Abstract

This paper presents a Late-Holocene chironomid-inferred July-air temperature record from a core obtained from Lake Uddelermeer in the Netherlands. A core interval, which dates from 2500 to 400 cal. yr. BP, was analysed at multi-decadal resolution for organic content, pollen, spores and NPPs (Non Pollen Palynomorphs), and chironomid head capsules. These proxies indicate that, from 2500 to 1140 cal. yr. BP, the lake was mesotrophic and sustained a *Littorellion,* while the chironomid assemblage was dominated by littoral species associated with macrophytes. At 1140 cal. yr. BP a shift in the lake ecology occurred from low-nutrient to high-nutrient conditions dominated by algae. This shift might be linked to a concurrent increase in human impact and is reflected in the chironomid assemblage by increases in eurytopic taxa, which are resistant to disturbances. Shifts in the chironomid record between 2500 and 1140 cal. yr. BP do not coincide with changes in lake ecology and are presumably driven by climate change. Using a Norwegian-Swiss calibration dataset as a modern analogue, we produced a chironomid-inferred temperature (C-IT) reconstruction. This reconstruction compares well to other regional temperature reconstructions in timing and duration with a Roman Warm period between 2240-1760 cal. yr. BP, a Dark Age Cold Period starting at 1760 cal. yr. BP and the Medieval Climate Anomaly beginning at 1280 cal. yr. BP. The C-IT record indicates a temperature drop of 1.5°C from the Roman Warm Period to the Dark Age Cold Period. Findings improve knowledge of the first millennium AD in NW Europe, which was characterised by changes in landscape, vegetation, society and climate.

Keywords

first millennium AD; non-biting midges; July air temperature; Dark Age Cold Period; Roman Warm Period; North-western Europe

1 Introduction

Many studies have shown that past climate fluctuations might be temporally linked to cultural shifts (Tinner *et al.* 2003; Büntgen *et al.* 2011; McCormick *et al.* 2012a; Büntgen *et al.* 2016). During the first millennium AD two large cultural transitions occurred in NW Europe: the decline of the Roman Empire and the later transition to medieval kingdoms. Recent studies (e.g. Büntgen *et al.* 2016b; Helama *et al.* 2017a; Helama *et al.* 2017b) have shown that climate in NW Europe during the first millennium was not as stable as previously assumed or as

evidenced from global climate reconstructions (Rasmussen *et al.* 2006; Vinther *et al.* 2006; Wanner *et al.* 2008). Riechelmann and Gouw-Bouman (2019) indicate the presence of a Roman Warm Period (RWP; 1950-1700 cal. yr. BP), a Dark Age Cold Period (DACP; 1700-1250 cal. yr. BP) and a Medieval Warm Period or Medieval Climate Optimum (MCA; 1250-950 cal. yr. BP) in NW Europe (table 1). Other climate reconstructions from the Northern Hemisphere also demonstrate the occurrence of significant climatic shifts during this time interval (e.g. Larsen *et al.* 2008; Ljungqvist 2010; Wanner *et al.* 2011; Gräslund and Price 2012; McCormick *et al.* 2012b; Büntgen *et al.* 2016b; Toohey *et al.* 2016; Helama *et al.* 2017a). The identification of similar warm and cold periods in numerous proxy records throughout NW Europe indicates a regional climate trend (Helama *et al.* 2017a; Riechelmann and Gouw-Bouman 2019).

Following the collapse of the Roman Empire a decrease in population density, from approximately 1680-1450 cal. yr. BP (AD 270 to AD 500), was seen in the Netherlands, this time period is also known as the Migration Period. This was followed by an exponential population growth from 1350 cal. yr. BP (AD 600) onward when the medieval kingdoms emerged (Pierik and van Lanen 2017; Groenewoudt and van Lanen 2018; Pierik *et al.* 2018) (table 1). Not only do these cultural shifts occur contemporaneously with climatic changes, they also are concurrent with large-scale landscape and vegetation changes in the Netherlands (Jansma *et al.* 2014; Pierik 2017). In the Rhine-Meuse delta flooding frequency and intensity increased between 1700 cal. yr. BP and 1100 cal. yr. BP and multiple avulsions are placed within this time frame (Stouthamer and Berendsen 2000; Erkens 2009; Toonen 2013; Cohen *et al.* 2016; Pierik *et al.* 2017). In the Dutch coastal area increased storm surges are observed from 1350 cal. yr. BP onward (Knol 1993; Vos and Van Heeringen 1997; Pierik *et al.* 2016). Contrastingly, a decrease in aeolian activity is visible during the Roman period (1950-1550 cal. yr. BP) in the Pleistocene cover-sand areas and an increase in driftsand activity took place at the end of the first millennium around 1050 cal. yr. BP (Pierik *et al.* 2018). Vegetation development during the first millennium AD is characterised by a reforestation phase between 1850 cal. yr. BP and 1250 cal. yr. BP. Although timing and magnitude vary, this reforestation trend is recognised at most palynological study sites in the Netherlands and neighbouring Germany (e.g. Teunissen 1990; Bunnik 1999; Kalis *et al.* 2008; Litt *et al.* 2009; Dörfler *et al.* 2012).

Although all climate, landscape, vegetation and population changes during the first millennium AD are concurrent and some relation among them seems indisputable, the exact influence of each of these factors remains unknown. It is therefore essential to obtain detailed and well-dated evidence of these changes to disentangle the cause and effect of human impact, climate, landscape and vegetation change during the first millennium AD.

Yet, detailed climate data from the Netherlands for the first millennium AD are at present not available. This is probably due to the scarcity of archives suitable to study for this important time interval. Pristine natural archives such as peat bogs and lake fills are often no longer present due to peat excavation, artificial drainage and other human disturbances. Lake Uddelermeer, located in a cover-sand area in the central part of the Netherlands, is a unique site as it contains an undisturbed sediment profile covering the last ca. 14,000 years (Engels *et al.* 2016).

Chironomids, or non-biting midges, are an excellent proxy for the reconstruction of past summer temperatures because they have a short life cycle and are sensitive to changes in temperature (Brooks *et al.* 2007; Telford and Birks 2011; van Asch 2012; Heiri *et al.* 2014). They have mainly been used to study Lateglacial temperature variability but have been proven to be good proxy for Holocene temperatures as well (Axford *et al.* 2009; Millet *et al.* 2009; Brooks *et al.* 2012; Nazarova *et al.* 2013). However, as a result of human interference in the environment, chironomid-inferred temperature reconstructions for the Late Holocene can be problematic. Even small-scale human impact such as Prehistoric farming has been shown to impact chironomid communities and distort the climate signal (Taylor *et al.* 2013; Taylor *et al.* 2017a; Taylor *et al.* 2017b). Therefore, a multi proxy approach is recommended as a method for Holocene climate reconstructions, to infer possible human impact on

the record, and to disentangle the effects of natural processes such as climate change from anthropogenic impacts on the landscape (McKeown and Potito 2016; Taylor *et al.* 2018).

The aims of this study are fourfold: (1) to present the first chironomid record from the Netherlands covering the first millennium AD on a multi-decadal scale, (2) to determine, using the sedimentological, palynological and chironomid records, to what extent human impact influenced the lake ecology and whether temperature is the main environmental driver of changes in the chironomid assemblage, (3) to assess whether absolute chironomid-inferred summer-temperature values are realistic and, (4) to assess whether the chironomid-inferred temperature reconstruction shows evidence for temperature change during known phases of changing climate.

2 Area description

Lake Uddelermeer is a pingo remnant located on the Veluwe (52º14'48''N; 5º45'40''E; 24-27 m a.s.l.) (Fig. 1). The pingo remnant is situated at the head of a periglacial valley, in the cover-sand area between the ice pushed ridges of Ermelo (max. elevation ca. 50 m a.s.l.) and Apeldoorn (max. elevation ca. 100 m a.s.l.) (Fig. 1) and in the subsurface an impermeable clay layer is present. These boundary conditions are typical for the occurrence of pingos in the Netherlands due to the presence of a ground water gradient and/or pressure. This is evidenced by the presence of another pingo remnant in this area: Lake Bleekemeer, which does not contain a complete Late Holocene lake infill due to peat cutting (Polak 1959).

Lake Uddelermeer is oval shaped, 200-300 metres in diameter and has a current maximum water depth of 1.3 metres (Engels *et al.* 2016). The total lake sediment infill reaches a maximum depth of 15.6 metres of which 12.9 metres covers the Holocene. The lake is fed by groundwater and a small brook is draining the south-side of the lake (Staverdense or Leuvenumse beek). The area directly surrounding the lake is slightly elevated, limiting inflow of surface water runoff into the lake (Fig. 1). The lake is currently eutrophic and directly surrounding the lake is an alder carr and a fringe of wetlands with reeds. The regional vegetation consists mainly of mixed oak and birch forest, grasslands and agricultural fields. Average July temperature for the period 1901-2017 in de Bilt (ca. 50 km SW of Lake Uddelermeer) is 16.95 °C (1901-1950 = 16.4 °C) (Royal Netherlands Meteorological Institute; www.knmi.nl)

Archaeological finds in the vicinity of the lake indicate the presence of human activities from the Middle Mesolithic onward (Groenewoudt *et al.* 2006). Neolithic (7250-3950 cal. yr. BP; 5300-2000 BC) burial mounds from the Trechterbeker culture (5350-4850 cal. yr. BP; 3400-2900 BC) are present at a distance of ca. 500 metres from the lake. There is also evidence of charcoal production in the direct surroundings of the lake during the 9th and 10th centuries (Kraanen and Pape 1965). Situated next to the lake is a medieval structure dating to the late 10th century (Heidinga 1987). This so-called Huneschans is a medieval ring fort (*ringwalburg*) which is approximately 100 metres in diameter, and is surrounded by a circular earthen wall and an outer ditch. The earthen wall is not fully circular, with an opening present on the side of the lake. The wall currently does not reach the lake itself, indicating that the water level of the lake was up to 1.7 metres higher during the time of construction of the fort (10th century; Engels *et al.* 2016). Earlier palynological studies by Engels *et al.* (2016), Bohncke (1999), Sohl (1983) and Polak (1959) show the first evidence of human activities at the beginning of the Subboreal at 5000 cal. yr. BP, which is concurrent with the construction of the burial mounds encountered in the area (Groenewoudt *et al.* 2006). Pollen records covering this period show an increase of *Corylus* and *Pteridium* indicating open forests as well as the occurrence of human indicators such as *Plantago* and Cerealia. From 4000 cal. yr. BP onward the human-induced deforestation trend, which initiated around 5000 cal. yr. BP, increased.

Human presence in the form of agriculture is continuous from 3450 cal. yr. BP onwards as indicated by a continuous Cerealia pollen curve (Engels *et al.* 2016).

Figure 1 around here

3 Methods

A 16-metre-long sediment core (ø 6 cm) was collected from the deepest part of the lake in April-May 2012 using a piston corer operated from an UWITEC coring platform. The lake infill was cored in 3 metre sections using overlapping cores, and coring tubes were subsequently cut to 1 metre intervals in the field to enable transport. In the lab the core segments were cut in half lengthwise, where one part was completely preserved and the other half was used for sampling. A continuous 1 cm sampling was carried out for Loss on Ignition (LOI) to determine organic content following the protocol by Heiri *et al.* (2001). A total of 437 samples of ca. 1 cm^3 were dried at 105º C for 12 hours and subsequently placed in an oven at 550º for 4 hours. The samples were weighed before and after each step, obtaining both the moisture as well as the organic carbon content. Pollen samples of 0.7 cm^3 were collected using a 5 cm sampling resolution for the section 100-500 cm below the sediment/water interface to obtain a high-resolution vegetation record capable of detecting the fast vegetation changes during the first millennium AD in detail. In total 70 pollen samples were prepared following the method described in Faegri and Iversen (1989) and Moore *et al.* (1991). Identification of pollen, spores and Non Pollen Palynomorphs (NPPs) was executed using a Zeiss microscope with 400x magnification and pollen and spores were identified using Beug (2004), Moore *et al.* (1991) and Punt (1976; 1980; 1981; 1984; 1988; 1991; 1995; 2003). NPPs such as algal remains and (fungal) spores were identified using van Geel *et al.* (2003), van Geel (1978) and van Geel (1972). An upland pollen sum of 300 pollen grains, excluding alder and grasses, was counted per sample. This pollen sum differs from the one used in Engels *et al.* (2016), as grasses and alder pollen are excluded from the pollen sum in this study since reed land (included in the Poaceae curve) and alder carr occur locally.

The sediment record was previously analysed for chironomids at a coarse temporal resolution by Engels *et al.* (2016). For the current research, additional chironomid samples were analysed to increase the temporal resolution from the section 200-500 cm below the sediment surface to detect the short climatic phases during the first millennium AD. From this section, a total of 31 samples were analysed at 5-25 cm resolution. In order to get a better overview of preceding and subsequent trends, the lower temporal resolution results from Engels *et al.* (2016) from the sections 100-200 cm and 500-550 cm are also included in this study. Sample preparation for these samples is described in Engels *et al.* (2016). The additional samples (14 in total, sample size: 0.335 cm^3) were added to a 5% KOH solution, heated to 90°C for 1 hour, and then passed successively through 212 µm and 90 µm mesh sieves. Chironomid head capsules were manually picked out of the sieving residues using a Bogorov sorting tray under a dissection microscope (40x magnification) and subsequently mounted on permanent slides in Euparal©. Chironomid head capsules were identified under a compound microscope (magnification 400x) following keys by Wiederholm (1983), Moller Pillot (1984a); Moller Pillot (1984b), Rieradevall and Brooks (2001) and Brooks *et al.* (2007). Information on chironomid ecology was derived from a.o: Moller Pillot and Buskens (1990), Brooks *et al.* (2007), Moller Pillot and Klink (2009), Engels and Cwynar (2011), Luoto (2011), Engels *et al.* (2012), Moller Pillot (2013) and Potito *et al.* (2014). The number of identified chironomid head capsules varied between 65 and 146 per sample. A Principal Component Analysis (PCA) with Square-root-transformed percentage-abundance data of the chironomid taxa was executed using the program C2 (Juggins, 2003).

The chironomid assemblages were subsequently used to quantitatively reconstruct mean July air temperatures. This reconstruction was executed using a chironomid-temperature inference model, which is based on a modern calibration dataset that consists of 274 lakes from Norway and the Alpine regions (Heiri *et al.* 2011).

This chironomid-climate calibration dataset spans a July air temperature range from 3.5 to 18.4°C (Heiri *et al.* 2011). For the model, a two component weighted averaging partial least-squares (WA-PLS) regression was used since this approach produced inference models with the lowest error (Heiri *et al.* 2011). The selected model had a bootstrapped root mean square error of prediction of 1.40°C after outlier deletion (Heiri *et al.* 2011). Bootstrapping was used to estimate the sample-specific errors for the fossil samples.

We evaluated the robustness of the chironomid-inferred July air temperature reconstruction by calculating the closest modern analogue of the fossil samples, as well as the goodness-of-fit to temperature (Birks *et al.* 1990) and the cumulative percentage of rare or absent species from the calibration dataset. The closest modern analogue was assessed based on squared Chi-squared distances using the program C2 (Juggins, 2003). Fossil samples with a distance to the closest analogue larger than the 2nd and 5th percentile of the distances of the modern samples in the calibration dataset were classified as having 'no close' and 'no good' analogue, respectively. Goodness-of-fit to temperature was assessed using a Canonical Correspondence Analysis (CCA) of the modern samples with temperature as the only constraining variable. In this analysis, the fossil samples were added passively. Fossil samples with a residual distance exceeding the 90th and 95th percentiles of the residual distances of the modern samples were identified as having a 'poor' and 'very' poor fit with temperature, respectively. The CCA was calculated using CANOCO for Windows version 4.51 (ter Braak and Šmilauer 2012). Both the pollen percentage diagram as well as the chironomid abundance diagram where produced using TILIA (Grimm 1991-2015). Zonation of the pollen and chironomid diagrams differs from Engels *et al.* (2016) as a result of the increased sampling resolution in this study and was established visually. The pollen diagram was subdivided into zones based on variations in the main pollen taxa and zonal boundaries were verified using CONISS (Grimm 1991-2015). The chronology of the core is based on the age-depth model of Engels *et al.* (2016), which is based on 26 samples for ^{210}Pb measurement for the top 65 cm of the core and 13 AMS radiocarbon samples (excluding 3 outliers) throughout the rest of the core. The age-depth model was produced using Bayesian modelling as included in Oxcal (Bronk Ramsey 2009). The radiocarbon samples contained terrestrial macrofossils, wood fragments and charred material such as grass epidermis and charcoal (Engels *et al.* 2016). The age-depth chronology of the core section discussed in this paper (100 to 550 cm sediment depth) is supported by six radiocarbon dates (excluding 1 outlier) and constrained at the top by the ^{210}Pb dates (Fig. 2). The resultant age-depth model gives well-constrained age estimates and a nearly linear sedimentation rate, confirming the reliability of the six dates included. All ages provided in this paper are rounded to the nearest five year interval and are expressed in cal. yr. BP unless explicitly stated otherwise.

Figure 2 around here

4 Results and interpretation

4.1 Sedimentology

The investigated core interval consists entirely of gyttja (Fig. 3). The bottom part, 550 cm up to 220 cm depth, consists of brown gyttja. From 220 cm upward this slowly shifts to a more greenish gyttja, indicating a larger component of algae. The LOI-record follows this trend with values around 60% from 550 cm up to 460 cm depth, followed by a more organic-rich sequence with values upward of 70%, until 270 cm depth. From 270 cm to 220 cm LOI values vary around 60% again and drop sharply to only 20% at 220 cm, which corresponds with the shift to a higher algal content. The drop in organic content is probably the result of increased silica production (a.o. diatom production) in the lake. Alternatively, an increase in sand input through increased aeolian activity could explain this decrease. However, no visible sand grains were found during visual core inspection, suggesting

that an increase of silica production is the most likely reason for the observed decrease in LOI values. From 220 cm upwards, LOI values gradually increase, reaching 60% at 140 cm after which they gradually decrease to 30%.

Figure 3 around here

4.2 Palynology

Zone Pa (500-382 cm depth; 2420-1730 cal. yr. BP) is characterised by high values of Arboreal Pollen (AP) and heather (Fig. 3). High values of deciduous tree species such as *Quercus, Fagus* and the occurrence of *Carpinus*, *Tilia* and *Ulmus* suggest the presence of a mixed-deciduous forest in the vicinity of the lake. *Fraxinus*, *Corylus* and *Betula* probably grew at the forest edge or in small bushes and thickets. Human presence in the area around Lake Uddelermeer is indicated by high percentages of upland herbs with typical anthropogenic indicators such as *Rumex*, *Plantago lanceolata* and *Artemisia vulgaris* and the presence of pollen grains of Cerealia, indicating arable fields nearby. Heathlands are also present in the area, as evidenced from the large proportion of *Calluna*. The lake was probably surrounded by an alder carr with grasslands in the vicinity and alder carr was likely also present in the brook valley of the Leuvenumse beek to the south. The high values of both *Isoëtes* and *Littorella* suggest relatively nutrient-poor and clear-water conditions in the lake itself. *Isoëtes* and *Littorella* are both adapted to low nutrient conditions, by a symbiosis with mycorrhiza to enable carbon uptake from the sediment, and a slow growth rate, and are therefore typical inhabitants of oligotrophic lakes, where they most often grow in water of 0 to 2 metres deep (Sand-Jensen 1978; Weeda *et al.* 1988; Engels *et al.* 2018). *Isoëtes* can grow in water up to 4.5 metres deep and prefers a sandy subsoil (Sand-Jensen 1978; Farmer and Spence 1986). Most likely *Littorella* also grew at the shore of the lake, since this species only flowers when it is not submerged (Weeda *et al.* 1988). Together, both species form the *Littorellion* which is a relatively stress tolerant plant community (Rørslett and Brettum 1989). However, when nutrient availability increases, macrophytes and algae can more easily inhabit the lake. As a result *Littorella* and *Isoëtes* receive less light and the *Littorellion* is fast replaced by reedlands (Weeda *et al.* 2000). The nutrient-poor conditions in the lake are confirmed by the presence of *Nymphaea alba* which probably grew in the deeper parts of the lake. The algae *Botryococcus,* which was present in Lake Uddelermeer continuously since the Late Glacial (Engels et al., 2016), can occur in a wide range of environments but has a preference for oligotrophic lakes (Padisák *et al.* 1998). Engels *et al.* (2016) reconstructed a water depth of around 2.5-3 metres during this time period, which is in line with the 2 metres suggested by the aquatic taxa present in the lake. Spores of *Glomus,* a fungus often found in soils, is present in the upper part of this zone. The occurrence of *Glomus* spores in lake sediments is indicative of soil erosion (van Geel *et al.* 2003).

Zone Pb (382-255 cm depth; 1730-1270 cal. yr. BP) is characterised by increasing values of AP and decreasing values of heather and to a lesser extent upland herbs (Fig. 3). The increase in AP can be mainly attributed to *Quercus, Fagus* and *Carpinus*. Anthropogenic indicators such as upland herbs (*Rumex, Plantago lanceolata* and *Artemisia vulgaris)* and Cerealia decrease in this zone. Pollen grains of Cerealia are still present, albeit in low abundances, and occasionally *Secale cereale* is found. These changes in the pollen assemblage suggest that deciduous forests have expanded at the expense of heathlands and arable lands. We also observe an increase of *Alnus* and a decrease of Poaceae suggesting that the local alder carrs are also expanding. The basal cells of Nymphaeaceae (NPP type HdV-127) are decreasing sharply during this zone, although *Nymphaea alba* is still present in the pollen record. *Nuphar lutea,* however, is nearly absent from zone Pb. The continued presence of *Isoëtes* and *Littorella* suggests continued nutrient-poor and clear-water conditions in the lake. Pollen-percentage values of *Littorella* however, are slightly decreasing. The occurrence of *Typha latifolia* pollen during this zone indicates the presence of reed lands at the lake fringe which possibly partly replaced the *Littorellion*.

Zone Pc (255-220 cm depth; 1270-1140 cal. yr. BP) is a transitional zone which shows decreasing AP values and increasing values of Cerealia and heather (Fig. 3). A mixed deciduous forest is still present but arable lands and heathlands are fast expanding. This is also visible from the increase in anthropogenic indicators such as Cerealia*, Plantago lanceolata,* a continuous curve of *Secale cereale* pollen, and an increase in the occurrences of charcoal. The alder carr decreases in size and becomes more open with more grass or reed land, as seen from the decreasing abundance of *Alnus* and increasing Poaceae values and the presence of *Typha angustifolia. Isoëtes* and *Littorella* are still present in the pollen record indicating relatively stable conditions in the lake through zone Pa, Pb and Pc. The water body must have remained clear enough throughout pollen zones Pa, Pb and Pc to sustain the *Littorellion*.

Zone Pd (220-100 cm depth; 1140-320 cal. yr. BP) is characterised by further decreasing values of AP and heather and increasing values of upland herbs and Cerealia (Fig. 3). The start of this zone is simultaneous with the shift to green algal gyttja indicating a higher production in the lake. This is also evident from the rapidly increasing values of algal remains such as *Scenedesmus* or *Pediastrum*. An increase in various algal species from ca. 25% to over 100% occurs at 185 cm depth (1030 cal. yr. BP). In our record the abrupt increase in algal remains coincides with increasing values of fungal spores of coprophilous fungi such as *Sporormiella, Podospora* and *Cercophora* which are indicative for the presence of dung. The increase in algae also coincides with the habitation phase of the Huneschans (late 10th cent.) and is most likely caused by increased nutrient input as a result of human impact. Engels *et al.* (2018) however, found sediment age and water depth to be the most likely explanatory variables for this ecosystem change. From 155 cm depth (1250-700 cal. yr. BP) onward *Cannabis*-type shows an increase from ca. 1% to ca. 35% which is likely the result of the retting of hemp in the lake to create hemp fibres for rope production. The practice of hemp retting in the Netherlands is known from the historic record and also evidenced at Lake Uddelermeer from the high values of *Chaetomium* spores which are cellulose-decomposers and occur among others, on decaying herbaceous stems (van Geel *et al.* 2003).
Overall zone Pd indicates an increase in human activity, with higher values of Cerealia, *Secale, Fagopyrum* and *Sinapis*-type and various herbs such as *Rumex* and Amaranthaceae. The presence of charcoal also increases during this zone, which might be linked to the charcoal production in the area. There are fewer deciduous tree species present indicating the disappearance of the closed and mixed deciduous forest, which are being replaced by more open oak forest with hazel and ash. Arable lands are expanding while the heathlands are decreasing. The alder carr is also disappearing and is being replaced by grassland. In the lake itself the eutrophic conditions are evident from the disappearance of *Littorella, Isoëtes* and *Nymphaea* and the concurrent increase of *Myriophyllum alterniflorum*. The occurrence of this aquatic perennial is often linked to an increase in phosphate (Roelofs *et al.* 1984). *Myriophyllum alterniflorum* grows in water up to 2 metres deep (Hannon and Gaillard 1997) suggesting that water depth remained stable during the entire period, in line with results by Engels *et al.* (2016).

Figure 4 around here

4.3 Chironomid record

Chironomids are well preserved and abundant throughout the record. Our record has an average count sum of 99 head capsules per sample (range 64-167). Most of the encountered chironomid taxa (e.g. *Lauterborniella, Parakiefferialla bathophila*-type) are commonly found in the littoral zone of meso- to eutrophic lakes and prefer warm or temperate conditions (Brooks *et al.* 2007, and references therein). Further, a number of taxa present in the record are often associated with macrophytes (e.g. *Ablabesmyia*). The chironomid diagram is divided into two zones Ch1 and Ch2, following major shifts in the chironomid assemblage, which correspond with the major lithological units in the core (Fig. 4).

Chironomid zone Ch1 (550-220 cm; 2525-1140 cal. yr. BP) is dominated by *Lauterborniella*, *Cladotanytarsus mancus*-type and *Parakiefferiella bathophila*-type which are all typical inhabitants of littoral zones of lakes. In addition, *Lauterborniella* and *P. bathophila*-type are often associated with submerged vegetation (Moller Pillot 1984b; Brooks *et al.* 2007; Moller Pillot and Klink 2009; Moller Pillot 2013). *Lauterborniella* is found in the warmer lakes included in the Norwegian-Swiss calibration dataset (Heiri *et al.* 2011). Chironomid zone Ch1 is further subdivided based on smaller changes in the abundance of the chironomid taxa.

Subzone Ch1a (550-470 cm depth; 2525-2240 cal. yr. BP) is marked by relatively high values of *Endochironomus albipennis*-type and *Pseudochironomus* and the presence of *Limnophyes/Paralimnophyes* and *Procladius*. Both *Pseudochironomus* and *E. albipennis*-type occur in the littoral of lakes (Brooks *et al.* 2007; Engels *et al.* 2012). *E. albipennis*-type is often associated with macrophytes (Moller Pillot 1984b) suggesting the presence of aquatic vegetation in the lake. This is in line with the pollen record, which indicates the presence of a *Littorellion* and Nymphaeaceae. Based on the presence or *Littorella* and *Isoëtes,* relatively nutrient-poor conditions are expected in the lake. However chironomid taxa such as *P. bathophila*-type and *Polypedilum nubeculosum*-type are typically found in eutrophic lakes (Moller Pillot 2013). *Lauterborniella* is often ascribed to eutrophic conditions (Moller Pillot 2013) but this genus has been found in oligotrophic lakes as well (Brodin 1986). Based on the combination of the presence of aquatic macrophytes that typically occur in oligo- to mesotrophic conditions and chironomid taxa that typically occur in meso- to eutrophic conditions we conclude that the lake was probably mesotrophic throughout zone Ch1. This conclusion is further supported by the occurrence of taxa such as *Pseudochironomus and Tanytarsus mendax*-type, which are inhabitants of mostly mesotrophic lakes (Moller Pillot 2013). Further, *Limnophyes/Paralimnophyes, Lauterborniella, P. nubeculosum* and *Pseudochironomus* are most often found in shallow lakes (Brooks *et al.* 2007; Engels *et al.* 2012), which is in line with the presence of the *Littorellion* and the estimated water depth of 2.5 to 3 metres by Engels et al (2016). *C. mancus*-type and *P. bathophila*-type have a preference of lakes with a water depth less than 5 metres (Luoto 2011). The majority of species present in this zone such as *E. albipennis*, *Procladius*, *C. mancus*-type are acidophilic which is also in line with the reconstructed nutrient-poor, clear-water conditions in the lake. In the calibration dataset, *Procladius* and *Limnophyes/Paralimnophyes* are both found along a large temperature gradient, including colder lakes, resulting in relatively low temperature optima for these taxa (Heiri *et al.* 2011).

The onset of subzone CH1b (470-390 cm depth; 2240-1760 cal. yr. BP) is defined by the appearance of *Parachironomus varus*-type and an increase of *Corynoneura edwardsi*-type and further characterized by the absence of *Limnophyes/Paralimnophyes* and *Procladius. P. varus*-type *and C. edwardsi*-type are both often associated with macrophytes and have relatively high temperature optima in the Norwegian-Alpine calibration dataset (Heiri *et al.* 2011) (Brooks *et al.* 2007). At the start of this subzone, *E. albipennis*-type reaches maximum values, directly followed by a strong decline from 19.2 % to 1.4%. *Lauterborniella* also reaches maximum values in this subzone. *Pseudochironomus* is still present, although at slightly lower abundances than in the previous subzone. *P. varus*-type is acidophobic (Brooks *et al.* 2007) suggesting less acidic conditions which is in line with the drop in *Procladius* and *E. albipennis*-type which are both acidophilic. Nevertheless, other acidophilic species such as *C. mancus*-type, *Psectrocladius sordidellus*-type are still present. We therefore conclude that the shift in the chironomid fauna associated with the Ch1a/Ch1b-transition does not reflect any significant changes in the lake ecosystem but rather a reorganization of the fauna already present in the lake.

Subzone Ch1c (390-255 cm depth; 1760-1270 cal. yr. BP) is defined by maximum values of *P. bathophila*-type (35.7%) and is further marked by the reappearance of *Limnophyes/Paralimnophyes* and *Procladius* and an increase in *P. sordidellus*-type and *P. nubeculosum*-type. *Lauterborniella* gradually declines from its maximum abundance of 35.2% to values of 15.3% during subzone Ch1c. *Pseudochironomus* and *P. varus*-type also reach lower abundances than in the previous subzone. Both *P. nubeculosum*-type and *P. sordidellus*-type typically occur in the littoral zone of temperate lakes (Engels *et al.* 2012; Luoto 2012), although

according to Moller Pillot (1984b) *P. nubeculosum*-type is found in lakes with a depth up to 18 m. The increase in *P. nubeculosum*-type, *P. bathophila*-type might suggest more nutrient-rich conditions in the lake. However, oligotrophic and mesotrophic taxa such as *Heterotanytarsus* and *Pseudochironomus* are still present indicating that conditions remained relatively nutrient poor.

The final subzone (Ch1d: 255-220 cm depth; 1270-1140 cal. yr. BP) is marked by higher values of *E. albipennis*-type, while abundances of *Lauterborniella* and *P. bathophila*-type are lower than in the preceding subzones. Taxa that appear or increase during this zone are *Glyptotendipes pallens*-type and *Polypedilum sordens*-type which are both found in the warmer lakes in the training set. The most distinct feature of this subzone, however, is the high abundance of *T. mendax*-type. This taxon consists of a large number of species and is found in a range of environments (Brooks *et al.* 2007). The taxon also occurs along a wide temperature range, but is absent from the coldest lakes (Heiri *et al.* 2011). *T. mendax*-type is sensitive to increases in phosphate but can occur in all trophic states and prefers mesotrophic conditions. This species mostly lives in the profundal zone and is most abundant in water over 5 metres deep. *E. albipennis*-type and *P. bathophila*-type have similar nutrient preferences although *P. bathophila*-type is indicative for warmer conditions. The shifts that we observe in the chironomid fauna during zone Ch1 do not coincide with shifts in ecology of the lake as reconstructed from the pollen and LOI records. We therefore suggest that the changes observed in the chironomid record were potentially driven by external factors such as climate change rather than by changes in within-lake processes.

The onset of chironomid zone Ch2 coincides with the transition of brown gyttja to green algal gyttja (220-100 cm depth; 1140-320 cal. yr. BP). Zone Ch2 is marked by increases or appearances of the chironomid taxa *Microtendipes pedellus*-type, *Cladopelma lateralis*-type, *Cricotopus laricomalis*-type, *Nanocladius branchicolis*-type and the Tanypodinae *Procladius* and *Ablabesmyia.* Zone Ch2 also shows an increase in the total number of chironomid taxa found, with a maximum of 25 taxa at 149 cm. Of the dominant taxa in zone Ch1, *C. mancus*-type and *P. bathophila*-type are still present in zone Ch2, while *Lauterborniella* strongly declines towards the upper part of this zone. In addition, the chironomid assemblage still includes a.o. *E. albipennis*-type, *P. nubeculosum*-type and *T. mendax*-type. Both the sedimentological and the palynological record indicate a strong shift in the water quality of the lake during this time period, with more nutrient-rich and turbid conditions present after 1140 cal. yr. BP. This transition is reflected in the chironomid-species composition where most species with specific habitat requirements such as the presence of aquatic macrophytes or low-nutrient levels decline in favour of *Procladius* and *Ablabesmyia.* These latter two taxa are typically interpreted as generalists and are able to persist in dynamic conditions (e.g. Vallenduuk and Moller Pillot 2007). *Ablabesmyia* prefers shallow, warm and still water and is associated with macrophytes (Engels *et al.* 2012). Additionally, *Procladius* is sensitive to increases in phosphate, can occur in acidified lakes and tolerates pollution well (Luoto 2011). *M. pedellus*-type is also often encountered in dynamic environments and together with *Ablabesmyia* is found in shallow lakes of less than five metres deep (Engels *et al.* 2008a; Engels *et al.* 2008b; Engels *et al.* 2012). Potito *et al.* (2014) found a relation with high agricultural cover and the occurrence of this chironomid taxon, which is in line with the low AP values and high upland herbs and Cerealia pollen percentages in this zone. *M. pedellus*-type however, has a preference for mesotrophic conditions and a stable oxygen regime (Moller Pillot and Klink 2009), and Engels *et al.* (2018) therefore suggested that this increase could be a relative increase, with other taxa decreasing faster under unfavourable conditions than *M. pedellus*-type. Other taxa that indicate higher trophic conditions are e.g. *G. pallens*-type, *Chironomus anthracinus*-type, *Chironomus plumosus*-type, *C. lateralis*-type, *Dicrotendipes nervosus*-type. Overall, the combined proxy-records indicate a shift in the lake ecology from the clear-water mesotrophic conditions of zone Ch1 to the eutrophic, turbid conditions of zone Ch2.

Figure 5 around here

4.4 Factors controlling the chironomid fauna composition of Lake Uddelermeer

The most important precondition to establish a C-IT reconstruction is that temperature fluctuations are the main factor influencing the chironomid composition. This is especially important for Holocene temperature reconstructions, since the amplitude of temperature fluctuations in e.g. the mid-latitudinal areas of the northern Hemisphere, was small when compared to Late Glacial studies. Chironomid communities of shallow, temperate lakes such as Lake Uddelermeer are especially sensitive to changes in the environment since dominant controls on the chironomid composition like hypolimnetic oxygen depletion and climatic extremes are lacking (Langdon *et al.* 2006). Based on the sedimentological, palynological and chironomid record, conditions in the lake itself remained stable with clear-water, nutrient-poor conditions during the interval between 2500 and 1140 cal. yr. BP i.e. covering chironomid zone Ch1 and the pollen zones Pa, Pb and Pc. The strong eutrophication of the lake at the onset of chironomid zone Ch2 is visible in the sediment core as a colour change, in the pollen record (here zone Pd) as an increase in algal species, and in the chironomid record as an increase of generalists such as *Ablabesmyia* and *Procladius* (Fig. 5). Together these changes indicate a significant ecosystem shift in Lake Uddelermeer from mesotrophic clear-water conditions to more nutrient-rich and turbid conditions. This conclusion is in line with results by Engels et al. (2018), who reconstructed stable clear-water conditions in Lake Uddelermeer from 6000 cal. yr. BP onward and an increase in nutrient availability at 1030 cal. yr. BP from sedimentary pigments, chironomids and pollen. Engels *et al.* (2018) placed the change to turbid lake-water conditions at 1030 cal. yr. BP, which corresponds to the maximum increase in algae abundances at 185 cm in the pollen data. Our high-resolution record indicates that the first onset of change occurred from 1140 cal. yr. BP onward, with increasing percentages of algae and fungal spores and decreasing pollen percentages of *Littorella* and *Isoëtes* and a shift to brown-green gyttja (Fig.5).

The pollen record additionally indicates changes in the regional vegetation during the investigated period, with a reforestation phase in zone Pb from 1730 till 1270 cal. yr. BP (Fig. 5). These regional changes in forest cover did not result in significant changes in the aquatic vegetation in the lake during Ch1. It is possible that the presence of a slightly raised area surrounding Lake Uddelermeer, as seen on the LIDAR elevation map (Fig. 1), limited inflow of surface water runoff into the lake from the surrounding area, limiting the impact of regional changes in land use. Increased sediment and nutrient input into the lake as a result of agriculture and deforestation are often the main actor in ecosystem changes in lakes. Potito *et al.* (2014) identified agricultural land cover as one of the most dominant environmental variables influencing chironomid composition. Nevertheless, chironomid inferred temperatures can still be valid from these lakes when agriculture remained stable during the investigated time period (Potito *et al.* 2014). From the pollen record the presence of agriculture in the area was evident, albeit in low percentages which remained constant in pollen zones Pa and Pb and only slightly increased during Pc. In addition, consistently high lake levels are reconstructed for the investigated period (Engels *et al.* 2016), suggesting that changes in water level, which could also affect the chironomid assemblages (Engels and Cwynar 2011), did not play a role either. We therefore conclude that environmental conditions in the lake remained stable in the period between 2525 cal. yr. BP and 1140 cal. yr. BP and suggest that the chironomid record could provide a reliable temperature reconstruction for this period. The chironomid fauna that was existent during the formation of the upper samples (220-100 cm depth), obtained from the green algal gyttja (Ch2), was strongly influenced by the local eutrophication process. These samples are therefore deemed unreliable for temperature reconstruction purposes and will not be discussed.

Figure 6 around here

4.5 Chironomid-inferred mean July air temperature reconstruction

Reconstructed mean July air temperature values vary between 16.1 and 19.1°C with an average reconstructed temperature of 17.6°C (Fig. 6). This places the reconstruction in the upper part of the temperature range of the calibration dataset (3.5-18.4 °C) (Heiri *et al.* 2011). Sample-specific errors range between 1.4 and 1.6 °C.

A number of temperature fluctuations can be observed between 2525 and 1140 cal. yr. BP. At the start of the investigated period (2525-2240 cal. yr. BP, or 550-470 cm depth), mean July air temperature values are low, with an average temperature of 17.4°C. For the period between 2240 and 1760 cal. yr. BP (470-390 cm), slightly higher temperatures are reconstructed, with an average temperature of 18.6°C. Maximum reconstructed temperatures of 19.1°C are reached at a depth of 464 cm (2197 cal. yr. BP). Slightly colder conditions, with an average mean July air temperature of 17.1°C, prevailed in the period between 1760 and 1280 cal. yr. BP (390-255 cm). The coldest phase is reconstructed from 330-304 cm (1551-1465 cal. yr. BP) with an average mean July air temperature of only 16.5°C. This is followed by slightly higher (average 18.3°C) values for the period between 1280 and 1140 cal. yr. BP (255-220 cm).

The down-core evaluation analyses suggest that most chironomid assemblages in the fossil record are classified as having both ‘no close’ or ‘no good’ modern analogue and a ‘poor’ or ‘very poor’ fit with temperature. Only two samples contain taxa which are not included in the calibration dataset, reaching values of maximum 2%. Therefore, even though the composition of the chironomid assemblages in the fossil record differs from the modern assemblages, the individual taxa in the fossil samples are well represented in the modern samples. WA-PLS can perform relatively well in no-analogue conditions as long as the majority of the chironomid assemblage is well represented in the calibration data set (Birks 1998).

Reconstructed mean July air temperatures in part, exceed the maximum mean July air temperature of the modern samples in the calibration dataset of 18.4 °C. This might have affected the absolute values of the temperature reconstruction. The magnitude of the observed fluctuations (1.39-1.56 °C) is similar to the sample-specific error of the reconstructed temperatures. Nevertheless, the fluctuations are recorded in multiple samples on a high temporal resolution, thus giving a consistent picture of these temperature changes. Moreover, observed fluctuations approximately coincide with shifts in the chironomid assemblage. For example, during the two colder oscillations, taxa with relatively low optimum temperatures are present, such as *Limnophyes/Paralimnophyes*, *Procladius* and *P. sordidellus*. Similarly, the sample with the highest reconstructed mean July air temperature (464 cm) coincides with maximum abundances of *E. albipennis*-type, which is found in the warmer lakes of the calibration dataset (Heiri *et al.* 2011) suggesting that temperature is indeed the main driver of the chironomid fauna in this part of the record. When we compare the reconstructed C-IT from Lake Uddelermeer to the average July temperature of 17 °at de Bilt (50 km SW of Lake Uddelermeer) for the period 1901-2017 it seems that our reconstructed temperatures are relatively high. Even during the DACP reconstructed temperatures are similar to recent conditions (17 °C vs. 17.1°C) indicating that the record is likely overestimating the absolute temperature. Potito *et al.* (2014) found that sites with agriculture in their catchment can overestimate temperature as a result of increased production in the lake. Other chironomid records from NW Europe also indicate that temperature during the DACP was at least 1°C lower than current temperature values (Northern England: Langdon *et al.* 2004; Barber *et al.* 2013; Cairngorms UK: Dalton *et al.* 2005; northern Alps: Millet *et al.* 2009). Additionally, the reconstructed temperature range is located in the upper ranges of the Norwegian/Alpine training set which could result in so called edge-effects. It therefore seems likely that the absolute values of our C-IT reconstruction overestimate past July air temperatures.

5 Discussion

Based on the chronology of the record, we can correlate the observed temperature oscillations in the record to climate fluctuations as recorded in the Northern Hemisphere (e.g. Ljungqvist 2010). The slightly higher reconstructed temperatures in the period from 2240-1760 cal. yr. BP probably correspond with the RWP. The subsequent cold phase (1760-1280 cal. yr. BP) can be correlated to the DACP. The warmer conditions reconstructed for the upper part of the record (1280-1140 cal. yr. BP) can be linked to the MCA (Fig. 6). The C-IT record shows that temperature during the Iron Age (till 2240 cal. yr. BP) was lower than during the RWP by an estimated 1.2 °C. To evaluate the representability of these temperature trends in NW Europe we will first compare our results to other C-IT records. In a second step we will compare our results to other available climate reconstructions from NW Europe including detailed tree-ring records and global data compilations.

Figure 7 around here

5.1 Chironomid-inferred temperature reconstructions from NW Europe

To our knowledge only two other Late Holocene C-IT reconstructions, which have been identified as representative NW-European temperature trends for the period discussed here, are available. Both of these sites are located in Northern England: Talkin Tarn (Langdon *et al.* 2004) and Bigland Tarn (Barber *et al.* 2013). A RWP, a distinct DACP and the MCA can be distinguished in the record from Bigland Tarn (Fig. 7). These phases might also be visible in the record from Talkin Tarn, although the comparison with that record is less robust, due to the lower sampling resolution and uncertain chronology of that site. The similarity between the three sites, both in timing as well as amplitude of temperature change, suggests that the reconstructed temperature fluctuations in Lake Uddelermeer record reflect a regional climate signal. The overall trend of the reconstruction from Uddelermeer is very similar to that of Bigland Tarn and Talkin Tarn. The RWP is the warmest phase in the Uddelermeer record with an increase in temperature of 1.2 °C compared to the Iron Age. This is similar to the increase in the Bigland Tarn record of 1°C. The average temperature drop from the RWP to the DACP in the Uddelermeer record is 1.5 °C whereas this shift in the Bigland Tarn record is slightly bigger with 2.2 °C. The MCA forms the warmest period in the Bigland Tarn record with an average temperature of 13.7°C. The MCA in the Uddelermeer is only partly present and as seen in the Bigland Tarn record, the first part is not the warmest part of the period. When we compare absolute values of the independent reconstructions, it becomes apparent that reconstructed temperatures from both sites in England are consistently lower by 4-5 °C than the reconstruction from Lake Uddelermeer (Fig. 7). This could in part be the result of the more western location and higher elevation of these sites. The current average July temperatures of both Bigland Tarn as Talkin Tarn are around 15°C, compared to the average July temperature of 17°C at Uddelermeer. Additionally, previous studies have shown that the application of different chironomid-climate calibration datasets to the same fossil record will yield C-IT records that are up to several degrees different in absolute reconstructed temperatures (e.g. Engels *et al.* 2014; Bajolle *et al.* 2018). The temperature reconstructions from England are based on the Norwegian calibration dataset, which has a lower maximum temperature (16 °C; Brooks and Birks 2000) than the extended and combined Swiss-Norwegian dataset used for the reconstruction from Uddelermeer (18.4 °C; Heiri *et al.* 2011). However, it is likely that a large part of the difference in absolute temperatures is the result of a temperature overestimation in the record from Lake Uddelermeer.

Figure 8 around here

5.2 Regional evidence from the NH for the RMP, DACP and MCA

When we compare the start and end dates of the climatic phases indentified in the record from Uddelermeer to other temperature reconstructions and overviews from the Northern Hemisphere we observe that overall there is a good match between the available records (Fig. 8). All datasets shown in Fig. 8 show a similar starting date for the MCA, which is placed around 1300 cal. yr. BP. The start of the DACP shows slightly more variation in timing with starting dates ranging between 1536-1760 cal. yr. BP. Taking into account all age uncertainties it is likely that all records and overviews show the same simultaneous event. The start of the DACP in Uddelermeer is the earliest of the available estimates with a suggested starting date of 1760 cal. yr. BP. The 500-year duration of the DACP in the Uddelermeer record is 150 years longer than the duration of the DACP in the tree-ring record presented by Büntgen *et al.* (2011).

The latter part of the DACP in the tree-ring record of Büntgen *et al.* (2011) dated at 1414-1290 cal. yr. BP (536-660 AD) was later termed the Late Antique Little Ice Age or LALIA (Büntgen *et al.* 2016). This LALIA shows a strong temperature decline and is causally linked to a cluster of volcanic eruptions in 1414; 1410 and 1403 cal. yr. BP (536, 540 and 547 AD). Büntgen *et al.* (2017) promote the substitution of the DACP by the LALIA. However, the LALIA has not been identified in a large range of proxies and sites, and falls within the previously defined DACP. Additionally, since the timing and the causality differ, with a link to volcanism for the LALIA and an unknown cause for the DACP, the LALIA cannot be used as a substitution of the DACP. It therefore seems more appropriate to refer to this cold stage as a whole as the DACP (sensu Helama *et al.* 2017b; Helama *et al.* 2017a). The Uddelermeer record does suggest a colder second part of the DACP which starts at 1550 cal. yr. BP and lasts till 1450 cal. yr. BP. It is possible that this colder phase reflects the LALIA, although the chronology of the cold period observed in our Uddelermeer record does not match the timing and duration observed in the tree ring record (Büntgen *et al.* 2017). More detailed and well-dated studies covering this time period would contribute to a better understanding of this coldest phase of the DACP.

An earlier start and a longer duration of the DACP in the Netherlands, compared to the DACP recorded in the tree ring record, could be the result of different local climatic conditions. Nevertheless, a longer and earlier DACP is in line with both the Bigland Tarn record as well as the two overview studies by Ljunqvist (2009) and Helama (2017). Aside from the tree-ring data set, the Uddelermeer chironomid record is the most detailed temperature record reconstructing absolute temperature values during the Dark Ages Cold Period in for NW Europe.

The start of the RWP cannot be identified in all studies presented in Fig. 8. In the Bigland Tarn and Uddelermeer records the start of the RWP is placed at 2365 cal. yr. BP and 2240 cal. yr. BP, respectively. Taking into account the error margins of the chronology of both studies, this could be a simultaneous event. In the tree-ring data set no clear RWP is evident, but the start of a warmer phase does coincide with the start of the RWP at Uddelermeer. However, this warm period as identified in the tree ring record (Büntgen *et al.* 2016) is interrupted by a colder phase. The reconstructed temperatures in Uddelermeer and Bigland Tarn are both stable during the RWP and show no evidence of a brief colder period. The most probable explanation for this discrepancy are different climatic conditions in the Alps in contrast to the lower lying sites, as well as differences in sampling resolution and proxy sensitivity. In the chironomid record from the northern French Alps by Millet *et al.* (2009), which is not interpreted as a representative temperature reconstruction for the first millennium, also no clear RWP was visible. Different climatic conditions might also explain the differences in duration and the start of the DACP across the European continent. Overall, the start and end dates of the different climatic phases fall within the dating uncertainties and current results indicate that especially the MCA and DACP and to a lesser extent the RWP can be considered as simultaneous events across NW Europe.

6 Conclusions

We presented the first high-resolution chironomid record for the late Subatlantic in the Netherlands from Lake Uddelermeer. Our data shows that in the period 2500 to 1140 cal. yr. BP the lake was mesotrophic with clear-water conditions and sustained a *Littorellion.* From 1140 cal. yr. BP onward a shift in the water quality was reconstructed with high-nutrient turbid conditions and a dominance of algal species. The conditions in the lake in the period 2500-1140 cal. yr. BP do not signal large ecological changes or effects of human impact and thus suggest that this record is suitable for a temperature reconstruction. In this C-IT record from Lake Uddelermeer, we identified a RWP, a DACP and the MCA. The RWP is placed in the period from 2240-1760 cal. yr. BP, the DACP starts at 1760 cal. yr. BP and the MCA starts at 1280 cal. yr. BP. Our detailed summer temperature record shows that the average temperature drops by 1.5°C from the RWP to the DACP. Overall the temperature reconstructions appears to be too high, however, the trends, temperature fluctuations and timing of the cold and warm periods in this records are in agreement with other records and reconstructions indicating that the Uddelermeer record can be used as an representative record for temperature in the Netherlands during the first millennium AD.

Acknowledgements

This work is part of the project “The Dark Age of the Lowlands in an interdisciplinary light: people, landscape and climate in the Netherlands between AD 300 and 1000’ (NWO, section Humanities; 2012-2019: 360-60-110; www.darkagesproject.com). Loss on Ignition measurements were executed by T. Winkels and an initial low-resolutions set of chironomid samples were analysed by M. Wolma. The chironomid data was transferred to a temperature reconstruction by O. Heiri. We thank Keith Barber, who sadly passed away, for providing the chironomid data of Bigland Tarn and Talkin Tarn. The authors would like to thank H. Middelkoop and O. Heiri for useful comments on the paper. We thank T. Poelen and Kroondomein Het Loo for granting access to the site.

Minimum / maximum age range of age model

Figure 1 (a) Location of Lake Uddelermeer; (b) Lidar elevation model of the central Netherlands (AHN; www.ahn.nl) and (c) the area directly surrounding Lake Uddelermeer. Yellow star indicates location core. Numbers indicate sites discussed in the text. 1 Ice pushed ridge Garderen-Ermelo max. 50 m A.S.L.; 2 Ice pushed ridge Apeldoorn max. 100 m A.S.L. ; 3 Lake Uddelemeer; 4 Lake Bleekemeer; 5 brook Leuvenemse beek; 6 medieval ringfort (ringwalburg) (Koomen & Maas, 2004; Heidinga, 1987). For visibility purposes (c) is plotted with a different colour range, only a relative elevation legend is shown for both maps.

Figure 2 Bayesian modelled age-depth model of core section 50 - 650 cm depth for central Core E from Lake Uddelermeer (figure adapted from Engels et al. (2016)). The 95% probability distribution range is shown in grey, calibrated C^{14} ages and 95% probability ranges are shown as black squares with error bars.

Figure 3 Percentage diagram of selected pollen, spores and NPPs from Lake Uddelermeer showing regional (A) and local (B) vegetation development in and around Lake Uddelermeer. All curves are shown with an additional fivefold exaggeration. Diagram plotted on sediment depth (cm) with a secondary scale (cal. yr. BP) plotted for comparison. Sedimentological and Loss-on-Ignition (represented as organic content% in 3A) profiles are plotted to the left of the pollen curves. The presence of charcoal (indicated with '+' present; '++' present in large quantities) is plotted to the right of the pollen curves.

Figure 4 Percentage diagram showing all chironomid taxa and the chironomid count sum (head capsules/ sample) for Lake Uddelermeer. Diagram plotted on sediment depth (cm) with a secondary scale (cal. yr. BP) plotted for comparison. The sedimentological profile is plotted to the left of the chironomid curves. To the right the scores of the chironomid samples on the first axis of a PCA performed with square-root-transformed percentage data is shown.

Figure 5 Selected percentage curves of pollen, NPPs and chironomid taxa as indicators for regional vegetation change, lake ecology and chironomid assemblage. Diagram plotted on sediment depth (cm) with a secondary scale (cal. yr. BP) plotted for comparison. The sedimentological profile is plotted to the left of the curves.

Figure 6 Chironomid inferred July air temperature (CI-T) reconstructions from Lake Uddelermeer with sample specific error estimates. Curves plotted on age (cal. yr. BP) with a secondary scale of sediment depth (cm) plotted for comparison. Warm (red) and cold (blue) periods for the period 2550 - 1140 cal. yr. BP are indicated; the part of the record which is not included in the reconstruction is shown in grey. To the right of the reconstruction, the distance of the fossil sample to the nearest modern analogues in the Norwegian/Alpine training set (squared chi^2-distance (sq.x^2d.): the vertical lines indicate the 2nd and 5th percentiles of all squared chi^2-distances in the Norwegian/Alpine training set and are defined here as 'no close' and 'no good' analogues respectively (after Birks et al. 1990); the goodness-of-fit of the fossil samples to temperature (squared residual distance; sq.res.d): the vertical lines indicate the 90th and 95th percentiles in residual distances of the modern samples to the first axis in a constrained CCA and are defined here as a ‘poor’ and ‘very poor’ fit respectively (e.g. Birks et al. 1990); and the cumulative percentage

(Frequency %) of fossil chironomids that are absent (%absent) from the modern calibration set are given

Figure 7 CI-T reconstructions for Lake Uddelermeer (this paper); Bigland Tarn (Barber et al. 2013) and Talkin Tarn (Langdon et al. 2004) plotted on a cal. yr. BP timescale. Calibrated AMS radiocarbon dates and their 2 sigma error ranges are plotted to the right of each temperature reconstruction.

Figure 8 Warm (red) and cold (blue) periods in NW European temperature reconstructions for the period 1000 - 2500 cal. yr. BP (grey is not identified/available). IA: Iron Age; RWP: Roman Warm Period; DACP: Dark Age Cold Period; MCA: Medieval Climate Anomaly. A: CI-July air temperature Uddelermeer (this paper); B: CI-July air temperature Bigland tarn UK(Barber et al. 2013) also included in overview record D; C:Tree ring inferred JJA temperature for the Alps (Büntgen et al. 2011) also included in overview records D, E and F; D:Compilation various archives from NW Europe summer - winter and annual temperature (Riechelmann and Gouw-Bouman 2019); E:Compilation various archives N Hemisphere summer - winter - annual temperature (Ljungqvist 2009); F: compilation various archives globally temperature (Helama et al. 2017a). For the records A and C zone boundaries were placed where the temperature curve crossed the mean. When available, age uncertainty (minimum and maximum of the age model) is plotted with black lines.
