire and 463 94 crossbred Yorkshire x Landrace) groups of 15 were created by mixing 3 pigs from 5 different 95 litters, resulting in 78 groups. Effort was made to standardise within-pen variation in body 96 weight across groups. Animals were weighed 24 hours post-mixing and showed an average live 97 weight of 27.6 kg (SD = 5.6) and an average age of 72 days (SD = 4.3). Pigs were housed in 4.0 x 98 3.2 m partially slatted pens (30% slats, 70% lightly bedded solid flooring) with a floor space 99 allowance of 0.85 m² per pig. Pigs were fed dry pelleted food *ad libitum* from a single space 100 feeder and had constant access to water via a nipple drinker.

101

102 2.2. Skin lesion traits

103 Lesions were counted immediately prior to mixing, and again 24 hours post-mixing by a 104 single observer, and were grouped by location on the body: anterior (head, neck, front legs, and 105 shoulders), central (flanks and back), posterior (rump, hind legs, and tail). The pre-mixing 106 lesion count was subtracted from that taken 24 hours post-mixing for each pig. This served to 107 ensure that only those lesions that occurred as a result of mixing aggression (SL24h) were 108 included in all analyses. Recently received lesions were counted again three weeks post-mixing 109 (89.8 days (SL3wk) [SD = 5.2]). One uninterrupted scratch was classed as a single lesion, 110 regardless of length or severity. A lesion was considered to be recent if it was vivid red in colour 111 or recently scabbed.

112

113 2.3. Behavioural traits

114 Groups were video recorded for 24 hours post-mixing. Time, duration (s), and outcome 115 of reciprocal (RA) and non-reciprocal (NRA) aggression were recorded. Reciprocal aggression 116 was defined as a fight that lasted more than one second where both pigs were involved in 117 pushing, head knocking or biting. Non-reciprocal aggression involved the delivery of these 118 behaviours with no retaliation from the receiver. Non-reciprocal aggression could occur as a 119 unique event independent of a reciprocal fight, as a component of a reciprocal fight, or at the 120 end of a reciprocal fight as the loser retreated. In addition, for each fight, observers recorded the 121 duration of time spent engaged in injurious fighting. This is opposed to behaviour such as 122 pushing, head knocking, or chasing, which were not deemed injurious. These basic data were 123 used to derive quantitative aggressive behavioural traits that were used in the statistical 124 analysis in the current study (Table 1). Three observers used time-lapse video equipment to 125 extract the duration of each behavioural bout to the nearest second. Analysis of three 1-hour 126 samples of data showed a significant degree of inter-observer agreement (r = 0.83, P < 0.001) 127 (Turner et al. 2009).

128

129 2.4. Characteristics of the data

130 Skin lesion and behavioural data were available for all 1,166 animals in 78 groups. 131 Animals were mixed with an average growth rate of 881 g/day over an 86 day (SD = 4) growth 132 period (Yorkshire: 880 g/day [SD = 155]; Yorkshire x Landrace: 881 g/day [SD = 186]). The 133 average weight of pigs at the time of mixing was 27 kg (Yorkshire: 27 kg [SD = 5.1]; Yorkshire x 134 Landrace: 29 kg [SD = 5.4]) and the average weight at the end of the finishing period was 104 kg 135 (Yorkshire: 103 kg [SD = 11.24]; Yorkshire x Landrace: 106 kg [SD = 12.49]). The characteristics 136 of the data for the variables used in the analyses are presented in Table 2. Negative values for 137 skin lesions at 24 hours post mixing are partly due to observer error and partly due to lesions 138 healing between pre and post mixing lesion number counts. Within further analysis of the data, 139 these negative values were set to zero. The lesion numbers and behavioural traits showed

- skewed distributions (Table 2); therefore the data were log transformed (y = *LS* + 1) and the
- 141 transformed values were used in all subsequent analyses.

142 2.5. Statistical Analyses

143 To account for systematic influences on behavioural traits and skin lesions, the effects of 144 breed type (purebred Yorkshire, Yorkshire × Landrace), sex (females, males, and castrates) and 145 experimental batch (pigs were mixed on 14 separate days) were fitted as class variables, and 146 body weight as a covariate in the statistical models. The group effect was modelled by including 147 the pen in which the animals were mixed as random effect. The analysis was carried out using 148 the MIXED procedure of SAS (version 9.1). To predict the individual animal associations and to 149 identify the change in aggression of animals over time, Pearson correlations were obtained 150 between the residuals of all behavioural traits and SL24h with SL3wks. Aggression is often 151 discussed in terms of the individual animal, however pigs are housed in social groups, and the 152 welfare of an individual is likely to be greatly affected by the level of social stability within the 153 group in which it is housed. In order to compare group-level associations between behaviour 154 and lesion numbers, correlations between estimates of pen effects were calculated.

155

156 To further explore the relationship between aggression at mixing and skin lesions for 157 individual animals at two time points, a multiple linear regression model was developed that 158 resulted in the best model to predict lesion numbers from a set of behavioural traits. A series of 159 multiple stepwise regression analyses using the REG procedure of SAS (version 9.1) were 160 performed, in which the estimated residuals for lesion and behavioural traits from the initial 161 mixed models for SL24h and SL3wk were set as response variables, and residuals for all 162 behavioural traits were set as predictors. Behaviour traits explaining significant variance in 163 lesion numbers (P < 0.05), as predicted by the regression analyses, were included in the final 164 model. Many behavioural traits may be correlated among each other; therefore multicollinearity 165 between behavioural variables included in the final model was estimated using variance 166 inflation factors (VIF); however no VIF were above 1.38, suggesting that multicollinearity was 167 not a concern. Using residuals of behavioural traits, the final model produced regression

- 168 coefficients that predicted how various behaviours influenced lesion numbers at both time
- 169 points, independent of systematic effects described above.

171 **3. Results**

172There were large variations among pen group means of SL24h, suggesting that groups173differed significantly in levels of aggression. There was less variation among pen group means174for SL3wk than SL24h. However the averages of all pen group means for SL24h were similar to175SL3wk at the centre or posterior of the body but not for those observed at the anterior area176(Table 3). The distribution of pen group means of skin lesions was approximately normal, as177assessed by the skewness and kurtosis (Table 3), with the exception of posterior SL24h, which178was slightly negatively skewed.

179

180 *3.1. Fixed and random effects on skin lesions*

181 Batch and breed type*sex were included in the mixed models as fixed class effects while body 182 weight at mixing was included as a covariate. Batch effects were statistically significant for 183 almost all lesion traits except for anterior and central SL24h (posterior SL24h: F = 8.59; P < 184 0.001; anterior SL3wk: F = 5.25, P < 0.001; central SL3wk: F = 7.70; P < 0.001; posterior SL3wk: 185 F = 5.72, P < 0.001). Breed type*sex affected anterior and central SL3wk (anterior F = 5.25; P < 0.001). 186 0.001; central F = 3.12; P = 0.014). Cross bred females received significantly fewer anterior and 187 central SL3wk (P < 0.05) than purebred females. Anterior and posterior SL24h showed 188 significant regression coefficients (P < 0.001 and P = 0.046) on body weight at mixing. 189

190 *3.2. Lesion numbers*

The proportions of the phenotypic variance attributed to pen effects were significant (*P*< 0.05) in the range from 4 to 12% and 3 to 21% for skin lesions (on the diagonal of Table 4)
and most behavioural traits, respectively (Table 5).

On the pen group level, lesions across body regions at the same time point were
positively correlated (SL24h: 0.28 to 0.77; *P* < 0.01, SL3wk: 0.65 to 0.75; *P* < 0.001). Between
time points, anterior or central pen group SL24h were positively correlated with anterior or
central SL3wk (0.24 to 0.36; *P* < 0.05). Lesions to the central region of the body were also

198	positively correlated on a pen group level across time points (0.24; $P < 0.05$) (above diagonal,
199	Table 4).

199	Table 4).
200	At the individual animal level, lesions across body regions recorded at the same time
201	point were positively correlated for both SL24h (0.38 to 0.54; $P < 0.001$), and SL3wk (0.50 to
202	0.65; $P < 0.001$). Between these time points, there were significant but small positive
203	correlations between central (0.07; P < 0.05) or posterior (0.07; P < 0.05) SL24h and anterior
204	SL3wk. In contrast, there was a small negative but significant correlation between anterior
205	SL24h and central SL3wk (-0.06; $P < 0.05$) (below diagonal, Table 4).
206	
207	3.3. Correlations between behavioural and lesion traits on group (pen) level
208	Between pen groups correlations of behavioural with lesion traits are presented in
209	Table 5. The aggressive behavioural traits showed mostly significant positive correlations with
210	SL24h (0.23 to 0.61; $P < 0.05$), except for the trait proportion of injurious fights, which was
211	negatively correlated with the posterior region at 24 hours (-0.27; $P < 0.01$). In contrast,
212	significant correlations of behavioural traits with SL3wk were consistently negative (-0.23 to -
213	0.33; $P < 0.05$). Between pen groups, behavioural traits were primarily associated with skin
214	lesions to the anterior regions of the body at 24 hours post-mixing, and to the central region of
215	the body at 3 weeks post mixing. In addition, most significant correlations were found for
216	behavioural traits that were defined as reciprocal aggression, with the exception of total non-
217	reciprocal aggression received (0.24; $P < 0.05$) which positively correlated with the posterior
218	SL24h, and duration of non-reciprocal aggression received, which positively correlated with
219	central (0.23; $P < 0.05$) and posterior (0.23; $P < 0.05$) SL24h (Table 5). A summary of the main
220	correlations found between pen groups is presented in Figure 1.

221

222 3.4. Correlations between behavioural and lesion traits on individual animal level

Under unstable social conditions at mixing, all behavioural traits included in the analysis
showed positive correlations with anterior SL24h (0.13 to 0.56; *P* < 0.001) (Table 6). Except for

225	the behavioural traits proportion of fights won, all other analysed behavioural traits were
226	positively correlated with central SL24h (0.08 to 0.33; $P < 0.01$) but mostly at a lower
227	magnitude than those of anterior lesions. Even lower correlations were calculated between
228	behavioural traits and posterior SL24h (0.06 to 0.22; $P < 0.05$). The direction of these
229	correlations indicates that individuals that are involved in more aggression at mixing received
230	more SL24h, in particular to the anterior body region. A summary of the main correlations
231	found on individual animal level is presented in Figure 2.
232	
233	Many measures of aggressive behaviours at mixing correlated negatively with anterior
234	and central SL3wk but at a lower magnitude than at those found at 24 hours (-0.07 to -0.18; $P <$
235	0.05). The behavioural traits number of RA involved with, the duration of RA and NRA initiated,
236	and the average fight duration, showed the largest negative correlation with central SL3wk. The
237	behavioural traits total NRA received, number of pen mates bullied by, and the proportion of
238	fights with an ambiguous outcome were not associated with the number of anterior or central
239	SL3wk. The duration of NRA received was negatively associated with central but not anterior or
240	posterior SL3wk (Table 6).

241 3.5. Best model for prediction of lesion numbers

242 Of all skin lesion traits, anterior SL24h showed the highest predictability by behavioural 243 traits of aggression ($R^2 = 0.36$) (Table 7). Central SL24h were affected by the highest number of 244 behavioural traits. As found with the residual correlations, the regression model predicted a 245 positive association between behavioural traits of aggression at mixing and SL24h, with the 246 exception of the trait proportion of fights won, which was associated with slightly fewer central 247 (P < 0.001) and posterior (P = 0.015) SL24h. At three weeks, only lesions to the central region of 248 the body could be predicted by behavioural traits of aggression at mixing, however the R^2 value 249 was low. The model predicted a negative association between traits of aggression, with the 250 exception of the duration of NRA received, which was associated with slightly more SL3wk (P < 251 0.001) (Table 7). 252

Almost all behavioural traits included in all prediction models were significantly and positively correlated with each other (0.06 to 0.93; P < 0.05). The proportion of fights won was slightly negatively correlated with the total number of NRA received (-0.10; P < 0.001) and the duration of NRA received (-0.10; P < 0.001). There was no statistically significant correlation between the average duration of RA and NRA involved with and total number of NRA received (Table 8). However, highly correlated behavioural traits were not selected for each prediction model by the stepwise regression analysis so that multicollinearity was not a concern.

260 4. Discussion

261 *4.1. Behaviour and skin lesions on group level*

262 Aggression can be defined at the level of individuals or at a group level. Numbers of 263 lesions have been previously validated as a method of measuring the aggressiveness of 264 individual pigs at mixing (Turner et al., 2006^a) but not as a measure of aggression across entire groups. The current data set was an ideal opportunity to study the group level basis to skin 265 266 lesions. The direction of the correlations indicates that increased group level involvement in 267 reciprocal aggression, involving more pen mates, resulted in higher average anterior SL24h. 268 Pen level correlations between aggression and lesions at mixing suggest that skin lesions are a 269 useful measure of reciprocal aggression at mixing within a group, but only for anterior regions, 270 which have previously been linked to reciprocal aggression in individuals (Turner et al., 2008).

271

At the group level, behavioural variables that were positively associated with anterior SL24h were negatively associated with SL3wk; however this relationship was mainly significant for the central body region only. The vigorous, reciprocal aggression that accounts for many anterior lesions at mixing does not often occur in stable groups. Instead, aggression in stable groups is primarily seen in the form of head knocks and bites, often over a resource (Bolhuis et al., 2005), which could explain why a relationship was mainly found for the central region of the body.

279

Very few traits related to non-reciprocal aggression were associated with skin lesions on a group level, suggesting that skin lesions are not a useful measure of the amount of nonreciprocal aggression a group has been involved in. The majority of behaviour at mixing related to anterior SL24h on a group level, whereas lesions from non-reciprocal aggression are more likely to be inflicted to the centre and posterior region of the body as the recipient is often turned away from the attacker, as it attempts to escape. This is reflected in the group level

correlations, as the number and duration of non-reciprocal aggression received were positivelycorrelated with central and posterior SL24h.

288

289 If increased aggression at mixing increases social stability, it would be expected that 290 SL3wks relates to the quality of aggression performed. For example if many fights within a 291 group have definitive outcomes and are rarely repeated, the individuals involved might be more 292 certain of their social position, resulting in a more stable hierarchy. There was little evidence of 293 this in the current study, as skin lesions at SL3wk did not relate to the proportion of repeated 294 fights, fight intensity or ambiguous outcomes at mixing. Groups with a high proportion of 295 successful fights (proportion of fights won) tended to have low SL3wks. Correlations between 296 behavioural traits (results not presented) indicate that groups with a high proportion of fights 297 success also had a large number of unambiguous, intense fights. It is possible that social 298 relationships are influenced by a combination of traits related to fight quality although 299 individual traits do not correlate with skin lesions when considered in isolation.

300

301 Negative correlations between reciprocal aggression at mixing and SL3wk offer some 302 support for the hypothesis that increased initial reciprocal aggression on a group level reduces 303 aggression in the long term. Reduced aggression at three weeks could indicate a more stable 304 social hierarchy. If this was the case, it could be that certain fighting experiences, in particular 305 those related to reciprocal aggression, lead to less ambiguity over hierarchy positions, resulting 306 in fewer conflicts over resources.

307

308 *4.2. Behaviour and skin lesions on individual animal level*

At the individual animal level, residual correlations between aggressive behavioural variables and SL24h indicate that an increase in almost all measures of aggression at mixing results in more skin lesions across all three body regions. Lesions to the anterior body region have previously been shown to be associated with reciprocal fighting, and the posterior and

central regions of the body associated with receipt of non-reciprocal aggression (Turner et al.,
2006^a).

315

316 A multiple regression model was developed in the current study in order to further 317 dissect the relationship between various aggressive strategies and the receipt of lesion numbers. As predicted by residual correlations, a general increase in aggression - for example 318 319 long reciprocal fights - predicted higher lesions across all body regions 24h after mixing. Fight 320 success (proportion of fights won) predicted fewer SL24h to central and posterior body regions 321 when included in the model. This is likely to be because unsuccessful pigs receive more non-322 reciprocal aggression, resulting in slightly more lesions than their successful pen mates. 323 Although the receipt of non-reciprocal aggression was weakly negatively correlated with fight 324 success, the number and duration of non-reciprocal aggression received were positively 325 associated with other measures of aggression, including the number of reciprocal interactions 326 involved in and the number of pen mates bullied. Combined, these results suggest that while 327 increased aggression of all descriptions increases the risk of receiving skin lesions, within this 328 more aggressive cohort, the animals with a high fight success rate receive fewer skin lesions 329 than their less successful but aggressive pen mates. Animals that avoid involvement in 330 aggression altogether receive the lowest skin lesions at this time.

331

332 Correlations between aggressive behaviour at mixing and skin lesions recorded three 333 weeks post-mixing were lower than those calculated for skin lesions 24 hours post mixing. As 334 described earlier, aggression at mixing and in established groups tends to differ in its form and 335 motivation, lacking the intense reciprocal aggression that constitutes the majority of aggressive 336 behaviour at mixing (Bolhuis et al., 2005; Fraser, 1984). A strong correlation between the two 337 traits was therefore not to be expected. Despite this, many measures of aggression were 338 negatively correlated with SL3wk, indicating that the more aggression an individual is involved 339 in at mixing, the fewer lesions it receives under stable social conditions, particularly to the

anterior and central regions of the body. As found for associations with SL24h, behavioural
correlations with the posterior region of the body 3 weeks post mixing were lower than those
obtained for the anterior and central regions, resulting in extremely low correlations for this
body region at that time point. This pattern indicates that posterior lesions are not as
informative as lesions to the anterior body region. This may be because lesions are typically
inflicted to the rear of the body during the receipt of aggression, and are therefore not a
reflection of an individual's own behaviour, but rather that of its pen mates.

347

348 Behavioural traits accounted for very little variation in SL3wk, as predicted by the 349 multiple regression models. The models predicted that the proportion of fights won at mixing 350 accounted for most of the variation in central SL3wk, with the most successful animals receiving 351 the fewest lesions at this time. This implies that skin lesions in stable groups are chiefly related 352 to dominance, as it is likely that the most successful animals at mixing go on to achieve the 353 highest-ranking positions in stable groups. As reflected by the correlations on individual animal 354 level, the model predicted that an increase in the duration of non-reciprocal attacks received at 355 mixing was associated with slightly increased central SL3wk. The duration of non-reciprocal 356 attacks received was positively correlated with number and duration of non-reciprocal attacks 357 initiated, and the duration of reciprocal aggression involved in. Therefore the animals that 358 received much aggression were also actively involved in aggression. This finding reflects those 359 found in a previous study involving a different population (Turner et al., 2006^a). These results 360 demonstrate that non-reciprocal aggression at mixing is not received by the unaggressive 361 individuals in a group, but rather aggressive but unsuccessful animals, possibly as a means to 362 reinforce a fight outcome.

363

The results from the correlations and mixed model predictions indicate that while high fight success at mixing results in the lowest stable lesions, involvement in aggression at mixing, even when unsuccessful, leads to fewer lesions in the stable group than animals which avoid

367 aggression at mixing altogether. The simplest explanation is that pigs which avoid aggression 368 are simply the most subordinate individuals; however this does not explain the observations 369 made on a pen group level. It could be that simply engaging in aggression leads to less 370 ambiguity over social standing, resulting in fewer challenges to hierarchy positions. 371 Alternatively, it is possible that experience in physical aggression is necessary in learning to convey both dominant and submissive behaviours. Studies involving repeated mixing of pigs 372 373 (Coutellier et al., 2007; Giersing & Andersson, 1998) have shown that the amount of aggression 374 displayed reduces with increased mixing, whereas D'Eath (2005) found that early socialising of 375 piglets leads to faster hierarchy formation. Frischknecht et al., (1982) demonstrated how mice 376 that had experience of being defeated displayed significantly more submissive behaviours than 377 those that had never experienced agonistic interactions. In the present study, pen group lesions 378 at three weeks were negatively associated with traits related to reciprocal fighting. If important 379 social skills are learned via fighting experience, this may explain why we see more social 380 stability in groups that involved more reciprocal aggression between more group members.

381

382 Social instability in the form of long-term aggression may be caused by several factors. It is 383 possible that groups with increased aggression 3 weeks post mixing have a less stable hierarchy 384 than other groups, and therefore frequent physical aggression is required in order to re-385 establish or maintain dominance relationships. Alternatively, it may be that some individuals 386 fail to recognise dominance relationships, or continue to fight at inappropriate times. As no 387 behavioural data were available three weeks post-mixing, the stability of dominance 388 relationships could not be assessed. As such, it is impossible to deduce whether long-term social 389 instability was the result of unstable dominance relationships or socially dysfunctional 390 individuals within a group.

391

392 The results of these analyses confirm that skin lesions are a useful alternative measure of393 aggressiveness displayed by individual pigs in the first 24 hours post mixing. While increased

- aggression at mixing leads to more injuries at first, it may be beneficial for the individual in thelong term, even if the animal is not successful at fighting.
- 396

397 4.3. Lesion correlations

Lesions across body regions at the same time point were positively correlated meaning that animals that received high lesions to one region of the body were likely to receive lesions to other body regions. This is in accordance with the findings from the behavioural data in which animals that engage in a high amount of aggression of any form receive many lesions to all body regions.

403

Individuals that received high central and posterior SL24h were also somewhat likely to 404 405 receive high anterior and central SL3wk, although the correlations were of a very low 406 magnitude. These results appear to conflict with the direction of the correlations between 407 aggression at mixing and SL3wk. Although this seems counterintuitive at first, the correlations 408 between skin lesion traits are low, and contradicting correlations can occur due to the various 409 effects that influence the correlations. It can be hypothesised that the contradictory relationship 410 between aggressive behaviour and lesions at different time points may contribute to the 411 reduced correlations between lesions at mixing and the stable group.

412

Genetic correlations using the same population showed a moderate to strong positive
correlation between SL24h and SL3wk (Turner, 2009); however the same study also found
negative residual correlations between these traits. This relationship was also observed on a
group level, although the correlations were of a higher magnitude than those observed for
individuals.

Running head: Long-term Social Stability

5. Conclusions

Research into reducing aggression via a combination of genetic and management strategies are on-going. Phenotypic correlations such as those explored in the present study offer some evidence that within groups of mixed aggression levels, increased reciprocal aggression may be beneficial to long term group dynamics. It may prove challenging to identify any single management strategy that will simultaneously reduce both mixing-induced aggression and on-going chronic aggression. In contrast, genetic correlations (Turner et al., 2009) and experiments in which animals were grouped according to aggressive personalities (Erhard et al., 1997) support the theory that reducing the level of aggression displayed by individuals may result in reduced long term aggression. The environment (O'Connell & Beattie, 1999), group size (Andersen et al, 2004; Hemsworth et al., 2014), genetics (Canario et al., 2012; Turner et al., 2006^b; Turner et al., 2009), early life experience (D'Eath, 2005) and prenatal stress (Jarvis et al., 2006) have all been shown to affect social aggression in pigs. Further work is clearly required to disentangle these factors in order to better predict the possible consequences on aggression. In terms of genetic strategies to control aggression in pigs, this study raises the interesting question that selection for reduced aggression at mixing could result in increased levels of chronic aggression. Further studies should seek to calculate the genetic correlation between metrics of aggression at mixing and then during the stable state to uncover the genetic architecture of these two distinct traits.

The current study cannot address the question of whether skin lesions at three weeks not only relate to aggression, but that increased aggression in stable groups translates to poor welfare. Published studies examining the long term effects of social stress (usually by measuring cortisol or immune responses) have produced conflicting results (Blanchard et al., 1993; Mendl et al., 1992; Tuchscherer et al., 1998; Ekkel et al., 1997). In the present study, SL3wk were similar in number to SL24h for central and posterior lesions, indicating a comparable level of aggression at the two time points. It could be argued that dominance relationships are a part of the pig's

natural behaviour and therefore individuals should be equipped to deal with the stress that arises from these encounters. However in space-restricted pens animals are often unable to adequately avoid persistent attacks (Fraser et al., 1995).

Tables

Table 1. Definitions of skin lesion traits and behavioural traits used in the analyses

Trait	Description
Skin lesions at 24 hours (SL24h)	Number of skin lesions counted 24 hours post mixing
Skin lesions at three weeks (SL3wk)	Number of skin lesions counted 3 weeks post mixing (stable groups)
Reciprocal aggression (RA)	A fight lasting >1s in which the recipient of the attack retaliated
Non-reciprocal aggression (NRA)	An attack in which the recipient did not retaliate
RA involved with	Total number of reciprocal fights the focal pig was involved with, regardless of which pig initiated the attack
NRA involved with	Total number of non-reciprocal fights the focal pig was involved with, regardless of which pig initiated the attack
Total RA initiated/received	The total number of times an individual initiated or was the recipient of an attack which was reciprocated
Total NRA initiated/received	The total number of times an individual initiated or was the recipient of an attack which was not-reciprocated
Number of pen mates focal pig attacked (RA)	The number of pen mates the focal pig attacked in which the attack was reciprocated
Number of pigs attacked by (RA)	The number of pen mates the focal pig was attacked by which the focal pig retaliated against
Number of pen mates focal pig bullied	The number of pen mates the focal pig attacked which did not reciprocate
Number of pen mates bullied by	The number of pen mates the focal pig was attacked by which it did not reciprocate against

Long-term	Social	Stability
-----------	--------	-----------

Trait	Description
Pen mates involved with	Total number of pen mates with which the focal pig had any aggressive interactions
Average duration RA & NRA involved (s)	Average duration of all aggressive encounters in which the focal pig was involved
Duration of RA initiated (s)	Duration of time spent in RA in which the focal pig was the initiator
Duration of RA received (s)	Duration of time spent in RA in which the focal pig was the recipient of the attack
Duration of NRA initiated (s)	Duration of time spent in NRA in which the focal pig was the initiator
Duration of NRA received (s)	Duration of time spent in NRA in which the focal pig was the recipient of the attack
Proportion of fights won	Proportion of all reciprocal fights which the focal pig won
Proportion of repeated fights	Proportion of all pen mates fought with which the focal pig had more than one aggressive interaction
Proportion with ambiguous outcome	Proportion of reciprocal fights the focal pig was involved with in which the winner cou not be determined
Proportion injurious RA involved with	Proportion of time the focal pig spent in reciprocal fights engaged in what was deemed to be injurious fighting

^a For each body region, cumulative R² values represent the proportion of the total

phenotypic variance explained by the corresponding predictor in addition to predictors

listed in previous rows of the table.

Running head: Long-term Social Stability

1 Table 8. Residual correlations between estimates of aggressive behaviours included in final models, as presented in Table 7

	Trait	b	С	d	е	f	g	h
