18 **Running page head** Individual foraging behaviour

19

20 **Abstract**

21

22 Individuals can specialise such that mutually exclusive home ranges arise and the
23 acquisition of site familiarity early in life can favour individual site fidelity in mature
24 animals. Non-territorial Individual Foraging Site Fidelity (IFSF) has been reported
25 frequently and among seabirds, foraging theory predicts that IFSF is more likely in

26 short-ranging, benthic foraging species, because their prey occur predictably at small
27 scales. We tracked 17 adult and two immature black guillemots *Cepphus grylle*
28 (mean mass 406g, median of individual maximum foraging range 4.3km). Individuals
29 consistently returned to the same feeding areas, such that IFSF was significantly
30 greater than the null expectation at spatial scales of 0.1 – 5 km and did not decay
31 significantly over ten days. Immature birds ranged more widely than adult birds. Our
32 study demonstrates that space use varies between individuals and that processes or
33 threats occurring within the foraging range of a given colony may act
34 disproportionately on some individuals rather than be equally distributed across a
35 population. This finding contributes to a growing body of research on IFSF, which
36 may have important implications for species management.

39 home range.

40 **1. Introduction**

41 Many established foraging theories assume that individuals within a species or
42 population are ecologically equivalent (Fretwell & Lucas 1969). However, it is now
43 recognised that individuals often specialise in their foraging behaviour or occupy only
44 a small portion of the habitat potentially available to them (Bolnick et al. 2003, Piper
45 2011). It is well known that territorial animals, such as tigers (Sunquist 1981) and
46 colonies of ants (Hölldobler and Lumsden 1980), establish discrete home ranges and
47 maintain these through aggression and that territoriality therefore promotes foraging
48 site fidelity. Latterly however, it has been also shown that many mobile, non-
49 territorial, animals are also highly consistent in where and how they forage, at the
50 individual level (Ceia & Ramos 2015). That is, individual foraging site fidelity (IFSF) –
51 when individuals consistently forage in only a small part of their population's home
52 range – is higher than the null expectation. This form of individual specialisation has
53 been shown even among colonial central-place foragers, such as pinnipeds (Baylis
54 et al. 2012) and seabirds (Harris et al. 2014, Baylis et al. 2015, Wakefield et al.
55 2015), which share common breeding or resting places, and might therefore be
56 expected to share common foraging areas. High IFSF has important implications for
57 our understanding of these groups. For example, conservation managers may need to
58 account for the fact that potential threats, such as offshore windfarm developments
59 or conversely protection measures, such as Marine Protected Areas, impact
60 individuals within populations asymmetrically. The current challenge is therefore to
61 detect IFSF and understand why it occurs.

62

63 Several theories have been proposed to explain how individual foragers select
64 foraging locations. The 'Win-stay, lose-shift' strategy (Kamil 1983, Davoren et al.
65 2003) proposes that birds revisit areas where previous foraging was successful until
66 they encounter poor foraging success, after which they seek a new foraging area.
67 The 'Information centre hypothesis' (Ward & Zahavi 1973) suggests that individuals
68 may locate such areas using 'public' information gained from other birds at the
69 colony. For example, they might emulate the bearing of other birds leaving the
70 colony. The 'Always stay' strategy (Switzer 1993), suggest that animals gain a
71 fitness advantage by consistently feeding in an area where they have previous
72 experience or 'private' information (referred to as 'site familiarity' (Irons 1998, Piper
73 2011)). Both the win-stay, loose-shift and always stay strategies assume that birds
74 have the capacity to memorise and evaluate patch location and/or quality
75 (Benhamou 1994). Birds using the win-stay, loose shift strategy would be expected
76 to exhibit high IFSF in the short term, but this would decline over time. Always-stay
77 foragers would have high IFSF regardless of time scale. A simpler strategy, not
78 reliant on memory, would be to search for prey anew each time the bird left the
79 colony. This would result in low IFSF. Theory predicts that IFSF should be highest
80 when prey availability is most predictable (Weimerskirch 2007). Seabirds are a
81 diverse group and vary in the degree of predictability in the environments in which
82 they feed. Tropical and wide-ranging pelagic species, and those that forage at
83 oceanic fronts experience relatively less predictable environments than temperate,
84 polar, neritic, coastal and short-ranging species (Weimerskirch 2007).

85

86

87 The collection of seabird tracking data has mushroomed with the availability of
88 affordable tracking technology (Lascelles et al. 2016, Wakefield et al. 2017) but
89 some species and age classes remain elusive to tracking because either their size or
90 behaviour prevents them from being tracked. Immature age classes are also less
91 frequently the subject of tracking studies (Votier et al. 2017) but younger age classes
92 are predicted to show less IFSF and more prospecting behavior as they explore
93 potential feeding and breeding locations and then use memory-based learning to
94 concentrate their selection with experience (Guilford et al. 2011, Wakefield et al.
95 2015). One species which has rarely been tracked is the black guillemot (*Cepphus*
96 *grylle*) which, like some other crevice breeding alcids, can be sensitive to capture,
97 causing low recovery rates of devices (Harris et al. 2012, Masden et al. 2013, Shoji
98 et al. 2015). In temperate regions this species also forages towards the most
99 predictable end of the spectrum of foraging habitats (Ewins 1990). Their main prey in
100 our study region is butterfish (*Pholis gunnellus*; Ewins 1990; Walton 2004) which
101 occupy static habitat features (kelp and rocky subtidal zones), only moving offshore
102 to spawn during December (Sawyer 1967). Koop and Gibson (1991) showed that
103 butterfish are sedentary, moving an average of only 21m in 6 days. In the same
104 study, butterfish returned to an area within two tidal cycles of their removal, although
105 numbers were reduced to 27–52% of the initial population. In temperate populations,
106 black guillemots remain close to their breeding colonies for the whole year and
107 forage over short distances (Ewins 1990).

108

109 We use novel field methods and high-precision global positioning systems (GPS)
110 telemetry to track individual breeding adult and colony-attending immature black

111 guillemots to (1) determine whether IFSF occurs; (2) whether IFSF declines over
112 time; and (3) whether it is higher in adults than immatures.

113

114 **2. Material and Methods**

115 **2.1 Data collection**

116 Our study colony, Grassholm, is a three-hectare island (59.06° N, 2.93° W) lying in a
117 shallow channel between the mainland of Orkney and the island of Shapinsay in
118 Northern Scotland. Surveys recorded 13 black guillemots at the colony in 1984
119 (Lloyd et al. 1991) and three nests in 1991, all located in natural crevices (P.
120 Hollinrake, unpubl. data). In 1996, artificial stone nesting cairns were built and by
121 2000, 50 individuals were counted on land (Mitchell et al. 2004). The current
122 population is approximately 60 breeding pairs, 80-90% of which use artificial nesting
123 cairns. The surrounding water is shallow (<15m depth) with areas of sandy and rocky
124 seabed, the latter densely covered in fucoid algae.

125

126 Black guillemots are burrow or cavity nesters. Due to concern that they may
127 abandon breeding or evade recapture if caught from the burrow by hand, tagged,
128 and then recaptured a few days later to retrieve the tag (Masden et al. 2013, Shoji et
129 al. 2015), we caught birds primarily by intercepting those entering or leaving the
130 colony using a mist net positioned between 2 and 20m from the colony edge. We
131 used remote download tags which negated the need to recapture birds since we
132 expected tags to be shed after 10-20 days. Two birds were caught in the burrow and
133 one of these recaptured to remove the tag and check for signs of damage to plumage

134 or skin. Immature black guillemots, which attend colonies in small numbers, were
135 distinguishable from adults based on plumage characteristics (Cramp 1985).

136

137 Following capture, we attached an Ecotone Uria GPS tag, weighing 11g including
138 attachment material. This is ~ 2.8 % body mass (range 2.4 - 3.1 %), and therefore
139 generally below the mass thought to have an acceptably small effect on bird
140 behaviour (Phillips et al. 2003, Schacter and Jones 2017). We attached tags to the
141 feathers on the lower back, just below the widest part of the body, using 3 strips of
142 tesa tape (Tesa, Norderstedt, Germany). We used this position, rather than mounting
143 between the wings, to reduce the likelihood of tags impeding birds as they passed
144 through burrow entrances. We programmed tags to record one GPS position every
145 10 minutes and expected battery life to be 5 - 10 days and fitted birds with a field-
146 readable colour ring with a unique 2-letter combination. Birds were released within 6
147 minutes of capture. Archived data were downloaded automatically from the tags to a
148 base station via a VHF link whenever birds were within 1 km. Examination of the
149 attachment location of the bird re-caught by hand revealed no visible ill effects. Black
150 guillemots are synchronous breeders at the colony (Cramp 1985). Therefore, where
151 nest locations of tagged birds were not known we assumed the adults were either
152 incubating eggs or brooding chicks, depending on observations of the breeding state
153 of the population as whole, which is easily observed at this colony. In 2013, three
154 tags were deployed on adults and one on an immature in June when the population
155 were incubating eggs and four tags were deployed on adults and one on an
156 immature in July during brooding. In 2014, 13 tags were deployed on adults in July
157 during brooding.

158

159 We monitored breeding success on the island over five visits spanning the breeding
160 season in 2013, during which the contents of all nests on the island were recorded.
161 In 2014, we completed one visit in late chick rearing to record the number of chicks
162 expected to fledge. During all visits to the colony we noted prey species being
163 carried by chick-provisioning black guillemots opportunistically.

164

165 **2.2 Analysis**

166 The GPS loggers tended to omit locations during birds' dives. To ensure a constant
167 10-minute interval between locations, we re-sampled tracks by linear interpolation.
168 Exploratory analysis showed that speeds were binomially distributed. Some birds
169 frequently roosted on fixed objects, such as buoys and rocks, outside the study colony,
170 and some visited neighbouring colonies, in addition to their own (see Results). We
171 identified all potential roosting features using Admiralty navigation charts, Google
172 Earth and the Seabird 2000 colony database (Mitchell et al. 2004). We classified birds'
173 locations as *roosting* when they were within a minimum distance of the centre of those
174 features (where distance was defined separately for each feature depending on its
175 size and type – see Table S1) and their speed was < 0.5 m/s. All remaining locations
176 were classified as *at-sea*. Tortuosity at each location L_0 was the straight-line distance
177 between L_{-1} and L_1 divided by the distance between L_{-1} and L_1 passing through L_0 , and
178 was binomially distributed. All locations defined as 'at-sea' were classified as putative
179 foraging locations if tortuosity was ≤ 0.9 . We defined foraging trips as sets of
180 contiguous locations >250 m from the study colony spanning ≥ 20 minutes, due to the
181 temporal resolution of the tracking data it was not possible to detect shorter trips.

182

183 We estimated each individuals' 50% foraging utilisation distribution (UD) by
184 calculating the kernel density of foraging locations on a regular 100 m grid, with a
185 smoothing factor (h) of 50 m (Worton 1989). The apparent degree of overlap
186 between UD contours estimated using this technique is sensitive to both the
187 percentage contour chosen and h , which effectively sets the spatial scale of the
188 analysis. Therefore, to test whether IFSF was greater than expected by chance, we
189 developed a multi-scale approach, based on comparing individual UDs for different
190 periods, as described by Wakefield et al. (2015). We confined this part of our
191 analysis to 2014, when most data were collected. Wakefield et al. (2015) compared
192 the UDs of gannets tracked across consecutive foraging trips at two-minute
193 resolution. Exploratory analysis showed that too few tracking locations were
194 recorded in each foraging trip to estimate UDs reliably at this level, because foraging
195 trip length was short relative to the tracking interval (see Results). We therefore
196 calculated UDs for each day, d , as our unit of analysis. To do so, we first
197 transformed the locations of black guillemots to Lambert Azimuthal Equal Area
198 projection. We then overlaid a grid in this projection, centred on the study colony,
199 comprising x hexagonal cells with centres spaced s m apart. We next calculated
200 $\hat{UD}_{i,d}$ at each grid cell as the proportion of the i th individual's locations on the d th day
201 falling in that cell. For each individual, we then picked two daily UDs at random and
202 calculated the Bhattacharyya's affinity, BA , between them, where

203

$$204 \quad BA_i = \sum_{\text{All } x} \sqrt{\hat{UD}_{i,1}(x)\hat{UD}_{i,2}(x)} \quad (1)$$

205

206 In this case, BA quantifies the similarity between the UD's of the bird on the two days
207 and ranges from 0 (no spatial consistency) to 1 (perfect spatial consistency) (Fieberg
208 & Kochanny 2005, Wakefield et al. 2015). We then calculated BA_{obs} , the median BA
209 across individuals. We tested the hypothesis that this is greater than the median
210 similarity expected under the null hypothesis that bird identities are exchangeable,
211 BA_{null} . If this hypothesis is rejected, individuals consistently occupy only a small
212 proportion of their population's home range, which is equivalent to the well-known
213 definition of individual specialisation (Bolnick et al. 2002). To determine the
214 distribution of BA_{null} , we repeated the above procedure 10000 times, randomly
215 reassigning bird identities without replacement at each iteration. We then calculated
216 the exact probability that $BA_{obs} > BA_{null}$ as $p = (b+1)/(m+1)$, where b is the number of
217 instances where $BA_{null} > BA_{obs}$ and m is the number of iterations (Phipson and Smyth
218 2010). As the spatial scale at which UD's are discretised on a grid increases, those
219 UD's will inevitably become more similar. To check how scale affected the test, we
220 repeated it 11 times, on grids with cells spacing of $s = \{100, 150, 225, \dots, 5767\}$ i.e. s
221 ranged from 100 m to approximately two thirds of the maximum foraging range that
222 we observed (see Results).

223

224 To determine whether birds used a win-stay, lose-shift strategy within the study
225 period we tested whether spatial consistency decayed over time. To do so, we
226 calculated BA_t (on a grid with $s = 1$ km) for each bird by substituting the UD's of that
227 bird on day two and day t into equation 1 above. Day two was chosen as the
228 reference day, rather than day one, in case the behaviour of birds was initially

229 affected by tag attachment. We then modelled BA_t as a function of lag using a
230 generalised linear mixed model (GLMM) fitted in the R package nlme (Pinheiro et al.
231 2016). We arcsine transformed BA_t to improve normality and specified correlated
232 random slopes and intercepts for individuals. Both this and the previous analysis was
233 carried out firstly on all at-sea locations and secondly on putative foraging locations
234 only. Lag t ranged from 1 to 9 days (data were obtained from only one individual at
235 greater lags).

236

237 **3. Results**

238 **3.1 Summary of data**

239 We successfully downloaded GPS data from 19 of 23 (83%) tags deployed (Table 1;
240 Figure S1). The average tracking period was 8.4d (1-17d). In 2013, we caught and
241 tagged two immature, first summer birds - one in June and the other in July. The
242 remainder of tagged birds were assumed to be breeding adults. This assumption
243 was supported by the fact that all birds had visible brood patches and commuted
244 repeatedly to and from the colony (Fig. S1). We were able to monitor the nests of
245 five of the eight breeding adults tagged in 2013 (Table 1). At three of these nests,
246 birds were caught by mistnet and later observed entering or exiting nests. At the
247 other two, the bird was originally caught on the nest, during incubation. The two
248 nests where birds were caught had lower productivity than the three nests where
249 birds were caught in a mistnet, where all three nests fledged the maximum of two
250 chicks. Opportunistic observations of prey were dominated by butterfish but shanny
251 (*Lioophrys pholis*) and sea scorpion (*Taurulus bubulis*) were also observed.

252

253 3.2 Individual foraging site fidelity

254 Black guillemots foraged within a maximum distance from the colony of 8.04km
255 (Median 1.7 km, Inter Quartile Range 3.6 - 5.88 km; 10.1km avoiding land; Table 2;
256 Figure S2). Both tracks (Figure 1; Figure S1) and 50% utilization distributions of
257 putative foraging locations (Figure 2) show that there was little overlap among the
258 core areas used by individuals. The 50% UD were small showing that individuals
259 concentrated their foraging into a few small areas. Home ranges in 2013 were on
260 average slightly larger than in 2014 but the difference between group means was
261 not statistically significant (one-way ANOVA: $F(1,15) = 2.497$, $p = 0.135$). Neither
262 tag duration (Estimate = 0.023, $p = 0.175$), year (Estimate = 0.000, $p = 0.999$), nor
263 breeding stage (Estimate = 0.007, $p = 0.968$) were significant predictors of home
264 range area (linear model: Adjusted R-squared = -0.03325, $F = 0.8069$, $df = 3,15$, $p =$
265 0.5094).

266

267 IFSF increased with spatial scale (Table 2). When all locations were considered,
268 IFSF was significantly greater than the null expectation at all scales considered (i.e.
269 $BA_{obs} > BA_{null}$), other than 5.8 km. When only putative foraging locations were
270 considered, IFSF was significantly greater than the null expectation at all scales. The
271 gradient of IFSF with temporal lag did not differ significantly from zero, indicating that
272 IFSF did not decay significantly with time over a period of ten days (Table 3, Figure
273 3).

274

275 The two immature birds behaved somewhat differently to adults (Figure 2). IFSF
276 was lower for immatures than adults at all but the smallest (100m grid) of the 11
277 scales tested (Table S2). One immature (tag 47), tracked during July, when adults
278 were chick-rearing, ranged more widely than adults and the second (tag 29), tracked
279 during June when adults are incubating, visited different colonies, perhaps
280 prospecting for a breeding site or partner.

281

282 Twelve of the 19 individuals (including the two immature birds) roosted on buoys,
283 fish farm cages (including those not currently stocked with fish), other colonies or
284 rocks while away from the colony (Figure 4) and all available man-made objects
285 (buoys and fish farms) within the observed foraging range were visited by one or
286 more of the tracked black guillemots.

287

288 **4. Discussion**

289 Variation in the space use among individuals affects how populations are distributed
290 and how they are affected by natural and anthropogenic impacts. It is becoming
291 clear that individual foraging site fidelity occurs in many seabird species, yet it
292 remains poorly characterised, especially among small, short ranging species and
293 immatures (Ceia & Ramos 2015). We found that breeding black guillemots exhibited
294 IFSF even at small spatial scales (500m) over up to 10 days, while foraging close to
295 the colony, in shallow waters between islands, where resources were presumed to
296 be relatively spatiotemporally predictable. In line with predictions of the exploration-
297 refinement hypothesis, two immatures showed less IFSF than adults.

299 Our study adds black guillemot to the list of species including penguins, albatrosses,
300 shearwaters, gulls, gannets, shags, cormorants and other auks (reviewed in Ceia &
301 Ramos 2015), where IFSF has been documented during the breeding season and,
302 along with these previous studies, makes the generalization that seabirds forage on
303 unpredictably distributed prey (Lack 1968) seem overly simplistic. For example, IFSF
304 in Northern gannets (*Morus bassanus*) breeding on Bass Rock, Scotland, persisted
305 not only within but across breeding seasons. Most individuals foraged in consistent
306 areas over time, though some were highly inconsistent (Wakefield et al. 2015).

307 These gannets were feeding in wider variety of habitats than the black guillemots in
308 our study, including more dynamic thermal front areas and less productive offshore
309 waters. They were also feeding on schooling prey as opposed to the sedentary
310 species black guillemots prefer. In the shallow waters surrounding the Orkney
311 archipelago, the highly regular actions of the tides and daylight are likely to result in
312 a much more predictability structured prey field than in more pelagic environments.
313 In turn, this is likely to favour individual foraging site fidelity. The finding that black
314 guillemots show IFSF even at very small spatial scales accords with expectations
315 that a species feeding in a predictable environment should profit from repeatedly
316 feeding in a preferred area (Weimerskirch 2007).

317 Comparing the degree of IFSF quantitatively between species from published
318 accounts is currently complicated by the wide variety of methods used to quantify
319 IFSF (Piper 2011). For example, the mean BA of gannet home ranges reported by
320 Wakefield et al. (2015) was around 0.4 which was lower than the typical BA for black
321 guillemots, but the scale at which IFSF is compared across these two species differs,
322 making the comparison invalid. It would be useful for studies to describe the level of

323 IFSF at different spatial scales so that the resultant curves could be compared
324 across species or populations (Figure S3). Comparing IFSF across species and
325 populations could identify factors and mechanisms resulting in animals adopting
326 IFSF strategies. In our study, IFSF did not decrease over the tracking period. This
327 could be regarded as evidence that they used an 'always stay' rather than a win-
328 stay, loose-shift strategy. However, our observation period was relatively short (<2
329 weeks). Moreover, the gradient of IFSF with time was negative and approached
330 significance for the foraging locations-only model and the slopes for most individuals
331 were negative. Therefore, while we did not observe a significant decay in IFSF over
332 this period, win-stay, loose-shift foraging may occur over a longer timescale.

333

334 A key advantage of IFSF for black guillemots is likely to be increased site familiarity
335 (Piper 2011). Short ranging results in short return times to prey patches over
336 successive visits. Because little time has elapsed, prey conditions are less likely to
337 vary between trips, favouring repeated visits to the same location (Weimerskirch
338 2007). Compared to the environments many seabirds forage in, black guillemot
339 foraging areas are characterised by rocky, shallow substrates and tidal races. The
340 former are static and offer physical features that individuals could learn to associate
341 with prey. The latter are highly dynamic but predictable in time and space so that
342 individuals could learn that at particular tidal states and locations certain types of
343 prey would be likely to be found. These factors together favour the premium added
344 by accruing local knowledge.

345

346 Riotte-Lambert et al. (2015) demonstrated that the ability of birds to evaluate and
347 memorise patch quality could theoretically lead to IFSF. The idea that long-lived
348 seabirds have the capacity to remember where and when prey become available is
349 increasingly well supported (Ceia & Ramos 2015). For example, kittiwakes
350 repeatedly chose specific areas and tidal stages for foraging suggesting that they
351 can predict prey resources in both space and time (Irons et al 1998). The capacity
352 for black guillemots in this study to evaluate patch quality would seem to be high
353 because of their short ranging tendencies and static foraging habitats.

354

355 The two immatures we tracked showed less IFSF than adults, presumably because
356 their behaviour was more exploratory. Apparent exploratory behaviour in immatures
357 has now been reported in several seabird species (e.g. Guilford et al. 2011, Votier et
358 al. 2017) with foraging choices narrowing in later life. Conservation managers
359 therefore need to consider that threats such as pollution or development are likely to
360 impact age classes differently, with younger age classes likely to be exposed to a
361 lower level of impact but across a larger number of birds than older adults using
362 IFSF.

363

364 From a conservation biology perspective, the discovery that a species exhibits IFSF
365 changes its management because there is a shift from a situation in which
366 individuals are exposed equally to a risk (e.g. from pollution, bycatch or industrial
367 development) to one in which some individuals are exposed disproportionately.
368 Moreover, IFSF suggests that foragers do not necessarily choose the optimal habitat
369 from those available, violating a key assumption of the Ideal Free and Ideal Despotic

370 models (Fretwell & Lucas 1969), two of the benchmark theories in foraging ecology
371 that are used by conservation managers (Boyd et al. 2018). Occurrence of IFSF also
372 implies that the behaviour of individuals, such as successive choices about where
373 and when to forage, may not be independent, even at wide temporal lags. This will
374 result in strong within-individual temporal autocorrelation in for example tracking
375 data, that must be accounted for when modelling habitat selection. A related
376 advantage to both researchers and study animals, of high IFSF, is that the usage of
377 an individual can be characterised by observing that individual for a relatively short
378 period of time. In turn this may make it practicable to track more individuals, thereby
379 leading to better predictions of space use (Wakefield et al. 2017). However, planning
380 to protect the average of a population may actually harm the specialists within it
381 (Bolnick et al. 2003), affecting populations particularly if those specialists are a
382 demographically important part of the population. Specialists have been shown to
383 have higher reproductive output than generalists in some seabird populations. For
384 example, Pigeon guillemots *Cepphus columba* feeding a specialist diet had higher
385 breeding success and fed larger prey items than generalists (Golet et al. 2000) and
386 black-browed albatrosses *Thalassarche melanophris* which were more faithful
387 between years to a foraging location had higher reproductive success than non-
388 specialists (Patrick & Weimerskirch 2017).

389

390 The frequent observations of roosting in this species invites further investigation.
391 Mandt's Black guillemots (*Cepphus grylle mandtii*) have also been observed to roost
392 frequently though this was outside the breeding season and mostly at night on sea
393 ice (Divoky et al. 2016). Our observations of birds resting on buoys etc. may have
394 been due to birds attempting to save energy. For example, canvasback ducks

395 (*Aythya valisineria*) resting in water of 35°C have a metabolic rate of 4kcal/hr
396 whereas in air of the same temperature the rate is 2.7kcal/hr. In colder water of 0°C
397 the metabolic rate was much higher at 10.5kcal/hr (Alisauskas and Ankney, 1992).
398 Roosting may also allow self-feeding (as opposed to chick feeding) birds to rest
399 outside the colony between foraging bouts (Schreiber & Chovan 1986) or roosting
400 sites could offer a vantage point from which to socialise or monitor the foraging
401 behaviour of other birds (i.e. to gather public information). Ward & Zaharvi (1973)
402 propose that communal roosts serve as information centres giving birds knowledge
403 of local feeding resources, but individual black guillemots appear to segregate
404 feeding areas rather than feed communally. It is also possible that black guillemots
405 alight on structures outside the colony to stay stationary while waiting for favourable
406 foraging conditions e.g. particular tidal states. Black guillemots could also use
407 roosting sites to display or even defend a feeding territory. Such behaviour is almost
408 unknown among seabirds (Drury & Smith 1968) but was observed anecdotally in one
409 pair of pigeon guillemots (*Cepphus columba*) in Alaska (Kathy Kuletz *pers comm*).
410 The fact that black guillemots appear to have a high propensity to roosting on man-
411 made objects is relevant to their conservation, particularly where devices which
412 present a potential collision risk, such as tidal turbines (Furness et al. 2012, Masden
413 et al. 2013), are placed close to colonies. Such devices should be designed with
414 limited space for roosting to ensure that black guillemots are not attracted to
415 installations with moving parts.

416

417 We demonstrate that individual foraging site fidelity is a strong determinant of space
418 use in a small, locally foraging seabird and that roosting away from the colony was
419 common. Both these factors should be considered when designing spatial

420 conservation measures or assessing the potential impacts of developments such as
421 tidal energy devices. Individuals cannot be assumed to be ecologically equivalent.
422 Instead, the population-level consequences of threats or ecological processes act
423 through a filter of individual variation.

424

425 *Acknowledgements* – We are grateful to Emily Scragg and Stacey Adlard who
426 collected tracking data in 2014 and numerous volunteers constructing tystie igloo
427 cairns. Ian Cleasby and Linda Wilson and 3 anonymous reviewers provided
428 comments which improved the paper. Funding was provided by the RSPB, Scottish
429 Natural Heritage and the UK Natural Environment Research Council (grant
430 NE/M017990/1).

549 **Tables**

550 Table 1: The number of black guillemots tracked each year, duration of tracking,
 551 breeding status and foraging range. Tags with zero days deployment were those that
 552 never re-established contact with the base station either because the tag failed or
 553 because the bird removed the tag or was absent from the colony. *On nest for
 554 deployment and a second time to remove device.

| Year | Bird ID (logger number in brackets) | Breeding status | Days of deploy- ment | Max Foraging range (km) | Capture method | Nest success at end of season (nest site number) |
|------|--|--------------------|-------------------------------|----------------------------------|-------------------|--|
| 2013 | 25/AA (6) | Inc. adult | 6 | 4.38 | On nest | 1 chick (nest 22) |
| 2013 | 26/AB (13) | Inc. adult | 4 | 3.40 | Mistnet | 2 chicks (nest 42) |
| 2013 | 27/AC (5) | Inc. adult | 0 | No data | Mistnet | 2 chicks (nest 9) |

556 Table 2: Observed (BA_{obs}) and null (BA_{null}) Bhattacharya's Affinity (BA) scores
557 comparing within-individual consistency in foraging areas against between-individual
558 consistency. A randomisation procedure tests the hypothesis that the median
559 observed BA is \leq than the null median BA. Individual consistency is high if median
560 BA_{obs} is $>$ the 95th percentile of median BA_{null} . Other percentiles of BA_{null} describe the
561 shape and range of the null distribution and P is the probability that BA_{obs} is $\leq BA_{null}$.

562

| Subset | Scale (km) | N birds | Median BA_{obs} (min, max) | Percentiles of median BA_{null} | | | | P |
|---------------------|---------------|------------|---------------------------------|-----------------------------------|------|------|------|--------|
| | | | | 25th | 50th | 75th | 95th | |

604 1. Measured from centre of feature.

605 2. Buffer size dependent on size of feature.

606 Table S2: One-way ANOVA showing differences between levels of IFSF (BA scores)
607 of immature (n=13 bird*day) and adult (n=76 bird*day) black guillemots at each of 11
608 scales from 100m to 5.7km. (df 1, 87).

609

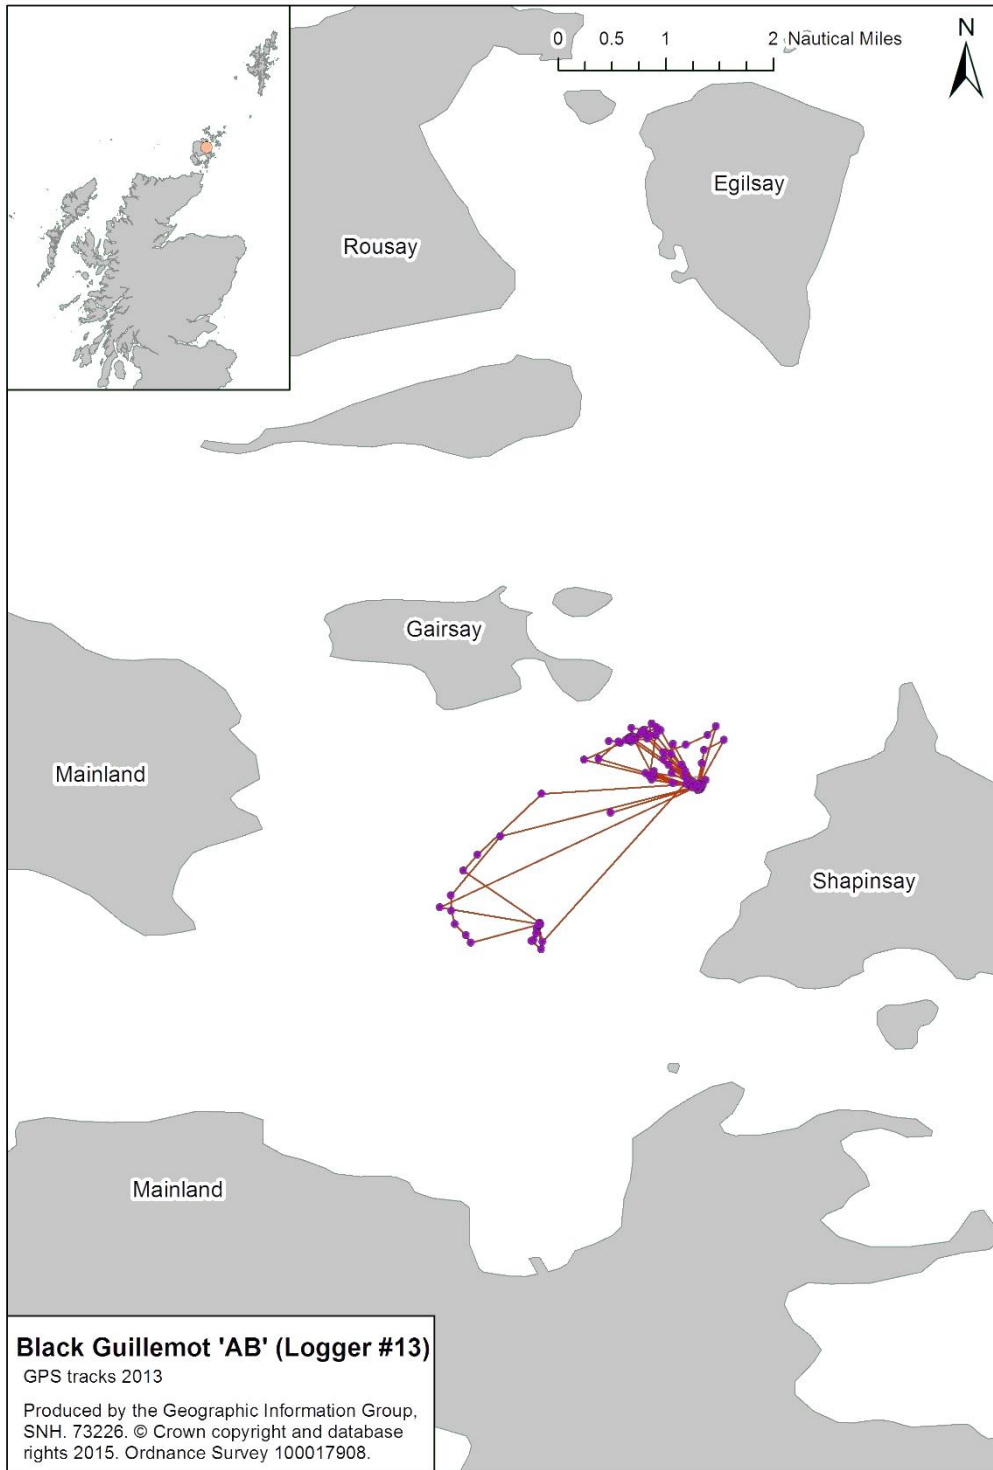

| Scale (km) | F | P |
|---------------|-------|--------|
| 0.1 | 3.25 | 0.075 |
| 0.15 | 8.67 | 0.004 |
| 0.225 | 11.70 | 0.001 |
| 0.338 | 17.67 | <0.001 |
| 0.506 | 15.48 | <0.001 |
| 0.759 | 16.83 | <0.001 |
| 1.139 | 15.31 | <0.001 |
| 1.709 | 14.57 | <0.001 |
| 2.563 | 33.55 | <0.001 |
| 3.844 | 13.75 | <0.001 |
| 5.767 | 22.72 | <0.001 |
