23 and then adopted to evaluate the accuracy of the existing slenderness limits (for classifications
24 of plate elements and cross-sections) and local buckling design rules for S690 high strength
25 steel welded I-sections in bending, as set out in the European, Australian and American
26 standards. The results of the evaluation revealed that the codified slenderness limits are
27 generally safe when used for the classification of the constituent plate elements of the examined
28 S690 high strength steel welded I-section beams, except for that given in the American
29 specification for slender/non-slender outstand elements in compression. All of the three
30 considered design standards were shown to yield accurate cross-section bending moment
31 capacity predictions for compact (Class 1 and 2) S690 high strength steel welded I-section
32 beams bent about both the principal axes and non-compact (Class 3) S690 high strength steel
33 welded I-section beams bent about the major principal axes, but resulted in a rather high level
34 of conservatism in predicting the cross-section bending moment capacities for non-compact
35 (Class 3) S690 high strength steel welded I-sections in bending about the minor principal axes
36 and slender (Class 4) S690 high strength steel welded I-sections subjected to both major-axis
37 bending and minor-axis bending.

43

44

45 **1. Introduction**

46

47 High strength construction materials have been increasingly used in bridge and structural
48 engineering. Compared with normal strength mild steels (e.g., grades S235, S275 and S355),
49 high strength steels (with the nominal yield strengths greater than 460 MPa) possess superior
50 mechanical strengths, and enable the achievement of structural components designed with
51 smaller cross-section sizes and lighter self-weights, which lead to structures with (i) more
52 usable interior space between vertical and horizontal components and (ii) lighter overall weight,
53 resulting in great savings in the costs of foundations and reduction in seismic loads. However,
54 high material strength is accompanied by low material ductility, and thus high strength steels
55 are not desirable for fabricating beam-to-columns joints, where the rotation capacity (largely
56 dependent on the material ductility) is a major design concern. The lack of experimental
57 verification of high strength steel structural members and joints at present limits the actual
58 application of high strength steel in construction engineering. Experimental investigations have
59 therefore been prompted to verify the structural behaviour of various types of high strength
60 steel components (e.g., stub columns [1–4], long columns [5–9] and beam-columns [10]) of I-
61 shaped sections, quantify their cross-section (or member) capacities, and develop precise
62 design approaches. However, it is worth noting that research into S690 high strength steel
63 welded I-section beams remains relatively scarce, despite three previous studies carried out by
64 McDermott [11], Beg and Hladnik [12] and Wang [13].

65

66 To expand the experimental and numerical data pool on S690 high strength steel welded I-

67 section beams and further examine their flexural behaviour and strengths, a thorough testing
68 and finite element simulation study was conducted and presented in this paper. An experimental
69 study was firstly conducted on six S690 high strength steel welded I-sections, and involved
70 initial local geometric imperfection measurements and twelve in-plane four-point bending tests,
71 with six bent about the major principal axes and another six bent about the minor principal axes.
72 This was followed by a numerical modelling investigation, where finite element models were
73 firstly developed and validated against the test results and afterwards used to conduct
74 parametric studies, aiming at generating additional numerical data over a broader range of
75 section sizes. Finally, the experimentally and numerically obtained results were used to assess
76 the accuracy of the local buckling design rules for S690 high strength steel welded I-section
77 beams, specified in the European code EN 1993-1-12 [14], Australian standard AS 4100 [15]
78 and American specification ANSI/AISC 360-16 [16].

79

80 **2. Experimental study**

81

82 *2.1. General*

83

84 A structural testing programme was performed to examine the in-plane bending behaviour and
85 capacities of S690 high strength steel welded I-section beams. Six different I-section sizes were
86 adopted in the present testing programme: I-50×50×5, I-70×70×5, I-80×60×5, I-90×70×5, I-
87 100×100×5 and I-140×70×5, and all the I-sections were fabricated from the same batch of 5
88 mm thick S700MC high strength steel hot-rolled plates by gas metal arc welding. Overall, the

89 testing programme involved twelve in-plane four-point bending tests, with six performed about
90 the major principal axes and another six conducted about the minor principal axes, together
91 with the initial local geometric imperfection measurements of the beam specimens.

92

93 *2.2. Measurements on material properties and membrane residual stresses*

94

95 Prior to in-plane four-point bending tests, material testing was carried out to derive the material
96 stress–strain responses of the examined S690 high strength steel and measurements on
97 membrane residual stresses were conducted to determine their distributions and amplitudes in
98 S690 high strength steel welded I-sections. The test rigs and procedures were fully reported in
99 Sun et al. [3], with only a brief summary provided herein. Two longitudinal coupons and two
100 transverse coupons were extracted from the same batch of S700MC plates as that used for
101 fabricating the beam specimens, and tested utilising a Schenck 250 kN hydraulic testing
102 machine under displacement control, with the resulting strain rates being in conformity with
103 the specific requirements given in EN ISO 6892-1 [17]. Fig. 1 [3] shows the stress–strain curves
104 measured from both the longitudinal and transverse coupons, while the key average measured
105 material properties, including the Young’s modulus E , the yield stress f_y , the ultimate stress f_u ,
106 the ultimate-to-yield stress ratio f_u/f_y , the strain at the ultimate stress ε_u and the fracture strain
107 ε_f , are reported in Table 1. The membrane residual stress magnitudes and distributions in the
108 examined S690 high strength steel welded I-sections were measured by means of the sectioning
109 method, with the rig and procedures being in compliance with those recommended in Ziemian
110 [18]. On the basis of the experimental results, a new predictive model [3] was proposed

111 specifically for predicting the membrane residual stresses in S690 high strength steel welded
112 I-sections, with the distribution pattern shown in Fig. 2 and the amplitudes of the peak
113 membrane residual stresses presented in Table 2.

114

115 *2.3. Measurements on initial local geometric imperfections*

116

117 Initial geometric imperfections are primarily introduced into steel components during the
118 manufacturing process, and may result in premature failure of the steel components with low
119 load-carrying capacities and steep post-ultimate load–deformation responses. The focus of the
120 present study is on the in-plane flexural (local buckling) behaviour of S690 high strength steel
121 welded I-section beams, and thus the initial local geometric imperfection of each specimen was
122 measured, based on the test rig shown in Fig. 3, where the specimen is clamped on the base
123 table of a milling machine, whilst an LVDT is attached to the head of the milling machine and
124 moved along the centreline of each of the three constituent plates (i.e. one web and two flanges)
125 of the specimen to measure the local deviations [19]. It is worth noting that imperfection
126 measurements were all carried out over the central 75% of the specimen lengths, in order to
127 eliminate the effect of flaring of specimen ends upon cutting. For each constituent plate element
128 of the S690 high strength steel welded I-section beam specimen, the maximum initial local
129 geometric imperfection amplitude was taken as the largest deviation from a linear regression
130 surface fitted to the corresponding measured data set [20–23], and presented in Table 3, where
131 ω_w , ω_{f1} , ω_{f2} are the measured maximum local imperfection amplitudes of the web and two
132 flanges, respectively, while the initial local geometric imperfection amplitude of the S690 high

133 strength steel welded I-section beam specimen ω_0 was taken as the maximum of ω_w , ω_{f1} and
134 ω_{f2} .

135

136 *2.4. Four-point bending tests*

137

138 For each S690 high strength steel welded I-section, two four-point bending tests were
139 conducted about both the major and minor principal axes, to study the in-plane flexural
140 behaviour and bending moment resistances. The member lengths and cross-section geometric
141 sizes of the beam specimens were carefully measured, and presented in Table 3, where L is the
142 specimen length, h is the outer section depth, b_f is the flange width and t is the wall thickness.

143 The four-point bending test procedures and setup conformed to those recommended in Ziemian
144 [18]. Displacement-controlled loading scheme was adopted to drive the actuator of an
145 INSTRON 2000 kN hydraulic testing frame, with a constant speed of 2 mm/min. Fig. 4 shows
146 the setup for the four-point bending tests about the minor principal axes, where two pairs of
147 steel rollers are employed to provide the four-point bending configuration, with one pair located
148 at a distance of 50 mm from the end sections of the beam specimen and the other pair placed
149 at third-points of the flexural span (i.e. the span between the two end rollers) of the beam
150 specimen, solid wooden blocks are inserted into the beam specimen at the two loading points
151 as well as the two supports, in order to avoid the occurrence of crippling failure of flanges, and
152 three string potentiometers are placed at the two loading points and mid-span to record the
153 respective vertical deflections. The four-point bending tests about the major principal axes were
154 performed using a similar test rig, as shown in Fig. 5, but with G-clamps vertically mounted

155 onto the spreader beam to act as lateral restraints for preventing any lateral or torsional
156 deformation of the beam specimens and eliminating the possibility of member lateral-torsional
157 buckling.

158

159 All the tested S690 high strength steel welded I-section beam specimens exhibited visible in-
160 plane deformation and failed by local buckling; Fig. 6 and Fig. 7 depict the failure modes of
161 typical beam specimens I-100×100×5-MA (in major-axis bending) and I-100×100×5-MI (in
162 minor-axis bending), respectively. The key test results, obtained from the four-point bending
163 tests, are presented in Table 4, including the failure moment M_u , the ratios of M_u/M_{pl} and M_u/M_{el} ,
164 in which M_{pl} and M_{el} are the cross-section plastic and elastic moment resistances with respect
165 to the considered bending axis, and respectively calculated as the plastic (W_{pl}) and elastic (W_{el})
166 section moduli multiplied by the material yield stress f_y , and the beam rotation capacity R [24–
167 26]. Figs 8 and 9 depict the normalised moment–curvature curves for the examined S690 high
168 strength steel welded I-section beam specimens in major-axis bending and in minor-axis
169 bending, respectively, where the curvature κ is calculated from Eq. (1), in which D_L and D_M are
170 the corresponding vertical deflections at the loading points and at the mid-span, as measured
171 from the string potentiometers, and L_m is the distance between the two loading points.

$$172 \quad \kappa = \frac{8(D_M - D_L)}{4(D_M - D_L)^2 + L_m^2} \quad (1)$$

173

174

175

176

177 **3. Numerical investigation**

178

179 *3.1. General*

180

181 In conjunction with the structural testing performed in Section 2, a numerical modelling study
182 was performed, utilising the nonlinear finite element (FE) software ABAQUS [27], and
183 reported in the present section. A numerical validation study was initially conducted to validate
184 the developed FE models against the obtained experimental results, followed by a parametric
185 study to derive additional numerical results on S690 high strength steel welded-I-section beams
186 over a wider spectrum of cross-section sizes.

187

188 *3.2. Development of finite element (FE) models*

189

190 Having been successfully and widely utilised in previous numerical modelling of high strength
191 steel welded I-section members [3,28,29], the four-node shell element S4R [27] was also
192 employed herein for simulating S690 high strength steel welded I-section beams. The element
193 size was selected upon a mesh sensitivity study examining a range of element sizes from $0.5t$
194 to $3t$; it was generally found that an element size equal to the material thickness t led to accurate
195 incorporation of the membrane residual stresses into the FE models and also resulted in both
196 precise numerical results and adequate computational efficiency, and was thus assigned to each
197 beam FE model. The stress–strain curves, measured from the longitudinal coupons, were firstly
198 converted into the true stress–true plastic strain curves and then inputted into ABAQUS [27].

199 The membrane residual stress distributions and amplitudes, as derived from the proposed
200 predictive model [3] (see Section 2.2), were incorporated into the beam FE models through the
201 ‘*INITIAL CONDITIONS’ command [27]; Fig. 10 displays a typical membrane residual stress
202 pattern incorporated into the FE models for the beam specimens I-100×100×5-MA and I-
203 100×100×5-MI.

204

205 For the ease of setting boundary conditions, each of the two sections of the beam FE models at
206 the end supports was coupled to a reference point, positioned at the bottom web-to-flange
207 junction for major-axis bending or at the mid-point between the two bottom flange tips for
208 minor-axis bending. In order to replicate the simply-supported boundary condition used in the
209 testing, one reference point was allowed to translate longitudinally and rotate about the axis of
210 bending while the other one was only allowed for rotation about the same bending axis. Besides,
211 the cross-section at each loading point was also coupled to a reference point, which was located
212 at the top web-to-flange junction for major-axis bending or at the mid-point between the two
213 top flange tips for minor-axis bending, and allowed to have translations along both the
214 longitudinal and vertical directions and rotation about the axis of bending, to mimic the four-
215 point bending configuration. With regards to the modelling of beams bent about the major
216 principal axes, additional lateral and torsional restraints were applied to those cross-sections
217 that were restrained by G-clamps in the testing, to eliminate the possibility of lateral-torsional
218 buckling.

219

220 Initial local geometric imperfections were incorporated into the S690 high strength steel

221 welded I-section beam FE models, with the distribution patterns taken as the lowest elastic
222 buckling mode shapes in four-point bending and derived from a prior elastic eigenvalue
223 buckling analysis [30–35]. Four initial local imperfection amplitudes, including the measured
224 imperfection value w_0 and 1/10, 1/30 and 1/100 of material thickness t , were then used to factor
225 the derived imperfection patterns, enabling the sensitivity of the established S690 high strength
226 steel weld I-section beam FE models to imperfection amplitudes to be evaluated.

227

228 *3.3. Validation of finite element models*

229

230 Upon establishment of the S690 high strength steel welded I-section beam FE models,
231 nonlinear static Riks analysis [27] was conducted to determine the numerical ultimate bending
232 moments, moment–curvature responses and failure modes. Based on the comparisons of the
233 numerical results against their experimental counterparts, the accuracy of the established beam
234 FE models was evaluated. The FE to experimental ultimate moment ratios for the tested S690
235 high strength steel welded I-section beam specimens are reported in Table 5, in which the
236 results generally indicate that all the four adopted initial local geometric imperfection
237 amplitudes yield precise and consistent predictions of the experimental failure moments, with
238 the best agreement obtained when the local imperfection amplitude equal to 1/100 of the
239 material thickness was used in the numerical simulation. Figs 6 and 7 depict the comparisons
240 between the experimental and numerical local buckling failure modes for typical beam
241 specimens I-100×100×5-MA and I-100×100×5-MI subjected to major-axis bending and minor-
242 axis bending, respectively, indicating excellent agreement. The experimentally and numerically

243 derived normalised moment–curvature responses for a typical beam specimen I-140×70×5-MA
244 in major-axis bending are compared in Fig. 11, while a similar graphic comparison is shown in
245 Fig. 12 for a typical beam specimen I-100×100×5-MI in minor-axis bending, both revealing
246 that the established beam FE models are capable of replicating the full experimental normalised
247 moment–curvature histories. Moreover, the normalised numerical moment–curvature curves
248 were also derived from the beam FE models without inclusion of membrane residual stresses
249 and shown in Figs 11 and 12; the normalised numerical moment–curvature responses with and
250 without membrane residual stresses were observed to almost coincide, revealing that the effect
251 of membrane residual stresses on the in-plane bending behaviour of S690 high strength steel
252 welded I-section beams is negligible, as also highlighted in previous similar numerical studies
253 [33,35]. In sum, the developed beam finite element models have been proven to be capable of
254 precisely simulating the four-point bending tests on S690 high strength steel welded I-section
255 beams.

256

257 *3.4. Parametric studies*

258

259 On the basis of the beam FE models established and validated in Section 3.3, parametric studies
260 were performed to derive additional numerical data beyond those derived from the experiments.
261 In the present parametric studies, the material stress–strain responses measured from the
262 longitudinal coupons were employed, while the incorporated initial local imperfection
263 amplitudes were selected as $t/100$. The flexural spans of all the numerically modelled I-section
264 beams were equal to 1500 mm, whilst the two loading points were positioned at third-points of

265 the flexural spans. Regarding the cross-section sizes of the modelled I-section beams, the outer
266 depths were fixed at 150 mm, with the flange widths taken as 75 mm, 100 mm and 150 mm,
267 respectively, resulting in a range of cross-section aspect ratios being considered; the thicknesses
268 of the web and flanges of each modelled I-section were set to be equal and varied between 2
269 mm and 15 mm, which led to a broad spectrum of cross-section geometric sizes being examined.
270 In total, 185 and 101 numerical data on S690 high strength steel welded I-section beams under
271 major-axis and minor-axis bending were respectively generated through parametric studies.

272

273 **4. Assessment of existing international design codes**

274

275 *4.1. General*

276

277 In the present section, the beam test results, obtained in Section 2, together with the numerical
278 data, acquired in Section 3, were used to evaluate the accuracy of the slenderness limits and
279 design rules for S690 high strength steel welded I-section beams susceptible to in-plane
280 bending failure, as specified in the existing European code EN 1993-1-12 [14], Australian
281 standard AS 4100 [15] and American Specification ANSI/AISC 360-16 [16]. The unfactored
282 design cross-section bending moment resistances ($M_{u,EC3}$, $M_{u,AS}$ and $M_{u,AISC}$) were firstly
283 calculated in accordance with the three considered design codes and afterwards compared
284 against the test (and numerical) ultimate bending moments, with the mean test (or numerical)
285 to predicted ultimate bending moment ratio ($M_u/M_{u,EC3}$, $M_u/M_{u,AS}$ or $M_u/M_{u,AISC}$) for each design
286 code given in Table 6.

287

288 4.2. European code EN 1993-1-12 (EC3)

289

290 4.2.1. General

291

292 The current Eurocode EN 1993-1-12 [14] was developed specifically for high strength steels
293 with grades greater than S460 up to S700, though mirroring most of the design provisions given
294 in EN 1993-1-1 [36] for normal strength mild steels. Regarding the design of S690 high
295 strength steel welded I-sections subjected to bending, EN 1993-1-12 [14] adopts the same
296 concept of cross-section classification (i.e. the strength of the cross-section is dependent on the
297 class of the cross-section) as that utilised in EN 1993-1-1 [36]. Four cross-section classes were
298 specified in the Eurocodes [14,36]: Class 1 and 2 (plastic) sections in bending can achieve the
299 plastic moment capacities (M_{pl}), Class 3 (elastic) sections subject to bending are capable of
300 attaining the elastic moment capacities (M_{el}), and Class 4 (slender) sections fail before the
301 material yield stresses f_y are attained, with the design bending moment resistances limited to
302 the effective moment capacities (M_{eff}). To determine the class of a welded I-section in bending,
303 all of its constituent plate elements (i.e. outstand flanges and internal web) are firstly classified
304 through comparisons of the respective flat width-to-thickness ratios (c_w/t and c_f/t , in which c_w
305 and c_f are respectively the flat widths of the web and flange) against the slenderness limits
306 specified in the Eurocodes [14,36], and the class of the most slender plate element is then
307 defined as the overall class of the examined I-section. The EC3 Class 3 and Class 2 slenderness
308 limits for classifying internal and outstand plate elements under various loading conditions (i.e.

309 compression, bending and compressive stress gradients) are listed in Table 7(a), where $\varepsilon_{EC3} =$
310 $\sqrt{235/f_y}$ is the EC3 material parameter to consider the effect of material strength on the plate
311 element slenderness limits, and k_σ is the buckling factor and dependent on the stress distribution
312 and boundary condition of the plate element. In the following sub-section 4.2.2 and sub-section
313 4.2.3, the accuracy of the EN 1993-1-12 slenderness limits and design bending moment
314 capacities were respectively evaluated.

315

316 *4.2.2. Cross-section classification limits*

317

318 The Class 3 slenderness limits for outstand plate elements in compression and internal plate
319 elements in bending were assessed based on the experimental and FE data on S690 high
320 strength steel welded I-section beams bent about the major principal axes, with the results of
321 the graphic assessments respectively depicted in Fig. 13 and Fig. 14, where the test and
322 numerical ultimate bending moments, normalised by the cross-section elastic moment
323 resistances, are plotted against the $c_f/(t\varepsilon_{EC3})$ and $c_w/(t\varepsilon_{EC3})$ ratios of the examined S690 high
324 strength steel welded I-sections, together with the EC3 Class 3 slenderness limits (normalised
325 by ε_{EC3}) for outstand plate elements in compression $c_f/(t\varepsilon_{EC3})=14$ and internal plate elements in
326 bending $c_w/(t\varepsilon_{EC3})=124$. It was generally found that the established Class 3 slenderness limits
327 in EN 1993-1-12 [14] are safe but conservative when used for the classification of internal
328 webs (in bending) and outstand flanges (in compression) of S690 high strength steel welded I-
329 sections subjected to major-axis bending. The ultimate bending moment resistances, derived
330 from the structural testing and finite element modelling on S690 high strength steel welded I-

331 section beams in minor-axis bending, were then utilised to assess the accuracy of the current
332 EC3 Class 3 slenderness limit for outstand plate elements under triangular compressive stress
333 gradients ($c_f/(t\epsilon_{EC3})=21k_\sigma^{0.5}$, in which $k_\sigma=0.57$) in Fig. 15. The results of the assessments
334 generally revealed that the EC3 Class 3 slenderness limit for outstand plate elements under
335 triangular compressive stress gradients is rather conservative though safe when used for the
336 classification of outstand flanges of S690 high strength steel welded I-section beams in minor-
337 axis bending.

338

339 A similar graphic evaluation was also performed on the established EC3 Class 2 slenderness
340 limit for internal plate elements in bending ($c_w/(t\epsilon_{EC3})=83$), based on the test and numerical data
341 on S690 high strength steel welded I-section beams under major-axis bending, as given in Fig.
342 16. The EC3 Class 2 slenderness limits for outstand plate elements in compression
343 ($c_f/(t\epsilon_{EC3})=10$) was evaluated, based on the derived experimental and FE data on S690 high
344 strength steel welded I-section beams bent about both the major and minor principal axes, as
345 depicted in Fig. 17. The results of the graphic evaluations in Figs 16 and 17 generally revealed
346 that the Class 2 slenderness limits established in EN 1993-1-12 [14] are safe and accurate when
347 used for the classifications of internal webs (in bending) and outstand flanges (in compression)
348 of S690 welded I-section beams.

349

350 *4.2.3. EC3 Cross-section bending moment resistance predictions*

351

352 The EC3 predictions of cross-section bending moment capacities for S690 high strength steel

353 welded I-section beams were assessed through comparisons against the obtained test and FE
354 ultimate bending moments. The current EN 1993-1-12 [14] prescribes the use of cross-section
355 plastic (M_{pl}) and elastic (M_{el}) moment capacities as the design bending moment capacities for
356 Class 1 (and 2) and Class 3 sections, respectively, and adopts the effective width method to
357 predict the cross-section bending moment resistances for those slender Class 4 sections. The
358 effective width method makes due allowance for loss of effectiveness owing to local buckling
359 by reducing the flat widths of the slender constituent outstand and internal plate elements. The
360 effective (reduced) widths c_{eff} of slender flanges (outstand elements) and webs (internal
361 elements) of I-sections can be respectively calculated from Eq. (2) and Eq. (3) [37], in which
362 $\bar{\lambda}_p$ is the slenderness of the plate element, as defined by Eq. (4), where k_σ is the buckling
363 factor, dependent on the type of the plate element and stress distribution throughout plate width,
364 and can be calculated in accordance with Tables 4.1 and 4.2 of EN 1993-1-5 [37]. Upon
365 calculation of the effective widths of all the slender plate elements of the Class 4 welded I-
366 section, the EC3 effective section modulus ($W_{eff,EC3}$) and effective bending moment capacity
367 ($M_{eff,EC3}=W_{eff,EC3}f_y$) can then be derived; it is worth noting that cumbersome iterations may be
368 involved in the calculation of $W_{eff,EC3}$ due to the shift in effective neutral axis along with each
369 round of calculation.

$$370 \quad c_{eff} = c_f \left(\frac{1}{\bar{\lambda}_p} - \frac{0.188}{\bar{\lambda}_p^2} \right) \leq c_f \quad (2)$$

$$371 \quad c_{eff} = c_w \left(\frac{1}{\bar{\lambda}_p} - \frac{0.22}{\bar{\lambda}_p^2} \right) \leq c_w \quad (3)$$

$$372 \quad \bar{\lambda}_p = \frac{c/t}{28.4 \varepsilon_{EC3} \sqrt{k_\sigma}} \quad (4)$$

373

374 The ratios of the test and FE ultimate bending moments to the EC3 cross-section bending
375 moment resistance predictions are plotted against the c/t ratios of the flanges of the examined
376 I-sections, and depicted in Fig. 18, while Table 6(a) presents the mean experimental (and
377 numerical) to EC3 design cross-section bending capacity ratios $M_u/M_{u,EC3}$, together with the
378 corresponding coefficients of variation (COVs), for different classes of S690 welded I-sections
379 in bending. The results of both the graphic and numerical comparisons revealed that the cross-
380 section bending moment resistances are well predicted by the current EN 1993-1-12 [14] for
381 Class 1 (and Class 2) S690 high strength steel welded I-section beams bent about both the
382 principal axes and Class 3 S690 high strength steel welded I-section beams in major-axis
383 bending, while EN 1993-1-12 [14] yields overly conservative bending moment capacity
384 predications for Class 3 S690 high strength steel welded I-section beams bent about the minor
385 principal axes and Class 4 S690 high strength steel welded I-section beams in both major-axis
386 bending and minor-axis bending.

387

388 *4.3. Australian Standard AS 4100*

389

390 The current Australian standard AS 4100 [15], which provides design provisions for both
391 normal strength mild steels and high strength steels with grades up to S690, also employs the
392 cross-section classification framework for the design of welded I-section beams failing by local
393 buckling. Through comparisons of the flat width-to-thickness ratios against the slenderness
394 limits for all the constituent plate elements, cross-sections in bending are classified as compact,
395 non-compact and slender sections in AS 4100 [15], corresponding to Class 1 (and 2), Class 3,

396 and Class 4 sections defined in EN 1993-1-12 [14]. Note that the AS 4100 slenderness limits
397 between non-compact and compact plate elements and between slender and non-compact plate
398 elements are respectively termed as the plasticity and yield slenderness limits (corresponding
399 to the EC3 Class 2 and Class 3 slenderness limits), as presented in Table 7(b), where $\varepsilon_{AS} =$
400 $\sqrt{250/f_y}$ is the AS material parameter. Graphic evaluation of the AS yield slenderness limits
401 for outstand elements in compression ($c_f/(t\varepsilon_{AS})=14$), internal elements in bending ($c_w/(t\varepsilon_{AS})=115$)
402 and outstand elements in triangular compressive stress gradients ($c_f/(t\varepsilon_{AS})=22$) as well as the
403 AS plasticity slenderness limits for internal elements in bending ($c_w/(t\varepsilon_{AS})=82$) and outstand
404 elements in compression ($c_f/(t\varepsilon_{AS})=8$) was carried out based on the relevant test and FE data,
405 and shown in Figs 19–23, respectively. The results of the graphic evaluations generally
406 indicated that the current AS yield limits are safe but considerably conservative when used for
407 the classification of both internal webs and outstand flanges of S690 high strength steel welded
408 I-section beams, while the plasticity slenderness limits yield a good level of accuracy in the
409 plate element classification.

410

411 The current AS 4100 [15] adopts M_{pl} as the design bending moment resistances for compact
412 welded I-section beams, but with an upper limit of $1.5M_{el}$, as given by Eq. (5), and takes into
413 due account partial plasticity in the predictions of cross-section bending moment resistances
414 for non-compact welded I-section beams, with the design formulation shown by Eq. (6), where
415 M_c is taken as the minimum of M_{pl} and $1.5M_{el}$ of the examined non-compact I-section, λ_s is
416 equal to the c/t ratio of the most slender constituent plate element of the non-compact I-section
417 in bending; note that the most slender constituent plate element is defined as the element with

418 the greatest plate element c/t to yield slenderness limit (see Table 7(b)) ratio, and λ_{sy} and λ_{sp} are
419 the corresponding yield and plasticity limits for the most slender constituent plate element and
420 presented in Table 7(b). Regarding slender welded I-section beams, the effective bending
421 moment resistances, specified in AS 4100 [15], are determined through multiplying the cross-
422 section elastic moment capacities M_{el} by the reduction factor ρ , as given by Eq. (7); note that
423 the reduction factor ρ is calculated as (λ_{sy}/λ_s) and $(\lambda_{sy}/\lambda_s)^2$ for welded I-sections with the most
424 slender plate element being subjected to uniform compression (i.e. major-axis bending case)
425 and stress gradients (i.e. minor-axis bending case), respectively.

$$426 \quad M_{u,AS} = M_{pl} \leq 1.5M_{el} \quad (5)$$

$$427 \quad M_{u,AS} = M_{el} + (M_c - M_{el}) \left(\frac{\lambda_{sy} - \lambda_s}{\lambda_{sy} - \lambda_{sp}} \right) \quad (6)$$

$$428 \quad M_{u,AS} = \rho M_{el} \quad (7)$$

429

430 The accuracy of the current Australian standard AS 4100 [15] for the design of S690 high
431 strength steel welded I-section beams failing by local buckling was assessed by comparing the
432 obtained experimental and FE ultimate bending moments with the AS predicted cross-section
433 bending moment capacities. As evident in Fig. 24 and Table 6(b), the current AS 4100 [15]
434 yields accurate and consistent cross-section bending moment capacity predictions for compact
435 S690 high strength steel welded I-section beams in both major-axis bending and minor-axis
436 bending and non-compact S690 high strength steel welded I-section beams subjected to major-
437 axis bending, but excessively under-estimates the cross-section bending moment resistances
438 for non-compact S690 welded I-section beams bent about the minor principal axes and slender
439 S690 high strength steel welded I-section beams in both major-axis and minor-axis bending.

440

441 *4.4. American specification ANSI/AISC 360-16*

442

443 The existing American specification ANSI/AISC 360-16 [16], with the scope of application
444 covering steels with grades up to S690, also adopts the cross-section classification framework
445 for the design of welded I-section beams prone to local instability. Through comparisons of the
446 flat width-to-thickness ratios against the corresponding slenderness limits for all the constituent
447 plate elements, the existing ANSI/AISC 360-16 [16] classifies cross-sections subjected to
448 bending as slender, non-compact and compact sections, similar to the current AS 4100 [15];
449 note that the flat element widths of flanges of I-shaped sections are given as half of the full
450 flange widths in ANSI/AISC 360-16 [16], while the flat element widths of webs are defined as
451 the clear distances between the flanges. The American specification ANSI/AISC 360-16 [16]
452 terms the slenderness limits for slender/non-compact and non-compact/compact plate elements
453 as non-compact and compact limiting width-to-thickness ratios, as listed in Table 7(c), where
454 $\epsilon_{AISC} = \sqrt{E/f_y}$ is the AISC material parameter and $k_c = 4 \sqrt{t/c_w}$ is a geometric parameter to
455 account for the influence of the size of the internal web on the slenderness limit of the outstand
456 flange. The test and FE numerical results on S690 welded I-section beams were adopted to
457 evaluate the accuracy of the AISC non-compact limiting width-to-thickness ratios for outstand
458 elements in compression ($c_f/(t\epsilon_{AISC}k_c^{0.5})=1.14$), internal elements in bending ($c_w/(t\epsilon_{AISC})=5.7$)
459 and outstand elements in triangular compressive stress gradients ($c_f/(t\epsilon_{AISC})=1.0$) as well as the
460 compact limiting width-to-thickness ratios for internal elements in bending ($c_w/(t\epsilon_{AISC})=3.76$)
461 and outstand elements in compression ($c_f/(t\epsilon_{AISC})=0.38$), with the results of the respective

462 graphic assessments shown in Figs 25–29. It was found that that all the AISC limiting width-
463 to-thickness ratios are safe and generally accurate when used for the classification of plate
464 elements of S690 high strength steel welded I-section beams except for the non-compact
465 limiting width-to-thickness ratios for outstand elements in compression ($c_f/(t\epsilon_{AISC}k_c^{0.5})=1.14$),
466 which results in unsafe plate element classification.

467

468 With regards to welded I-section beams bent about the cross-section major principal axes,
469 ANSI/AISC 360-16 [16] prescribes the use of plastic moment resistances (M_{pl}) as the design
470 bending moment resistances for both compact I-sections and non-compact I-sections with
471 compact outstand flanges and non-compact internal webs, and takes into account partial
472 plasticity in the predictions of bending moment resistances for non-compact I-sections with
473 non-compact outstand flanges and compact or non-compact internal webs, as given by Eq. (8),
474 where λ_{pf} and λ_{rf} are the compact and non-compact limiting width-to-thickness ratios for
475 outstand flanges under compression, respectively, as listed in Table 7(c). The AISC design
476 cross-section effective (reduced) bending moment capacities for slender I-section beams with
477 (i) slender webs and compact flanges, (ii) slender webs and non-compact flanges and (iii)
478 slender flanges are calculated from Eqs (9)–(11), respectively. Regarding welded I-section
479 beams subjected to minor-axis bending, the current ANSI/AISC 360-16 [16] specifies the
480 design cross-section bending moment resistances as the minimum of M_{pl} and $1.6M_{el}$ for
481 compact I-sections, while the design cross-section bending moment resistances of non-compact
482 and slender I-sections are determined according to Eqs (8) and (12), respectively.

$$483 \quad M_{u,AISC} = M_{pl} - (M_{pl} - 0.7M_{el}) \left(\frac{c_f/t - \lambda_{pf}}{\lambda_{rf} - \lambda_{pf}} \right) \quad (8)$$

$$484 \quad M_{u,AISC} = M_{eff,AISC} = M_{el} \left[1 - \frac{c_w/(2c_f)}{1200 + 300(c_w/(2c_f))} (c_w/t - 5.7\epsilon_{AISC}) \right] \leq M_{el} \quad (9)$$

$$485 \quad M_{u,AISC} = M_{eff,AISC} = M_{el} \left[1 - 0.3 \left(\frac{c_f/t - \lambda_{pf}}{\lambda_{rf} - \lambda_{pf}} \right) \right] \leq M_{el} \quad (10)$$

$$486 \quad M_{u,AISC} = M_{eff,AISC} = M_{el} \frac{0.9k_c}{(c_f/t\epsilon_{AISC})^2} \leq M_{el} \quad (11)$$

$$487 \quad M_{u,AISC} = M_{eff,AISC} = M_{el} \frac{0.69}{(c_f/t\epsilon_{AISC})^2} \leq M_{el} \quad (12)$$

488

489 Graphic and quantitative evaluations of the AISC design cross-section bending moment
 490 capacities were carried out based on the experimental (and FE) ultimate bending moments of
 491 the examined S690 high strength steel welded I-section beams, with the results shown in Fig.
 492 30 and Table 6(c), respectively. It is evident that the test and FE ultimate bending moments of
 493 compact S690 high strength steel welded I-section beams (in bending about both the principal
 494 axes) and non-compact S690 high strength steel welded I-section beams bent about the major
 495 principal axes are well predicted by the current ANSI/AISC 360-16 [16], while the design
 496 cross-section bending moment capacity predictions of non-compact S690 high strength steel
 497 welded I-section beams in minor-axis bending and slender S690 high strength steel welded I-
 498 section beams in both minor-axis and major-axis bending, determined from ANSI/AISC 360-
 499 16 [16], are excessively conservative and scattered.

500

501 **5. Conclusions**

502

503 A testing and numerical modelling investigation into the in-plane flexural behaviour and
504 bending moment resistances of welded I-section beams made of grade S690 high strength steel
505 has been conducted and described in this paper. The experimental programme was conducted
506 on six different S690 high strength steel welded I-sections, and involved initial geometric
507 imperfection measurements, six four-point bending tests about the major principal axes and six
508 four-point bending tests about the minor principal axes. In parallel with the structural testing,
509 a finite element simulation study was performed, including a validation study to replicate the
510 four-point bending tests on S690 high strength steel welded I-section beams and a parametric
511 study to derive additional finite element data. The obtained test and finite element results were
512 adopted to assess the accuracy of the slenderness limits for the classifications of internal webs
513 and outstand flanges of S690 high strength steel welded I-sections in bending as well as the
514 local buckling design provisions for S690 high strength steel welded I-section beams, as
515 specified in 1993-1-12 [14], AS 4100 [15] and ANSI/AISC 360-16 [16]. The assessment results
516 generally indicated that (i) all the established codified slenderness limits are safe for the
517 classifications of plate elements and cross-sections of S690 high strength steel welded I-section
518 beams, with an exception being the AISC non-compact limiting width-to-thickness ratio for
519 outstand elements in compression, and (ii) the codified local buckling design rules in all the
520 three design standards [14–16] were shown to yield precise and consistent cross-section
521 bending moment capacity predictions for compact (Class 1 and 2) S690 welded I-section beams
522 in bending about both the principal axes and non-compact (Class 3) S690 welded I-sections

523 bent about the major principal axes, while the predicted cross-section bending resistances,
524 determined from all the three design standards [14–16], were unduly conservative for non-
525 compact (Class 3) S690 welded I-sections in minor-axis bending and slender (Class 4) S690
526 welded I-section beams in both major-axis and minor-axis bending.

Table 6

Comparisons of experimental and FE ultimate moments against predicted bending moment resistances.

(a) EN 1993-1-12 [14]

Axis of bending	Class of cross-section	Number of experimental data	Number of numerical data	$M_u/M_{u,EC3}$	
				Mean	COV
Major axis	Class 1 or Class 2 I-section	5	34	1.07	0.02
	Class 3 I-section	0	59	1.15	0.04
	Class 4 I-section	1	92	1.28	0.08
	Sub-total	6	185	1.18	0.09
Minor axis	Class 1 and 2 I-section	5	25	1.09	0.02
	Class 3 I-section	1	26	1.57	0.05
	Class 4 I-section	0	56	1.52	0.06
	Sub-total	6	101	1.44	0.19
Total		12	286	1.26	0.18

(b) AS 4100 [15]

Axis of bending	Class of cross-section	Number of experimental data	Number of numerical data	$M_u/M_{u,AS}$	
				Mean	COV
Major axis	Compact I-section	2	21	1.08	0.01
	Non-compact I-section	4	80	1.10	0.03
	Slender I-section	0	84	1.58	0.29
	Sub-total	6	185	1.31	0.31
Minor axis	Compact I-section	2	8	1.17	0.03
	Non-compact I-section	4	51	1.33	0.06
	Slender I-section	0	42	3.22	1.46
	Sub-total	6	101	2.05	1.38
Total		12	286	1.57	0.92

(c) ANSI/AISC 360-16 [16]

Axis of bending	Class of cross-section	Number of experimental data	Number of numerical data	$M_u/M_{u,AISC}$	
				Mean	COV
Major axis	Compact I-section	2	36	1.06	0.02
	Non-compact I-section	4	131	1.11	0.07
	Slender I-section	0	18	1.35	0.15
	Sub-total	6	185	1.12	0.10
Minor axis	Compact I-section	2	28	1.09	0.03
	Non-compact I-section	4	40	1.30	0.16
	Slender I-section	0	33	3.13	1.08
	Sub-total	6	101	1.81	1.11
Total		12	286	1.36	0.74

Table 7

Established slenderness limits in the current design standards.

(a) EN 1993-1-12 [14]

Plate element type	Loading condition	Class 3 limit	Class 2 limit
Outstand flange	Compression	$14\epsilon_{EC3}$	$10\epsilon_{EC3}$
Internal web	Bending	$124\epsilon_{EC3}$	$83\epsilon_{EC3}$
Outstand flange	Compressive stress gradient	$21\epsilon_{EC3}k_{\sigma}^{0.5}$	–

(b) AS 4100 [15]

Plate element type	Loading condition	Yield slenderness limit	Plasticity slenderness limit
Outstand flange	Compression	$14\epsilon_{AS}$	$8\epsilon_{AS}$
Internal web	Bending	$115\epsilon_{AS}$	$82\epsilon_{AS}$
Outstand flange	Compressive stress gradient	$22\epsilon_{AS}$	–

(c) ANSI/AISC 360-16 [16]

Plate element type	Loading condition	Non-compact limiting width-to-thickness ratio	Compact limiting width-to-thickness ratio
Outstand flange	Compression	$1.14\epsilon_{AISC}k_c^{0.5}$	$0.38\epsilon_{AISC}$
Internal web	Bending	$5.7\epsilon_{AISC}$	$3.76\epsilon_{AISC}$
Outstand flange	Compressive stress gradient	$1.0\epsilon_{AISC}$	–
