ABSTRACT

A film boiling heat transfer study was conducted with three different diameter cylindrical copper heaters over a wide range of pressures for nitrogen and argon with the heat transfer surface in the horizontal position.

The data were compared to the commonly used film boiling heat transfer relations. The common relations were found to be considerably in error for the range of variables covered in this investigation. A semi-empirical equation for corresponding states fluids which correlates the available data as a function of the reduced temperature and reduced pressure was derived and discussed.

ACKNOWLEDGEMENTS

The author wishes to express his sincere appreciation to Dr. E. L. Park for assistance, guidance and advice during this study.

The author acknowledges support of the National Science Foundation whose grant made this study possible.

The assistance of Mr. Richard Smith, R. T. Montgomery, T. C. Wilson, and the never ending encouragements of my wife, Louise, are furthermore appreciated.

CHAPTER I

INTRODUCTION

This study deals with film boiling as defined in the following discussion and shown in Figure 1. Figure 1 is the entire boiling curve as first predicted by Nukiyama (18)* in 1934. This curve is broken up into four distinct regions which can best be understood by considering a heat transfer surface submerged in a saturated liquid. As the temperature of the surface is raised slightly above the saturation temperature, convection currents circulate the liquid and evaporation occurs at the free surface. This region is described as the convection region (region I in Figure 1). As the surface temperature is raised further, bubbles begin to form at specific points on the surface. The locations where bubbles form are called nucleation sites. This region, characterized by the formation of nuclei is named the nucleate boiling region (region II, in Figure 1). As the temperature is increased further, more sites are activated until the surface is completely covered with bubbles forming a continuous vapor film which is specified as point A on Figure 1. This point is known as the burn-out point or the critical heat flux point. The nucleate boiling region is of special importance, because of the very high heat fluxes obtained with a small temperature difference.

As the temperature is further increased, the film forms and collapses rapidly, causing an increased resistance which quickly drops the heat transfer rate. This unstable film region continues until point B (the Leidenfrost point). The Leidenfrost point is the point where the film is continuous and becomes stable even though the film surface is in violent agitation.

* Numbers in parentheses refer to listings in Bibliography.

The region to the right of the Leidenfrost point is denoted as the film boiling region (region IV), and is of interest in this investigation.

The film boiling data presently available over a wide range of pressures seem to be very limited. More data are required in order that theoretical equations and the effects of pressure and diameter on film boiling can be checked.

This study was originated to provide data for the above reasons and to provide design data for nitrogen and argon.

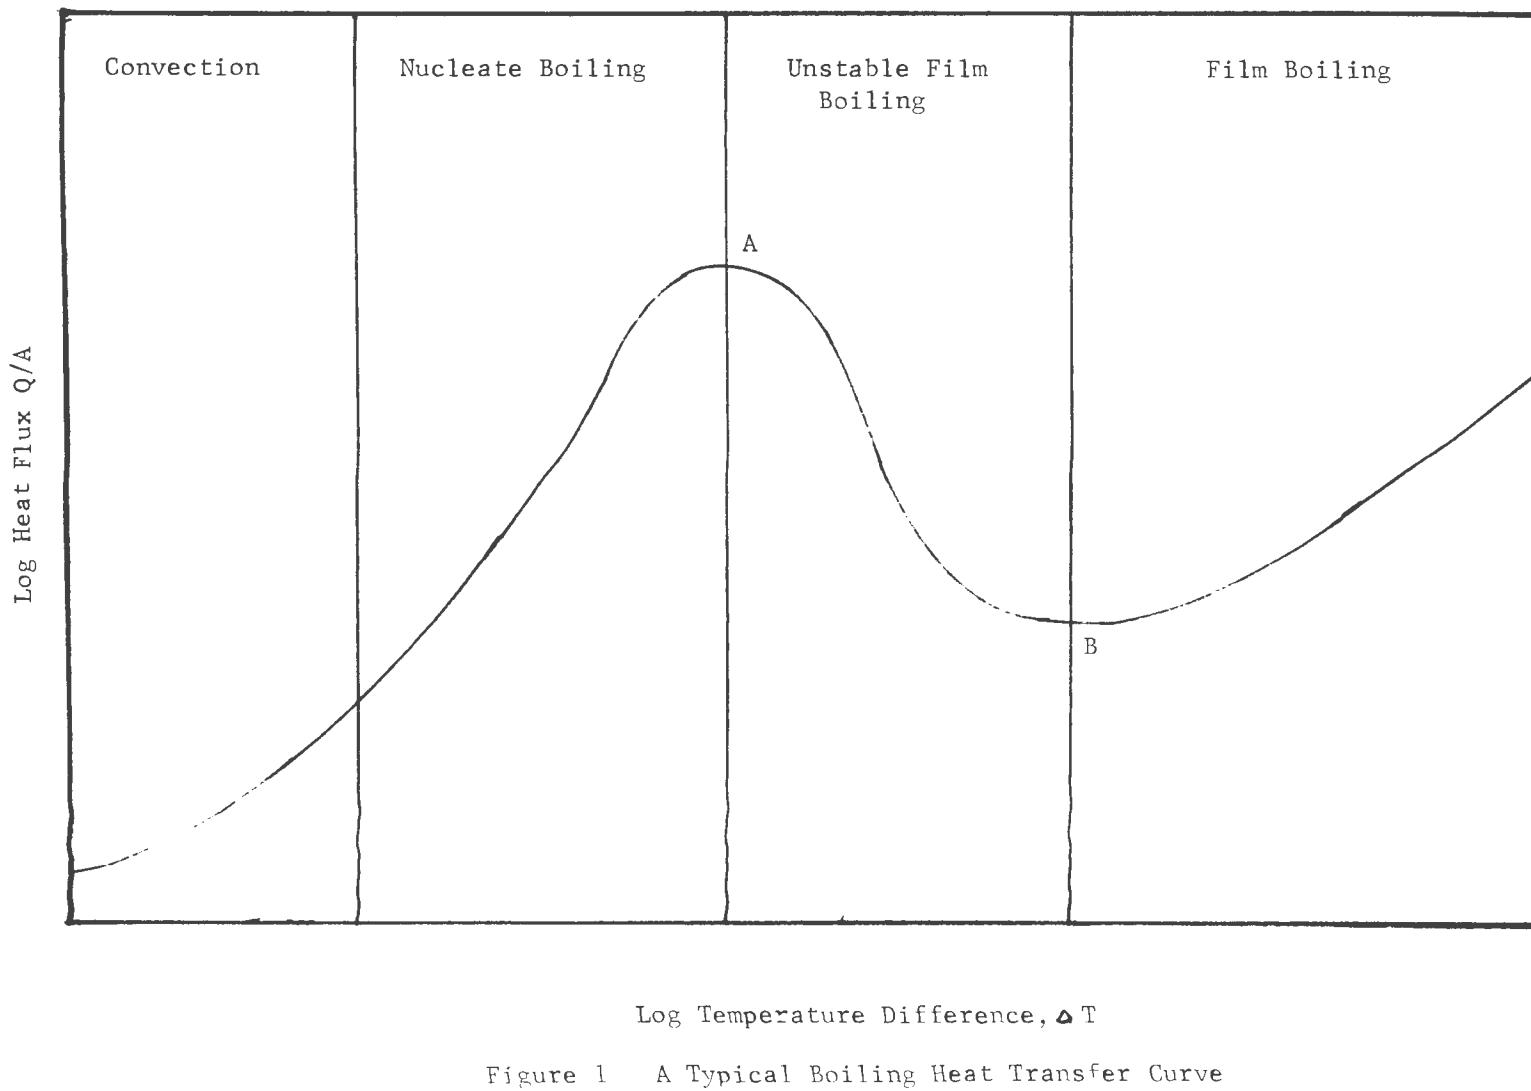

Figure 1 A Typical Boiling Heat Transfer Curve

CHAPTER II

PREVIOUS WORK

Scorah and Farber (11) were the first investigators to completely describe the boiling curve. Nukiyama (18) had difficulty in his work. He was not able to describe the region between the maximum and minimum points, A and B. The work of Scorah and Farber also predicted a heat transfer element material dependence in the stable film boiling region. Later work contradicts these findings.

The first investigator to suggest a method of predicting heat transfer coefficients for natural convection film boiling was Bromley (4). Bromley derived a relation analogous to Nusselt's equations for condensation by replacing ρ in Nusselt's equation by $\rho_1 - \rho_v$. The resulting equation was:

$$h = \text{Const} \left[\frac{k^3 \rho_v (\rho_1 - \rho_v) g}{\Delta T \mu_v D} \right]^{\frac{1}{4}} \quad (1)^*$$

The relation is for horizontal tubes. The value of the constant was found by empirical means to be 0.62. By theoretical considerations, the value of the constant should be 0.512 if the liquid is assumed stagnant and 0.724 if the liquid moves with the vapor. Bromley suggested that correction for radiation could be made by assuming parallel plates, which in effect assumes that the transmissivity of the liquid is zero.

Bromley's assumed relation predicts that the heater material had no effect on the convective coefficient and his experimental data confirmed the assumption.

The work of Banchero, Barker and Boll (2) for film boiling of liquid oxygen over a large pressure range with considerable variation in heater

* Numbers underlined in parentheses refer to equations.

diameters pointed out the limitations of Bromley's equation. They point out that Bromley's relation seems to be limited to diameters of 0.069 inches to 0.127 inches. The authors present the following (equation 2) which is a modification of Bromley's relation (equation 1).

$$h = a \left(\frac{1}{D} + C \right) F \quad (2)$$

$$C = \text{constant}$$

$$F = \left[\frac{k^3 \rho_v (\rho_1 - \rho_v) g \lambda}{\Delta T \mu} \right]^{\frac{1}{4}}$$

where a equals a constant which is dependent on the boiling substance.

The above equation seems to give a better correlation for the entire range of variables than Bromley's (3). The form of the equation also allows it to be adapted to flat plates. The values of a and C are determined by a trial and error fit of the available data. The authors found the quantity a to be a temperature dependent function and C to be equal to 36.5 inches^{-1} .

Bromley corrected his relation to account for the sensible heat of the vapor (5). His corrected relation is given below:

$$h = 0.62 \left[\frac{k^3 \rho_v (\rho_1 - \rho_v) g \lambda'}{\Delta T \mu D} \right]^{\frac{1}{4}} \quad , \quad (3)$$

$$\text{where } \lambda' = \lambda \left(\frac{1 + 0.4 C_p T}{\lambda} \right)^2$$

Subsequently it was shown (3) that a better fit could be obtained by equation 1 if the correction constant used in equation 3 was 0.34 rather than 0.4.

Bromley (5) also suggested that his relation could easily be adapted to vertical surfaces, by substituting L for D , and changing the value of the constant C_2 . Bromley's vertical surface relation is given:

$$h = C_2 \left[\frac{k^3 \rho_v (\rho_1 - \rho_v) g \lambda'}{\mu_v L \Delta T} \right]^{\frac{1}{4}} \quad . \quad (4)$$

Again, a better fit can be obtained by using 0.34 (3) instead of 0.4.

The theoretical value of C_2 is 0.667 if the liquid is stagnant and 0.943 if the liquid has the same velocity as the vapor. Bromley presented no data to check his vertical surface relation; however, Hsu and Westwater (14) investigated this condition and found that Bromley's relation (3) predicted heat transfer coefficients much too low when compared to their experimental values for tubes in the vertical position. The authors used a method suggested by Colburn (9) for film type condensation on vertical surfaces. This relation converted to film boiling is:

$$h \left[\frac{\mu_v^2}{k^3 \rho_v (\rho_1 - \rho_v) g} \right] = \frac{\left(\frac{4W}{\pi D \mu} \right)}{22 \left(\frac{C_p \mu}{k} \right)^{-1/3} \left[\left(\frac{4W}{\pi D \mu_v} \right)^{0.8} - 364 \right]} + 12,800 . \quad (5)$$

The above relation produces better results than Bromley's relation for all Reynolds numbers above 2000. The Reynolds number is defined as $\frac{4W}{\pi D \mu}$ where W is the maximum vapor mass flow rate. This Reynolds number points out the main limitation of Bromley's equation, the fact that laminar flow was assumed. In later work, Hsu and Westwater (13) proposed another relation for film boiling on vertical surfaces. They used an approach which assumed a turbulent core and a laminar sublayer and ignored the buffer zone between the regions. The division between the zones was determined by the universal velocity profile. The relation is given below:

$$\frac{hL}{k_v} = \frac{2 \lambda' \mu_v Re^*}{3 k_v \Delta T} + \frac{B + 1/3}{A} \left[\left\{ \frac{2}{3} \left(\frac{A}{B + 1/3} \right) (L - L_o) + \left(\frac{1}{y^*} \right)^2 \right\}^{3/2} - \left(\frac{1}{y^*} \right)^3 \right] , \quad (6)$$

where

$$A = \left(\frac{g(\rho_1 - \rho_v)}{\rho_v} \right) \left(\frac{1}{\mu_v Re^*} \right) ,$$

$$Re^* = \frac{y^* u^* \rho_v}{\mu_v} , \text{ and}$$

$$B = \left[\mu_v + \frac{f_{\rho_v} \mu_v Re^*}{2\rho_v} + \frac{k_v \Delta T}{\lambda} \right] \sqrt{\frac{k_v \Delta T}{\lambda}} .$$

Chang (7) suggested that, possibly, a relation for film boiling could be obtained by analyzing the waves formed in vapor release or by applying the instability concept of Taylor. Chang (7) suggested that equation (7) be used to correlate film boiling data from horizontal surfaces.

$$Nu = 0.234 (Pr^* Gr^*)^{1/3} \quad (7)$$

$$Pr^* = \frac{\gamma}{a_c}, \quad Gr^* = \frac{g \rho_v^2 L^3}{\mu_v^2} \left(\frac{\rho_1 - \rho_v}{\rho_v} \right),$$

$$Nu = \frac{Lh}{k_v},$$

$$a_c = \frac{k_v \theta_v}{2 \lambda \rho_v}, \quad \theta_v = T_{sat} - T_w,$$

$$Pr^* = Pr \left(\frac{2\lambda}{c_{pv} \theta_v} \right),$$

$$y^* = \frac{2 \mu_v^2 Re^{*5}}{g \rho_v (\rho_1 - \rho_v)},$$

$$L_o = \frac{\mu_v Re^* \lambda' y^*}{2 k_v \Delta T},$$

and

$$Re^* = 100.$$

For low subcooled boiling ($\theta_1 = 10^\circ F$)

$$Pr^* = Pr \left[\left(\frac{2\lambda}{c_{pv} \rho_v} \right) + \left(\frac{2 \theta_1 c_{p1} \rho_1}{\theta_v c_{pv} \rho_v} \right) \right].$$

The L_o denotes the point at which Bromley's equation fails to correlate with published data and y^* denotes distance normal to the surface of maximum vapor velocity. Re^* was given a value of 100 which denotes the transition between viscous

and turbulent flow as supported by Rohsenow's (25) computation of 80 to 120 for critical Reynolds numbers during condensation on vertical surfaces in the presence of large shear stresses. Using the data for water, the relation's of Bromley (3) and Chang (7) were compared. The Chang relation seemed to fit the data much better than that of Bromley relation. For the case of subcooling, the thermal diffusivity α_c used in the calculation of the generalized Prandtl number must be found from another equation which is considerably more complicated. Chang presents a correction for radiation. In the case where radiation should be considered, the value of equivalent thermal diffusivity α_c must be corrected in the relations.

Chang also proposed an equation for the surface in the vertical position. The vertical position relation is (8).

$$(Nu) = \frac{L'h}{k_v} = 0.72 (\text{Pr}^* \text{Gr})^{\frac{1}{4}} . \quad (8)$$

Berenson (1) used the above approach in developing a correlation for film boiling from horizontal surfaces. His relation is

$$h = 0.425 \left[\frac{k_v^3 \rho_v g (\rho_1 - \rho_v)}{\mu_v \Delta T \left(\frac{g_c \alpha}{g(\rho_1 - \rho_v)} \right)^{\frac{1}{2}}} \right]^{\frac{1}{4}} . \quad (9)$$

The major difference between (9) and Bromley's (3) is the term $\left(\frac{g_c \alpha}{g(\rho_1 - \rho_v)} \right)^{\frac{1}{2}}$. The relation (9) seemed to be effective only near the minimum point of the film boiling region.

Breen and Westwater (3) continued the investigation of film boiling from a cylindrical surface with its axis in the horizontal position. They conducted experiments with a large variation in diameter and with two different fluids. The range of diameters used was from 0.185 to

1.895 inches. They found that the heat flux and the heat transfer coefficient were not monotonous functions of tube diameter. The data showed that as the diameter was increased the heat transfer coefficient began decreasing rapidly and then increased slowly to a flat plateau. This behavior was explained by the critical diameter which must be a function of the fluid. The curves seem to support the hydrodynamic wave length theory. When Bromley's equation (3) was compared to the data, Bromley's equation failed to predict the value of heat transfer coefficient at wave lengths much greater than the hydrodynamic wave length. The hydrodynamic wave length λ_D for a flat plate is:

$$\lambda_D = \sqrt{3} \lambda c \quad (10)$$

where

$$c = 2\pi \left[\frac{g_c \sigma}{g (\rho_1 - \rho_v)} \right]^{\frac{1}{2}}. \quad (11)$$

Breen and Westwater using these parameters claimed a general relation (12) for film boiling from horizontal cylinders.

$$\frac{h(\lambda c)^{\frac{1}{4}}}{F} = 0.59 + 0.069 \frac{\lambda c}{D}. \quad (12)$$

They also proposed an alternate relation due to the asymptotic characteristics of the equation at large and small diameters and the agreement with Bromley's equation (3) at intermediate diameters. The alternate relations are given in equations 13A, 13B, and 13C

$$\text{for } \frac{\lambda c}{D} < 0.8, \frac{h(\lambda c)^{\frac{1}{4}}}{F} = 0.60 \quad . \quad (13A)$$

$$\text{for } 0.8 < \frac{\lambda c}{D} < 8, \frac{h(\lambda c)^{\frac{1}{4}}}{F} = 0.62 \quad . \quad (13B)$$

$$\text{for } \frac{\lambda c}{D} > 8, \frac{h(\lambda c)^{\frac{1}{4}}}{F} = 0.16 (\lambda c/D)^{0.83}. \quad (13C)$$

Park (21) attempted to fit his data with the Breen and Westwater correlation. He found that the correlation was not general and would not give a satisfactory fit to these film boiling data for nitrogen and methane over a considerable pressure range. He also noticed that the high temperature difference data indicated a temperature difference dependence not accounted for in the Breen and Westwater correlation. Park (21) reported a decrease in the heat flux as the critical pressure is approached. This effect became apparent at reduced pressures greater than 0.9 (the reduced pressure is defined as the absolute pressure divided by the critical pressure of the substance).

Sciance (26) did not record this effect in his continuation of the work of Park; however, his pressures did not exceed a reduced pressure of 0.9.

Wayner and Bankoff (29) have reported some interesting work. They have increased heat transfer rates by the use of porous plates and removing the vapor being formed by suction through the plate. Within certain limits the heat flux and vapor rate could be independently varied, and there was an increase in the heat transfer coefficient by a factor of as much as 2.5 over the nonporous film boiling. Pai and Bankoff (20) reported a continuation of this work.

Tachibana and Fukui (28) reported the effects of film boiling in a subcooled liquid. They presented curves of the effect of the subcooled liquid on film boiling of water from horizontal wires.

The objective of this investigation is to provide film boiling data for design purposes and to determine whether film boiling data for corresponding states fluids can be correlated by application of the principle of corresponding states.

CHAPTER III

DESCRIPTION OF THE EXPERIMENTAL EQUIPMENT

The equipment used in the investigation consisted of three heat transfer elements, a pressure vessel, a power source, a pressure gauge, and a recording potentiometer.

Three heat transfer elements (0.95, 0.75 and 0.55 inches O.D.) were constructed and were designed so that they could withstand the thermal shock of going through the burnout point and operating with a 1000°F temperature difference. The design consisted of heat treated Lavatite cores of 0.40 inch diameter for the 0.75 and 0.95 O.D. heaters and of 0.25 inch diameter for the 0.55 inch O.D. heater. The cores were threaded 12 threads per inch and in the threads, number 26 gauge tungsten wire was wrapped. The tungsten wire was held by nuts on 4-40 machine screws which were screwed into the end of the cores. The screws also acted as the power terminals for the heaters. After the tungsten wire was wrapped on the heaters, they were coated with Sauereisen Electrical Resistor Cement, #78 paste, and allowed to air dry. The cores were then cemented into the outer heat transfer surface with the same cement and dried in a furnace for two hours at 200°F. The heat transfer surfaces consisted of three copper cylinders three inches long with 0.95, 0.75, and 0.55 inches O.D. and with 0.5, 0.5, and 0.35 I.D., respectively.

In each of the three heat transfer surfaces, three thermocouple wells 0.052 inches in diameter and 1 inch deep were drilled 90 degrees apart. Solder was then melted in the wells until they were full. While the solder was molten, 25 gauge copper-constantan thermocouples were placed in the wells. The solder minimized the contact resistance between the heat transfer element and the thermocouples.

Styrofoam plugs with the same diameters as the heaters and of $\frac{1}{2}$ inch thickness were attached to the ends of the heaters to reduce the end losses.

The power was supplied by a Hobart 300 amp, 40 volt, Model M B 204 D.C. Welder connected in a series with a load box which consisted of several fixed size resistors which could be added or subtracted in parallel. The load box and the fine and coarse voltage controls on the welder were used for power control.

The power was measured by using a Weston Model I (class 50) voltmeter to measure the voltage drop across the heater. A Weston Model I (class 50) ammeter was used to measure the current flow through the heater.

The pressure vessel was a one gallon autoclave, described by Sciance (26), which was manufactured by Autoclave Engineers, Inc. The autoclave was 5 inches I.D. by twelve inches deep and was fitted with two $1\frac{1}{2}$ inch diameter windows, which were horizontally opposed. The flange of the vessel was fixed and the high-pressure cylinder could be raised or lowered pneumatically to or from the flange. The power leads and thermocouples were brought in through openings in the flange. The gland mounted in the flange for the thermocouples was a Conax MHM-062-A160T gland with Teflon sealant. The copper-constantan thermocouples leads passing through the gland were Conax 310SS6T-B-PJFC-NONE-18", which were connected to the heater thermocouples. The power leads supported the heater from the flange so that the autoclave could be opened for inspection without disturbing the heater.

The pressure of the vessel was controlled by the amount of liquid nitrogen passing through the internal cooling coils (Figure 2). The liquid nitrogen was stored in Linde LS 110B and LS 156 dewars and was delivered to the system at 235 psig. The system was protected from over pressurization by a Black, Sivall and Bryson rupture disc rated at 960 psi at 72°F.

The pressure of the autoclave was measured with a Heise Bourdon tube pressure gauge with a 16 inch dial. This gauge was graduated from 0 to 1000 psi in 1 psi increments with an accuracy of ± 1 psi. All connections shown in Figure 2 were 316 stainless steel $\frac{1}{2}$ inch tubing with $\frac{1}{2}$ inch O.D. and 0.065 wall. The valves were Whitey No. 1 Series 0.25 inch valves (number IRS4-316).

The thermocouple leads came from the flange to a liquid nitrogen reference junction and then were connected to a Leeds and Northrup rotary thermocouple switch which was used in conjunction with Texas Instruments, Servriter II, single pen recorder. One iron-constantan thermocouple was also used to check for subcooling and was read with a Leeds and Northrup 2436 portable potentiometer.

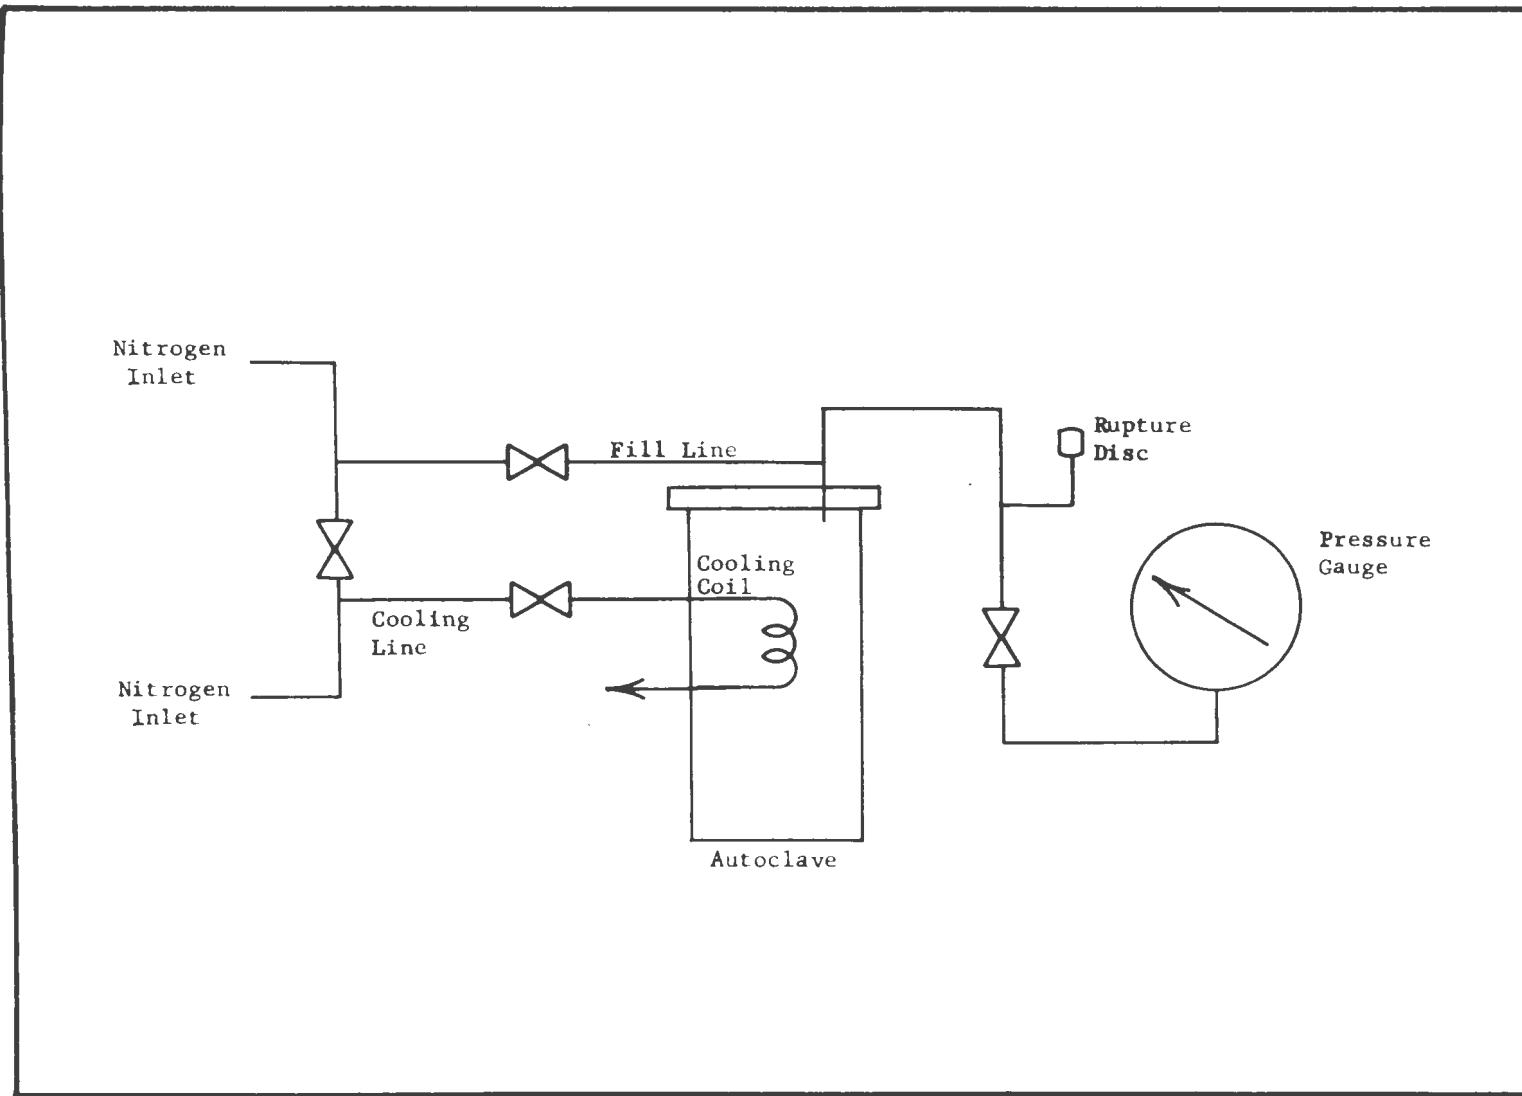

Figure 2. Pressure and Condensing System - Schematic Diagram

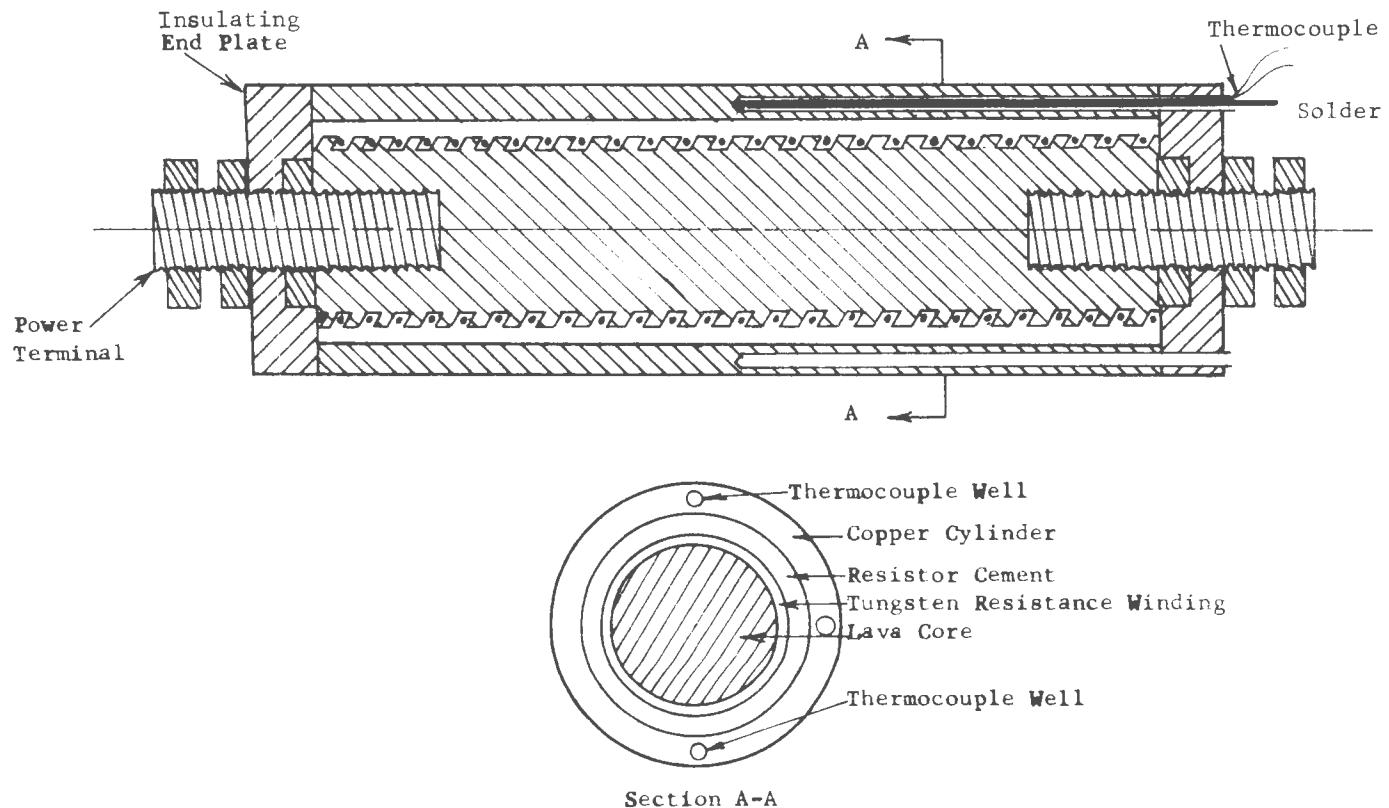

Figure 3. Heat Transfer Element

CHAPTER IV

EXPERIMENTAL PROCEDURE

A series of runs was made with each heater in the horizontal position. Each series consisted of runs at seven different pressures from atmospheric pressure up to 95 percent of the critical pressure for both argon and nitrogen.

To begin a series of runs, the autoclave was cooled by allowing nitrogen to flow through the fill line into the autoclave and out the vent opening in the vessel. The valve was also opened slightly to the cooling coil to maintain the coils at the proper temperature (Figure 2). When the level of the liquid nitrogen reached the top of the window (seven inches), the fill line was closed and the vent plug replaced. The system was then checked for leaks and the pressure raised or lowered to reach 34 psig. The pressure was controlled by regulating the amount of nitrogen flowing through the condensing coils. After reaching 34 psig, the power at the minimum setting was turned on and the system examined for malfunctions. The power was then increased until the burn-out point was reached and then controlled until the heat transfer surface temperature was approximately 70°F. Steady state adjustments were made by watching the temperature versus time plots from the recording potentiometer and making adjustments with the fine adjustment on the power source. After reaching steady state, the three thermocouple outputs were recorded. The power was then reduced and another operating point was recorded. Steady state observations were made with the heat transfer surface temperature range varying between 70°F and approximately 60°F above the boiling point of the fluid, which is a function of pressure. The pressure was then increased to the next pressure and the procedure repeated. After completing the six pressure runs, the pressure was again reduced to 34 psig.

and another run made to check the reproducibility of the data.

The power was then turned off and the fill line was opened to the atmosphere allowing the nitrogen to bleed off to the surroundings.

The equipment was left open for an hour at which time the argon bottle was connected to the fill lines. The autoclave was pressurized to 50 psig with gaseous argon and again vented to the surroundings to reduce the contamination. The liquid nitrogen was then allowed to flow through the condensing coils and the regulator on the argon bottle was set at 50 psig and the fill line opened. After a period of time, the argon began condensing. When the argon level reached the top of the window (7 inches) the regulator and the fill line valve was closed.

The pressure was then adjusted to 56 psig and maintained at this level for the first argon run. The procedure was exactly the same as for the nitrogen.

After completing the seven runs for the argon, the autoclave was lowered and a dewar of liquid nitrogen was put in place of the autoclave to make an atmospheric nitrogen run. The same procedure used for the other runs was used during the atmospheric run. The atmospheric nitrogen run could not be done in the autoclave because the condensing coils were not large enough to maintain zero gauge pressure.

During each run the bulk temperature of the boiling liquid was monitored to assure the boiling liquid was at its saturation temperature.

CHAPTER V

THEORY OF CORRESPONDING STATES AS APPLIED TO FILM BOILING

The theory of corresponding states may be safely regarded as the most useful by-product of the van der Waal's equation of state. Presently this equation is recognized to be of little or no value, but the theory of corresponding states correctly applied is extremely useful and accurate.

Pitzer (22) has stated a set of assumptions sufficient to lead to the principle of corresponding states for liquids and showed that argon, krypton and xenon have several properties in accordance with the principle. Pitzer's assumptions are:

- I. "Classical statistical mechanics will be used".
- II. "The molecules are spherically symmetrical, either actually or by virtue of rapid and free rotation".
- III. "Intramolecular vibrations will be assumed the same in the liquid and gas states".
- IV. "The potential energy will be taken as a function only of the various intermolecular distances".
- V. "The potential energy for a pair of molecules can be written $A\phi(R/R_0)$ where R is the intermolecular distance, A and R_0 are characteristic constants and ϕ is a universal function".

Guggenheim (11) restates the assumptions above. He restates assumption one as, "that any distinction between Fermi-Dirac statistics and Bose-Einstein statistics has a negligible effect"; and assumption II as, "that effects of quantization of the translational degrees of freedom is negligible". Assumptions I and II are satisfied provided $(mKT)^{1/2}v^{1/3} \gg h$, where m denotes molecular mass, T absolute temperature and v volume per molecule.

Assumption III is restated to say the intramolecular degrees of freedom are assumed to be completely independent of the volume per molecule. This assumption and assumption II and IV rule out highly polar molecules. Assumption V turns out to be a useful approximation for many non-polar molecules.

With these five assumptions satisfied, it can be shown that the equation of state is of the form

$$\frac{P}{P_c} = u \left(\frac{T}{T_c}, \frac{V}{V_c}, Z_c \right) \quad (14)$$

$$\text{where } Z_c = P_c V_c / R T_c$$

where u is a universal, but complicated function. The above expression is the general expression of the principle of corresponding states.

Examining some characteristics of fluids which obey the principle of corresponding states, it is noticed that of the critical compressibility factor of argon, krypton, nitrogen, oxygen, carbon monoxide and methane all are within 1.5% of 0.292. Another interesting characteristic is the temperature where change of sign of second virial coefficient occurs called the Boyle point (where the virial equation of state is $\frac{P_v}{RT} = 1 + \frac{B(t)}{v} + \frac{C(t)}{v^2}$). When the Boyle point is divided by the critical temperature for neon, argon and oxygen, the values agree within 1%; for nitrogen, carbon monoxide and methane, it agrees within 5 to 8%. The second virial coefficient divided by the critical volume plotted against the reduced temperature ratio has approximately the same shape for all these gases. This property means that physical properties of corresponding states fluids can be expressed as functions of the reduced temperature and the reduced pressure or the reduced volume. Thodos (10, 19, 27) has done considerable work in predicting thermal conductivity, viscosity, surface tension and coefficients of thermal expansion in this manner.

In film boiling studies with corresponding states fluids, the properties of interest seem to be density of the vapor, viscosity, thermal conductivity, specific heat, and latent heat of vaporization. These properties for any of the corresponding states fluids then can be evaluated by an equation, which is a function only of the reduced temperature and pressure. If saturation conditions are defined, the equation will only be a function of reduced temperature. With this result, the data of this investigation should be able to be correlated as a function of the reduced temperature, reduced pressure and the diameter of the heat transfer element. The equation should be of the form given below:

$$h = f(T_r, P_r, D)$$

or:

$$h = f(T_r) \text{ if } D \text{ and } P_r \text{ are constant } (15)$$

CHAPTER VI

RESULTS

During the course of taking the experimental data a radial temperature difference was noticed between the three thermocouples spaced 90° apart. Similar gradients were also noticed by Park (21) and Sciance (26). The data for the 0.95" and the 0.75" heaters were completely duplicated. All the data for a given pressure run were fitted using a least squares program. This program gave the local best polynomial fit of the experimental data. The program finds the best fit by minimizing the standard deviation. The experimental data for one representative sample run are shown in Figure 4.

The best fit for the data in Figure 4 is a straight line with an average deviation of 8.98% and a maximum deviation of 26.2%. This figure not only gives an example of the data taken, but points out the degree of reproducibility of the results. The data taken in all the runs are shown in appendix A. The average of the average deviation for all the data are 3.60% and the maximum average deviation for any set of data was 11.05% which was the data for argon at 655 psig using the 0.95 inch heater. The least square fits for all data taken for the three different heaters in argon and nitrogen are shown in Figures 5 through 10. It should be pointed out that the data are plotted as the heat flux versus the temperature difference. This is not the standard procedure in boiling heat transfer. Typically the plots are made with the logarithm of the temperature difference versus the logarithm of the heat flux. This procedure of plotting the logarithms tends to disguise the scatter of the data.

CHAPTER VII

DISCUSSION OF RESULTS

The curves for argon at 655 psig for all heaters point out a decrease in the heat flux when operating close to the critical pressure, but this phenomenon is questionable in the nitrogen data. A decrease is noticed in the data for 0.95 inch diameter heater, but for the other two heaters, a decrease is not present over the complete range of temperatures. Park (21) reported this decrease in heat flux for both nitrogen and methane, but Sciance (26) did not find it to exist in his continuation of Park's work, however, Sciance and Park's pressure ranges are not the same. In all of the data, crossing of the constant pressure curves can either be seen or extrapolation of the curves would yield the crossing. This indicates that an increase in heat flux with pressure does not occur over the entire ΔT range. Instead, the increase or decrease of heat flux with pressure is a function of the absolute value of the temperature difference and also the closeness to the critical point in some cases. Excluding the behavior near the critical point it can be seen that at low temperature difference, a decrease in heat flux is experienced with increasing temperature and at high temperature differences an increase is experienced. The point of crossing seems to be somewhere between 75°F and 150°F which is approximately 200°F lower than the value predicted by Park.

The experimental data were compared with Bromley's predicted curve (equation 3) in Figures 11 and 12. The plots clearly show that there would be a large error if Bromley's equation (equation 3) is used to predict heat transfer coefficients in this range of temperature differences and for these pressures. The equation could be modified by changing the constant

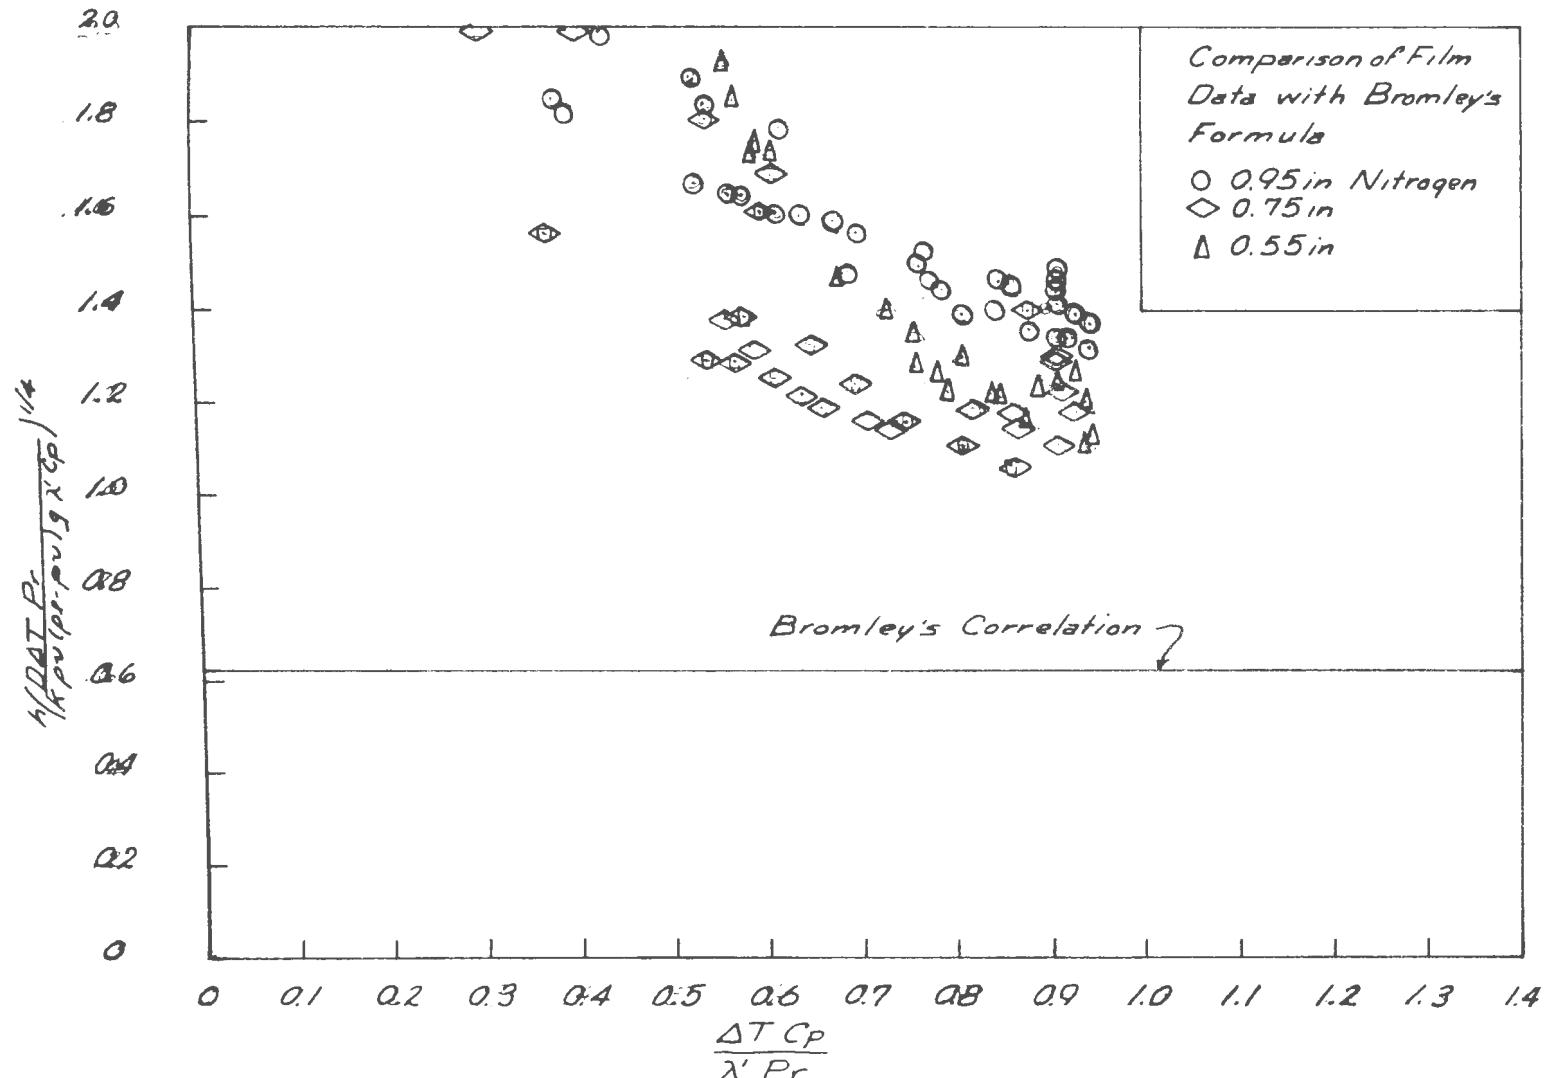

Figure 11 Comparison of Nitrogen Film Boiling Data with Equation 3

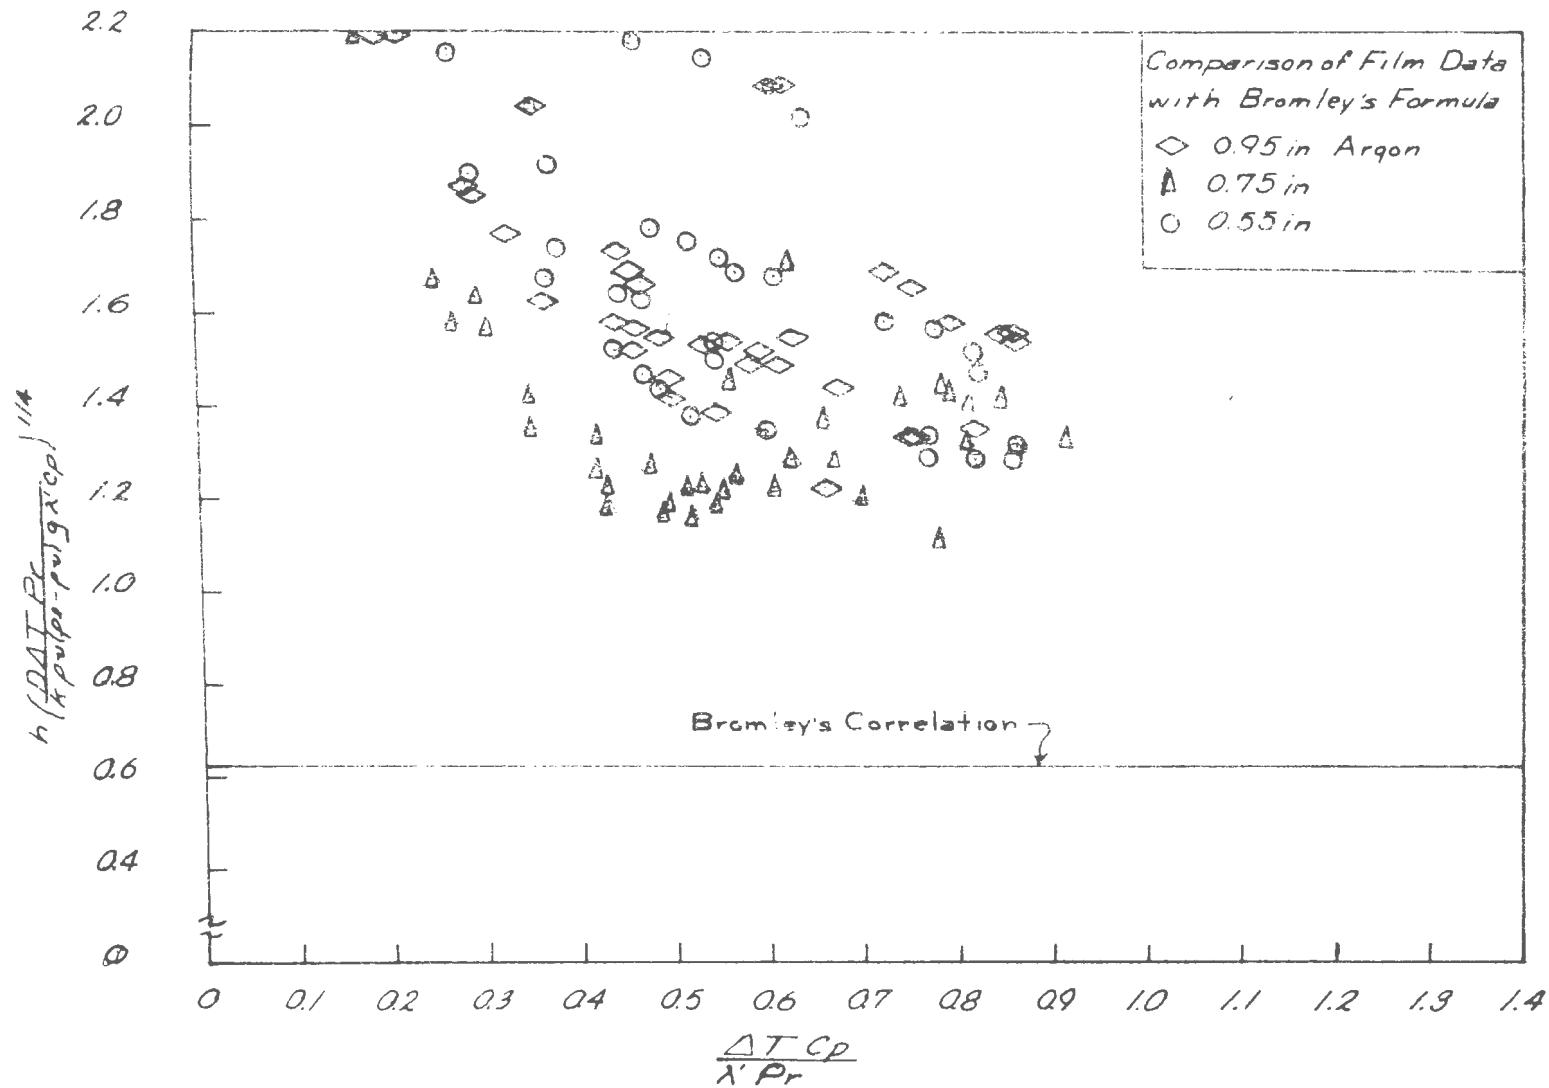

Figure 12 Comparison of Argon Film Boiling Data with Equation 3

in order to obtain a curve which would pass through the center of the data. But this modification still would not yield a satisfactory relation, and the increase in the constant would be difficult to justify.

The experimental data were also compared to the predicted curve of Breen and Westwater,⁽³⁾ Figures 13 and 14. The only restriction placed on the predicted curves was that the diameter of the heater does not equal "the most dangerous wave length". This wave length varied from 0.00187 ft. at 655 pounds per square inch to 0.0291 ft. at 56 pounds per square inch for argon and from 0.00306 ft. at 453 pounds per square inch to 0.0332 ft. at atmospheric pressure for nitrogen. The diameters of the heaters were 0.0458, 0.0625, and 0.0792 ft. which are above the value of "the most dangerous wave length". With "the most dangerous wave length" requirement satisfied, these data should be a test of the generality of the predicted curve. The comparison of the data obtained with Breen and Westwater's equation is shown in Figures 13 and 14. In both cases, the data show that equation (12) is not general. A relation could be made by passing a modified curve through the data. The difficulty in doing this is that, in each run, the data tends to all be plotted at a constant value of λ_c/D for each different pressure.

The real difficulty in this type of relation is in using the quantity F as defined by Bromley (4). The properties that define F are found at the mean film temperature and then F is found by taking the fourth root of $k^3 \rho_v (\rho_1 - \rho_v) \lambda'$. Taking the fourth root of this quantity tends to remove or smooth the variation due to temperature. Also, the values used in defining F can be very difficult to obtain. The difficulty in finding data or physical properties becomes especially apparent when the pressures

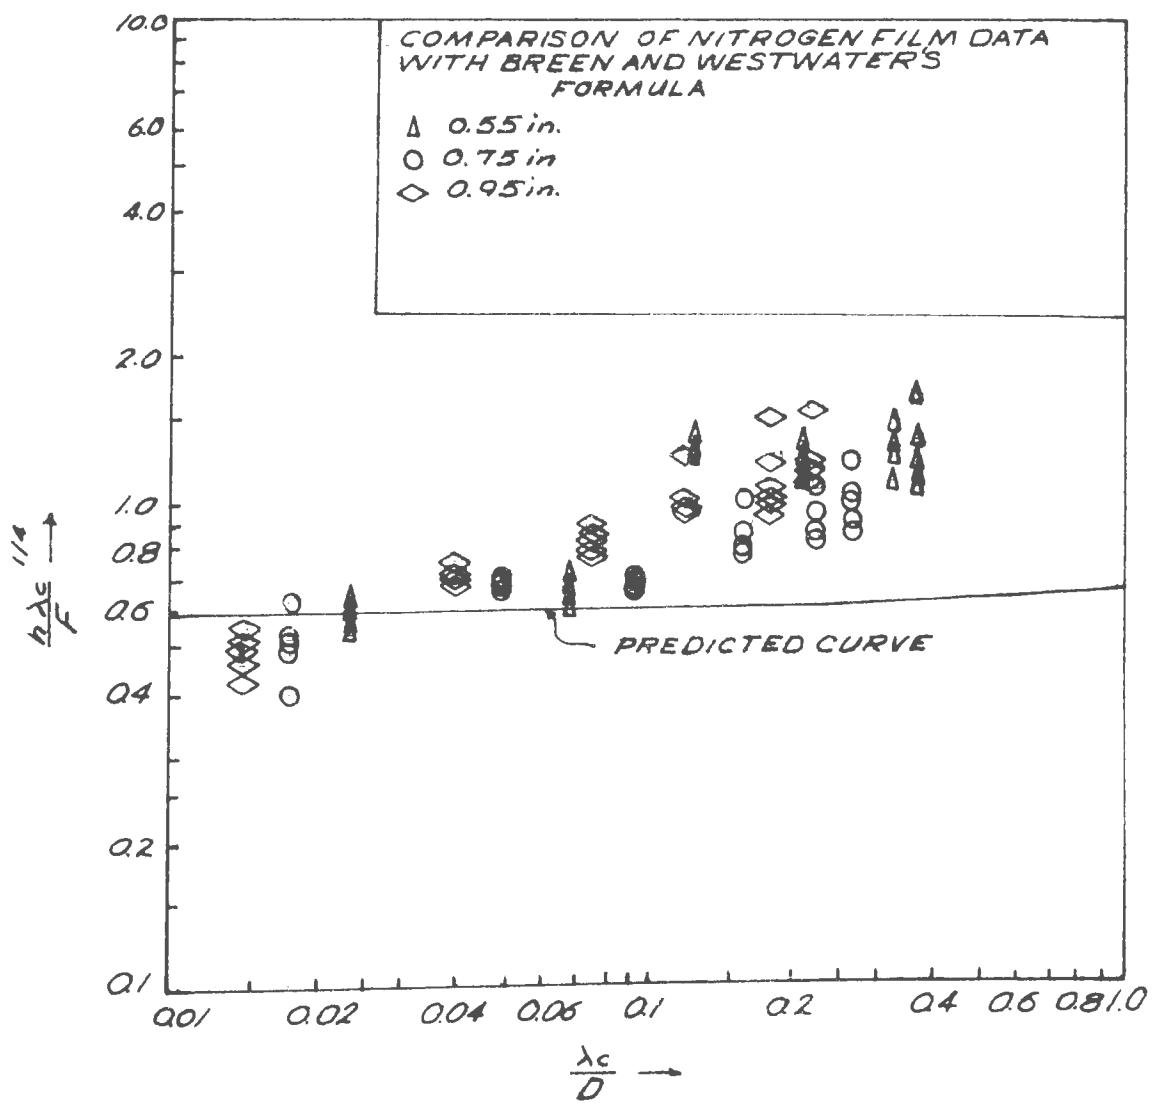

Figure 13 Comparison of Nitrogen Film Boiling Data with Equation 12

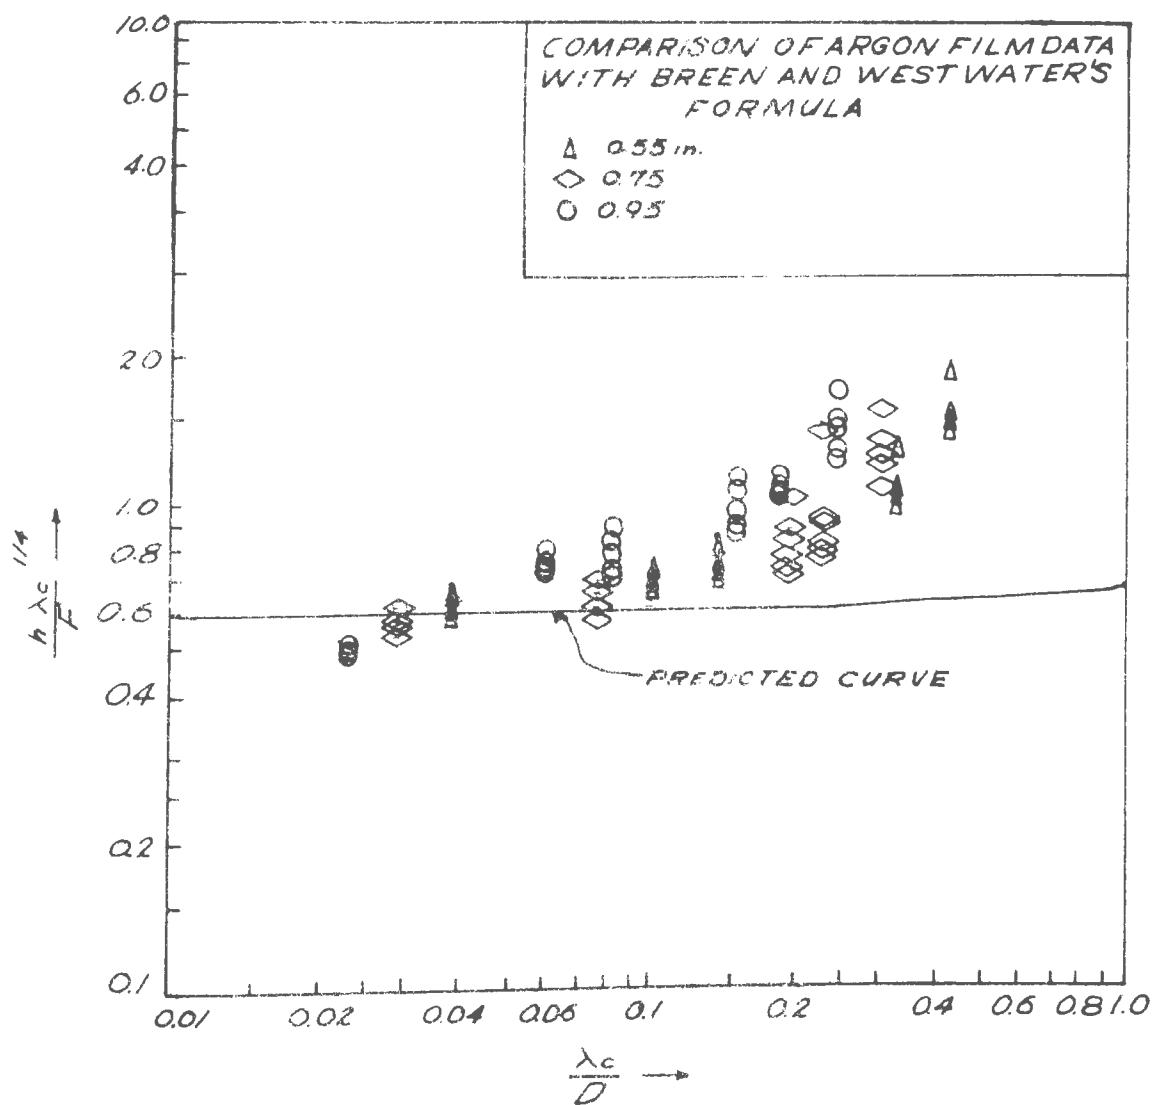

Figure 14 Comparison of Argon Film Boiling Data with Equation 12

approach the critical pressure. In this study, the thermal conductivity, viscosity and surface tension at high pressures were found by using the values predicted by Park⁽²¹⁾ for nitrogen. For argon, the generalized compressibility charts (13) were used to obtain the density, specific heat, and latent heat of vaporization. Viscosity and surface tension were predicted as discussed in Appendix C. Tables (16,22) were available for the other properties. With this difficulty in defining the properties, it is hard to evaluate the validity of a relation.

Another interesting phenomenon was noticed in the plot of the Breen and Westwater relation: the results for high temperature differences were always closer to the predicted curve and results for the low temperature difference were always farther away. This phenomenon was also reported by Park (21).

The difficulty in evaluating the properties in Bromley's and Breen and Westwater's relations makes a correlation like the one of Branchero, Barker and Boll (2),

$$h = a_2 \left(\frac{1}{D} + c \right) P^{\frac{1}{4}}, \quad (16)$$

shown in Figure 15 and 16 especially attractive. The only problem is that the values for a_2 were evaluated for oxygen. Assuming that the values of a_2 for oxygen are correct for nitrogen and argon, the data are compared to the correlation in Figure 15 and 16. It can be seen that the correlation is not satisfactory, but there are some interesting aspects to be discussed. The appearance of the equation is very similar to what was predicted in the theory section for corresponding states fluids. The heat transfer coefficient is given as a function of temperature difference, pressure and diameter.

Considering this approach, the values of a_2 were modified by taking

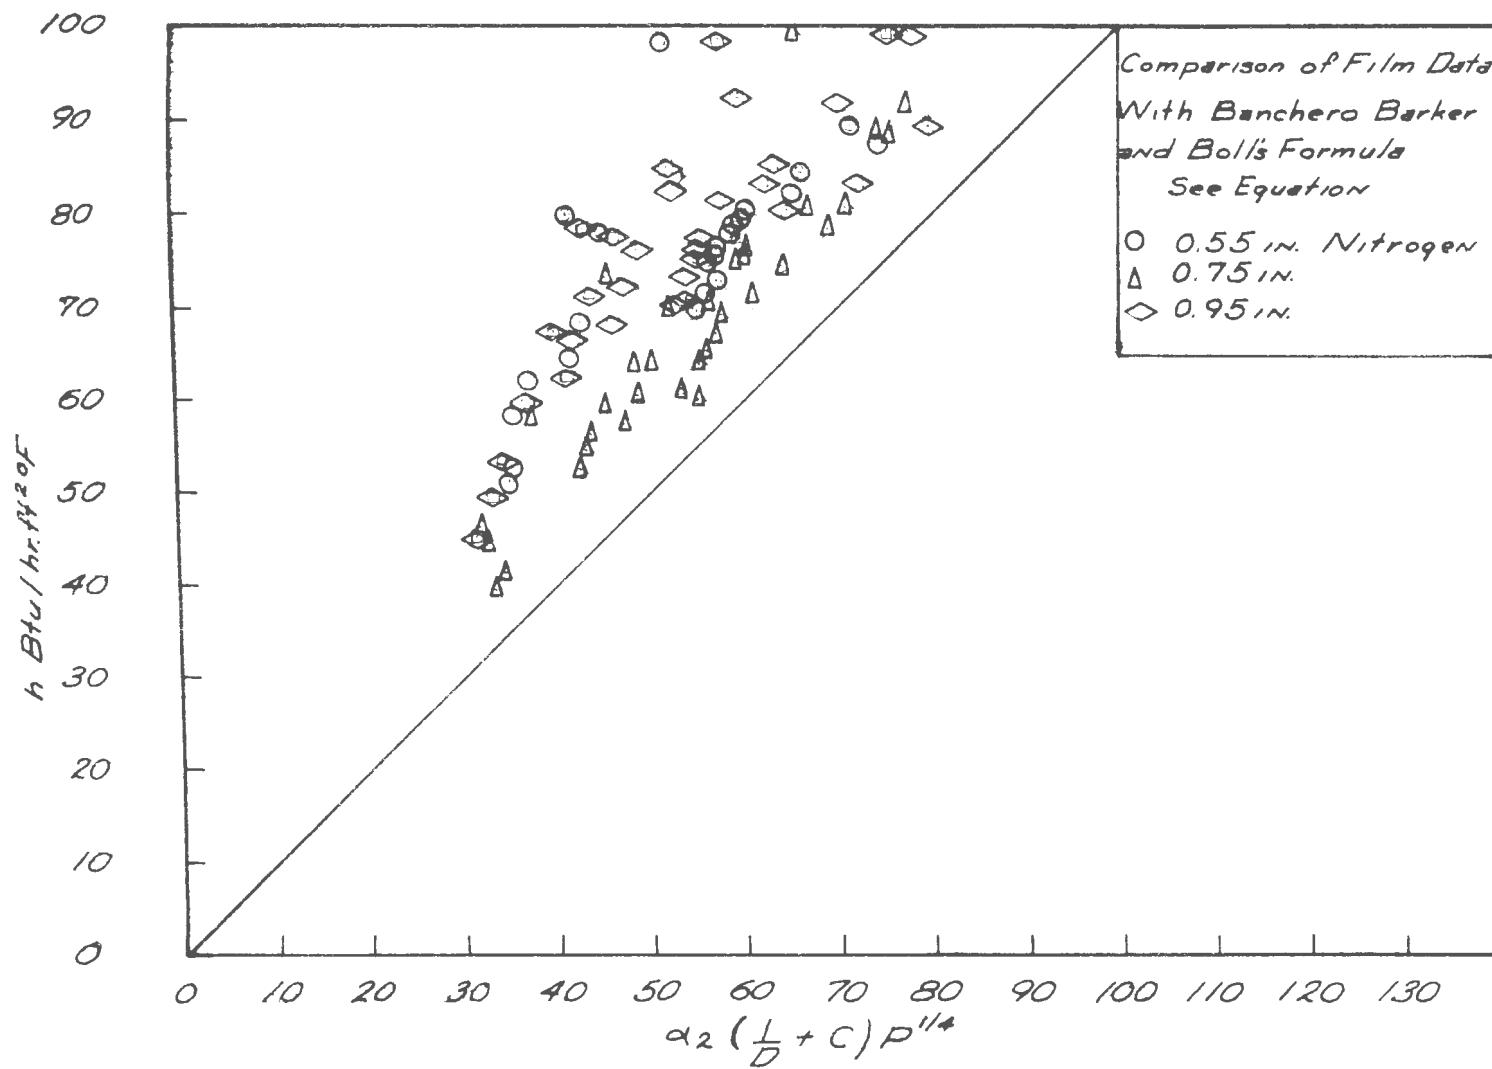

Figure 15 Comparison of Nitrogen Film Boiling with Equation 16

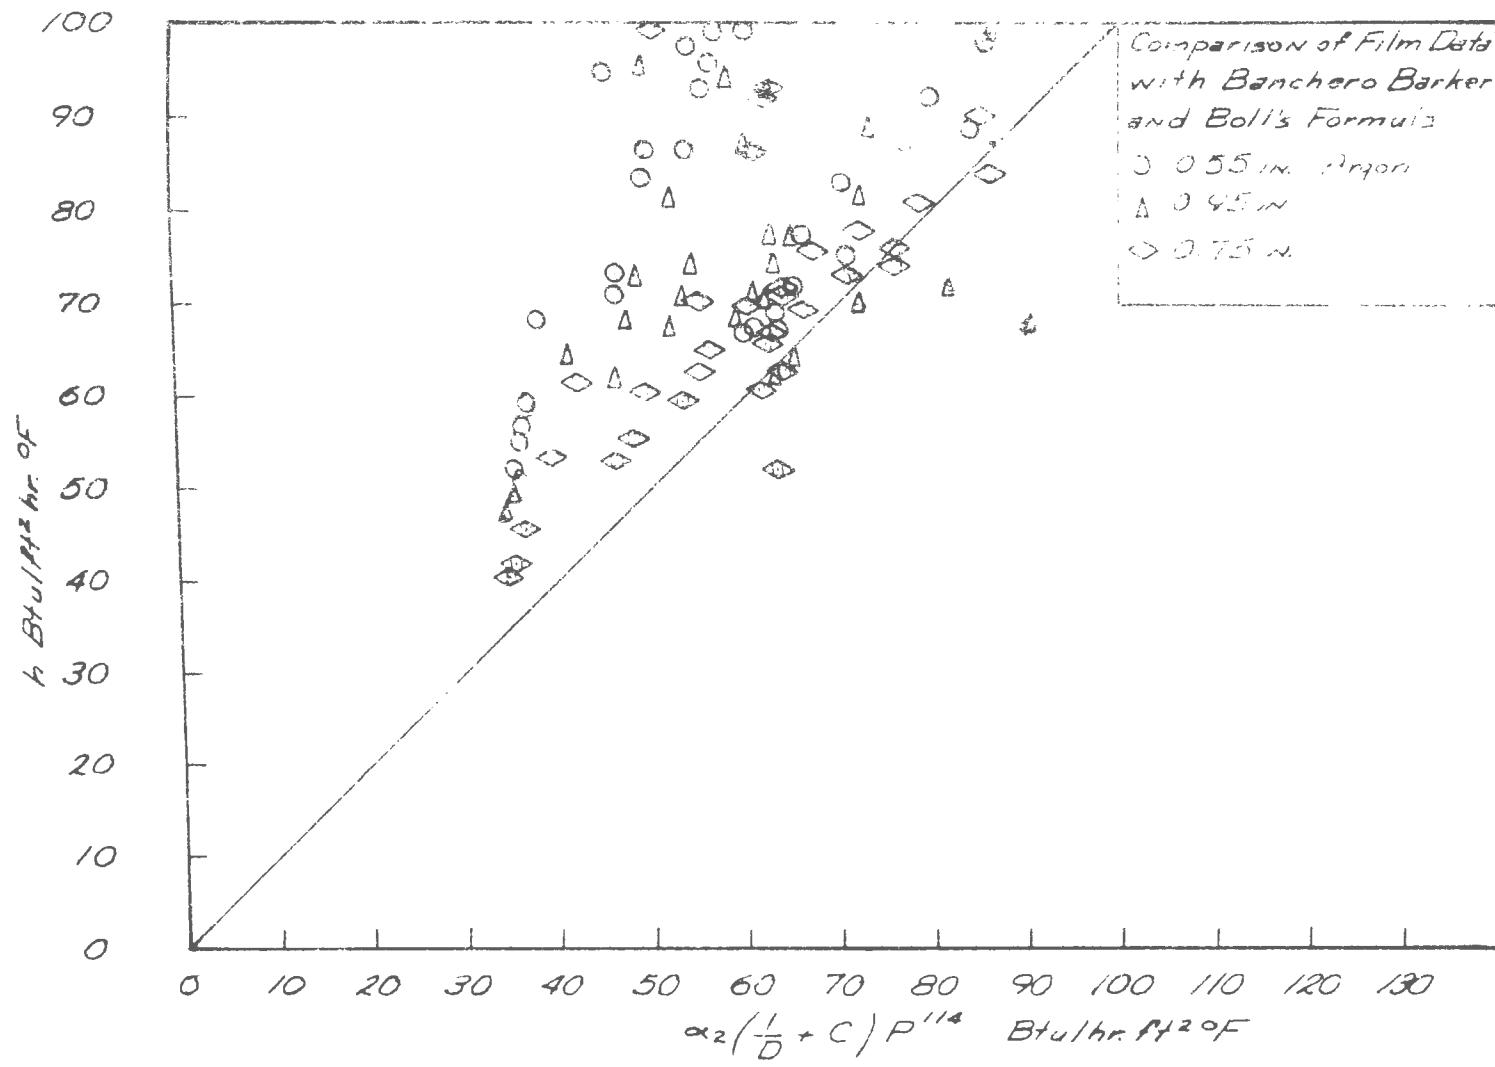

Figure 16 Comparison of Argon Film Boiling with Equation 16

a ratio of the critical temperatures raised to a power and the ratio of the critical pressures raised to the one fourth power. This relation for nitrogen is shown in Figure 17. The ratio of critical temperatures was raised to 1.25 power and multiplied by α_2 . The relation seems to fit the nitrogen data well, but it would be expected that this same ratio should produce a satisfactory correlation for the argon data. This relation was compared to the argon data in Figure 18. It is noticed that the deviation is large. In order to obtain a satisfactory fit for the argon data, the power of the ratio was increased to 9.4. The results are shown in figure 19. Even though the variation of α_2 cannot be justified in terms of corresponding states, it is pointed out that a correlation can be found for the data just by varying α_2 . This means that the diameter change can be accounted for by the factor $(1/D + C)$ where $C = 36.5 \text{ in.}^{-1}$ and that the effect of changing pressure is a function of $P^{\frac{1}{4}}$.

With the function known for the change in diameter and the change in pressure, an equation of the form:

$$h = \alpha_2 \left(\frac{1}{D} + C \right) P_r^{\frac{1}{4}} \quad \text{where } C = 36.5 \text{ in.}^{-1} \quad (17)$$

will be assumed. The changes made in the Barchero, Barker, and Boll relation are: instead of the absolute pressure raised to the one fourth power the reduced pressure ratio is substituted. And, α_2 will be expressed as a function of the mean film reduced temperature ratio. This equation is truly a corresponding states equation and is of the form predicted in the theory section.

The variation of α_2 was found by dividing the experimental heat transfer coefficient by the diameter and pressure factor and recorded at the value of the mean film reduced temperature ratio. The values of α_2 were calculated for all the nitrogen and argon data of this investi-

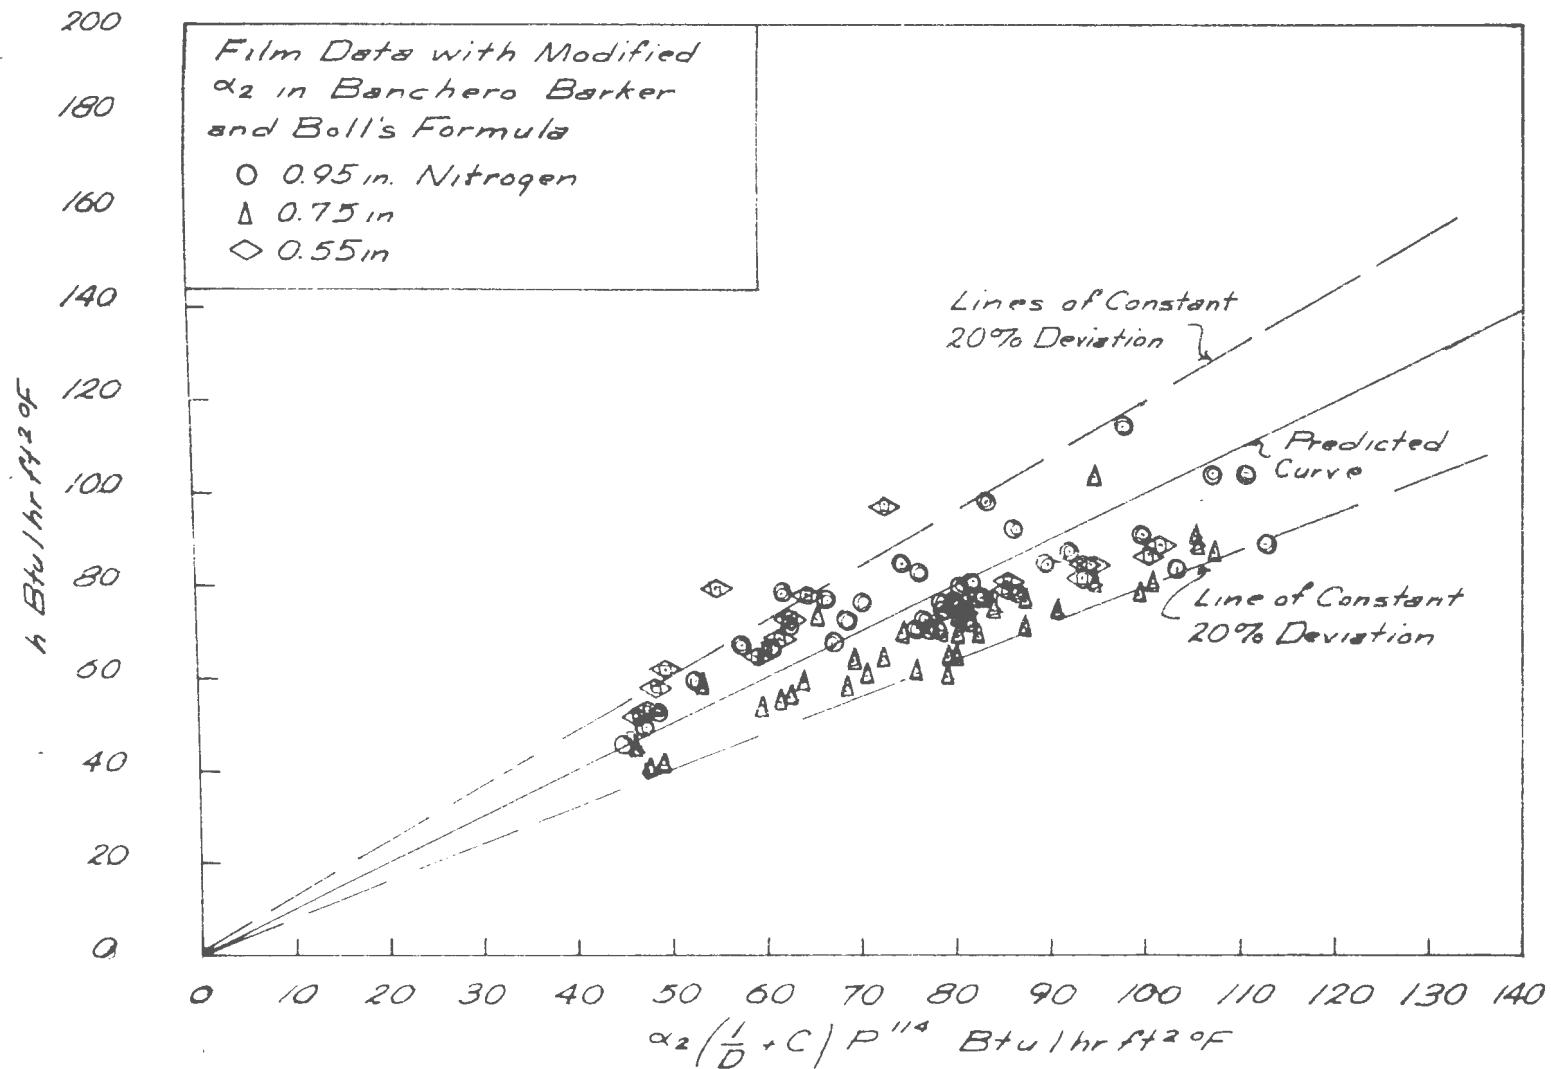

Figure 17 Comparison of Nitrogen Film Boiling Data with Modified Equation 16

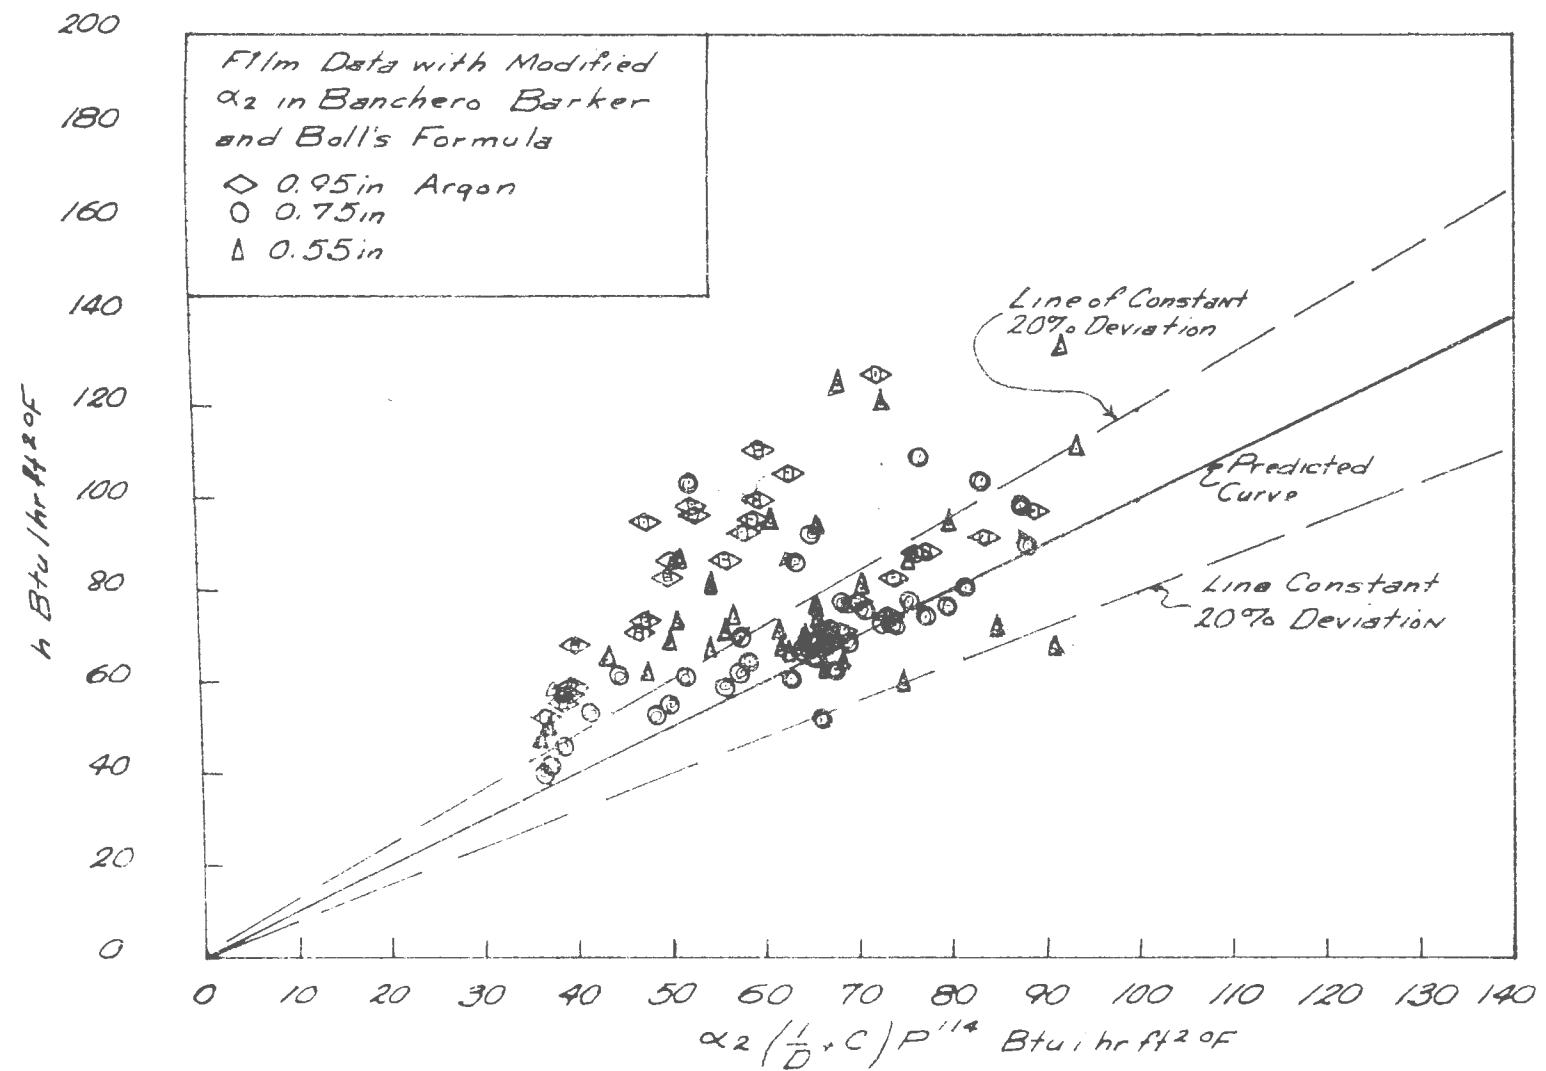

Figure 18 Comparison of Argon Film Boiling Data with Modified Equation 16

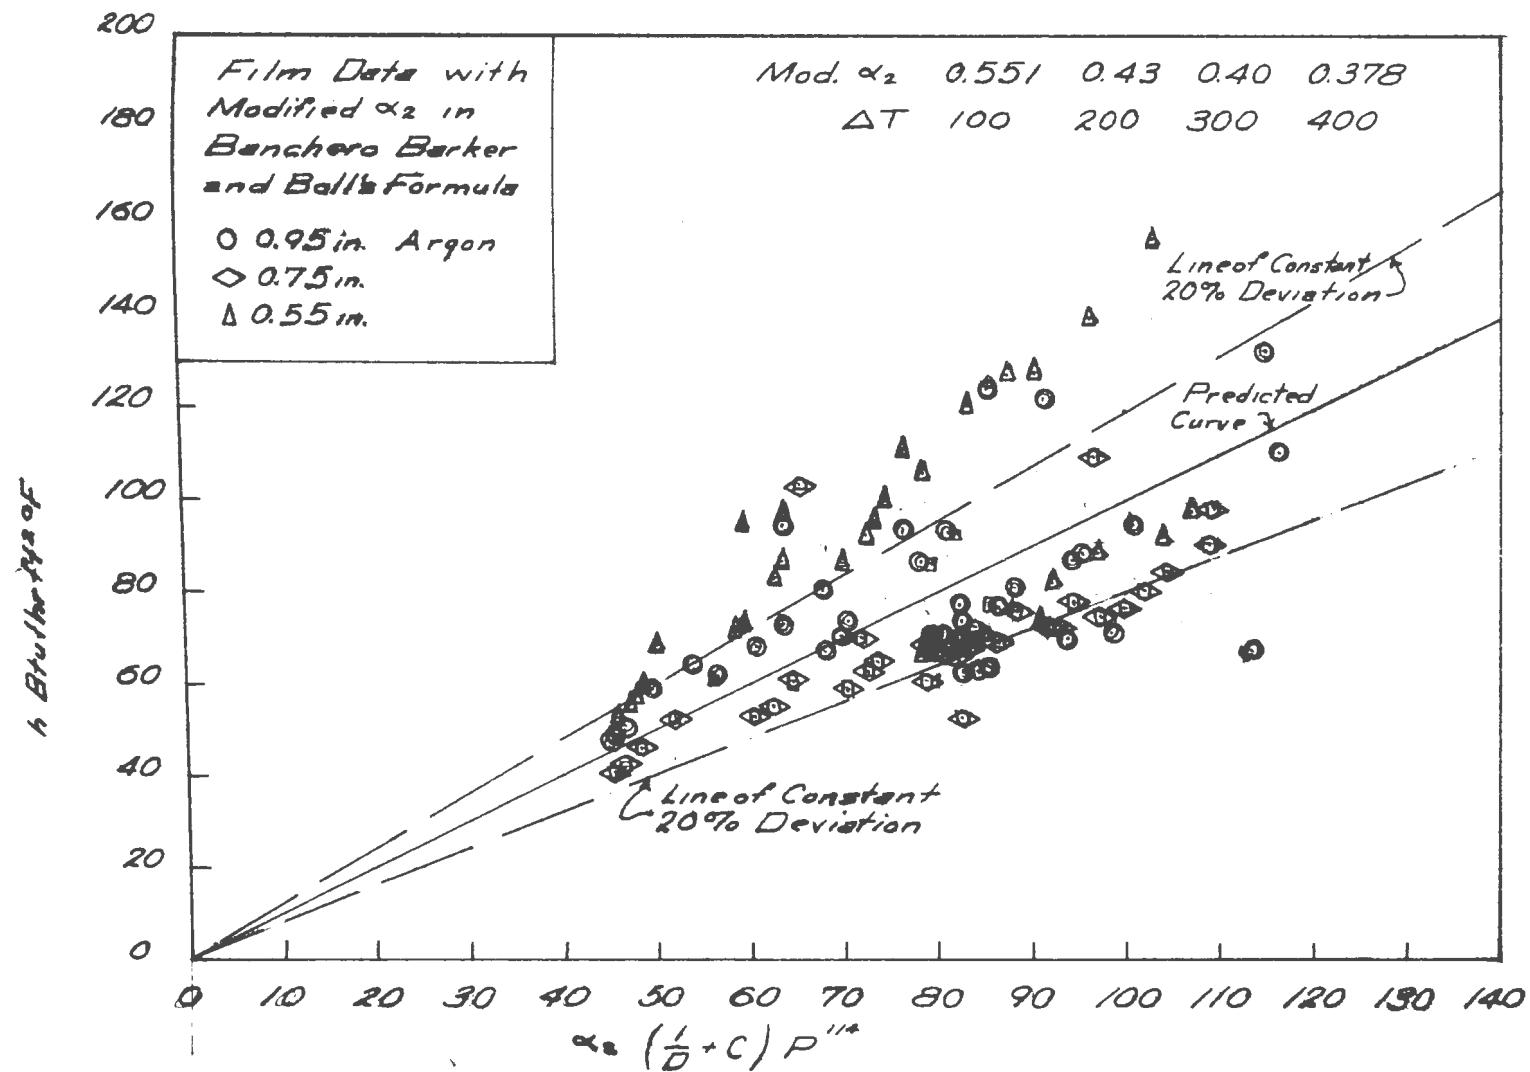

Figure 19 Comparison of the Argon Film Boiling Data with Modified Equation 16

gation and for the data of Park (21) and Banchero, Barker and Boll (2).

Values of α_2 versus mean film critical temperature ratio were then fitted with a least squares program. The least squares fit was a third degree polynomial and the data were fitted with an average deviation of 18.71%. The polynomial least squares fit was:

$$\alpha_2 = 8.49 - 8.24T_r + 2.97T_r^2 - 0.267T_r^3 .$$

Using this α_2 and equation (17), the predicted values of h were calculated and plotted in Figure 20.

Referring to Figure 20, most of the data fall within the 20% deviation lines plotted on the graph, except for some of the low temperature difference argon data and the data of Park. The data of Park do not seem to vary in any given relation, but seems to be scattered over the entire curve. The Banchero, Barker, and Boll data were lower than the predicted curve, but within 20% of it in most cases. It might be pointed out that the average deviation of Figure 20 is the same as the deviation of α_2 .

The α_2 versus mean reduced temperature ratio was also fitted using only the data of this experiment. The least square fit again was a third degree polynomial. The polynomial was given as:

$$\alpha_2 = 13.38 - 15.53T_r + 6.14T_r^2 - 0.588T_r^3 .$$

This polynomial fitted the data of this investigation with an average deviation of 14.54%. The predicted values of h for this investigation were calculated using the equation above and plotted in Figure 20. It is noted again that at some of the higher values of h for the argon, considerable disagreement occurred.

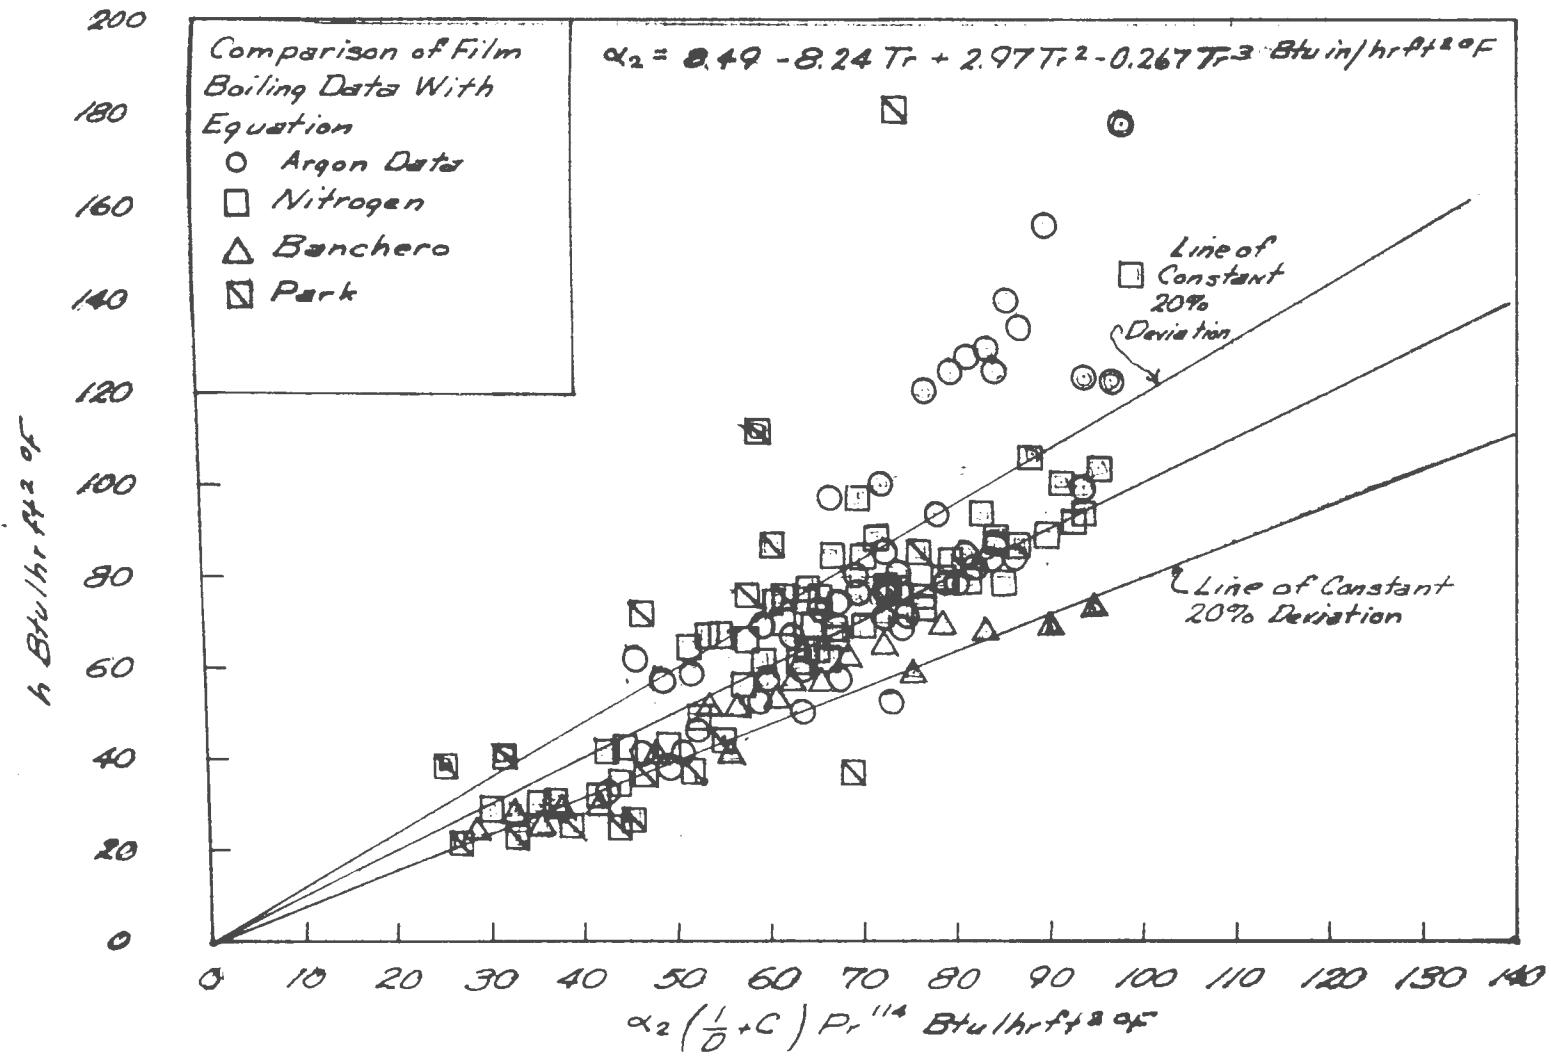

Figure 20 Comparison of Film Boiling Data with Equation 17

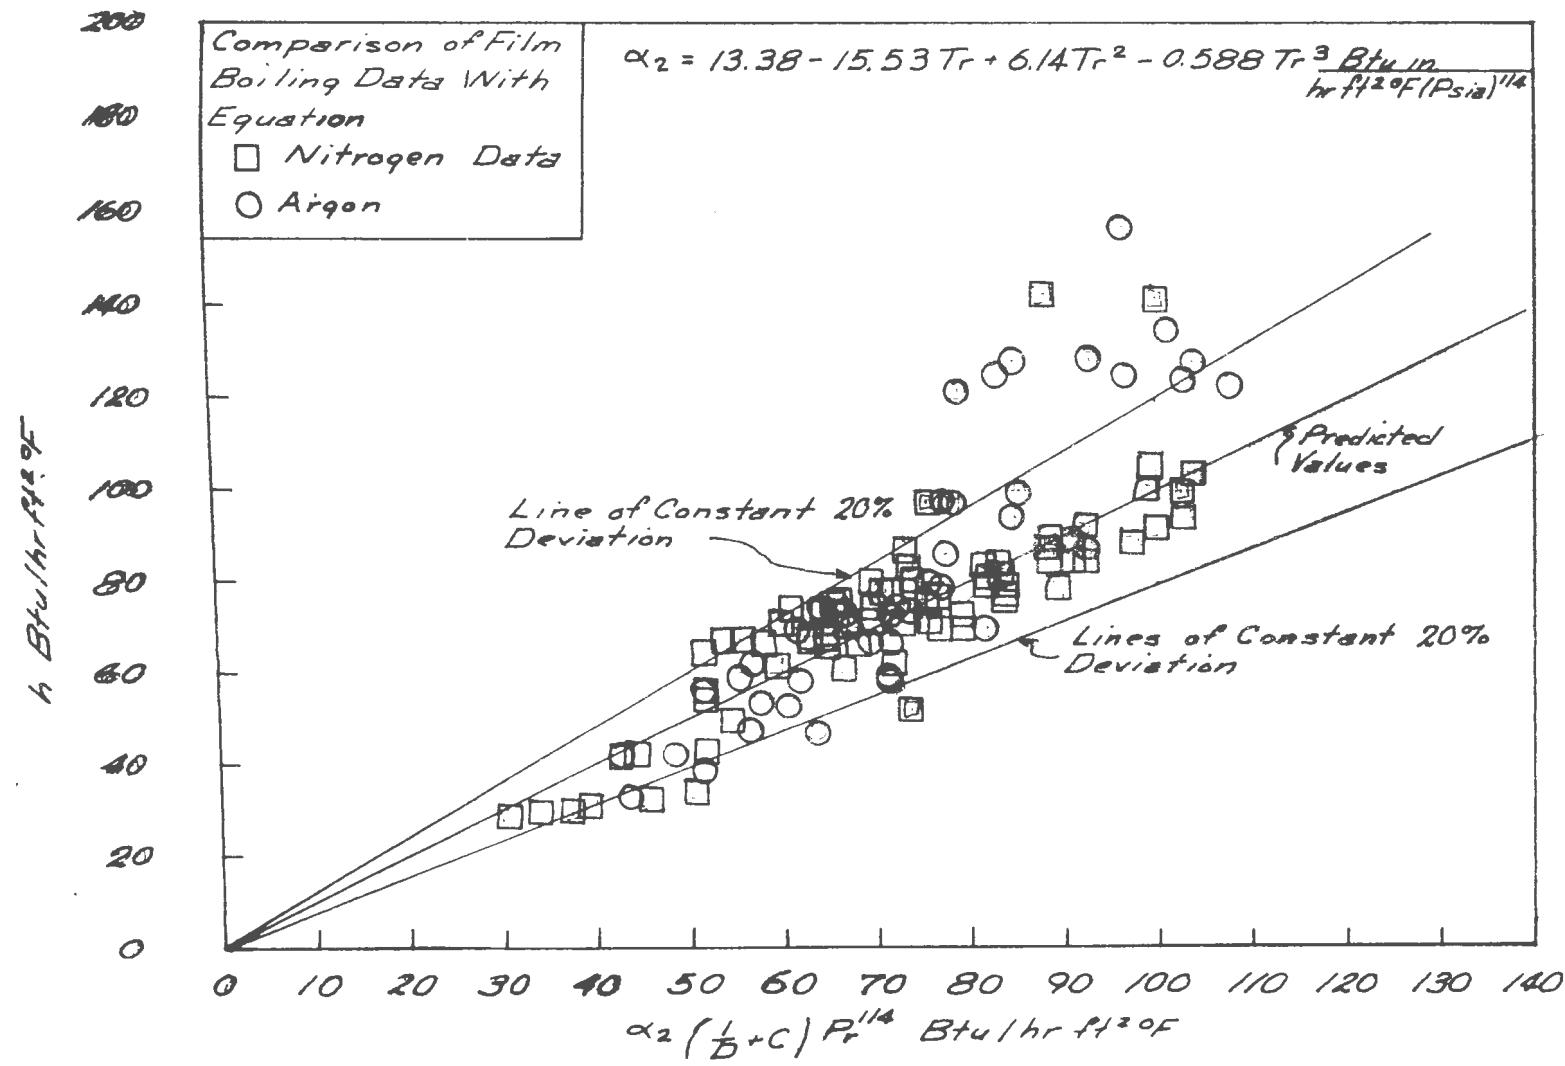

Figure 21 Comparison of the Argon and Nitrogen Film Boiling Data with Equation 17

It should be pointed out that the disagreement of the α_2 's is not as large as it might seem by examining the two polynomials. The values are almost equivalent at the lower values of h , but vary at the higher values. Corresponding states theory would predict that the polynomials would be equivalent.

A restriction must be placed on α_2 in these relations; it should be noted that the range of data was from a mean film reduced temperature ratio of 1.7 to approximately 0.8 and any extrapolation could be in error. This is especially true for the results at low values of this ratio.

It should also be pointed out that in the figures not all the data were plotted, but only a representative sample. Selection was always made to include the entire temperature range of the data.

While taking the data for this investigation, an interesting phenomenon was observed which might have some effect on further film boiling work. It was noticed that the bubbles physical characteristics were different while the equipment was at steady state as compared to the transient state involved in changing steady state operating points. The bubbles were large and of varied spacing at steady state but were small and fairly evenly spaced during transients. This phenomenon would question the validity of using transient data for steady state conditions or vice-versa.

It was also noticed during the course of the investigation that surface effects did not affect the heat transfer. The initial runs were made in February and the final runs in May and June. The heaters were left exposed to the atmosphere, and surface conditions changed considerably due to oxidation over this period. Even with this change in surface conditions, there did not seem to be any difficulty in reproducing the data.

CHAPTER VIII

DISCUSSION OF ERROR IN MEASUREMENT

Park (21) discussed in detail the inherent error associated with nucleate and film boiling; therefore, error analysis will not be discussed in great detail here.

The current could be read accurately within ± 0.125 amps and the voltage, when less than 30 volts, could be read accurately within ± 0.075 volts. The product of these errors is less than 1 percent.

The thermocouples could be read accurately to ± 0.005 millivolts which corresponds to $\pm 0.25^\circ\text{F}$. The thermocouples were calibrated by placing the reference junction in liquid nitrogen and the three heaters in a liquid nitrogen bath in a solid-liquid, acetone bath and an ice water bath. The fixed temperature of the three baths allowed the calculation of the deviation from standard tables (N. B. S. Circular 561). The calibration for the thermocouples in the heater was only possible for thermocouple number 2 and 4. The thermocouple lead in the flange for the number 1 thermocouple was broken during operation. The deviations for the two thermocouples of the three heaters and the bath thermocouple are given in Table I.

The locations of the thermocouples during each run should also be pointed out. Thermocouple number 1 was on top of the heater, thermocouple number 2 was spaced 90° from 1 on the side of the heater, and number 4 was on the bottom. During the first set of runs for the 0.75 and 0.95 inch heaters, the thermocouples were attached to the heater as described by Cobb (8). Considerable temperature variation was recorded, so the thermocouple mounting was then changed by filling the wells with molten solder.

TABLE I

Deviation of Thermocouples from Standard Tables

| 0.55 in. Heater | | |
|-----------------|--------------|----------------------|
| TEMPERATURE °C | THERMOCOUPLE | DEVIATION MILLIVOLTS |
| -196.18 | 2 | -0.000 |
| | 4 | -0.000 |
| | Bath | -0.085 |
| -94.6 | 2 | 0.024 |
| | 4 | 0.026 |
| | Bath | -0.043 |
| 0.0 | 2 | .057 |
| | 4 | .050 |
| | Bath | 0.00 |
| 0.75 in. Heater | | |
| -196.18 | 2 | 0.00 |
| | 4 | 0.00 |
| -94.6 | 2 | 0.025 |
| | 4 | 0.027 |
| 0.0 | 2 | 0.054 |
| | 4 | 0.051 |
| 0.95 in. Heater | | |
| -196.18 | 2 | 0.00 |
| | 4 | 0.00 |
| -94.6 | 2 | 0.026 |
| | 4 | 0.025 |
| 0.0 | 2 | 0.053 |
| | 4 | 0.052 |

and inserting the thermocouples. The temperature variation was reduced considerably. Insertion of thermocouples in wells filled with solder is considered a much better method of thermocouple mounting.

The magnitudes of heat lost from the end of the cylinders can be calculated for the cylinders if the equation $q = -kA\Delta t/dx$ is written in the form $q = \frac{kA\Delta T}{\Delta x}$ and if temperature measurements are made axially along the cylinder. Park (20) did this in his investigation and found that the maximum heat loss for film boiling was 4.8%. Banchero, Baker and Boll (2) with a cylindrical heater having an L/D of 0.375 reported that axial temperature gradient were virtually eliminated. Park's heaters had an L/D of 0.547 and the heaters used in this investigation had L/D of 0.316, 0.40 and 0.546. Therefore, temperature gradients would be expected to be in the range of Park's and Banchero's copper heaters, since all heaters were fabricated of copper. Thus the heat loss would be in the range reported by Park.

CHAPTER IX

CONCLUSIONS

1. Film boiling heat transfer of corresponding states fluids can be correlated using the principle of corresponding states with less than 20% average deviation.
2. The variation of the heat transfer coefficient in film boiling with cylindrical heaters due to a change of diameter is a function of the reciprocal of the diameter of the heat transfer element.
3. The change of the heat transfer coefficient due to a change of pressure is a function of the pressure raised to the one fourth power.
4. The decrease in film boiling heat flux at a given temperature difference as the critical pressure is approached as stated by Park (20) is questionable. More work in this area is needed before a conclusive statement can be made.
5. It is questionable whether surface chemistry affects the film boiling heat flux.
6. It is questionable whether transient film boiling data can be used for steady state design applications.

NOMENCLATURE

A - Area, ft²

a - constant in equation 2,

a_2 - constant in equation 16, $\frac{\text{Btu in}}{\text{hr ft}^2 \text{F}}$ (psia),

C - constant in equation 2, inches⁻¹,

c_p - Heat Capacity, Btu/lb°F,

D - Diameter, Ft,

E - Potential, volts

F - $\frac{k^3 \rho_v (\rho_1 - \rho_v) g \lambda'}{\Delta T_u}^{\frac{1}{4}}$, $\frac{\text{Btu}}{\text{hr ft}^2 \text{F}}$,

g - Acceleration due to gravity, ft/sec²

g_c - Gravitational Constant, $\frac{\text{lb}_m \text{ ft}}{\text{lb}_f \text{ sec}^2}$,

Gr* - Generalized Grashof Number,

h - Heat Transfer coefficient, Btu/hr ft² °F,

I - Current, amp,

k - Thermal Conductivity, Btu/hr ft²°F/ft,

L - Length, ft,

M - Molecular Weight, lb/lb-mole,

Nu* - Generalized Nusselt Number,

P - Pressure, psi,

Pr - Prandtl Number,

Pr* - Generalized Prandtl Number,

Q - Rate of heat transfer, Btu/hr,

T - Temperature, °R,

ΔT - Temperature Difference ($T_{\text{surface}} - T_{\text{wall}}$), °F or °R,

v - Specific volume, ft³/lb,

W - Maximum vapor mass flow rate, lb_m/sec,

Greek Symbols

σ - Surface Tension, lb/ft,

$$\lambda = \frac{g \sigma}{g_c (\sigma_1 - \sigma_v)}^{\frac{1}{2}}, \text{ ft},$$

μ - Viscosity, lb/ft hr,

ρ - Density, lb/ft³,

α - Equivalent Thermal Diffusivity, ft²/hr,

γ - Kinematic Viscosity, ft²/hr,

λ - Latent Heat of Vaporization Btu/lb_m,

θ - Temperature difference, °R

Subscripts

c refers to the critical point,

v refers to the vapor,

l refers to the liquid,

r refers to reduced property, (T/T_c, etc.)

APPENDIX B

SAMPLE CALCULATION

A. Sample Calculations for the first data point of 34 psig nitrogen
0.95 inch heater

$$\text{Data: } E = 16.0 \text{ volts}$$

$$I = 15.2 \text{ amps}$$

$$\Delta T_1 = 324.3^\circ\text{R}$$

$$\Delta T_2 = 295.8^\circ\text{R}$$

$$\Delta T_4 = 313.8^\circ\text{R}$$

$$A = 6.21 (10)^{-2} \text{ ft.}^2$$

1. Calculation of the heat flux

$$Q/A = \frac{(31413EI)}{A} = 13.32(10)^3 \text{ B.t.u./hr. ft.}^2 \text{ }^\circ\text{F}$$

2. Calculation of the heat transfer coefficient predicted

$$Q/A \text{ for } 324.3^\circ\text{F} = 14.61(10)^3 \text{ B.t.u./hr. ft.}^2$$

$$h = Q/(A \Delta T) = 41.0731$$

B. Sample Calculation for twentieth data point of 429 psig nitrogen
0.75 inch heater

$$\text{Data: } h = 41.07 \text{ B.t.u./hr. ft.}^2 \text{ }^\circ\text{F}$$

$$T_s = 222^\circ\text{R}$$

$$\Delta T = 311.5^\circ\text{R}$$

$$T_{ave} = 377.55^\circ\text{R}$$

$$\rho_1 = 28.3 \text{ lb./ft.}^3 \text{ from reference } \underline{\underline{22}} \text{ (Perrys)}$$

$$\rho_v = 2.88 \text{ lb./ft.}^3 \text{ from reference } \underline{\underline{22}} \text{ (Perrys)}$$

$$\sigma = 0.32 \times 10^{-5} \text{ lb/ft. from reference } \underline{\underline{21}}$$

$$K_v = 0.0125 \text{ B.t.u./hr. ft.}^2 \text{ }^\circ\text{F}/\text{ft. from reference } \underline{\underline{21}}$$

$$\mu_v = 0.0346 \text{ lb/ft. hr. from reference } \underline{\underline{21}}$$

$$\lambda = 26.6 \text{ B.t.u./lb. from reference } \underline{\underline{22}}$$

$$T_c = 227^\circ\text{R from reference } \underline{\underline{22}}.$$

$$P_c = 33.3 \text{ Atm from reference } \underline{\underline{22}}.$$

$$\lambda = 2\pi (g_c \sigma)/g (\rho_1 - \rho_v)^{-\frac{1}{2}} = 19.15(10)^{-3}$$

2. Calculation of λ'

$$\lambda' = \lambda \left[1 + \left(\frac{0.34 c_p \Delta T}{\lambda} \right)^2 \right]^{1/2} = 120 \text{ B.t.u./lb.}$$

3. Calculation of F

$$F = \left[\frac{k_v^3 \rho_v (\rho_1 - \rho_v) g \lambda'}{\Delta T \mu_v} \right]^{\frac{1}{4}} = 27.3$$

4. Calculation of $(h \lambda_c^{\frac{1}{4}})/F$

$$h \lambda_c^{\frac{1}{4}}/F = 0.56$$

C. Sample Calculation for the first data point for 0.95 in heater at 550 psig with argon.

$$h = 74.01 \text{ B.t.u./hr. ft.}^2 \text{ }^{\circ}\text{F}$$

$$T_s = 43.5 \text{ }^{\circ}\text{F}$$

$$T_c = 151.2 \text{ }^{\circ}\text{K from reference 12}$$

$$T_{ave} = 383.25 \text{ }^{\circ}\text{R}$$

$$T_r = 1.41$$

$$P_r = .8$$

$$Z = .923 \text{ from reference 12}$$

$$T_{r \text{ sat}} = 0.967 \text{ from reference 12}$$

$$\left(\frac{H^*-H}{T_c} \right)_v = 2.36 \frac{\text{B.t.u.}}{\text{Mole } ^{\circ}\text{F}} \text{ from reference 12}$$

$$\left(\frac{H^*-H}{T_c} \right)_l = 8.28 \frac{\text{B.t.u.}}{\text{Mole } ^{\circ}\text{F}} \text{ from reference 12}$$

$$\rho_c = 0.531 \text{ gm/cm}^3$$

$$\rho_{rl} = 1.633 \text{ from reference 12}$$

$$C_p - C_p^* = 1.3 \text{ from reference 12}$$

$$P_c = 710 \text{ psia}$$

$$C_p^* = 4.96 \frac{\text{B.t.u.}}{\text{mole}^\circ\text{F}} \text{ from reference 12}$$

$$R = 82.1 \text{ (cc) (atm) / (g - mole) (K)} \text{ from reference 12}$$

$$\sigma = 4.1 \times 10^{-5} \text{ lb./ft. from Appendix C}$$

$$M = 39.95 \text{ lb./mole from reference 12}$$

$$\rho_c = .531 \text{ gm/cm}^3$$

1. Calculation of ρ_v

$$\rho_v = \frac{P}{RT} = 0.0872 \text{ gm/cm}^3$$

2. Calculation of

$$\left[\frac{\left(\frac{H^* - H}{T_c} \right)_1 - \left(\frac{H^* - H}{T_c} \right)_v}{M} \right] T_c = 40.25 \frac{\text{B.t.u.}}{\text{lb.}}$$

3. Calculation of ρ_1

$$\rho_1 = \rho_{r1} \rho_c = 0.868 \text{ gm/cm}^3$$

Calculation of c_p

$$C_p - C_p^* = 1.495$$

$$C_p = \frac{C_p}{M} = 0.1615 \frac{\text{B.t.u.}}{\text{lb.}^\circ\text{F}}$$

APPENDIX C

CALCULATED PHYSICAL PROPERTIES

TABLE C-I ARGON SURFACE TENSION

TABLE C-II ARGON VISCOSITY

Surface tension data was calculated by extrapolating low pressure data using the Mcleod equation as suggested by Prutton and Marion (23).

The viscosity data for argon was predicted using the method suggested by Jossi, Stiel and Thodos (25).

TABLE C-I

SURFACE TENSION FOR SATURATED LIQUID ARGON

| TEMPERATURE °R | SURFACE TENSION ($\sigma \times 10^5$) lb/ft |
|----------------|--|
| 192 | 59.1 |
| 222 | 38.0 |
| 243 | 15.32 |
| 263 | 4.1 |
| 268 | 3.08 |
| 270 | 1.03 |

TABLE C-II
VISCOSITY OF ARGON VAPOR
($\mu \times 10^5$) CENTIPOSES

| PRESSURE PSIA | TEMPERATURE °R | | | | |
|------------------|----------------|------|------|------|------|
| | 250 | 300 | 350 | 400 | 450 |
| 71 | 1151 | 1360 | 1570 | 1400 | 1970 |
| 212 | 1200 | 1400 | 1600 | 1875 | 2010 |
| 353 | 1240 | 1430 | 1630 | 1855 | 2030 |
| 568 | 1255 | 1457 | 1660 | 1829 | 2050 |

| 670 | 1300 | 1495 | 1690 | 1770 | 2110 |

VITA

Virgil James Flanigan Jr., son of Mr. and Mrs. Virgil J. Flanigan was born at the Confederate Soldiers Home of Missouri, on December 31, 1938.

He attended Higginsville High School and graduated in May, 1956. In September, 1956, he enrolled in Missouri School of Mines and Metallurgy and completed requirements for a Bachelor of Science degree in Mechanical Engineering in May of 1960. He spent the next year in industry and the U. S. Army. In September of 1961 he enrolled at Missouri School of Mines and Metallurgy as a graduate student in Mechanical Engineering. He completed the requirements for Master of Science degree in Mechanical Engineering in October of 1962. He spent the next two years on the faculty of Missouri School of Mines and was married to Miss Louise Bettie on June 13, 1964. He then accepted a position with the Boeing Company as a research engineer. He returned to the University of Missouri at Rolla in September of 1965 and was admitted as a candidate for the Doctor's degree in Mechanical Engineering.

He and his wife were blessed with the birth of a son, Virgil Jr., one year old at the time of this writing.
