22   **Abstract**

23

1   ***Purpose*** To determine whether or not commercial golf gloves influence performance variables and

2   forearm muscle activity during golf play. ***Methods*** Fifteen golfers participated in the laboratory

3   based study, each performing 8 golf swings with a Driver and 7-iron whilst wearing a glove and 8

4   without wearing the glove. Club head speed, ball speed and absolute carry distance performance

5   variables were calculated. Surface electromyography was recorded from the flexor digitorum

6   superficialis and extensor carpi radialis brevis on both forearm muscles. ***Results*** Club head speed,

7   ball speed and absolute carry distance was significantly higher when using the Driver with the glove

8   in comparison to the Driver without the glove ($p < 0.05$). No significant differences were evident

9   when using the 7-iron and no significant differences were displayed in muscle activity in either of the

10   conditions. ***Conclusion*** Findings from this study suggest that driving performance is improved when

11   wearing a glove.

27   **Introduction**

1   Golf has become an increasingly popular sport for players of differing ages and skill levels (Farrally et

2   al., 2003). A golfer's prime objective is to finish a golf round using minimum shots. Several key

3   factors for improving golf performance have been previously identified; including improving physical

4   characteristics through golf training programmes (Lephart, Smoliga, Myers, Sell, & Tsai, 2007) and

5   coaching to improve swing mechanics (Hume, Keogh, & Reid, 2005). In addition, golfers will also

6   change equipment in an attempt to improve performance, which is also common amongst other

7   sports (Stefanyshyn & Wannop, 2015).

8   Commercial golf gloves are not a required piece of equipment when playing golf but are often used

9   by golfers to assist perceived level of performance. Leading manufacturers claim that the golf glove

10 helps to create friction between the hand and golf grip when holding the club, thus potentially

11 increasing the performance of the golfer. However, to our knowledge, there is no published research

12 to support these performance enhancement claims. The friction created between the fingers/palm

13 of the hand and different types of sports equipment can often influence how well the athletes are

14 able to perform (Lewis et al., 2014). The friction generated not only controls how well different

15 objects can be gripped, but also how the equipment feels to the athlete and what the perceived

16 level of performance is (Lewis et al., 2014). For example, during wheelchair rugby the use of gloves is

17 promoted to increase the friction between the hand and wheelchair. Lutgendorf et al. (2009)

18 showed that the use of an NFL glove significantly increased acceleration and agility compared to

19 various other gloves and therefore increased performance of the athlete. It was found that,

20 acceleration and agility were also reduced when athletes did not wear a glove (bare hand).

21 A key component in improving golf performance is being able to increase the distance and accuracy

22 of the golf shot within the long game. Fundamentals to this are club head speed (CHS), ball speed

23 (BS) and club face angle at impact (Fradkin, Sherman, & Finch, 2004). Egret et al. (2003) reported a

24 CHS of 161 km/h whilst using a Driver and Sorbie et al. (2016) reported CHS of 126 km/h when using

25 a 7-iron, thus clearly showing distinct differences between longer and shorter golf clubs. Due to

these high levels of CHS, a significant force from the forearm is required in order to allow the golfer to maintain grip throughout the golf swing (Komi, Roberts, & Rothberg, 2008).

Previous research has reported high levels of forearm muscle activity from the flexor and extensor muscles during the golf swing using the electromyography (EMG) technique. Farber et al. (2009) reported levels of up to 74% of maximum voluntary contraction (MVC) during the forward swing phase, and up to 128% of MVC during the acceleration phase when examining the extensor carpi radialis brevis (ECRB) muscle whilst using the golf Driver. Sorbie et al. (2016) reported somewhat lower levels of muscle activity from the flexor digitorum superficialis (FDS) (89.3%) and ECRB (87.8%) muscles of the forearm during the golf swing, however, these swings were performed using the 7-iron.

Several industrial studies have used EMG to assess forearm muscle activity when using gloves (Kovacs, Splittstoesser, Maronitis, & Marras, 2002; Larivière et al., 2004). Although these studies are not directly comparable to the golf swing, Larivière et al. (2004) reported changes in ECRB and FDS forearm muscle activation levels when performing handgrip tests with a glove compared to the bare hand (15% increase on average). Kovacs et al. (2002) also reported an increase in EMG forearm muscle activation levels when comparing the bare hand grip to several different glove materials. A biomechanical assessment using EMG could provide important information on the loading of the forearm muscles during the golf swing when using the golf glove compared to using the bare hand. Specifically, a reduction on the load placed on the forearm muscles may help prevent injuries to the elbow area (Dickerson, Martin, & Chaffin, 2007). Lateral and medial epicondylitis are two of the main elbow symptoms associated with golfers, especially golfers within the amateur category (Farber et al., 2009; Glazebrook, Curwin, Mohammad, Kozey, & William, 1994).

When considering the previously reported performance and muscle activity changes when using gloves in industrial work and specific sporting events, it was reasonable to hypothesise that performance variables and muscle activity may change during the golf swing when wearing a glove

1 compared to the bare hand. Furthermore, with the significant changes in CHS between the Driver

2 and iron clubs, an assessment between these clubs is also required when using the commercial golf

3 glove. Thus, the purpose of the present study was to determine how a commercial golf glove

4 influences performance CHS, BS and Absolute Carry Distance (ACD) and forearm muscle activity

5 during a golf swing whilst using the Driver and the 7-iron.

6 **Methods**

7 **Participants**

8 After obtaining ethical approval from the university ethics committee, fifteen right-handed male

9 golfers participated in this laboratory based study (height: 183.7 ± 7.3 cm, weight: 77.6 ± 9.8 kg, age:

10 24.3 ± 4.0 years, handicap: 18.0 ± 5.6, effect size < 0.5; α err prob = 0.05, Power = 80%). All

11 participants were free from injury. Participants were also required to have no elbow or wrist injuries

12 in the past year and no surgery in the identified areas in the past five years. The researchers

13 explained the procedures and purpose of the study to all participants. All participants completed a

14 physical readiness questionnaire and consent form prior to participation in the study.

15 **Apparatus**

16 The experimental set-up included: an artificial golf mat placed in the centre of the laboratory; an

17 enclosed golf net (Sports Net Company, United Kingdom) located 2 m from the golf mat (Longridge,

18 United Kingdom); an 8 camera Vicon Bonita (Oxford Metrics Ltd, United Kingdom) Motion Analysis

19 System operating at 250 Hz positioned at strategic positions around the golfer; a set of 8 EMG

20 Transmitters operating at 1000 Hz and filtered at 10-500 Hz (Myon 320, Schwarzenberg, Switzerland)

21 in conjunction with Surface Electrodes (AMBU, Cambridgeshire, UK) used to measure muscle

22 activity. A Digital Handheld Dynamometer (Medical research, Leeds, UK) was used to measure

23 Maximal Voluntary Contractions (MVC). The EMG system was synchronised in conjunction with the

24 Vicon Bonita Motion Analysis System to facilitate simultaneous data collection. The Voice Caddie

1   Swing Launch Monitor SC 100 GPS (La Mirada, CA, USA) was used to calculate CHS, BS and ACD of

2   each golf shot. The Launch Monitor was previously validated in-house against the Vicon Bonita

3   Motion Analysis System; Trackman™ III Golf Swing and Ball Flight Analysis System (Brighton, MI,

4   USA).

5   For the golf shots, a Taylormade (Basingstoke, UK) Speed Blade Stiff Shaft 7-iron, with a shaft length

6   of 37 inches and a Taylormade SLDR Stiff Shaft Driver, with a shaft length of 45.5 inches were used.

7   Titleist Pro-V1 (Titleist, Cambridgeshire, UK) golf balls were also used for all golf shots. Each of the

8   clubs had 4 retro-reflective markers attached to them; this enabled the determination of the five

9   phases of the golf swing using the Nexus 2 Vicon Data Capture Software. These markers were placed

10   on the base of the grip, halfway down the club, the hosel of the club, and the club head (Higdon,

11   Finch, Leib, & Dugan, 2012). To enable the analysis of the golf swing, researchers often divide the

12   golf swing into the five phases that are detailed in Figure 2 (Farber et al., 2009; Lim, Chow, & Chae,

13   2012; Marta, Silva, Vaz, Bruno, & Pezarat-correia, 2013; Marta, Silva, Vaz, Castro, & Pezarat-correia,

14   2015; Sorbie et al., 2016). Taylormade ST (Taylormade, Basingstoke, UK) synthetic gloves were used

15   as part of the experiment. Small, medium, medium/large, large, and extra-large groves were

16   available to participants. The glove was required to fit comfortably across the palm and finger

17   regions of the hand.

18   **Electromyography Procedure**

19   In order to reduce the impedance of the interface between the skin and electrode, the skin was

20   prepared by removing hair from the forearm, alcohol cleaned and abraded for electrical

21   connectivity. The electrodes were then placed on the ECRB and FDS forearm muscles on the left and

22   right arms (Figure 1). To standardise the placement of the electrodes of the ECRB muscle a line was

23   marked between the lateral epicondyle and the radial styloid process. The ECRB is located in the

24   proximal half of the forearm, just lateral to the line (Basmajian, 1989). The electrode for the FDS

1 muscle was placed towards the middle of the forearm, halfway from the ventral midline to the

2 medial border of the forearm (Blackwell, Kornatz, & Heath, 1999).

3 Following the EMG electrodes being secured and the signals verified, participants performed two 3 s

4 maximum isometric handgrip contractions in maximum flexion for the FDS reference. Participants

5 then performed two 3 s maximum isometric handgrip contractions in maximum extension for the

6 ECRB reference. Specifically, participants were instructed to slowly increase the force and be at

7 maximum effort after 3-5 s, and hold the maximum force for a further 3 s. Participants were given 5

8 minutes recovery time between each contraction. During the contractions, the forearm was secured

9 in a previously validated rig in order to minimize elbow and shoulder movement. The rig held the

10 elbow at approximately 120° during the handgrip recordings. The mean of 500 ms at the highest

11 signal portion of the MVC was examined in order to normalize the golf swing (Konrad, 2006). The

12 activity patterns of the golf swing were assessed every 20 ms and expressed as a percentage of MVC

13 (Farber et al. 2009).

14 **Experimental Design**

15 Prior to collecting golf swing data, participants were asked to perform a dynamic warm-up routine

16 targeting the full body. After the warm-up routine was complete the participants performed several

17 golf shots. The testing process comprised:

18 • 8 shots with the Driver using the glove (G)

19 • 8 shots with the Driver without using the glove (NG)

20 • 8 shots with the 7-iron using the glove (G)

21 • 8 shots with the 7-iron without using the glove (NG)

22 All golf shots in the session were hit at a rate of one shot every 30 s. During a pilot study, golfers

23 stated that this was a comfortable pace to perform the golf shots. Between each of the conditions

24 participants rested for 2 minutes to avoid muscular fatigue of the forearm. The participants were

1 asked to aim towards a red target pole which was situated behind the golf net and advised to take

2 into consideration the accuracy and distance of their normal Driver and 7-iron shots. The order of

3 this process was randomised using a processing generator (TextFixer: www.testfixer.com). This

4 minimised any systematic error in testing. During each of the golf shots that were performed, video,

5 EMG and performance data was recorded.

6 **Data Analysis**

7 For the performance variables and EMG data, mean values were calculated for 8 golf shots

8 performed by each participant during each of the 4 conditions. Following this, mean values were

9 calculated across participants. Normal distribution for all variables was assessed using the Shapiro-

10 Wilk test (McCormick et al. 2014). A null hypothesis for the tests was accepted due to all p values

11 being higher than 0.05. Upon this being determined a two-way repeated measures ANOVA was used

12 to identify differences in EMG data sets when using the golf glove compared to not using the golf

13 glove (bare hand), during the five phases of the golf swing (Farber et al., 2009; Lim et al., 2012;

14 Marta et al., 2013, 2015; Sorbie et al., 2016). Muscle activity was expressed as a percentage of the

15 MVC. All performance variables were analysed for statistical significance using a paired t-test.

16 Additionally, all calculations were performed on SPSS (version 22) and Microsoft Excel (version

17 2010), and $p < 0.05$ was considered significant.

18 <u>**Results**</u>

19 **Performance**

20 **Driver**

21 Participants displayed significantly higher CHS with the Driver G (150.76 km/h ± 7.63) in comparison

22 to the Driver NG (146.93 km/h ± 9.56) (p = 0.025) (Figure 3). Participants displayed significantly

23 higher BS with the Driver G (218.57 km/h ± 15.39) in comparison to the Driver NG (212.49 km/h ±

1   16.21) (p = 0.030) (Figure 4). The ACD was also significantly increased when comparing the Driver G

2   (204.41 M ± 28.83) to the Driver NG (193.50 M ± 27.28) (p = 0.012).

3   **7-iron**

4   Participants displayed no significant differences in CHS whilst using the 7 Iron G (130.83 km/h ± 9.74)

5   in comparison to the 7-iron NG (128.25 km/h ± 9.31) (p = 0.151) (Figure 3). No significant differences

6   were displayed in BS when comparing the 7-iron G (167.07 km/h ± 17.14) to the 7-iron NG (162.58

7   km/h ± 18.44) (p = 0.068) (Figure 4). No significant differences were displayed between the ACD

8   when comparing the 7-iron G (127.90 m ± 18.88) to the 7-iron NG (122.83 m ± 18.30) (p = 0.059).

9   **Muscle Activity**

10   **Comparison between Conditions (Glove vs No Glove)**

11   All participants displayed a similar trend in forearm muscle activity pattern when comparing the use

12   of the glove and the bare hand whilst using the Driver and 7-iron. The muscle activity for the FDS and

13   ECRB in the lead (left hand for right handed golfers) and trail (right hand for right handed golfers)

14   arm for the five phases of the golf swing are displayed on Table 1. No significant differences were

15   displayed in the FDS and ECRB muscle activity in the lead or trail arms during the five phases of the

16   golf swing when comparing the use of the commercial golf glove and the bare hand (all p > 0.05).

17   **Comparison between Phases**

18   The FDS and ECRB forearm muscles on the lead and trail sides displayed peak activation values

19   during the forward swing, acceleration and early follow-through phases (Table 1). All muscles

20   showed significant statistical differences between the peak activation (forward swing, acceleration

21   and early follow-through) phases compared to the lower activation phases (backswing and late

22   follow-through) (all p < 0.05).

23

1 **Discussion**

2 The aim of the present study was to determine how a commercial golf glove influences CHS, BS and

3 ACD when performing golf shots with the Driver and 7-iron. Secondly, the study aimed to investigate

4 the muscle activation levels from the forearm muscles when using the golf glove compared to the

5 bare hand whilst using the Driver and the 7-iron at the five phases of the golf swing.

6 The present study is in agreement with previously published research where performance in sports

7 has been shown to improve with the use of a glove (Lewis et al., 2014; Lutgendorf et al., 2009). With

8 similar results to the present study, where the researchers displayed a significant increase in CHS

9 and BS, Lutgendorf et al. (2009) showed that the use of a glove in wheelchair rugby significantly

10 increased acceleration compared to the bare hand. In addition to this, during ultimate frisbee, Lewis

11 et al. (2014) reported that using a glove when catching the frisbee increased friction and, therefore,

12 increased performance during the execution of the skill. The results of the present study also

13 support the claim made by leading golf manufacturers that the commercial golf glove increases

14 friction between the hand and the golf grip and, therefore, could have a positive impact on golf

15 swing performance (Golfsmith, 2016). However, the result of the present study only displays this

16 change to be significant when using the Driver and not the 7-iron. It could be suggested that the

17 contrasting results between the Driver and 7-iron could be due to the Driver generating a

18 significantly higher CHS when compared to the 7-iron ($p < 0.05$). These changes may also be a result

19 of the forearm muscles generating marginally higher activation levels when using the Driver

20 compared to the 7-iron, which supports previously published literature (Farber et al., 2009;

21 Glazebrook et al., 1994; Sorbie et al., 2016). The contrasting results could also be due to the Driver

22 having a longer shaft length compared to the 7-iron and the two clubs being used for different shots

23 in the golf game. The Driver is used to hit the ball as far as possible (Nagao & Sawada, 1973),

24 whereas the 7-iron club is mainly used for shots between 100 m – 150 m where high accuracy and

25 precision is essential (Egret et al., 2003).

1   With regards to forearm muscle activity, the present study is somewhat contrasting to other

2   published research. Larivière et al. (2004) and Kovacs et al. (2002) reported an increase in forearm

3   muscle activation levels during a handgrip test when wearing a glove compared to the bare hand. In

4   contrast, the present study shows that there is no significant change in forearm muscle activity when

5   wearing the golf glove compared to not wearing the golf glove whilst using the Driver or 7-iron.

6   These contrasting findings may be a result of the high variability of the muscle activation levels or

7   due to the static components of the handgrip test and the dynamic movement of the golf swing.

8   With no increased load placed on the forearm muscles when comparing the commercial golf glove

9   to the bare hand during the golf swing, it could be suggested that using the golf glove does not

10   reduce the risk of injury to the elbow (Dickerson et al., 2007). Previous studies have shown that

11   increased forearm muscle activity may increase the risk of medial and lateral epicondylitis when

12   performing the golf swing (Farber et al., 2009; Glazebrook et al., 1994).

13   With reference to the five phases of the golf swing, the present study displays distinct differences in

14   forearm muscle activation between the five phases. The results from the present study show that in

15   most cases the lead and trail forearm muscles are more active during the forward swing,

16   acceleration and early follow-through phases compared to the backswing and late follow-through

17   phases. These finding are in agreement with Farber et al. (2009) and Sorbie et al. (2016) where these

18   researchers displayed a similar trend when examining forearm muscle activity when using the Driver

19   and 7-iron clubs respectively. Specifically, Farber et al. (2009) showed that the ECRB muscle on the

20   lead arm increased progressively between the backswing (21.3% EMG), forward swing (74.2% MVC)

21   and acceleration (94.2% EMG) phases when examining amateur golfers. Additionally, muscle activity

22   then progressively reduced between the acceleration (94.2% EMG), early follow-through (32.1%

23   EMG) and late follow-through (31.1% EMG) phases of the golf swing. With regards to the muscle

24   activation values of the ECRB muscle, Farber et al. (2009) displayed higher values during the forward

25   swing, acceleration and late follow-through phases compared to the current study. These changes

26   may be a result of the higher mean handicap (18.0 mean handicap) in the current study compared

1 the study by Farber et al. (2009) (15.1 mean handicap). However, these changes may also be a result

2 of different methodologies used between the two studies. Farber et al. (2009) used fine-wire EMG to

3 collect muscle activity from the forearm muscles whereas the present study used surface EMG.

4 The researchers acknowledge that there are some limitations to the present study. Firstly, it must be

5 considered that EMG signal crosstalk from surrounding extensor and flexor muscles is a limitation to

6 the current study. The following steps were taken to reduce EMG signal cross-talk between muscles.

7 The surface electrodes were positioned within the middle of the muscle belly of the FDS and ECRB

8 forearm muscles and applied in parallel arrangement to the muscle fibres, with a centre to centre

9 inter-electrode distance of 2 cm. Secondly, this study only investigated one commercial golf glove

10 material. Future studies in this area could investigate the difference between using the leather and

11 the hybrid gloves. Thirdly, all participants in the present study used an interlock gripping style,

12 further research should be performed to investigate if different gripping styles have the same

13 significant effect between wearing a golf glove and not wearing a golf glove when using the Driver.

14 Finally, testing was limited to an indoor laboratory facility therefore ACD was calculated from the

15 CHS, BS and launch angle. Further investigation is also required to identify the point between the

16 Driver and 7-iron where the three performance variables tested are not significantly increased.

17 **Conclusion**

18 To summarise, the results of this study showed a significant increase in CHS, BS and ACD whilst using

19 a Driver with the glove compared to using a Driver without the glove, however, no significant

20 differences were evident when using the 7-iron. Muscle activity in the forearm did not change whilst

21 using the Driver or 7-iron in either of the variables that were tested, therefore, it is unlikely that the

22 commercial golf glove has any effect on elbow injuries within amateur golfers. The data from this

23 study suggest that golfers could increase their long game performance by wearing a glove if they

24 choose to use it whilst using the Driver.

Table 1: Mean and SD values for each muscle tested with and without the golf glove, in percentages of MVC

Method	FDS Lead Arm	ECRB Lead Arm	FDS Trail Arm	ECRB Trail Arm	FDS Lead Arm	ECRB Lead Arm	FDS Trail Arm	ECRB Trail Arm
Glove	(Driver G)				(7-iron G)			
Backswing	46.45 ± 18.89	36.78 ± 14.08	24.19 ± 8.20	46.54 ± 17.20	41.77 ± 17.41	35.83 ± 11.76	24.27 ± 7.98	47.83 ± 19.64
Forward swing	63.22 ± 24.80	44.54 ± 20.47	65.27 ± 19.49	59.42 ± 20.73	51.35 ± 19.54	44.79 ± 14.49	68.52 ± 24.46	54.04 ± 19.83
Acceleration	56.76 ± 20.41	69.61 ± 20.15	108.99± 30.36	55.35 ± 19.77	55.32 ± 17.42	76.49 ± 21.22	95.92 ± 17.68	55.64 ± 14.16
Early follow-through	46.46 ± 17.32	60.90 ± 23.31	80.06 ± 20.31	53.73 ± 22.68	45.55 ± 15.41	66.86 ± 20.68	67.26 ± 20.74	50.69 ± 18.50
Late follow-through	38.21 ± 17.74	35.40 ± 14.57	44.35 ± 21.35	35.55 ± 14.00	37.71 ± 19.15	32.49 ± 17.02	39.90 ± 17.53	33.08 ± 11.58
No Glove	(Driver NG)				(7-iron NG)			
Backswing	49.37 ± 19.49	37.33 ± 13.67	26.83 ± 9.93	45.13 ± 16.37	42.00 ± 16.67	38.38 ± 14.29	26.01 ± 7.64	48.22 ± 19.32
Forward swing	55.95 ± 20.32	48.49 ± 20.81	67.29 ± 18.08	56.68 ± 17.86	55.09 ± 23.24	46.63 ± 14.78	72.39 ± 20.40	56.24 ± 19.83
Acceleration	62.28 ± 20.25	66.69 ± 27.15	110.24 ± 21.74	62.94 ± 22.48	59.01 ± 19.92	78.62 ± 20.34	94.61 ± 18.80	57.36 ± 20.16
Early follow-through	47.10 ± 16.52	63.90 ± 23.41	85.63 ± 21.60	55.53 ± 21.51	46.84 ± 13.92	68.03 ± 20.68	68.67 ± 17.93	49.54 ± 13.73
Late follow-through	35.69 ± 15.23	35.45 ± 15.72	45.30 ± 23.87	40.46 ± 14.76	39.55 ± 18.60	32.77 ± 17.01	41.46 ± 15.62	34.70 ± 12.14

ECRB - Extensor Carpi Radialis Brevis; FDS - Flexor Digitorum Superficialis

Tables and Figures

Figure 1: Electrodes placed on the FDS and ECRB forearm muscles with transmitters secured to the forearm using Plastic Wrap Cling Film (UK) (Image from Participant 6).
