ABSTRACT

INSIGHTS INTO THE ASSEMBLY OF ARCTIC ALASKA: PROVENANCE AND
GEOCHEMICAL DATA FROM THE DOONERAK FENSTER AND ENDICOTT
MOUNTAINS ALLOCHTHON

William Patrick Frier

The Doonerak fenster of the central Brooks Range contains the Apoon assemblage, a suite of Early Paleozoic mafic-to-intermediate volcanic and siliciclastic rocks. The fenster exposes deep structural levels of the Brooks Range between regions of Laurentian and non-Laurentian origin in Arctic Alaska. During the Mesozoic to Cenozoic formation of the Brooks Range, Upper Devonian to Triassic siliciclastic and carbonate rocks of the Endicott Mountains allochthon were thrusted northward and juxtaposed over the top of this volcanic suite.

New geochemical data indicates that the Apoon assemblage formed as part of an island arc complex. The assemblage contains basaltic-to-andesitic rocks with diverse textures, including pillow basalts and cross-cutting dikes and sills. Enrichment in large ion lithophile elements (e.g. Cs, Rb, Ba, Th), depletion in high field strength elements (e.g. Nb, P, Zr, Ti), and chondrite-normalized rare-earth element (REE) trends within the Apoon volcanics are consistent with formation in an island arc setting and corroborate previous work.

Detrital zircon spectra from volcaniclastic portions of the Apoon assemblage show a prominent unimodal 440-530 Ma population centered on 504 Ma with only minor populations potentially derived from Laurentia. The siliciclastic units unconformably overlying the Apoon assemblage (Ellesmerian sequence) and those of the Endicott Mountains allochthon mostly lack detritus from this 504 Ma population and are instead dominated by 400-440 Ma populations centered on ~420 Ma. While this is dissimilar from the Apoon assemblage, detritus of this age is common in rocks of the Canadian Arctic, Svalbard, and eastern Greenland and is associated with the Caledonian orogeny.

The coexistence of Caledonian detritus alongside 800 - 550 Ma populations within samples from the northern margin of the fenster also indicates a connection to the Timanian orogen of northern Baltica. The youngest portions of the Apoon assemblage also show significant Laurentian and Caledonian age detritus. This shift in provenance could be explained by the closure of an oceanic basin, providing newly integrated sediment pathways. Collectively, evidence presented here indicates that the Apoon assemblage formed as part of an island arc, which initially formed in a relatively isolated geographic position and received detritus from mostly proximal sources (single unimodal 504 Ma population). This arc progressively approached and eventually docked onto the margin of northwest Laurentian during closure of the northernmost Iapetus Ocean, eventually amalgamating regions of Laurentian and non-Laurentian origin. Thus, the Doonerak fenster preserves an island arc complex and marks the location of a Paleozoic suture between Laurentian and non-Laurentian portions of Arctic Alaska.

To my niece and nephew:
Ashby Cole Frier and Quinn Andrew Frier.

If you grow up and decide you want to go camping in Alaska, let me know. I'm the uncle for that.

TABLE OF CONTENTS

Figure 1: Polar-view index map of the region north of the Arctic Circle showing topography and bathymetry of various physiographic regions (after Jakobsson et al., 2012, Pease et al., 2014). The dashed red line marks the approximate bounds of the Arctic Alaska - Chukotka microplate. The white star outlined in red marks the location of fieldwork for this study.
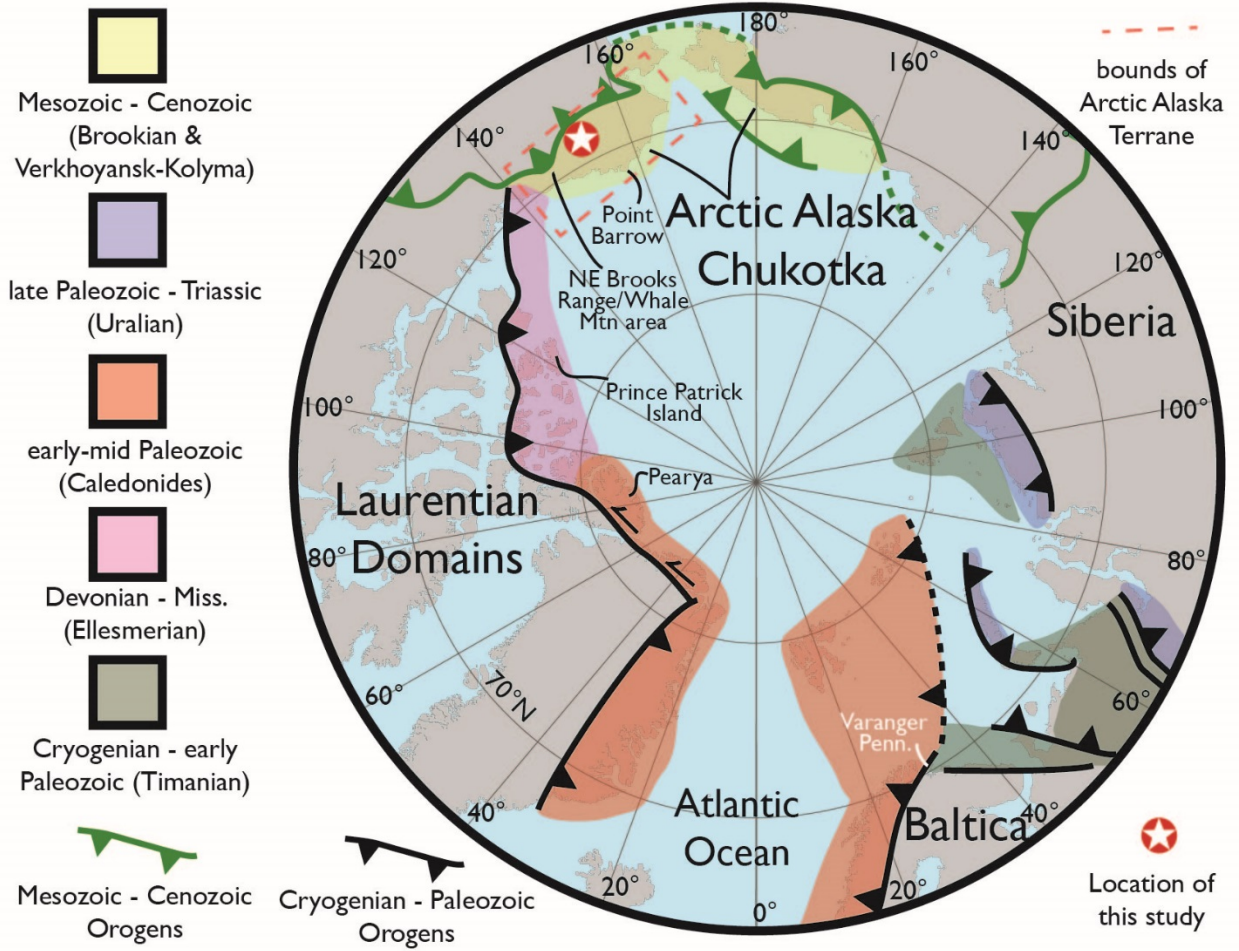

Figure 2: Simplified polar-view map showing the distribution of Proterozoic and Paleozoic orogens in the Arctic region. Modified from Colpron and Nelson (2011) and Strauss et al. (2013).
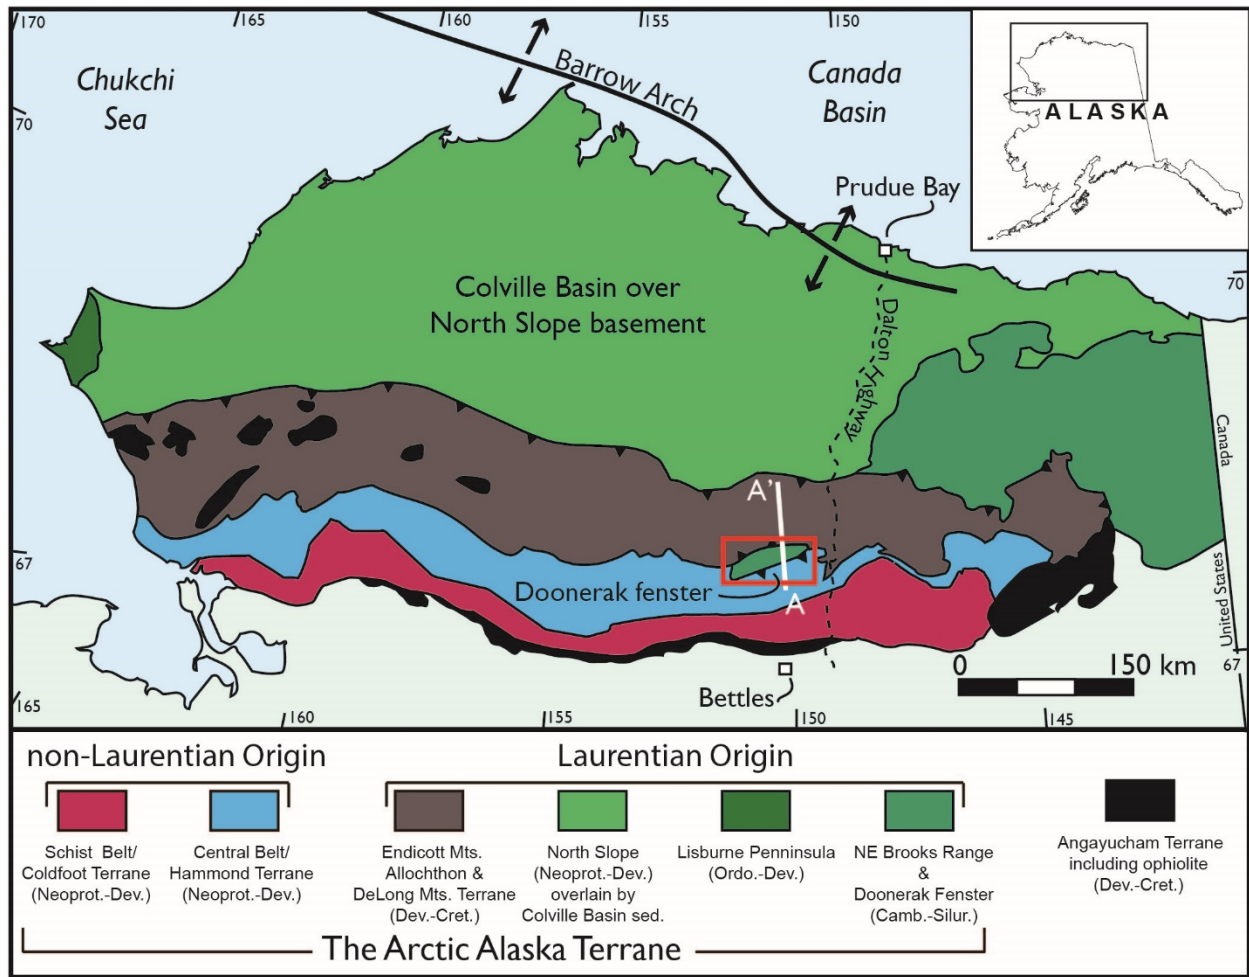

Figure 3: Simplified terrane map of Arctic Alaska colored to show regions of Laurentian and non-Laurentian origin (modified from Moore et al., 1994). Red box marks the location of the Doonerak fenster in the central Brooks Range, which is expanded in Figure 6. Line A-A' corresponds to the cross section in Figure 7.
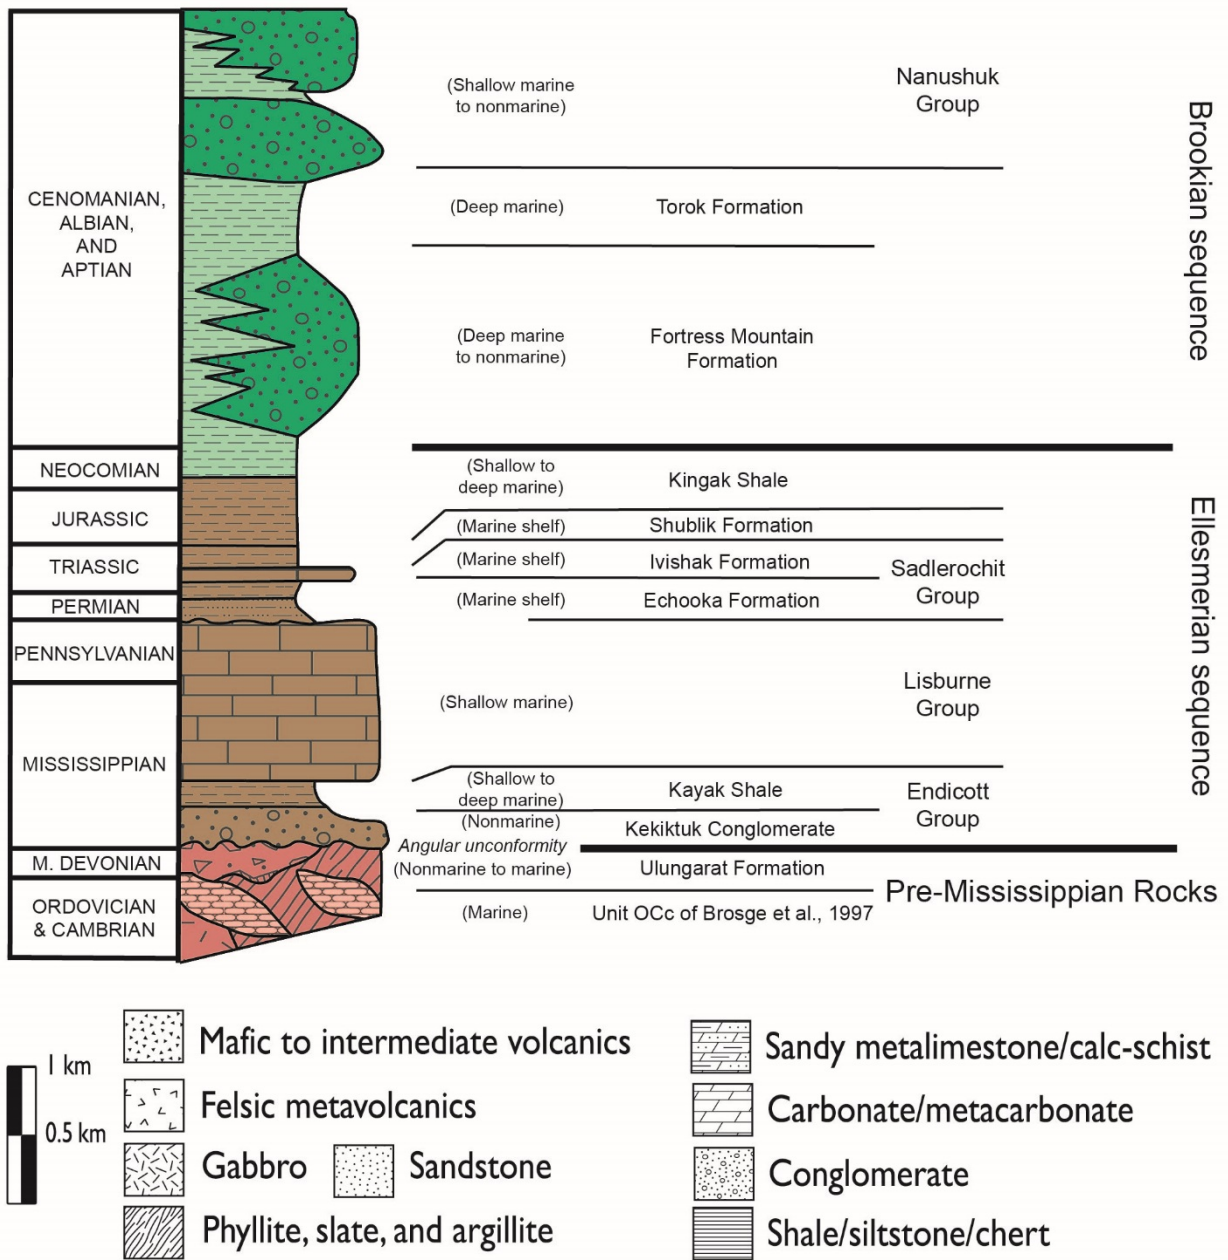

Figure 4: Generalized stratigraphic column of the North Slope portion of the Arctic Alaska terrane (pre-Mississippian rocks and Ellesmerian sequence) and the overlying terrigenous clastics of the Colville Basin fill (Brookian sequence). Column based on the southern portions of the North Slope, located ~ 100 km north east of the study area. Adapted from Moore et al., (1997).
Figure 5: Relative structural positions and stratigraphic relationships of the Hammond subterrane, Endicott Mountains allochthon, and Doonerak fenster in the central Brooks Range. Adapted from Moore et al., (1997) with nomenclature from Julian (1989), Julian and Oldow (1998) and Moore et al., (1997).
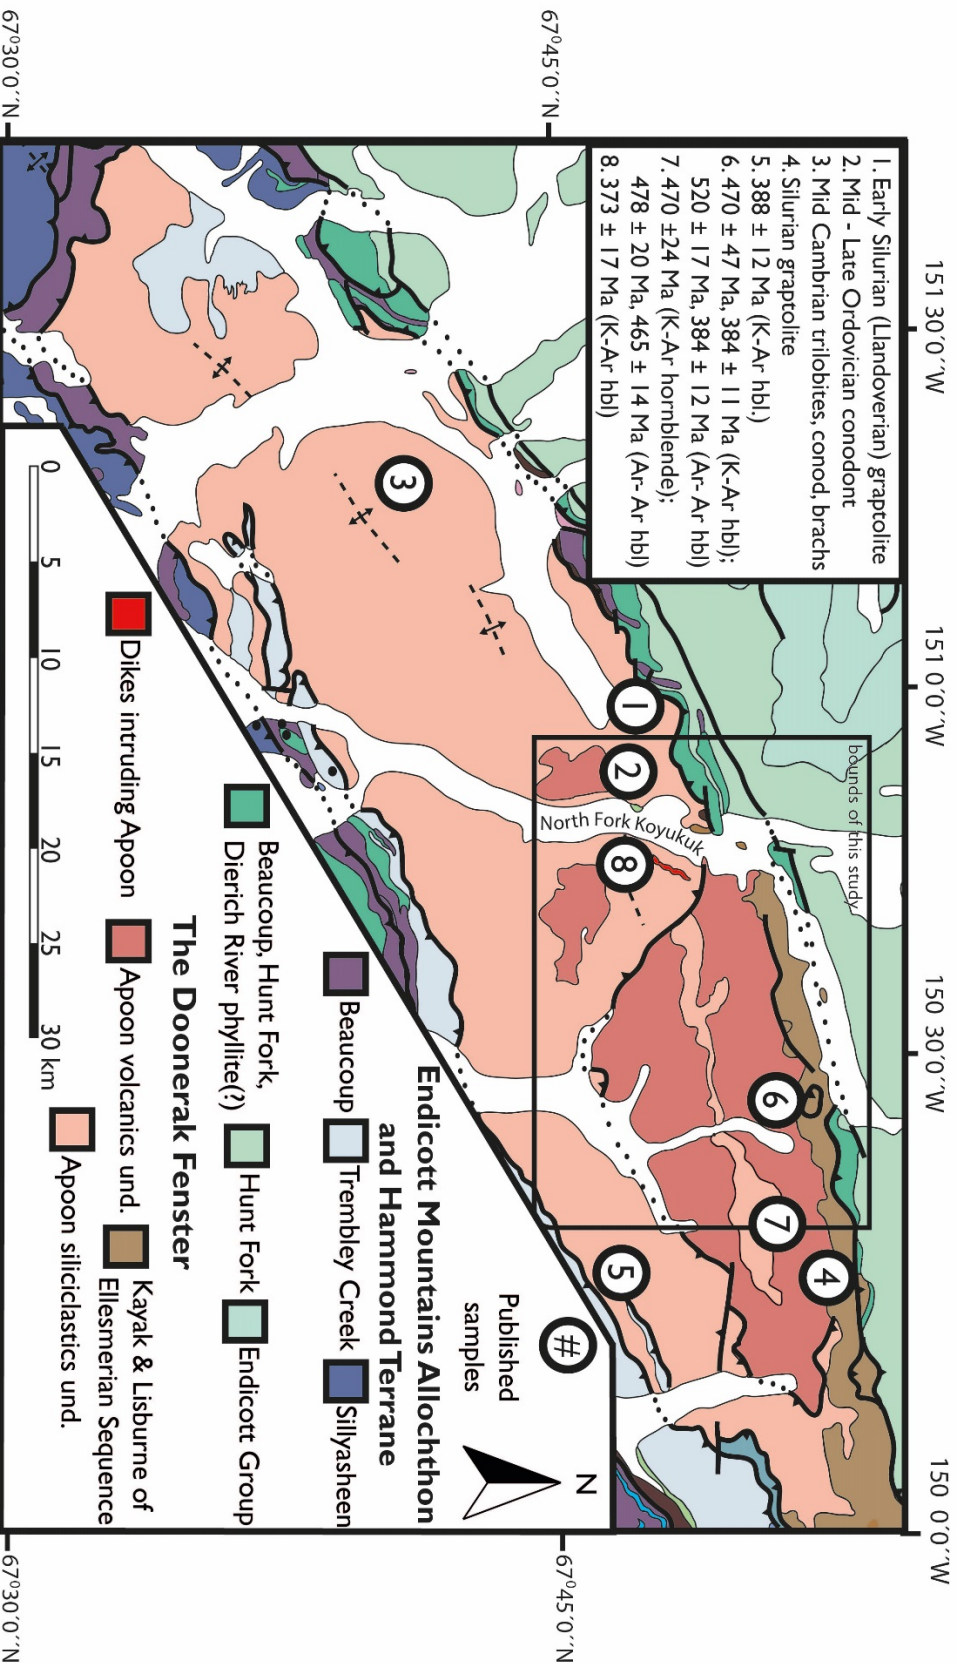

Figure 6: Simplified geologic map of the Doonerak fenster in the central Brooks Range after Dillon et al., (1986) and Strauss et al., (2017). Numbers represent samples from previous studies with age constraints from Dutro et al., (1976); Dutro et al., (1984); Julian and Oldow (1998); and Repetski et al., (1987). Numbers correspond to inset key. Box marks the approximate location of Figure 8.
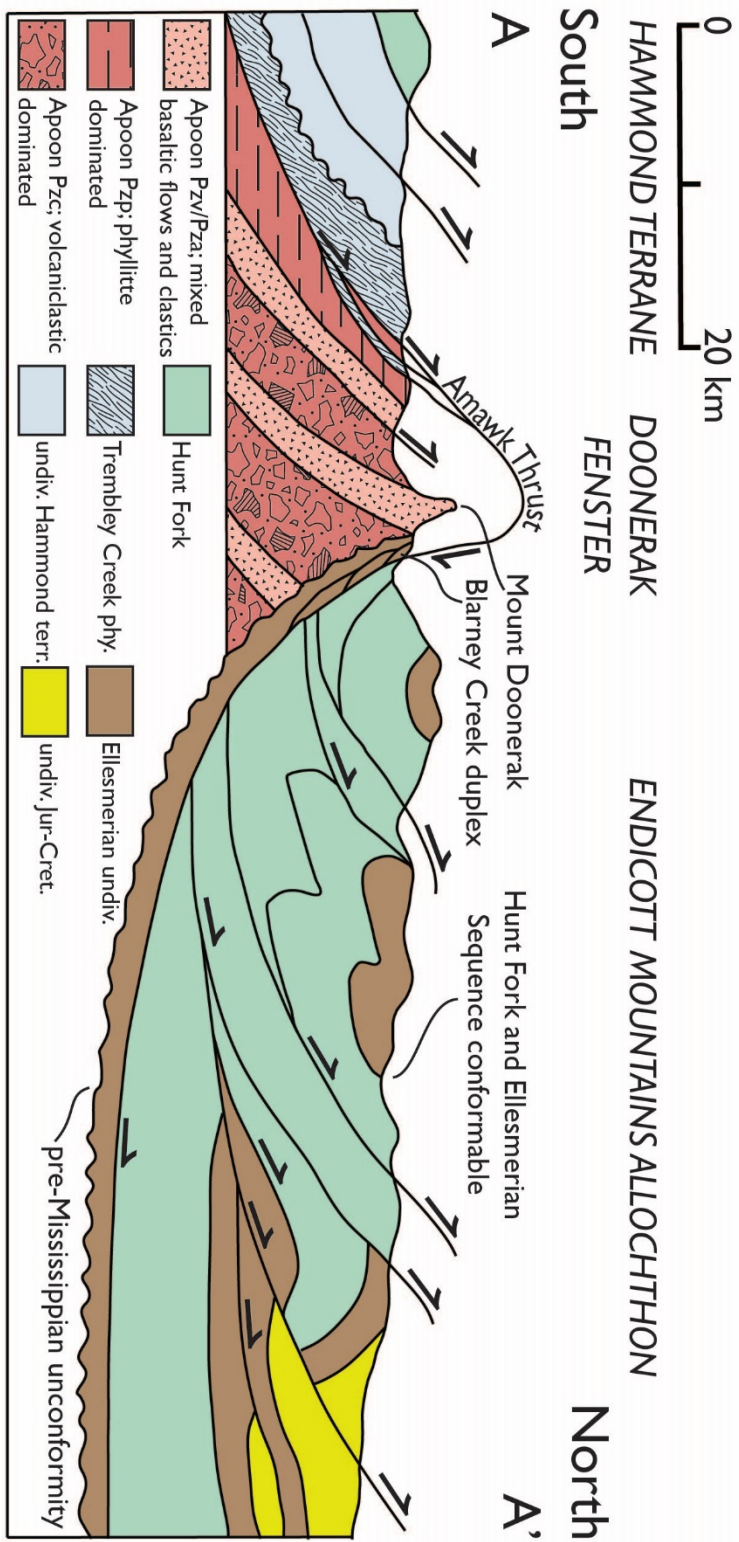

Figure 7: Schematic cross section (~ 2X vertical exaggeration) of the central Brooks Range illustrating the structural window at the Doonerak fenster modified after Dutro et al., (1976), Dillon et al., (1986), Mull et al., (1987), Oldow et al., (1987), Adams et al., (1997), Moore et al., (1997), and Julian and Oldow (1998). Cross section corresponds to the approximate location of line A-A' in Figure 3.
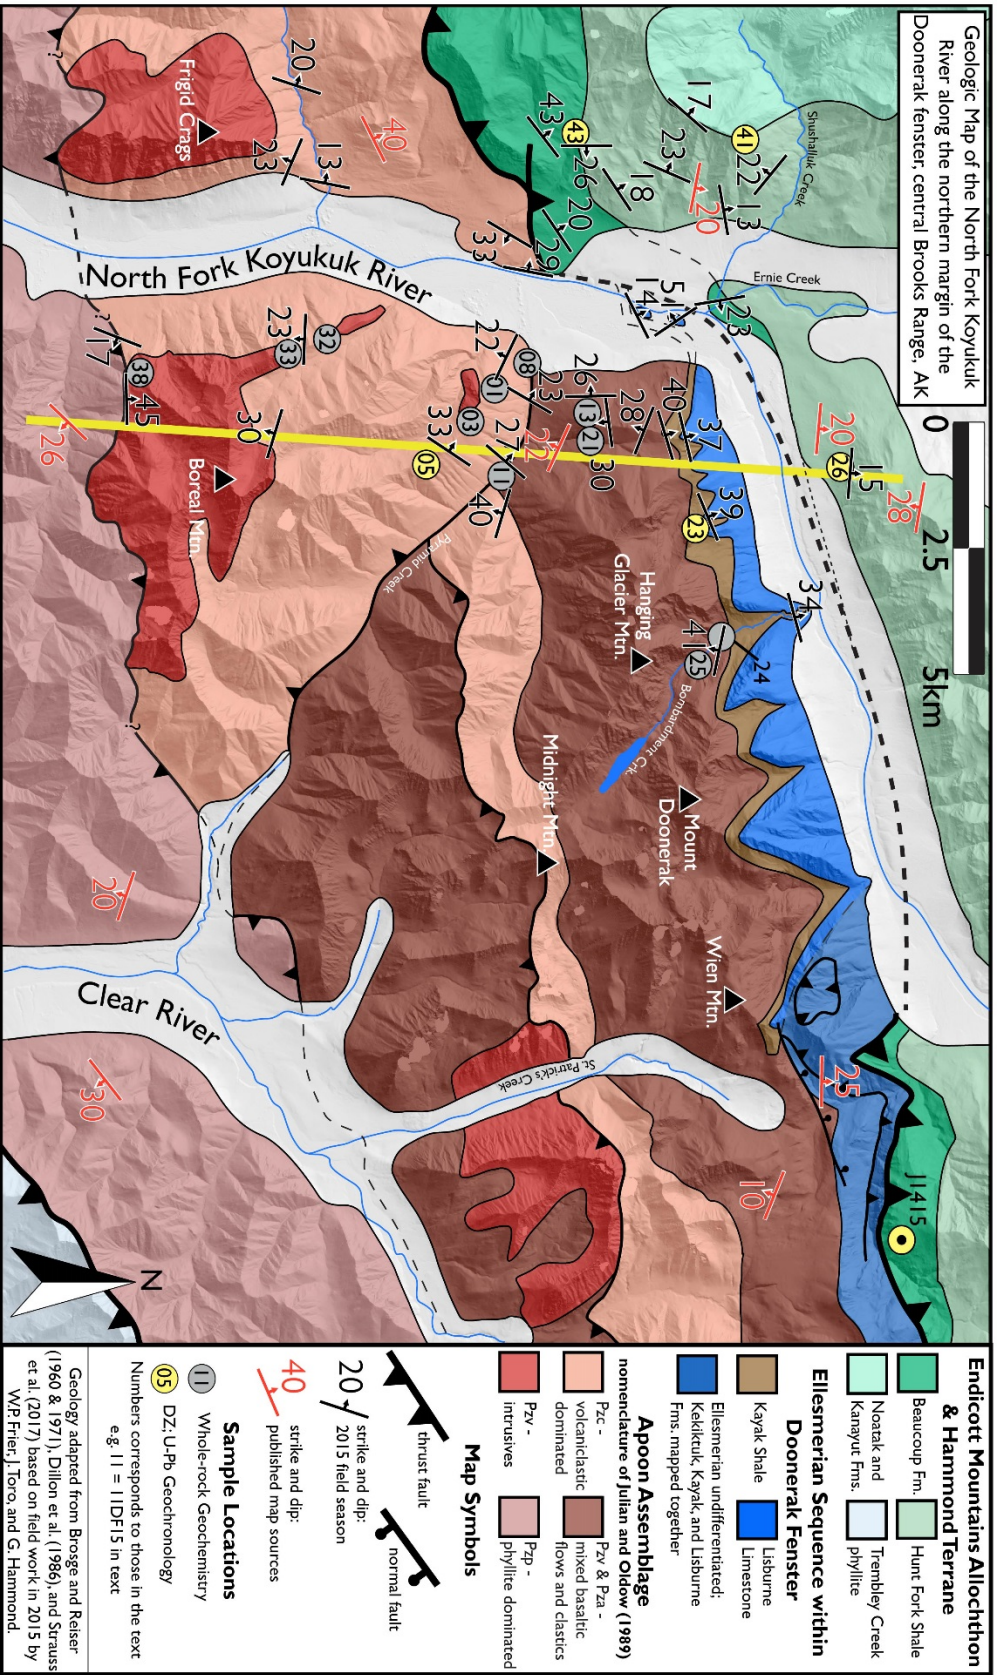

Figure 8: Simplified geologic map of the Doonerak fenster in the central Brooks Range showing structural data and sample locations. Structural data reflect the average of multiple strike and dip measurements taken in the field at that location. Yellow circles mark the location of samples collected for detrital zircon geochronology. Gray circles mark the location of samples collected for whole rock volcanic geochemistry. The northeast portion of this map (near sample J1415) is based on field mapping by J. Strauss in 2013, published in Strauss et al., (2017). All other field data comes from field work by W.P. Frier, J. Toro, and G. Hammond in 2015 and was supplemented by aerial and satellite imagery. The bold yellow line corresponds to Figure 9.
Figure 9: Schematic cross-section through the northern Doonerak fenster and southern Endicott Mountains Allochthon based on the map in Figure 8. Cross section corresponds to the bold yellow line in Figure 8. Notice the Ellesmerian Sequence unconformably atop the Apoon Assemblage and dipping beneath the Endicott Mountains Allochthon.
Figure 10: Field photo looking east along the North Fork of the Koyukuk River in the central Brooks Range. To the North (left) side of the image are of rocks of the Endicott Mountains allochthon, the Hunt Fork Shale. To the South (right) side of the image are rocks of the Lisburne Limestone, Kayak Shale (Ellesmerian sequence) and Apoon assemblage (pre-Mississippian basement) of the Doonerak fenster.
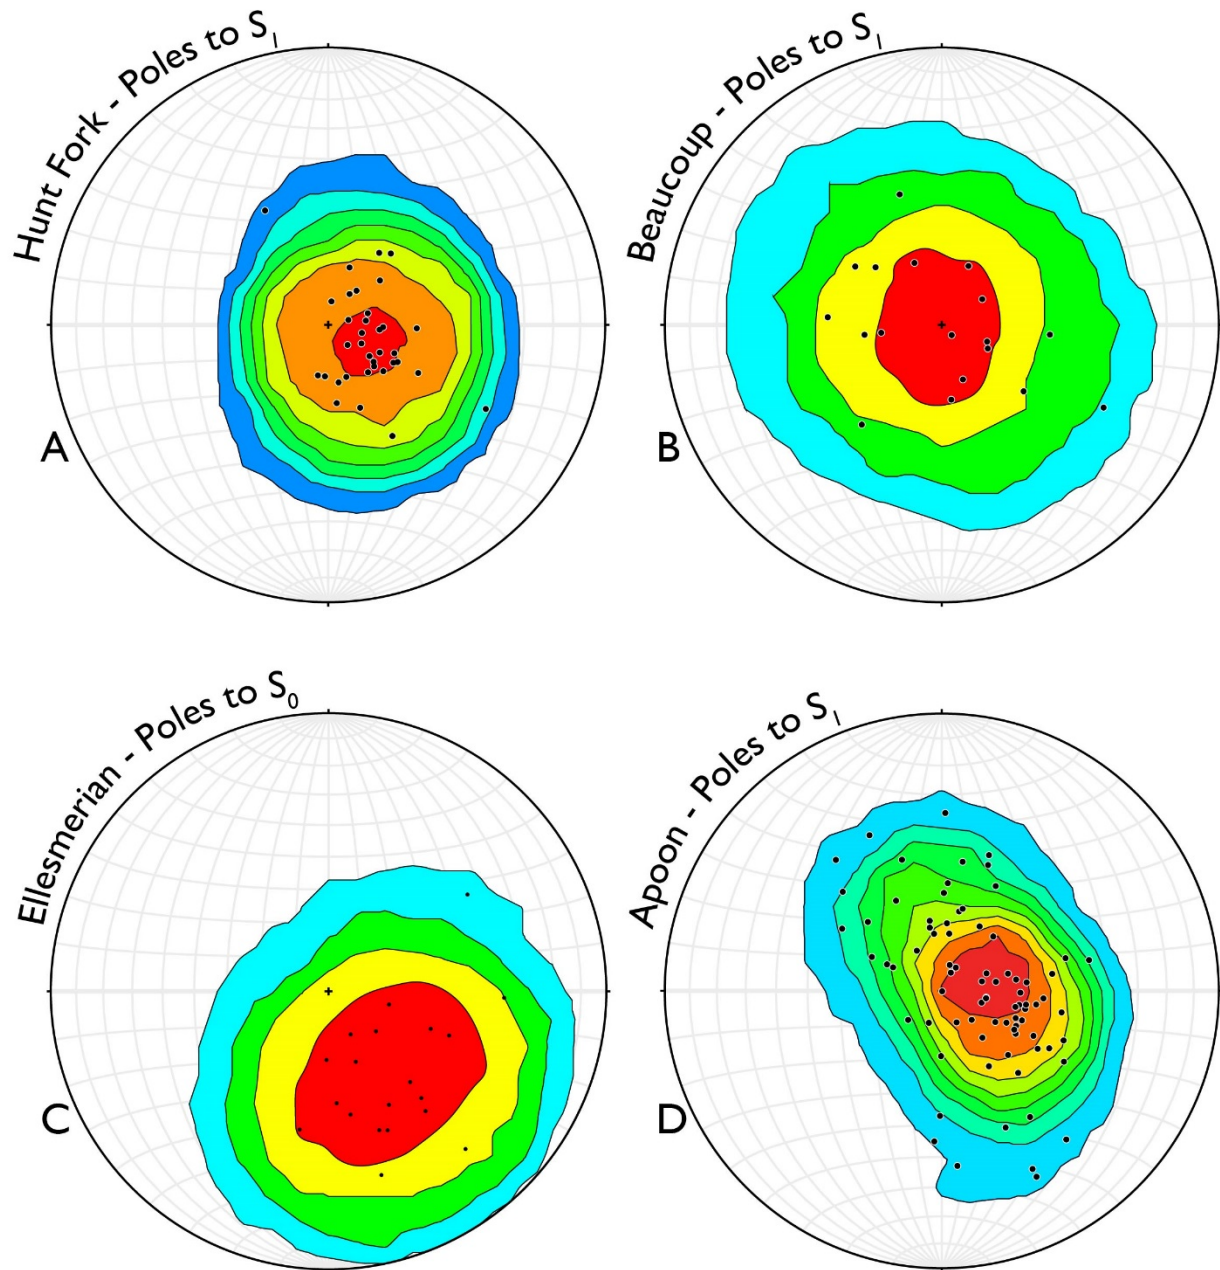

Figure 11: Contoured stereonets showing poles to dominant foliation (S_1) observed during the 2015 field season and organized based on lithostratigraphic association. In most cases the primary surface corresponds to dominate cleavage (S_1); however bedding (S_0) was evident within the Ellesmerian sequence consistently and periodically differentiated from cleavage in other formations.
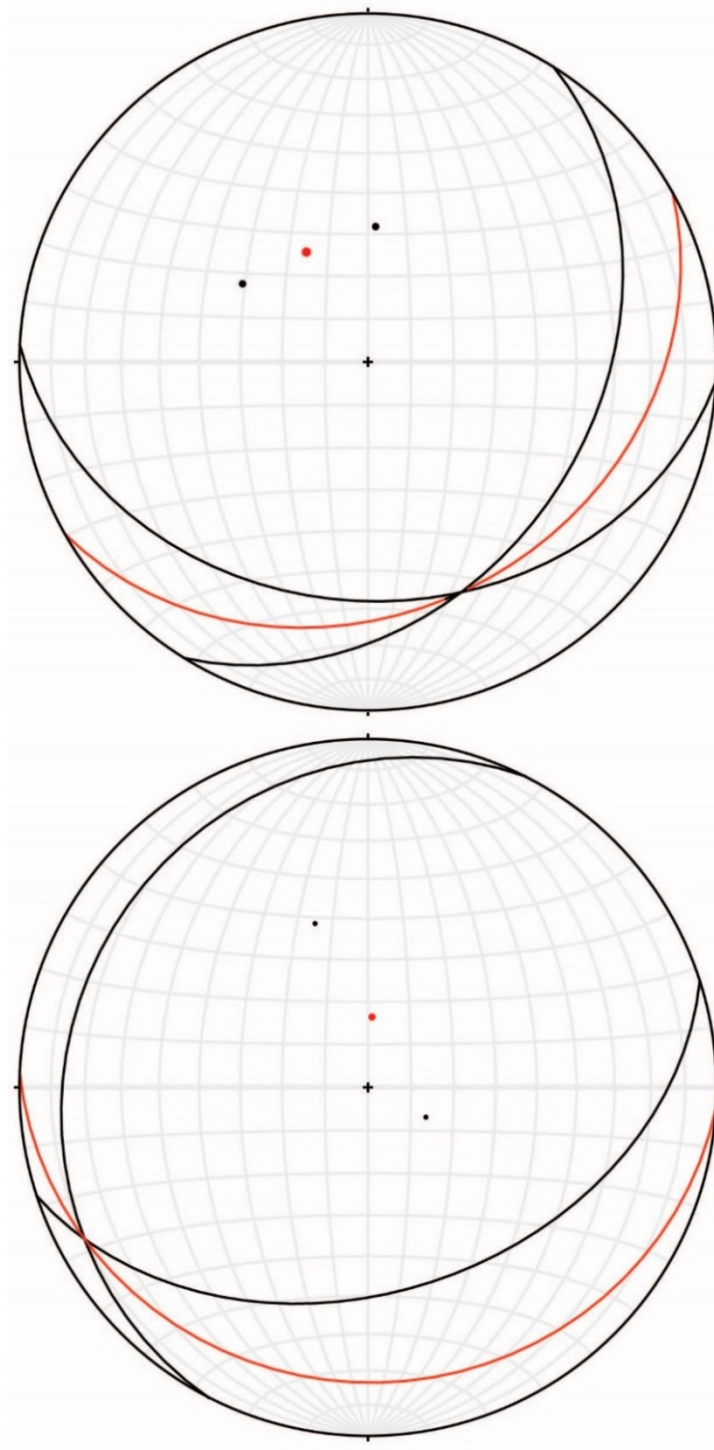

Figure 12: Great circles and their associated poles of bedding around folds observed within the Beaucoup formation, west of the North Fork Koyukuk River in 2015 (shown in black). The inferred fold axes are shown in red with their associated poles (also in red). The attitude of these folds is consistent with the dominant regional trend of Brookian folds.
Figure 13: Field photos from clastic/volcaniclastic portions of the Apoon assemblage, Pzc. A - outcrop of recumbent isoclinal folds within slate and lithic sandstone along Pyramid Creek. Field book pictured is 19 cm x 12 cm. B - En echelon vein array atop ridge south of Pyramid Creek, defining a small fault zone between slates and tuffs within the Apoon assemblage. Person pictured is ~ 1.8 m tall. C - Broad gently plunging open folds within phyllites of the Apoon assemblage along Pyramid Creek. Person is ~ 1.8 m tall. D - Example of fine-to-medium grained lithic sandstone with intermediate slate from ridge south of Pyramid Creek. Hand lens is ~ 2 cm in length E & F - Typical variety among rocks of the Apoon assemblage. Range from fine grained thinly bedded slates and well foliated phyllites to thin-to-medium bedded lithic sandstone interbedded among slates.
Figure 14: Field photos from volcanic/igneous portions of the Apoon assemblage. A & B - two images of the same outcrop along Pyramid Creek. Sill of andesite with crosscutting veins of quartz and calcite. Hammer pictured has a ~ 30 cm handle. Person pictured is ~ 1.8 m tall. C - aphanitic basalt pillows from Bombardment Creek. D - Porphyritic basaltic andesite from Boreal Mountain with large laths of plagioclase. E - Aphanitic greenstone found along Bombardment Creek (not in place) which likely formed as a basaltic flow top breccia. F - Fine grained basaltic greenstone north of Pyramid Creek with thoroughgoing brittle fractures.
Figure 15: Field photos from the Ellesmerian Sequence within the Doonerak fenster. A - folded limestone and shale within the Kayak Shale along Bombardment Creek. Pencil for scale is ~ 11 cm in length. B - Crinoids within the Kayak Shale. Hand lens is ~ 2 cm in length. C - Nodular chert within thickly-bedded limestone of the Lisburne formation. Field book is ~19 cm long. D - Outcrop of thickly-bedded Lisburne Limestone south of the North Fork Koyukuk River in the northern portion of the field area. Person pictured (far right) is ~ 1.8 m tall.
Figure 16: Field photos of other assorted formations. A - Kanayut Conglomerate: example of poorly-sorted quartz and chert pebble conglomerate. B - Hand samples of fine grained lithic sandstone found along the gradational transition from Hunt Fork Shale to Noatak Sandstone, stratigraphically below the Kanayut Conglomerate, northwest portion of map area.. C & D - Hunt Fork Shale - Examples of thin-to-medium bedded outcrop with small calcite filled veins and thinly-bedded, highly-foliated and fissile variety. E & F – Highly-foliated and sheared green-to-purple quartz and chert pebble conglomerate of the Beaucoup formation found just north of the North Fork Koyukuk River. Both photos are from the same outcrop.

Figure 18: Probability density plot and max depositional age estimation generated from detrital zircon geochronology for sample 05DF15 - Apoon assemblage. See Figure 9 - marked as 05 - for sample location on a map. The top panel shows the entire range of the probability density plot. The lower panel shows a probability density plot generated from only the youngest grains, younger than 1200 Ma. Dominate age groupings are labeled. Box heights in the max depositional age figure represent the 2 σ error on the analysis of that grain. The mean of the youngest population and its associated error is provided in the inset box.
Figure 19: Probability density plot and max depositional age estimation generated from detrital zircon geochronology for sample 23DF15 - Kayak formation. See Figure 9 - marked as 23 - for sample location on a map. The top panel shows the entire range of the probability density plot. The lower panel shows a probability density plot generated from only the youngest grains - younger than 1200 Ma. Dominate age groupings are labeled. Box heights in the max depositional age figure represent the 2 σ error on the analysis of that grain. The mean of the youngest population and its associated error is provided in the inset box.
Figure 20: Probability density plot and max depositional age estimation generated from detrital zircon geochronology for sample J1415 - Beaucoup formation. See Figure 9 for sample location on a map. The top panel shows the entire range of the probability density plot. The lower panel shows a probability density plot generated from only the youngest grains - younger than 1200 Ma. Dominate age groupings are labeled. Box heights in the max depositional age figure represent the 2 σ error on the analysis of that grain. The mean of the youngest population and its associated error is provided in the inset box.
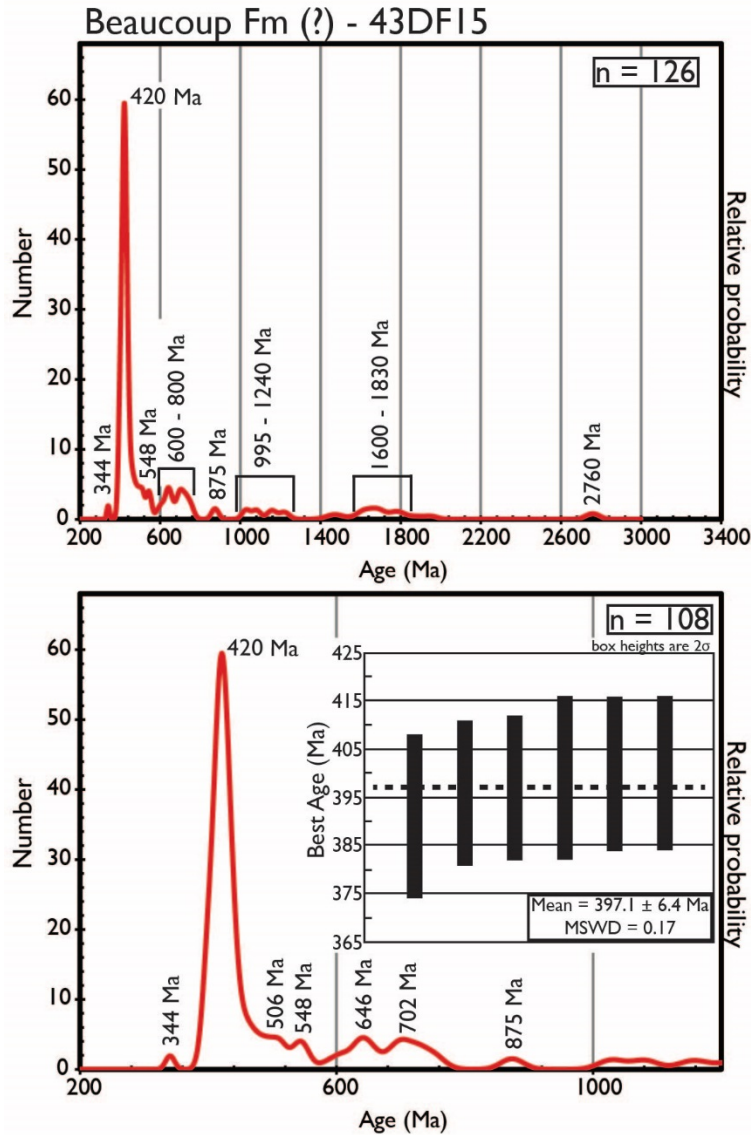

Figure 21: Probability density plot and max depositional age estimation generated from detrital zircon geochronology for sample 43DF15 - Beaucoup formation. See Figure 9 - marked as 43 - for sample location on a map. The top panel shows the entire range of the probability density plot. The lower panel shows a probability density plot generated from only the youngest grains - younger than 1200 Ma. Dominate age groupings are labeled. Box heights in the max depositional age figure represent the 2 σ error on the analysis of that grain. The mean of the youngest population and its associated error is provided in the inset box.
Figure 22: Probability density plot and max depositional age estimation generated from detrital zircon geochronology for sample 26DF15 - Hunt Fork (?) formation. See Figure 9 for sample location on a map. The top panel shows the entire range of the probability density plot. The lower panel shows a probability density plot generated from only the youngest grains - younger than 1200 Ma. Dominate age groupings are labeled. Box heights in the max depositional age figure represent the 2 σ error on the analysis of that grain. The mean of the youngest population and its associated error is provided in the inset box.
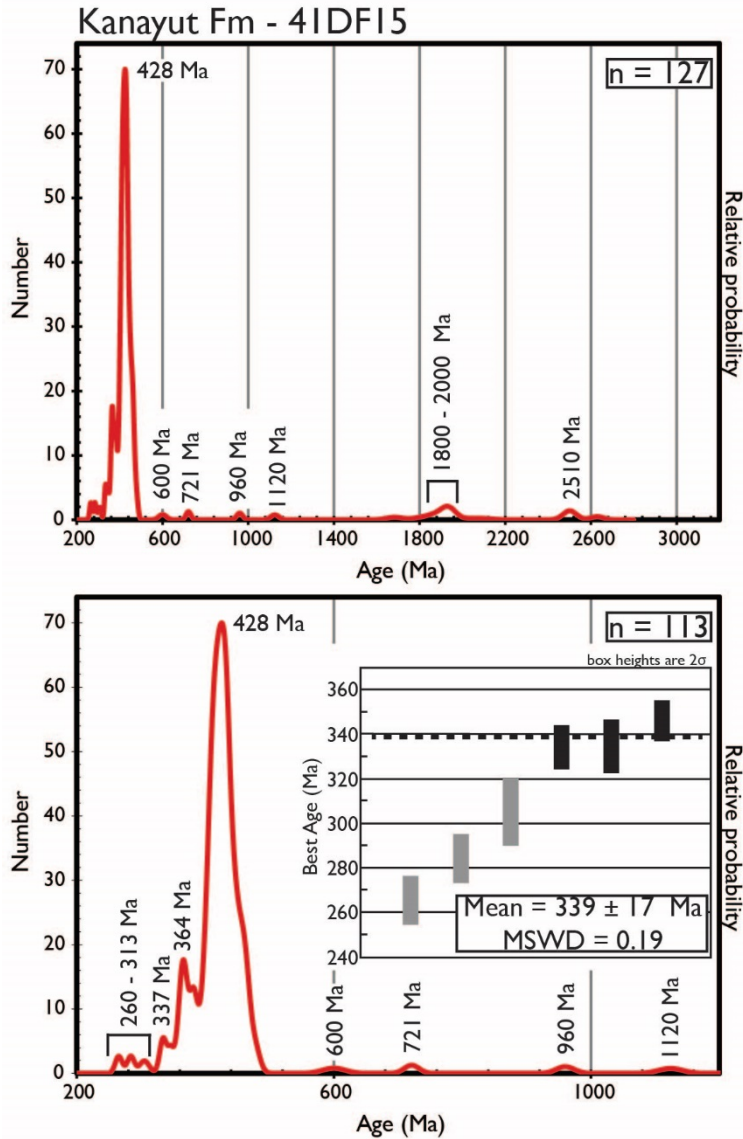

Figure 23: Probability density plot and max depositional age estimation generated from detrital zircon geochronology for sample 41DF15 - Kanayut formation. See Figure 9 for sample location on a map. The top panel shows the entire range of the probability density plot. The lower panel shows a probability density plot generated from only the youngest grains - younger than 1200 Ma. Dominate age groupings are labeled. Box heights in the max depositional age figure represent the 2 σ error on the analysis of that grain. The mean of the youngest population and its associated error is provided in the inset box.
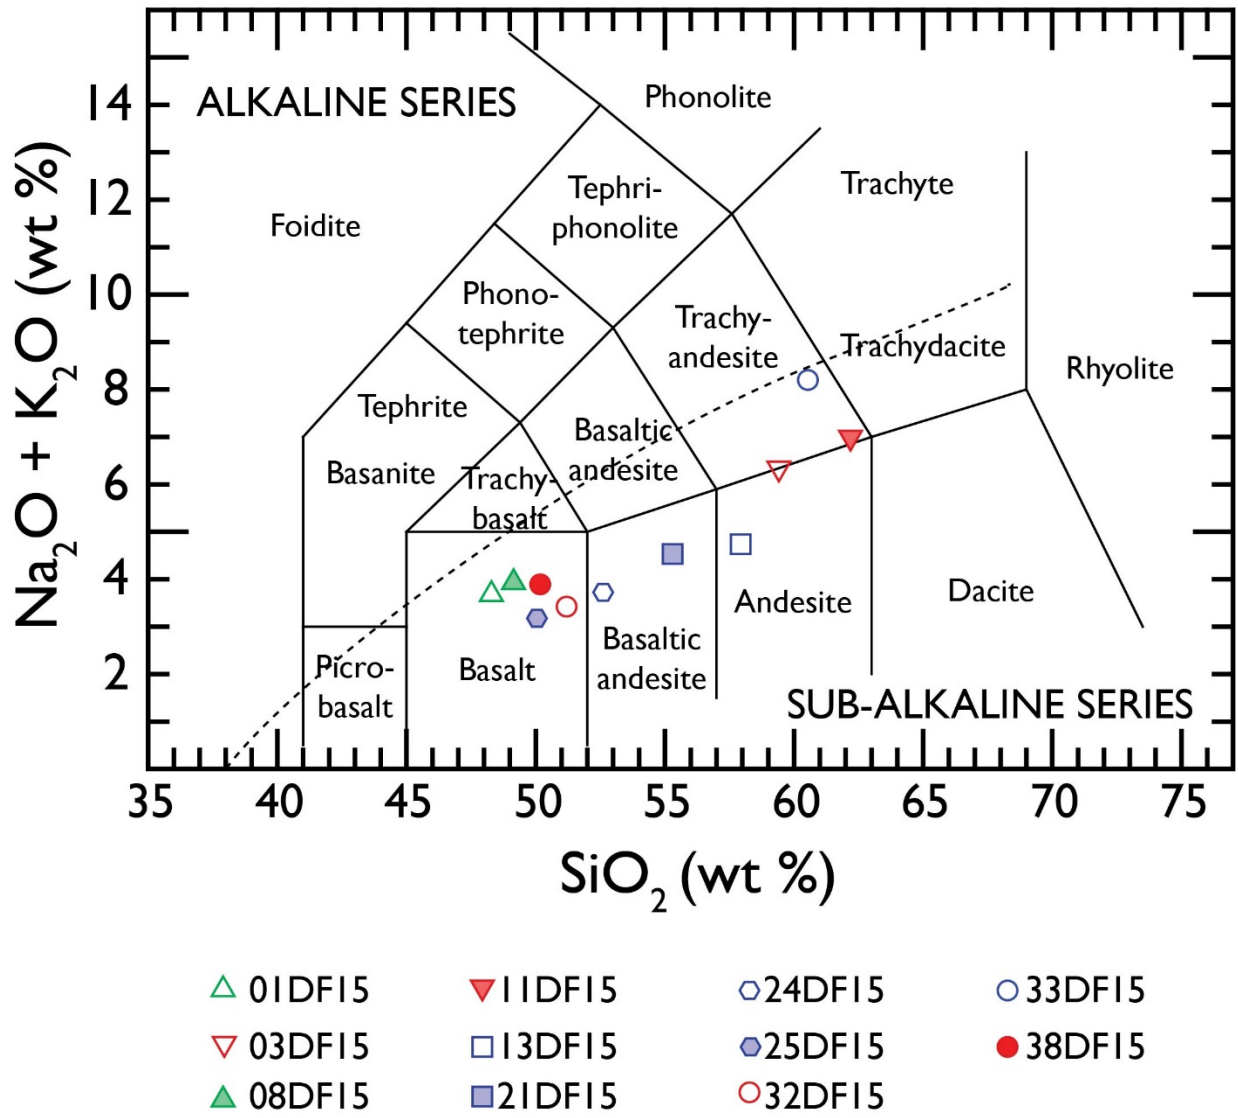

Figure 24: Total alkali ($Na_2O + K_2O$ in wt %) – silica (SiO_2 in wt %) diagram with fields after Le Maitre et al. (2002). Symbols used in this plot are used in all subsequent figures. Note that the Apoon rocks from this study all plot as subalkaline rocks and can be categorized as basalts, basaltic-andesites, andesites, and trachy-andesites. All samples are normalized to 100% anhydrous; raw geochemical data are presented in Supplemental Materials section.
Figure 25: Representative thin section photomicrographs from igneous rocks within the Apoon assemblage demonstrating the textural and compositional variety of the Apoon assemblage's igneous portions.
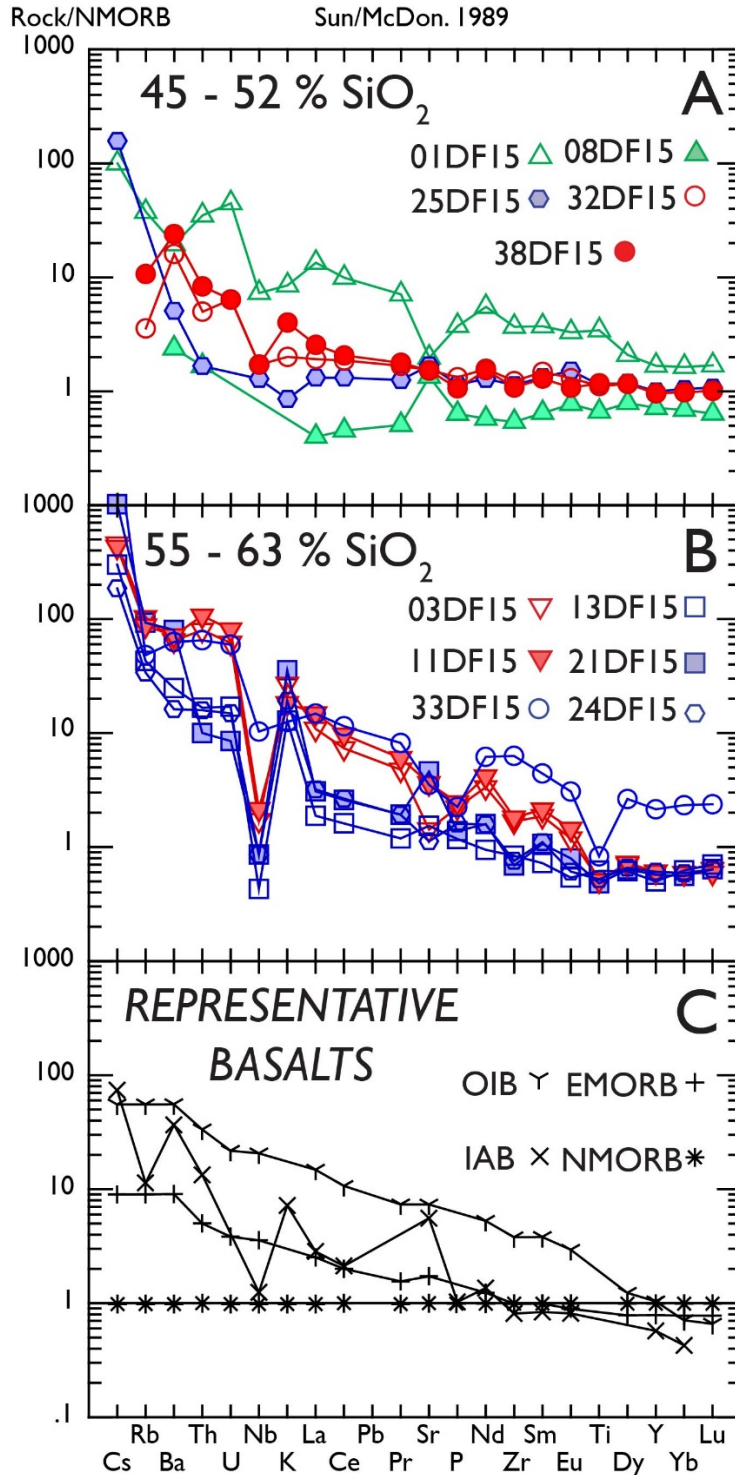

Figure 26: Trace element variation diagrams for eleven samples from the Apoon assemblage. All samples are normalized to the composition of a normal mid-ocean ridge basalt (NMORB) based on Sun and McDonnough (1989). The bottom frame plots representative basalt types from particular tectonic settings from Sun and McDonnough (1989) and Nye and Reid (1986). EMORB - Enriched Mid-Ocean Ridge Basalt; IAB - Island Arc Basalts; NMORB - Normal Mid-Ocean Ridge Basalt; OIB - Ocean Island Basalts.
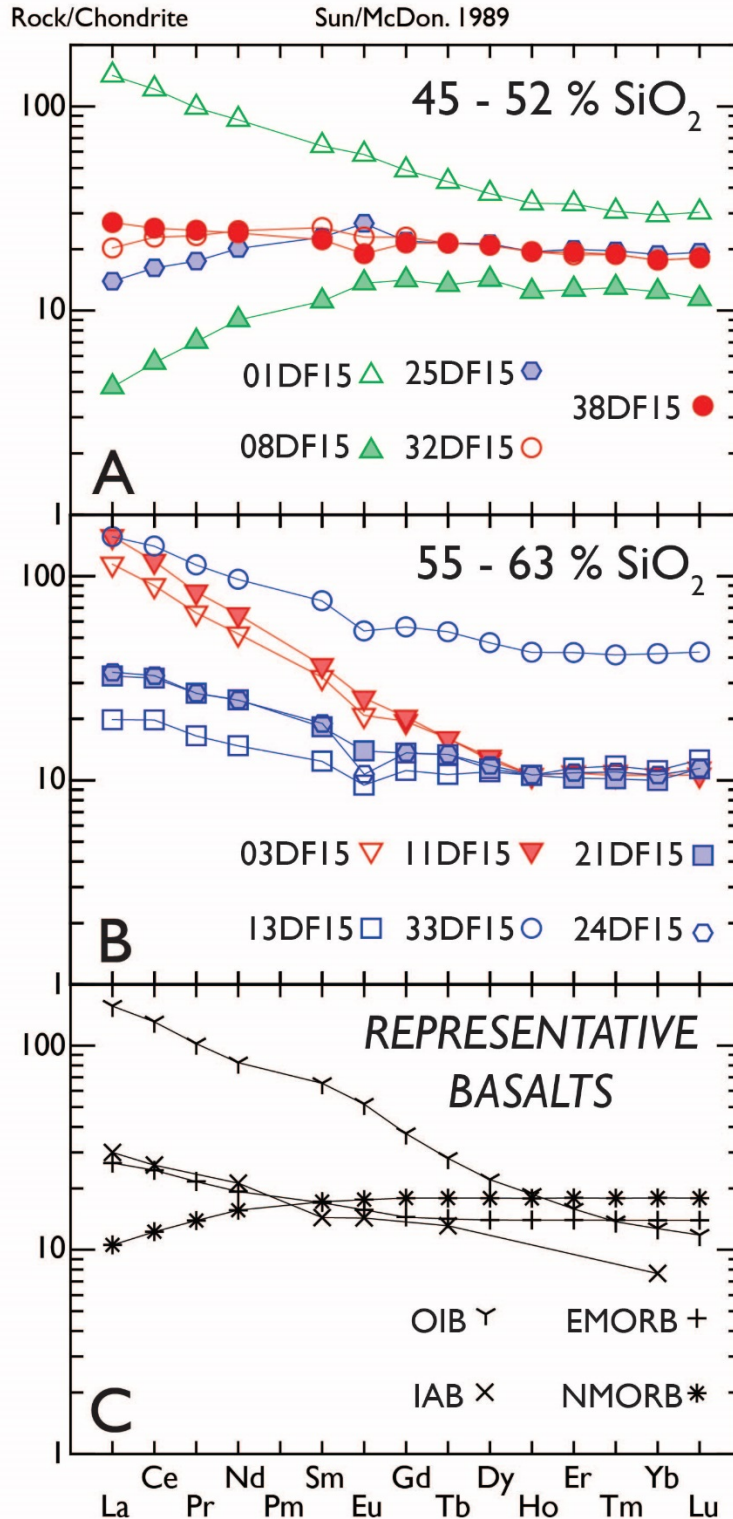

Figure 27: Chondrite-normalized trace element variation diagrams of the Apoon assemblage volcanic rocks (after Sun and McDonnough, 1989). The bottom frame plots representative basalt types from particular tectonic settings from Sun and McDonnough (1989) and Nye and Reid (1986). EMORB - Enriched Mid-Ocean Ridge Basalt; IAB - Island Arc Basalts; NMORB - Normal Mid-Ocean Ridge Basalt; OIB - Ocean Island Basalts.
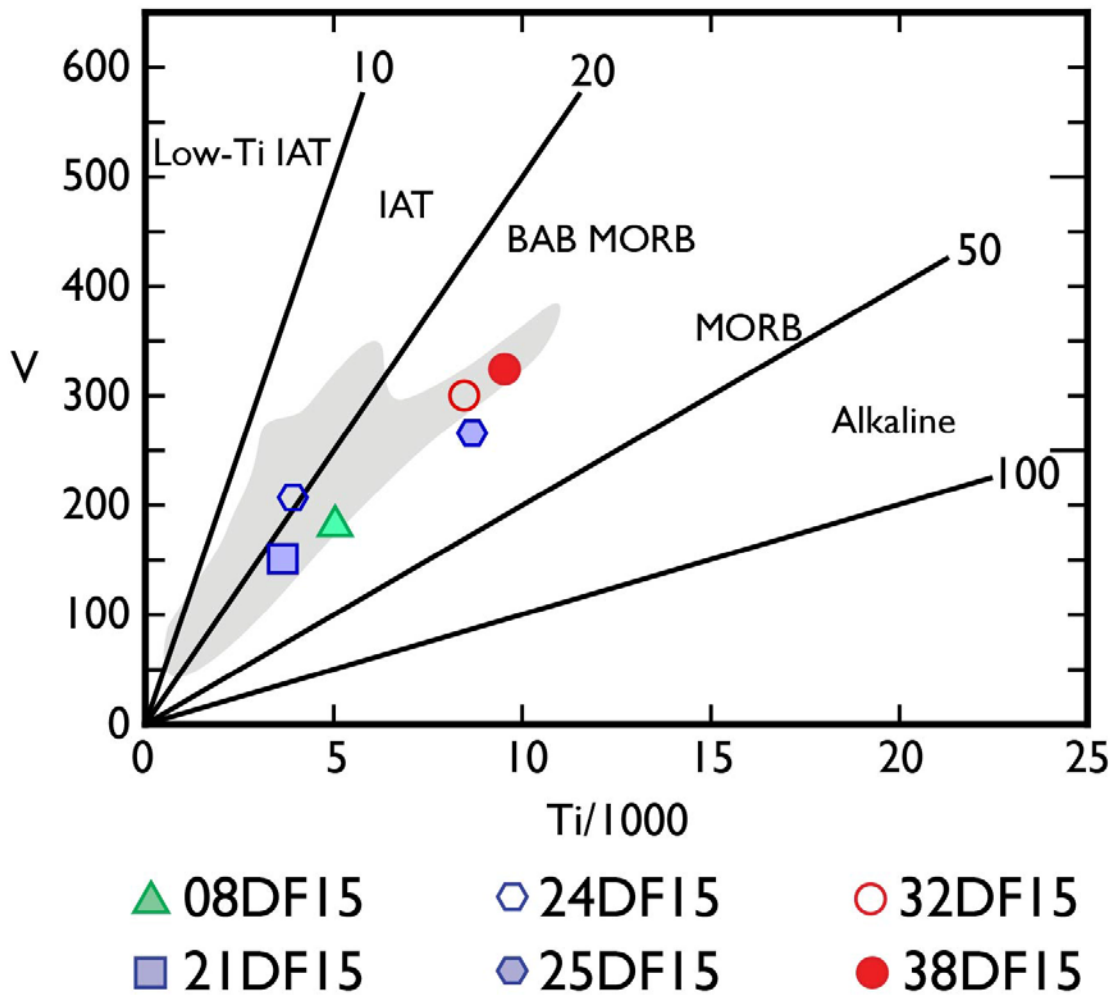

Figure 28: Ti - V tectonic discrimination diagram after Shervais (1982). The gray field marks the compositional range of samples from the Apoon assemblage from previous studies (Julian 1989; Julian and Oldow, 1998). The proportion of Ti:V is here used as a proxy for the oxygen activity within a magma during eruption and related to potential tectonic environments. BAB MORB - Back Arc Basin Mid-Ocean Ridge Basalt; IAT - Island Arc Tholeiitic; MORB - Mid-Ocean Ridge Basalt. Only those samples that classified as basalts and basaltic-andesite (i.e. <57 wt % SiO_2) were included in this plot (Shervais, 1982).
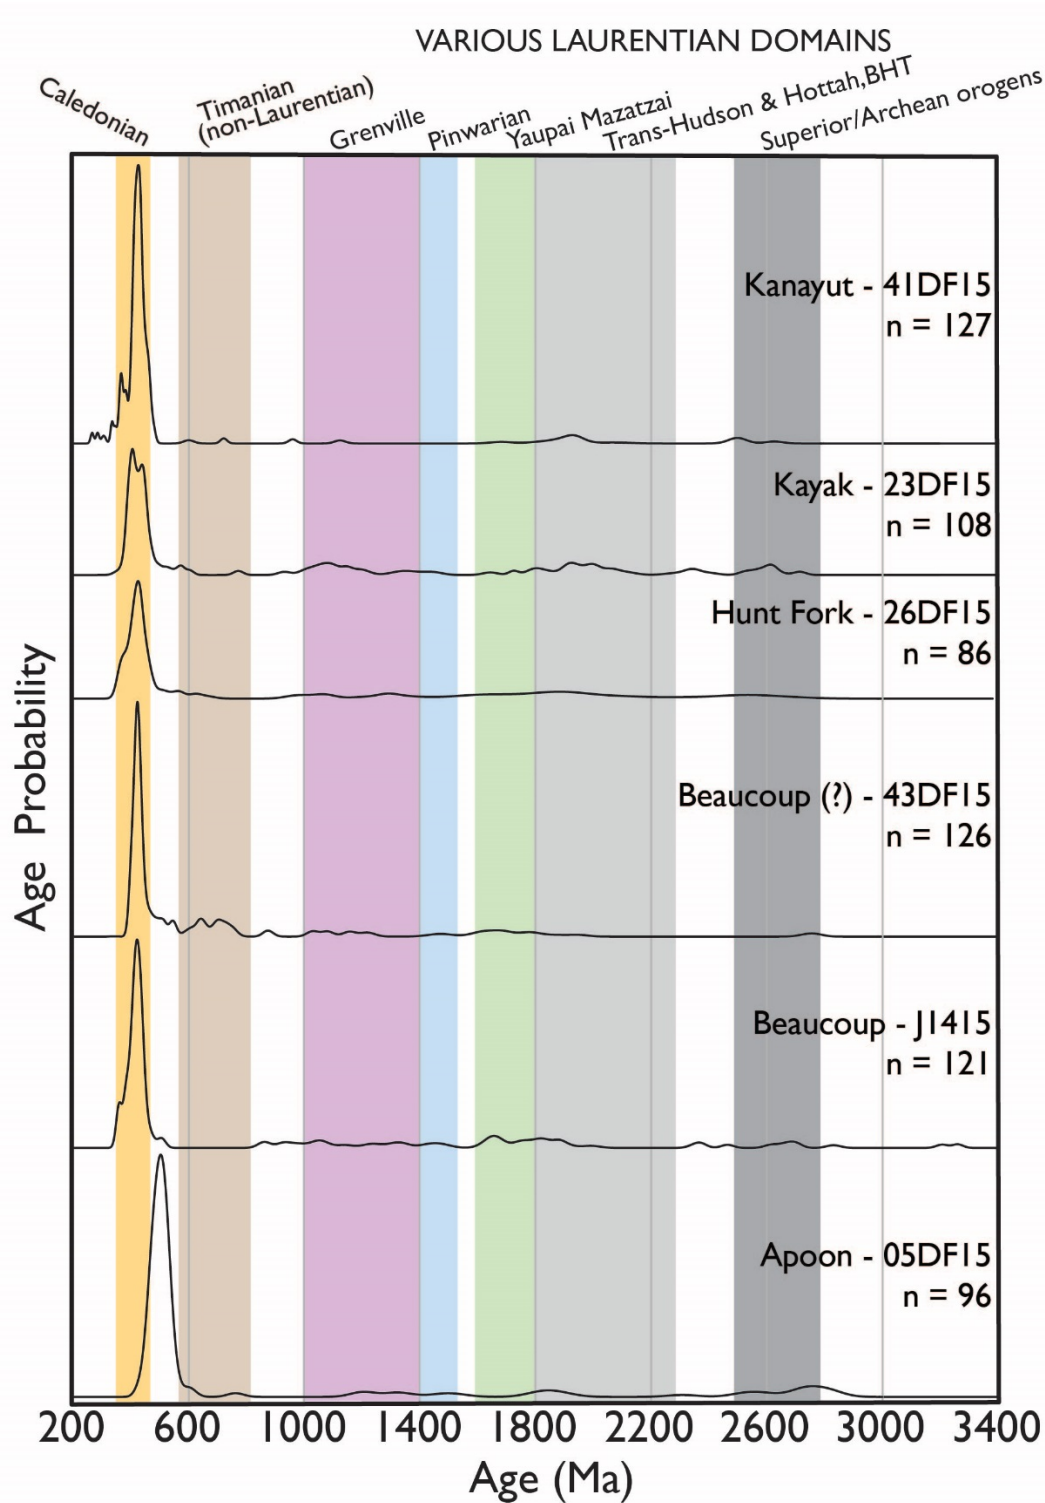

Figure 29: Stacked probability density plots from all samples within this study. Sample names and the number of grains in each analysis are given at the right side of the figure. The vertical colored bars represent the age of various orogenic episodes with affected rocks of the circum-Arctic.
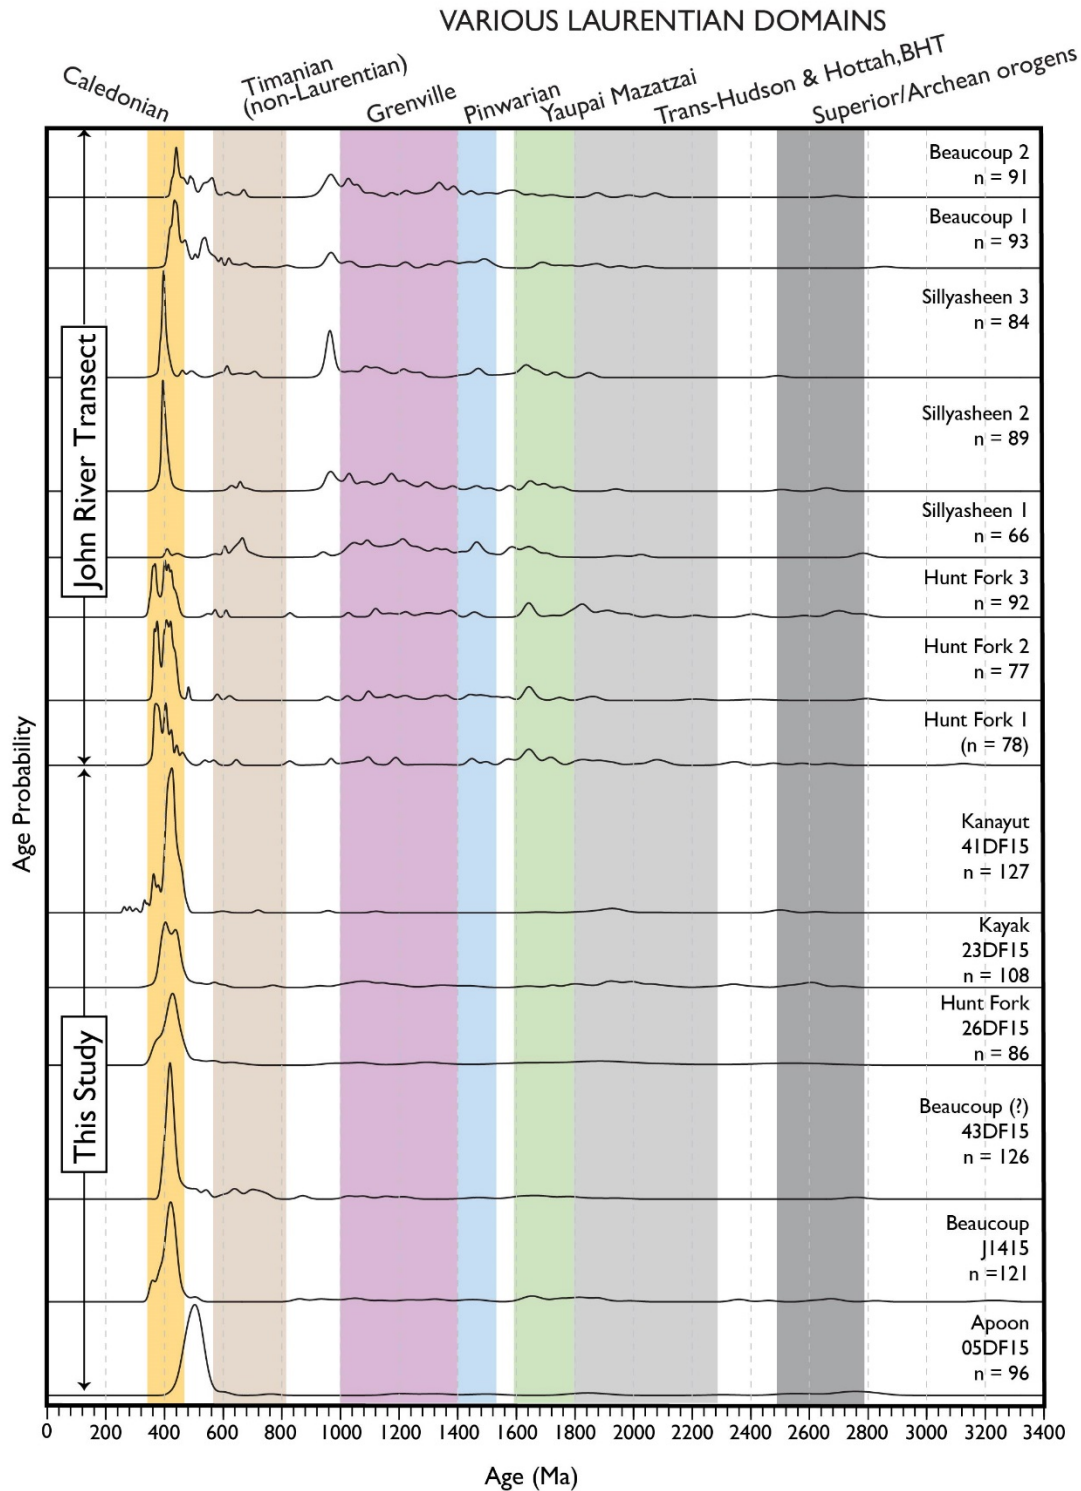

Figure 30: Stacked probability density plots from all samples within this study (lower portion of figure) and those from the John River transect of the central Brooks Range (west of Doonerak) by Miller, Pease, and Hoiland (unpublished data; upper portion of figure). Sample names and the number of grains in each analysis are given at the right side of the figure. The vertical colored bars represent the age of various orogenic episodes which may have contributed detritus to rocks of the circum-Arctic.
Figure 31: Stacked probability density plots from all samples within this study and those from Strauss et al. (2017). The curves from Strauss et al. (2017) provide the accumulated probability density plots from multiple samples from the same formations
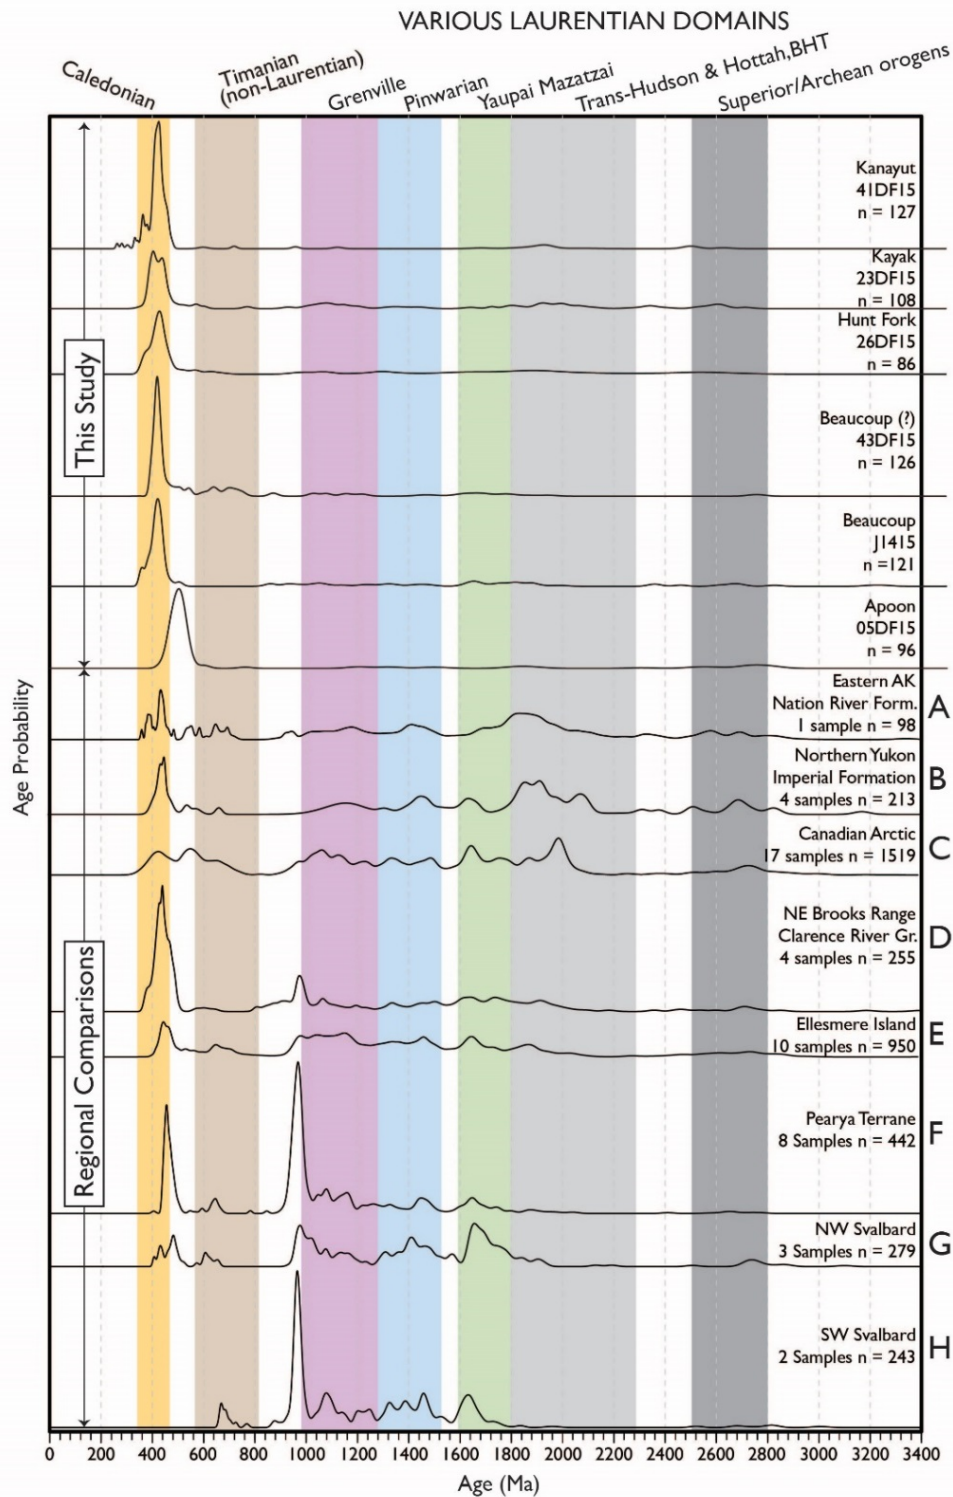

Figure 32: Stacked probability density plots from all samples within this study alongside those from a suite of regional published sources: (A) Ellesmerian clastic wedge of east-central Alaska (Gehrels and Pecha, 2014), (B) Ellesmerian clastic wedge in the Yukon (Beranek et al., 2010), (C) Ellesmerian clastic wedge in the Canadian Arctic Islands (Anfinson et al., 2012), (D) Clarence River Group of the northeast Brooks Range (Johnson et al., 2016), (E) Ellesmerian Island (Beranek et al., 2015), (F) Pearya terrane (Hadlari et al., 2014); (G) northwestern Svalbard (Petterson et al., 2010); and (H) Southwestern Svalbard (Gasser and Andersen, 2013).
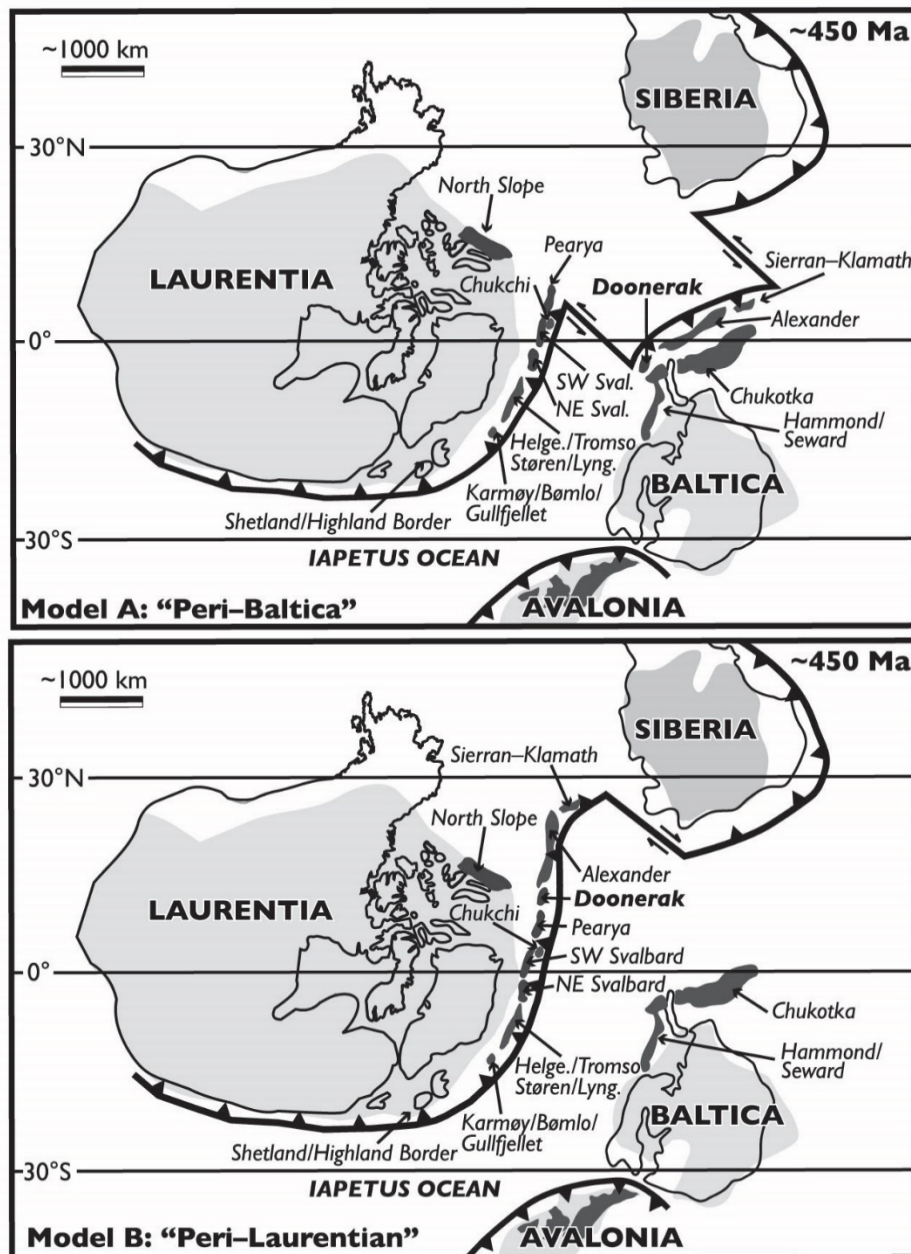

Figure 33: Schematic paleogeographic reconstructions of pertinent circum-Arctic paleo-continents, terranes, and microcontinents in the Late Ordovician from Strauss et al. (2017). Latitudinal positions are based on Cocks and Torsvik (2005, 2007, 2011, and references therein). The bulk of the North Slope of Arctic Alaska is on the peri-Laurentian margin following Strauss et al. (2013), Cox et al. (2015), and Johnson et al. (2016). (A) Paleogeographic model restoring Doonerak to a position proximal to Baltica in the Late Ordovician, in a setting similar to the Alexand er terrane and exotic portions of the Arctic Alaska-Chukotka microplate. In this model, Doonerak sits along the convergent margin of Baltica and there must be subduction polarity reversal to place Baltica on the lower plate during Scandian contraction. (B) Paleogeographic model that restores Doonerak and other circum-Arctic terranes to the northern extent of the Taconic orogenic system, proximal to Laurentia. Subduction polarity reversal is required to accrete the Pearya terrane and Doonerak onto the NE margin of Laurentia.

1. INTRODUCTION

Regional tectonic and paleogeographic models of the circum-Arctic (Fig. 1) are some of the least well constrained in the world due to the regions remoteness and complex geologic relationships (e.g. Pease et al., 2011). Many tectonostratigraphic terranes of the Arctic are remnants of oceanic and continental crust from the margins of the Paleozoic Iapetus Ocean and have Siberian, Baltic, Laurentian, Gondwanan, and/or Panthalassan affinities (e.g. Trettin, 1987; Amato et al., 2009; Colpron and Nelson, 2009, 2011; Grove et al., 2008; Miller et al., 2011; Beranek et al., 2013a&b). The Phanerozoic accretionary history of Laurentia (proto-North America) potentially involves the translation of exotic terranes (e.g. Arctic Alaska, Farewell, Alexander, Klamath-Sierra, and Pearya) across the continent's northern margin from the Caledonian-Appalachian orogen to the North American Cordillera (e.g. Colpron and Nelson, 2011; Cocks and Torsvik, 2011; Miller et al., 2011; and many others). These regional relationships make the Arctic a critical location for understanding the growth and evolution of continental margins by accretionary and, potentially, large-scale strike slip tectonics.

The Arctic Alaska terrane, one such tectonostratigraphic package, includes the Brooks Range, North Slope and Seward Peninsula of northern Alaska (Fig. 1 and 2). The northeast Brooks Range and most of the North Slope portions of the Arctic Alaska terrane share characteristics (stratigraphy, fossil assemblages, detrital zircon populations) with Laurentia (Fig. 3; Johnson et al., 2016; Strauss et al., 2013; Cox et al., 2015; McClelland et al., 2015; Lane et al., 2015), while the southwestern portion of the terrane, including the Hammond subterrane, Coldfoot subterrane, and Seward Peninsula, has dominantly Baltic and Siberian affinities (Fig. 3; Kos'ko et al., 1993; Patrick and McClelland, 1995; Natal'in et al., 1999; Blodgett et al., 2002; Dumoulin et al., 2002; 2014; Amato et al., 2009, 2014; Miller et al., 2006, 2010, 2011; Till et al.,

2014a, 2014b; Akinin et al., 2015). These relationships suggest that a suture must exist between these different areas within Arctic Alaska, which records the amalgamation and formation of the Arctic Alaska terrane itself. Although recent efforts have attempted to better define these relationships (e.g. Strauss et al., 2017), our understanding of the timing and location of this suturing event within Arctic Alaska remains poorly constrained. The goal of this project is to constrain the nature of this boundary within Arctic Alaska through analysis of the Doonerak fenster, a strategic location which exposes structural basement of the Brooks Range between these regions of Laurentian and non-Laurentian origin.

For instance, most Arctic plate tectonic models restore the northern portion of the Arctic Alaska terrane near Point Barrow, AK to a conjugate margin near Prince Patrick Island in the Canadian Arctic by Mesozoic time (Fig. 1 and 2; e.g. Grantz et al., 2011; Lawver and Scotese, 1990; Houseknecht and Connors, 2016). This may have been achieved by way of ~60° rotation of Arctic Alaska around a Euler pole in the Mackenzie Delta during the Early Cretaceous (e.g. Gottlieb et al., 2014); however, one of several unresolved questions related to refining tectonic models of the Arctic concerns the position of the North Slope of Arctic Alaska from the Middle Ordovician to Late Devonian at the time of the Caledonian-Appalachian orogen (ca. 470-350 Ma; e.g. Gee, 1975; Roberts, 2003; McKerrow et al., 2000). Recent detrital geochronology of pre-Mississippian units from the Whale Mountain area in the northeast Brooks Range (Fig. 1) records a major shift in provenance and sediment dispersal that coincides temporally with the Caledonian orogeny and could be related to closure of the northern Iapetus Ocean (Johnson et al., 2016, 2013). The continuity of these relationships in the central Brooks Range is unknown.

The Doonerak fenster provides a window into the pre-Mississippian basement of the central Brooks Range, exposes rocks somewhat similar to those found in the Whale Mountain

area, and has long been enigmatic within the central Brooks Range (e.g. Dutro et al., 1976) because it provides unique exposure of mafic-to-intermediate volcanic rocks of largely unknown origin. Recent igneous and detrital geochronology and Lu-Hf isotopic data from zircon in the Doonerak fenster suggest that the Doonerak area could contain a magmatic arc complex, potentially related to the boundary between rocks of Laurentian and non-Laurentian affinity in Arctic Alaska (Strauss et al., 2017). In this context, the Doonerak fenster is critically important for understanding magmatism along the northern margin of Laurentia and closure of the Iapetus Ocean. Resolving the full tectonic context of the rocks within the Doonerak fenster could have broad implications on Neoproterozoic - Paleozoic plate reconstructions of the circum-Arctic (e.g. Dutro et al., 1973; Moore et al., 1994; Strauss et al., 2013). Herein, I present new detrital geochronologic data from the Doonerak area (from the fenster itself and the overlying allochthonous package) and whole-rock geochemistry from Doonerak's suite of igneous rocks. The objective this work is to provide evidence to help resolve the tectonic setting of the Doonerak fenster and related areas of the Arctic Alaska terrane during Caledonian-Appalachian orogenesis and to further define the position and nature of the boundary between Laurentian and non-Laurentian rocks in Arctic Alaska.

2. THE ARCTIC LITHOSPHERE

2.1 The Arctic Oceanic Realm

The Arctic Ocean includes two distinct oceanic basins, the Eurasia and Amerasia Basins (Fig. 1), and is surrounded by continental landmasses that share many characteristics, such as floral and faunal assemblages, detrital zircon populations, and deformation histories (e.g. Pease

et al., 2014, 2011; Miller et al., 2010). However, the tectonic evolution that led to these relationships and to the modern configuration of these landmasses is poorly understood. The younger of these ocean basins, the Eurasia basin, formed by seafloor spreading along the northern portion of the modern Atlantic/Arctic spreading center, the Gakkel Ridge, during Cenozoic time. This spreading center marks the modern boundary between the North American and Eurasian lithospheric plates in the Arctic (Engen et al., 2003; Karasik, 1968; Kristoffersen, 1990; Savostin and Karasik, 1981; Vogt et al., 1979).

The Eurasia basin contains well-mapped magnetic anomalies, which indicate that spreading began in the Cenozoic (c. 58 Ma - magnetic chron A25) between the Lomonosov Ridge and the Barents-Kara continental margin (Brozena et al., 2003; Glebovsky et al., 2006; Grants et al., 2011; Karasik, 1968, 1974; Kristoffersen, 1990; Vogt et al., 1979). Rates of seafloor spreading along the Gakkel Ridge are among the slowest in the world (Cook et al., 1986; Glebovsky et al., 2006; Karasic, 1974; Vogt et al., 1979). Very slow spreading may have contributed to the great variability in topography of the basin as a product of interplay between variable magmatism and crustal production with extension of the crust itself (Louden et al., 1996; Mutter and Karson, 1992; Small and Sandwell, 1992).

The Lomonosov Ridge (Fig. 1) is a poorly understood fragment of Eurasian continental crust that extends from northern Greenland toward the Siberian continental shelf, bisecting the Arctic Ocean (Brozena et al., 2003; Glebovsky et al., 2006; Grantz et al., 2001; Jokat et al., 1992; Karasik, 1968, 1974; Kristoffersen, 1990; Vogt et al., 1979). The Amerasia Basin lies to the west of the Lomonosov Ridge (Fig. 1) and is surrounded by the Canadian Arctic Islands, northern Alaska, and the Chukotka peninsula of northern Russia. It is larger than the Eurasia Basin and highly heterogeneous. The pre-Amerasia Basin configuration of the Arctic's

landmasses and the processes by which the basin opened are both unclear. The Amerasia Basin consists of several different physiographic regions, including the Canada Basin.

The Canada Basin is the most pertinent portion of the Amerasia Basin in terms of this study. It is bordered to the north by the Alpha-Mendeleev ridge province, to the west by the Chukchi Borderland, to the southeast by the Canadian Arctic Islands (Ellesmerian Fold Belt), and to the southwest by the continental margin of Arctic Alaska (Fig. 1). The Canada Basin is enigmatic; there is no consensus as to the nature of its crust or the mechanisms by which it opened (e.g. Lawver and Scotese, 1990). Saltus et al. (2011) used magnetic data to conclude that the basin is underlain by crust that is not typical of oceanic lithosphere; however, gravity data (Laxon and McAdoo, 1994, 1998) and regional seismic lines (Dinkelman et al., 2008; Helwig et al., 2011) suggest the existence of an extinct spreading center. Despite a lack of direct dating of basement material, most models for the opening of the Canada Basin assume that sea-floor spreading occurred during the Cretaceous on the basis of stratigraphic similarities along the basin's margins (e.g. Lawver and Scotese, 1990; Grantz et al., 2011a; Mosher et al., 2012; Spencer et al., 2011; Lane, 1997).

2.2 The Arctic Continental Realm

One method to understand the evolution of the Arctic Ocean is to better define the linkages between the different tectonostratigraphic terranes of its surrounding landmasses. Many of the Arctic's landmasses include tectonostratigraphic terranes derived from oceanic and continental crust from the margins of the Iapetus Ocean. These include terranes of Siberian, Baltic, Laurentian, Gondwanan and Panthalassan affinities (e.g. Trettin, 1987; Amato et al.,

2009; Colpron and Nelson, 2009, 2011; Grove et al., 2008; Miller et al., 2011; Beranek et al., 2013). The Arctic Alaska - Chukotka Microcontinent (AACM) is one such tectonostratigraphic package. The AACM includes the Brooks Range, North Slope, and Seward Peninsula of Alaska, the Chukotka Peninsula, Wrangel Island, and New Siberian Islands of Russia, and the continental shelves surrounding the Bering, Beaufort, and Chukchi seas (Fig. 1 & 2; e.g. Miller et al., 2006). The southern terminus of the AACM is marked by the Angayucham suture in Alaska (e.g. Moore et al., 1994) and the South Anyui suture zone in Russia (e.g. Seslavinskiy, 1979; Sokolov et al., 2002), where belts of ophiolites record oceanic closure that occurred as terranes of southern Alaska and Siberia collided with the AACM (Moore et al., 1994; Pease et al., 2014; Nokleberg et al., 2000; Zonenshain and Napatov, 1989). The geology of the AACM preserves evidence of a long-lived multiphase accretionary history. Because of its location at the edge of the Canada Basin, the AACM also provides critical piercing points for developing Mesozoic reconstructions of the Arctic and opening of the Arctic Ocean (e.g. Miller et al., 2006). The AACM has important paleogeographic links with various circum-Arctic paleocontinents (Dumoulin et al., 2002, 2014; Blodgett et al., 2002; Amato et al., 2009, 2014; Macdonald et al., 2009; Cocks and Torsvik, 2011; Strauss et al., 2013; Cox et al., 2015); however, much of the older history has been overprinted by the relatively young Jurassic-Cretaceous orogenesis which formed the Brooks Range (Brookian orogeny) in Alaska (Moore et al., 1994 and references therein) and the Verkhoyansk-Kolyma and Chukotka orogenic belts in Russia (Fig. 2; e.g. Oxman, 2003 and references therein). These orogenic belts incorporated crust which had previously been affected by older circum-Arctic orogenic episodes (Fig. 2; section 3.4).

The Arctic Alaska terrane, the Alaskan portion of the AACM (Fig. 3), is internally complex, which complicates attempts to restore its paleogeography. The northeast Brooks Range

and North Slope portions of the Arctic Alaska terrane have stratigraphy, fossil assemblages, and detrital zircon populations that indicate a Laurentian (North American) origin (Johnson et al., 2016; Strauss et al., 2013; Cox et al., 2015; McClelland et al., 2015; Lane et al., 2015). Conversely, the Hammond and Coldfoot subterranes, to the southwest, have dominantly Baltic and Siberian affinities (Fig. 3; Kos'ko et al., 1993; Patrick and McClelland, 1996; Natal'in et al., 1999; Blodgett et al., 2002; Dumoulin et al., 2002; 2014; Amato et al., 2009, 2014; Miller et al., 2006, 2010, 2011; Till et al., 2014a, 2014b; Akinin et al., 2015). This implies that there must be a boundary between these different areas within Arctic Alaska. A presumably Paleozoic suture, which records the amalgamation and formation of the Arctic Alaska terrane, must lie between these crustal blocks separating Laurentian and non-Laurentian portions of the Arctic Alaska terrane. We do not know the precise timing or mechanism by which Arctic Alaska amalgamated; however, Ordovician-Silurian potentially arc-related rocks of the Doonerak fenster in the central Brooks Range could be related to that internal suture within Arctic Alaska (Mull, 1982; Moore et al., 1997; Grantz et al., 1991; Dumoulin et al., 2000; Strauss et al., 2013, 2017). As such, Doonerak is an important locale for understanding amalgamation of the Arctic Alaska terrane, Paleozoic magmatism, and the closure of the northern Iapetus Ocean.

2.3 Relationships between Arctic landmasses

Several models for the opening of the Canada Basin attempt to reconstruct the relationships between the Arctic's landmasses by placing portions of the North Slope in a position against the Canadian Arctic Margin in pre-Mesozoic time (e.g. Lawver and Scotese, 1990; Lawver et al., 2002; Miller et al., 2006; Colpron and Nelson, 2009; Macdonald et al.,

2009). These models all agree that parts of the Arctic Alaska terrane and Canadian Arctic Islands were previously contiguous because they share similar paleontological, detrital zircon, and stratigraphic relationships, but the models differ in the precise mechanisms by which Arctic Alaska achieved its modern position. Determining the precise pre-Canada Basin positions and relationships of these landmasses has direct bearing on developing viable paleogeographic reconstructions and models for basin opening. Defining the mechanisms by which Laurentian and non-Laurentian portions of Arctic Alaska amalgamated and simply defining the location of that boundary with more precision are needed to inform these models. This study provides new geochemical and geochronological data from border between Laurentian and non-Laurentian regions of Arctic Alaska in order to constrain these relationships.

One widely accepted model for the opening of the Canada Basin involves the clockwise rotation (~60-70°) of the AACM, including Arctic Alaska terrane, away from the Canadian Arctic Islands about a pole of rotation located in the Mackenzie Delta (e.g. Grantz et al., 2011; Lawver et al., 2002). This assumes that exotic terranes of Chukotka, Alaska, and the Canadian Arctic arrived against the Laurentian margin as the northern Iapetus Ocean closed, before any Mesozoic rifting (e.g. Lawver et al., 2002). The simple rotational model predicts opening of the Canada Basin as a consequence of this rotation, between the Canadian Arctic and Arctic Alaska; however, it fails to explain the overlap of the Siberian continental shelf and Canadian Arctic Islands (~600 km of overlap) implied by this restoration (Lane, 1997).

Miller et al. (2006) used a more complex combination of rifting and strike-slip displacement to rectify the overlap generated in the simple rotation model. This model allows portions of Arctic Alaska and Chukotka to behave as non-coherent, independent masses with different tectonic and depositional histories. Miller et al., (2006) use detrital zircon data from

Triassic sandstones of Siberia, Chukotka, northern Alaska, and northern Canada to suggest that Chukotka and the East Siberian Shelf were in a different pre-rift paleogeographic position than Arctic Alaska. During the Triassic, Chukotka and the East Siberian Shelf must have been in a position to receive detritus from the Siberian craton, while Arctic Alaska was receiving detritus from the northern margin of Laurentia near the Canadian margin (Miller et al., 2006).

The Paleozoic geographic position of these same landmasses is more unclear. Stratigraphic similarities between the Seward Peninsula (western AK), Chukotka Peninsula, and portions of the Brooks Range are suggestive of unified deposition in the Lower Paleozoic (Natal'in et al., 1999). Fossil evidence suggests a Siberian affinity for parts of Arctic Alaska and Chukotka in the mid-Paleozoic (Blodgett et al., 2002; Dumoulin et al., 2002) and that Arctic Alaska and Siberia shared faunal assemblages by the Early Ordovician (Dumoulin and Harris, 1994; Dumoulin et al., 2002). These data suggest that portions of Arctic Alaska may have rifted from Siberia in the Devonian or that they had Cambrian to Devonian ties to northeastern Baltica (e.g. Blodgett et al., 2002). Amato et al., (2009) used U-Pb zircon geochronology from igneous and detrital rocks, along with Nd isotopic data from basement rock of the Seward Peninsula to point to an origin exotic to western Laurentia. They also developed a pre-Canada Basin Mesozoic reconstruction in which the Brooks Range, Seward Peninsula, and North Slope are near the Canadian Arctic Islands from the Mississippian to the Jurassic.

2.4 Relation to research goals

In order to constrain its paleogeography, we need to better understand the internal complexity within Arctic Alaska and define the boundary between rocks of Laurentian and non-

Laurentian origin. Defining this boundary would provide greater constraints on Paleozoic-Mesozoic reconstructions and allow future studies to better evaluate the mechanisms and timing of that amalgamation. This study focuses on the Doonerak fenster, a strategic location in the central Brooks Range, which is one of the best candidates for identifying the Paleozoic suture that must exist between the Laurentian and non-Laurentian portions of Arctic Alaska. Thus, the overarching goal of this research is to provide evidence for the Paleozoic tectonic setting of the rocks exposed within the Doonerak fenster and to better understand their relationship to the allochthonous rocks which overlie the fenster within the Brookian fold thrust belt. To that end, the goals of this work are 1) determine the age and provenance of the metasedimentary rocks within the Doonerak area, both interior and exterior to the fenster and 2) characterize the geochemical affinities of the volcanic rocks exposed in the fenster that may be related to this presumed Paleozoic suture. The combination of these efforts will place tighter constraints on the Paleozoic suture and various paleogeographic models outlined above. We test the hypothesis that the Doonerak fenster preserves the remnant of an island arc complex and marks the location of the suture between Laurentia and Siberian portions of Arctic Alaska. The data presented herein complements recent publications focused on the northeastern Brooks Range and Doonerak fenster by Johnson et al. (2016) and Strauss et al. (2017) respectively.

3. THE DOONERAK FENSTER - LOCATION AND GEOLOGIC SETTING

3.1 Terranes and Subterranes - Context within Arctic Alaska

Broadly, northernmost Alaska contains two lithostratigraphic terranes: the Arctic Alaska terrane and Angayucham terrane (Fig. 3; Moore et al., 1994; Silberling et al., 1994). Both occupy

portions of the Brookian orogen. The Brooks Range is the 1000 km long E-W trending north-vergent fold-thrust belt that extends across northern Alaska and into the Yukon of Canada (e.g. Mull, 1982; Oldow et al., 1987a; Grantz et al., 1991; Moore et al., 1994).

The Angayucham terrane is the structurally highest nappe associated with the Brooks Range and contains mostly mafic and ultramafic rocks with minor pelagic rocks of Devonian to Jurassic age (Fig. 3; Roeder and Mull, 1978; Moore et al., 1994). Spatial relationships, stratigraphic associations, and geochemical trends from Angayucham's igneous rocks suggest that the terrane is an internally complex package of obducted oceanic crust which was transported northward and accreted onto the southern Arctic Alaska terrane during Jurassic to Cretaceous orogenesis (e.g. Roeder and Mull, 1978; Barker et al., 1988; Pallister and Budahn, 1989). The Arctic Alaska terrane is more extensive and underlies the Colville basin and Brooks Range (e.g. Mull, 1982; Moore et al., 1994). It can be divided into six subterranes or allochthons on the basis of stratigraphy, facies, metamorphic grade, and structural position (Fig. 3; e.g. Moore et al., 1994; Mull, 1982; Jones et al., 1987; Mayfield et al., 1988). From north to south (i.e. foreland to hinterland), these are the North Slope, Endicott Mountains, De Long Mountains, Hammond, Coldfoot, and Slate Creek subterranes. Variations in the nomenclature of the Brooks Range complicate understanding of the region in general (e.g. Karl and Mull, 1993). A belt nomenclature related to the metamorphic grade of these packages is also used to describe northern Alaska (Fig. 3). These nomenclatures are nearly equivalent, but the subterrane nomenclature will be used throughout this document.

The North Slope, the structurally lowest of Arctic Alaska's subterranes, includes rocks of the northeastern Brooks Range, Lisburne Hills, Barrow arch, and Colville basin subsurface (Fig. 3). In the Colville basin subsurface, these rocks are not extensively deformed by post-

Mississippian orogenesis, but in the northeastern Brooks Range the same units show considerable deformation by Cretaceous to Cenozoic contraction. The outcrop of North Slope units south of the Endicott Mountains, in the Doonerak fenster, indicates that the other subterranes within the Brooks Range are structurally emplaced above rocks that are related to the North Slope's basement (Fig. 3).

In some areas across the Brooks Range, the Endicott Mountains allochthon is structurally overlain by De Long Mountains subterrane. Both are imbricated packages of Paleozoic to Mesozoic rocks, but they differ in specific stratigraphic relations. The Hammond subterrane (Fig. 3), south of the Endicott Mountains and Doonerak fenster, includes most of the Proterozoic and lower Paleozoic sedimentary units found in the Endicott Mountains of the central Brooks Range; however, the Hammond subterrane includes ductile deformation structures and greenschist to blueschist facies mineralogy with only sporadic relict primary igneous and sedimentary textures (e.g. Moore et al., 1994). The Coldfoot and Slate Creek subterranes of the southern Brooks Range contain metamorphosed rocks of the Brookian hinterland. The Coldfoot subterrane contains blueschist and greenschist facies schist, calc-schist, marble, and metavolcanic rocks. The Slate Creek subterrane is mostly composed of phyllite and lesser metasandstone of Devonian age. The Colville basin, Koyukuk basin, and Beaufort Sea shelf flank the perimeter of the Arctic Alaska terrane and are post-tectonic basins, which have experienced only minor shortening from the Cretaceous to Cenozoic (Tailleur and Brosgé, 1970; Patton et al., 1994; Moore et al., 1994).

The various subterranes of Arctic Alaska can also be divided into two broad categories based on their paleogeographic relationships: those of Laurentian and non-Laurentian origin (Fig. 3). Several previous workers suggested a Laurentian origin for the North Slope and

northeastern Brooks Range portions of the Arctic Alaska terrane (e.g. Dutro et al., 1972; Moore et al., 1994, 2011; Lane, 2007; Johnson et al., 2016; Strauss et al., 2013, 2017), but others argue for an exotic origin on the basis of paleobiogeographic affinities of fossil assemblages and geochronologic constraints from the southwestern portion of Arctic Alaska (Dumoulin et al., 2002; Blodgett et al., 2002; Miller et al., 2006, 2010, 2011; Amato et al., 2009). It is important to define the boundary between these paleogeographically distinct regions in order to develop models for the Paleozoic tectonic evolution of the Arctic. The pre-Mesozoic origin of Arctic Alaska's subterranes and their relationships to Laurentia are also vitally important because they have direct bearing on developing constraints on kinematic models for the Jurassic-Cretaceous opening of the Amerasia Basin (e.g. Grantz and May, 1983) and on the development of hydrocarbon resources along the Arctic's continental shelves. The development of reliable piercing points for such Mesozoic tectonic reconstructions rests on constraining the relationships between the crustal fragments of the Arctic Alaska - Chukotka microcontinent.

3.2 Pertinent Stratigraphy

The Endicott Group unconformably overlies the lower Paleozoic volcanic and volcaniclastic rocks in the North Slope subsurface and within the Doonerak fenster. It consists of the Upper Devonian-to-Lower Mississippian Kekiktuk Conglomerate and the Lower Mississippian Kayak Shale (Fig. 4 & 5; Armstrong et al., 1976). The Kekiktuk Conglomerate is a terrigenous clastic succession which rests above a regional sub-Mississippian unconformity in the North Slope subsurface and northeast Brooks Range. Regionally, it ranges from many hundreds of meters thick in the North Slope subsurface (Melvin, 1993; Miller, 1991) to a

relatively thin and discontinuous unit in the northeast Brooks Range (Le Pain et al., 1994). The position of the Kekiktuk Conglomerate above the regional unconformity, its diversity of interpreted lithofacies and paleoenvironments, widespread distribution, and relationship to overlying marginal to shallow marine shales is suggestive of deposition along a progressively subsiding passive continental margin (e.g. Le Pain et al., 1994). The regional sub-Mississippian unconformity could reflect a transition from contractional tectonics below to extension and thermally controlled passive margin subsidence above (e.g. Le Pain, 1994, Anderson and Wallace, 1991; Moore et al., 1992; Anderson, 1993); therefore, the Kekiktuk Conglomerate (broadly correlative to the Kanayut Conglomerate of the Endicott Group within the Endicott Mountains allochthon; Fig. 5) is the basal terrigenous clastic portion of a larger continental margin succession - the Ellesmerian sequence (LePain et al., 1994; Moore et al., 1992).

En masse, the Endicott Group of the northeast Brooks Range is a transgressive succession (Brosgé et al., 1962; Armstrong, 1974; Armstrong and Bird, 1974; Nilsen, 1981). This succession is marked by the transition from the fluvial to marginal marine depositional settings of the Kekiktuk Conglomerate into the marginal marine to shallow marine lithofacies of the Kayak Shale. The unconformity at the base of the Kekiktuk is significant because it potentially marks cessation of the Devonian Romanzof (or Ellesmerian) orogeny, with dominantly contractional tectonics below and extension followed by thermal subsidence above (Churkin, 1969, 1975; Brosgé et al., 1962; Reed, 1968; Dutro, 1970; Sable, 1977; Oldow et al., 1987a&b; Moore et al., 1994; Lane, 2007; LePain, 1994). However, in the Endicott Mountains Allochthon (EMA), the sub-Mississippian unconformity is absent and Devonian age strata pass conformably up section into the Carboniferous (Fig. 5). The thick Upper Devonian to Carboniferous clastic package of the Endicott Mountains Allochthon (including the Devonian Beaucoup Formation,

Hunt Fork Shale, and Noatak Sandstone) is also considered to be part of the Endicott Group (Fig. 5), although within the Endicott Mountains allochthon the conglomeratic unit below the Kayak Shale is referred to as the Kanayut Conglomerate rather than the Kekiktuk Conglomerate. The Kanayut also reflects a transgressive-regressive-transgressive clastic wedge succession that formed as major fluvial-deltaic depocenters migrated along the Late Devonian to Early Carboniferous basin margin (Moore and Nilsen, 1984; Moore et al., 1992). The rocks of the Endicott Mountains allochthon (and the higher grade rocks of the Hammond subterrane; Fig. 3) were transported northward and emplaced into a structural position above the rocks of the Doonerak fenster during the Brookian orogen (Fig. 3, 5, and 7; e.g. Moore et al., 1997).

These regional relationships of Middle Devonian to Lower Carboniferous rocks in the Brooks Range characterize the early rift and drift phases in the evolution of a passive margin (Anderson and Wallace, 1991; Anderson et al., 1992; Moore et al., 1992; Anderson, 1993). The presence of the sub-Mississippian unconformity above the Apoon volcanics within the Doonerak fenster is similar to what is seen in the northeast Brooks Range and North Slope subsurface; however, the unconformity is absent in the overlying Endicott Mountains allochthon (EMA). This is one line of evidence used to suggest that the rocks interior to the Doonerak fenster are in fact structural "basement" to the Brookian fold-thrust belt, despite the fact that they only achieve greenschist metamorphic grade (e.g. Moore et al., 1994). The absence of the unconformity and generally thicker and more complete stratigraphic succession in the Endicott Mountains allochthon suggests that these rocks were deposited in a more basinal position relative to their coeval equivalents in the northeast Brooks Range and Doonerak fenster. The rocks of the Endicott Mountains mark the allochthonous portion of the Brookian orogen and should be restored to a position south of the Doonerak fenster. Understanding the provenance of the

Endicott Mountains rocks north of Doonerak would shed light on sediment pathways and variation in the Devonian section across the Brooks Range, prior to emplacement of those rocks above the Doonerak antiform.

3.3 Overview of orogenic events in northern Alaska and the Arctic

The Phanerozoic orogenic events of northern Alaska have historically been assigned to two major episodes, the Ellesmerian and Brookian (see review by Moore et al., 1994). Ellesmerian deformation affected units below the regionally recognizable sub-Mississippian unconformity in the North Slope subsurface and northeast Brooks Range (described in previous section) but its full extent is not well known. Lerand (1973) expanded the Ellesmerian orogeny to include all early Paleozoic deformation along the Arctic Ocean margin on the basis of presumably coeval sub-Mississippian structures in northern Alaska and the Canadian Arctic Islands. However, other work suggests that the deformation in the northeast Brooks Range is pre-Middle Devonian and therefore older than the Ellesmerian structures of the Canadian Arctic (e.g. Anderson et al., 1994). The pre-Middle Devonian deformation of the northeast Brooks Range is now treated as a distinct, yet related, orogenic event, the Romanzof Orogeny (Lane, 2007). Romanzof deformation was likely localized along the northwest margin of Laurentia and could be related to the Early-Middle Devonian accretion of the Whale Mountain allochthon onto the Laurentian margin (Johnson et al., 2016; Lane, 2007). The continuity of Romanzof vs. Ellesmerian structures elsewhere in Arctic Alaska is not well known, nor are the effects of this orogenic episode on sediment dispersal among other regions of Arctic Alaska containing early-mid Paleozoic stratigraphy.

The Brookian orogeny, the younger orogenic system of northern Alaska, formed the dominant east-west trending, north-vergent fold thrust system of the Brooks Range and occurred in two major phases (Gottschalk and Snee, 1998; Moore et al., 1994). Metamorphism of the southern Brooks Range and emplacement of far traveled thrust sheets in the northern Brooks Range occurred during the first Brookian phase in Middle Jurassic to Early Cretaceous time (Mull, 1982; Mayfield et al., 1988; Dillon 1989). The second Brookian phase formed structures in several deformational episodes affecting mid-Cretaceous and younger strata and occurred as a protracted series of deformational events. The uplift of the Doonerak antiform is attributed to this second phase (e.g. Moore et al., 1994; O'Sullivan et al., 1998). In the North Slope and Beaufort Sea, deformed Neogene and Quaternary units indicate that deformation continued into the recent geologic past (Grantz and May, 1983, Grantz et al., 1990).

Brookian deformation was also synchronous with regional metamorphism between 170 - 54 Ma, concentrated around 110 Ma (Turner et al., 1979), and contributed to the progressive uplift of the Brooks Range itself. Estimates of uplift from the Doonerak fenster in the central Brooks Range indicate ~8-12 km of denudation since ~70-65 Ma (O'Sullivan et al., 1998). Apatite fission-tracks suggest a minimum of ~4-6 km of denudation since the late Oligocene (O'Sullivan et al., 1998). Similarities between the Doonerak antiform and antiforms of the northeast Brooks Range and similarly rapid rates of denudation and uplift could indicate that the Doonerak antiform formed as the result of a deformational and uplift episode that affected both regions in the Oligocene (O'Sullivan et al., 1998).

Other regional orogenic episodes (Fig. 2) which may have contributed detritus to rocks pertinent to this study include the Caledonian orogeny of Greenland, Scandinavia, and the northernmost Atlantic and the Timanian orogeny of northernmost Europe (Baltica) and Russia.

Younger regional episodes, such as the Uralian orogeny of northern Baltica, which formed the Ural Mountains, the modern boundary between Europe and Asia, are generally too recent to have contributed detritus to rocks at Doonerak, but certainly may have overprinted portions of the Timanian fold thrust belt in northern Europe.

The Caledonian orogeny is the northern equivalent of the trans-Appalachian orogenic episodes associated with the closure of the Iapetus Ocean. It can be subdivided into numerous phases involving arc-arc and arc-continent collisions from Cambrian to Devonian time involving Laurentian, Baltican, and Avalonian crust (e.g. McKerrow et al., 2000). Early Caledonian phases are recorded in both Scandinavia and the United Kingdom and range from 550 - 500 Ma (e.g. Ramsay and Sturt, 1976; Sturt et al., 1978); however, the major collision between Laurentia and Baltica occurred from the Late Silurian to Early Devonian and is often referred to as the Scandian phase, which involved rapid subduction and the emplacement of plutonic igneous rocks between 490 - 390 Ma, with peak development around ~ 420 Ma (e.g. Gee, 1975; Roberts, 2003; McKerrow et al., 2000). The Ellesmerian and Romanzof structures and deformation along the Canadian and Alaskan margins may be related to the Caledonian orogen. Some paleogeographic models of the Arctic predict that terranes of Caledonian origin were transported along the Laurentian Arctic Margin in a strike-slip manner (Colpron and Nelson, 2009, 2011). These Caledonian terranes might have then been incorporated into the Ellesmerian and/or Romanzof orogenic episodes and could have provided pathways for sediment to move from the Caledonian realm toward Arctic Alaska.

The Timanian orogeny is a Neoproterozoic contractional event recorded in rocks of northern and eastern Baltica, spanning about 3000 km from the Ural Mountains of Kazakhstan to the Varanger Peninsula of northern Norway (Fig. 2; e.g. Gee and Pease, 2004 and references

therein). Timing of the Timanian orogen spans 800 - 550 Ma with igneous zircon from

northeastern Baltica dated to ~555 Ma, ~620 Ma, and ~670 Ma by Gee et al., (1995). Remizov

and Pease (2004) also defined Neoproterozoic cooling ages from a zircon bearing gabbro-norite,

in concert with the ages from Gee et al., (1995). Major element, trace (including rare earth)

element, and isotope (Rb-Sr and Sm-Nd) geochemistry from the basement of the Pechora Basin

(NW Russia) indicate that at least portions of the Timanian system are related to a juvenile island

arc, indicating that subduction related arc magmatism occurred along northeastern Baltica in the

Neoproterozoic (Dovzhikova et al., 2004). In northernmost Norway, on the Varanger Peninsula,

rocks of the Timanides are juxtaposed against those derived from the Caledonian orogen,

indicating that a suture exists between Timanian and Caledonian rocks in the Arctic (Fig. 2; e.g.

Gee and Pease, 2004). The Timanides and Caledonides are both important in the context of this

study because we recognize Timanian and Caledonian age detritus in Alaskan rocks of the

central Brooks Range (section 4).

3.4 The Doonerak fenster: location and basic relationships

The Doonerak fenster is a NE-SW trending doubly plunging antiform that exposes deep

structural levels of the Brooks Range (Fig. 3, 5, 6, & 7; Dutro et al., 1976; Mull et al., 1987;

Oldow et al., 1984). The fenster lies in the central part of the Brookian orogen below the basal

detachment of the Endicott Mountains allochthon, the Amawk Thrust. The Endicott Mountains

allochthon is a package of imbricated thrust sheets composed of Upper Devonian to Triassic

siliciclastic and carbonate rocks, which are juxtaposed above Doonerak as a foreland dipping

duplex (Fig. 6 & 7; e.g. Dutro et al., 1976, 1984a; Moore et al., 1994).

The polydeformed metamorphic core of the Brooks Range lies to the south of the Doonerak fenster, while the mildly deformed foreland thrust belt lies to its north (Fig. 7; e.g. Moore et al., 1994, 2015). Within this larger framework, the Doonerak area lies between the hinterland and foreland portions of the Brookian orogen (Fig. 3). Although the rocks at the core of the Doonerak fenster are Lower-to-Mid Paleozoic in age (Apoon Assemblage, Kekiktuk Conglomerate, Kayak Shale, Lisburne Limestone) and are overlain by allochthonous rocks also of Paleozoic age (Beaucoup Formation, Hunt Fork Shale, ect.) these two packages were not juxtaposed against each other until the Jurassic-Cretaceous Brookian orogeny. The modern antiform could have formed as recently as the Oligocene based on denudation and uplift calculated from apatite fission track data collected within the Doonerak fenster (O'Sullivan et al., 1998).

In the North Slope subsurface and northeastern Brooks Range portions of Arctic Alaska deformed lower Paleozoic and Proterozoic basement rocks similar to the Franklinian Sequence (e.g. Lerand, 1973; Carter and Laufeld, 1975) are separated from the overlying Ellesmerian Sequence by a regionally recognizable angular unconformity (Lerand, 1973; Grantz and May, 1983). In the northeast Brooks Range, the pre-Mississippian unconformity separates the Middle Devonian Ulungarat Formation from the Kekiktuk Conglomerate of the Ellesmerian Sequence (Fig. 4). Regionally, the pre-Mississippian unconformity likely formed following cessation of the Devonian Ellesmerian (or Romanzof) orogeny (Churkin, 1969, 1975; Brosgé et al., 1962; Reed, 1968; Dutro, 1970; Sable, 1977; Oldow et al., 1987a&b; Moore et al., 1994; Lane, 2007). The lower Paleozoic volcanic and volcaniclastic rocks in the interior of the Doonerak fenster, in the central Brooks Range, are known as the Apoon assemblage (next section) and are also interpreted as structural basement of the Brookian fold-thrust belt despite their modest

metamorphic grade (Fig. 5 and 7; Dutro et al., 1976, 1984a&b; Armstrong et al., 1976; Dillon et al., 1986; Mull, 1982; Mull et al., 1987; Oldow et al., 1987). The basement of the North Slope subsurface and northeast Brooks Range are both different than the rocks of the Apoon assemblage, but all three are overlain by an unconformity which separates basement rocks from the Ellesmerian Sequence of passive margin siliciclastics and carbonates (Moore et al., 1994 and references therein).

3.5 The Apoon Assemblage - Lower Paleozoic volcanic rocks

The Apoon assemblage of the Doonerak fenster consists of the lower Paleozoic "basement" rocks below the Amawk Thrust (Fig. 5 & 7), including volcanic and volcaniclastic rocks. The assemblage is subdivided into four poorly constrained lithologic units (Fig. 6 and 7): (1) a ~500 m thick unit dominated by volcanic rocks including basaltic lava and lapilli tuff mixed with pyroclastic breccia and rare phyllites - Pza , (2) a 1500 m thick mixed clastic unit of meta-argillite, phyllite, and siltstone interbedded with coarser lithologies of volcanic lithic sandstone, pebbly mudstone, and conglomerate - Pzc, (3) a highly variable ~400 m thick volcaniclastic unit containing basaltic lava flows, interbedded tuff, and litharenite with rare phyllite and argillite - Pzv, and (4) a ~3000 m thick mixed slate and phyllitic unit with occasional carbonates and thin isolated lenses of aphanitic greenstone - Pzp (Julian, 1989; Julian and Oldow, 1998). All of the Apoon rocks are strongly deformed and have experienced low grade metamorphism. The true stratigraphic thickness of the Apoon assemblage is very poorly constrained due to significant isoclinal folding and structural thickening - thicknesses above are approximate structural thicknesses based on mapping in the northeastern part of the fenster (Julian and Oldow, 1998).

Until recently, geochronologic constraints on the age of the Apoon assemblage were limited to six hornblende K-Ar and $^{40}Ar/^{39}Ar$ cooling ages from dikes and sills that range from ~520 - 373 Ma and exist in two primary groupings at ~380 Ma and ~470 Ma (Fig. 6; Dutro et al., 1976). Significantly, Strauss et al. (2017) conducted U-Pb SHRIMP-RG and Lu-Hf isotopic analysis on igneous zircon from a leucogabbro found in the Pzv section of the Apoon assemblage. This analysis yielded a $^{206}Pb/^{238}U$ age of 462 ± 8 Ma, in agreement with the ~470 Ma ages from hornblende by Dutro et al. (1976). Detrital zircons from the Apoon assemblage analyzed using LA-ICPMS methods yielded age groups of ca. 490 - 420, 540 - 520, 1250 - 960, 1500 - 1380, 1945 - 1750, and 2830 - 2650 Ma, with Lu - Hf data from the ~490 - 420 population indicative of juvenile crust and a distinct lack of crustal assimilation during presumed Ordovician-Silurian arc magmatism (Strauss et al., 2017).

A few sporadically located paleontological collections (Fig. 6; locations 1 - 4) also provide constraints on the age of the Apoon assemblage: (1) Middle Ordovician conodonts from siliceous volcaniclastics, probably of Pzv and Lower Silurian (Llandoverian) graptolites and conodonts presumably from Pzc identified by Repetski et al. (1987), (2) Silurian graptolites from Pzc near Amawk Mountain identified by Moore and Churkin (1984), and (3) early-middle Cambrian trilobites of Siberian affinity as well as proto-conodonts, hyolithids, and acrotretid brachiopods identified by Moore et al. (1984), probably from Pzp (Figure 3; also see Supplementary Materials section for a summary of age constraints). The ages and structural relationships between different subunits within the Apoon assemblage are not well defined and could benefit from detailed stratigraphic analysis. The oldest of Doonerak's fossils, early Cambrian trilobites of Siberian affinity, occur exclusively in the western portions of the fenster

(Moore et al., 1984), but the effects of structural thickening and the full suite of lithologies present in not well known.

Limited geochemical data from igneous rocks of the Apoon assemblage indicate compositions consistent with a magmatic arc complex and show similarities to the chemistry of volcanic rocks in the northeastern Brooks Range (Julian and Oldow, 1998; Moore et al., 1997; Moore, 1987). Despite some alteration, analyses from Pza and Pzv both show compositional overlap between major and trace element geochemical fields associated with calc-alkaline basalts, island-arc thoeliites, and mid-ocean ridge basalts (MORBs; Julian and Oldow, 1998; Moore, 1987; Julian 1989; Moore et al., 1997). These previous geochemical arguments by Julian and Oldow (1998) provide a good starting point for assessing the tectonic setting of the Apoon assemblage. Previous studies only considered a handful of trace element ratios and did not incorporate rare earth element trends or a sufficient diversity of trace elements, which are resistant to alteration by hydrothermal and metamorphic processes (Julian and Oldow, 1998; Moore et al., 1997; Moore, 1987). The detailed structure within the fenster and age relationships between these different igneous rocks are currently only known at a general level, which prevents determining if the variability within the geochemistry of these samples is the product of a genetically related series of melts or multiple distinct magma series.

Several important geologic features coexist within the Doonerak fenster: (1) Siberian fossils in the westernmost part of the fenster with (2) stratigraphic relationships indicative of Laurentian origin in the eastern part of the fenster – the sub-Mississippian unconformity overlain by the Ellesmerian Sequence as seen in the North Slope subsurface and (3) the presence of a wide range of potentially arc-related Early Paleozoic volcanic rocks within the Apoon assemblage. These data suggest that the Apoon assemblage of the Doonerak fenster could

represent an early Paleozoic magmatic arc succession based on limited lithological, geochemical, geochronological, and paleontological data, but its tectonic setting and full significance relative to the regional context of Arctic Alaska is unclear (Dutro et al., 1976; Moore, 1987; Julian, 1989; Julian and Oldow, 1998; Strauss et al., 2017). Previous workers have shown that the Doonerak area is a structural window (fenster) which exposes deep levels of the Brooks Range and that the Apoon assemblage is unlike other exposures in the central Brooks Range (e.g. Dutro et al., 1979; Moore et al., 1994; Moore et al., 1997). Limited geochemical data are inconclusive, but suggest that the Apoon assemblage may have formed in a subduction zone (Julian and Oldow, 1998; Moore et al., 1997). As such, the Doonerak fenster may delineate the boundary/suture between Laurentian and non-Laurentian rocks in Arctic Alaska, but more data is needed to address this hypothesis. Basic structural relationships, the general diversity of various map units, the textural and compositional diversity of the Apoon volcanics, and the provenance of various siliciclastic units all remain poorly constrained and are addressed in this study.

4. METHODS

4.1 Methodological goals

The goal of this study is to provide evidence which can be used to determine the tectonic setting of the Apoon assemblage of the Doonerak fenster and to better understand the relationship of the units exposed in Doonerak fenster to the rocks structurally emplaced above it, the Endicott Mountains allochthon. In order to do so, we constrained the age and provenance of detrital rocks from both above and below the basal detachment of the Endicott Mountains allochthon, the Amawk thrust, using U-Pb detrital zircon geochronology applied to the Apoon

assemblage, Ellesmerian Sequence and Endicott Group. Whole rock major and trace element geochemistry are used to define the tectonic setting in which the Apoon assemblage formed.

Fieldwork was conducted along the North Fork Koyukuk River, a throughgoing stream which passes through both the Endicott Mountains and the Doonerak Fenster. Fieldwork focused on an area which is approximately 17 km x 8.5 km centered on the North Fork Koyukuk River within the Gates of the Arctic National Park (Fig. 8). The following sections present data primarily focused on six sandstone samples collected for detrital zircon analysis and eleven igneous samples collected for geochemical analysis. The Supplementary Materials section of this document contains a table with a full list of all samples collected, basic descriptions and collection locations.

4.2 U-Pb Detrital Zircon Geochronology

U-Pb detrital zircon geochronology is a common tool for understanding the provenance and depositional age of sedimentary rocks (e.g. Dickinson and Gehrels, 2003; DeGraaf-Surpless et al., 2002; see review by Gehrels, 2014). Because zircon is mechanically and chemically resistant to breakdown it is commonly incorporated as a minor constituent in clastic sedimentary rocks. Dating zircons from a sedimentary rock provides information about that rock's depositional age and provenance. This can be achieved by comparing the ages calculated from detrital zircon within the rock in question to the ages of potential source regions that may have contributed primary igneous or metamorphic zircon grains as detritus. The U-Pb method is capable of capitalizing on three separate, yet related, radioactive geochronometers (^{238}U $\rightarrow$ ^{206}Pb, $t_{1/2}$ ~ 4.47 Ga; ^{235}U$\rightarrow$ ^{207}Pb, $t_{1/2}$ ~ 0.70 Ga; ^{233}Th $\rightarrow$ ^{208}Pb, $t_{1/2}$ ~14.01 Ga; Jaffey et al., 1971).

There are several analytical methods for measuring the abundance of various U, Th, and Pb isotopes within a zircon grain. Laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS) is commonly used to analyze large suites of zircon grains from sedimentary rocks because it is rapid, cost effective, and maintains precision and accuracy of 1-2% (e.g. Gehrels, 2014; Košler et al., 2013). This method uses a laser beam to ablate zircon material from a polished sample of zircon grains, extracted from the rock in question. The ablated material is fed into a stream of gas which flows into a mass spectrometer, where isotope analysis is conducted (e.g. Fryer et al., 1993; Košler et al., 2001; Košler and Sylvester, 2003). Zircon grains of a precisely known age (calculated by ID-TIMS) are used as standards and are periodically analyzed alongside unknown grains from the rock of interest in order to correct for downhole fractionation. $^{206}Pb/^{238}U$ ratios can be affected by fractionation during sample ablation. This periodic analysis of standard and unknown grains is referred to as standard-sample bracketing (e.g. review by Gehrels, 2014). Isotope ratios can then be used to calculate an age for each ablated zircon from the rock in question. The analyzed zircon grains are treated as a representative sample of the total population of detrital zircons within the rock of interest. Ideally, approximately one hundred to three hundred unknow zircon grains should be analyzed from each sample to allow for robust statistical treatment; however, it is common to report analyses with as few as 80 successful ages (e.g. review by Gehrels, 2014).

Six samples of sandstone from the vicinity of the Doonerak fenster in the central Brooks Range (both from the fenster itself and the overlying allochthonous package) were analyzed for U-Pb detrital zircon geochronology by LA-ICP-MS at the University of South Carolina's Center for Elemental Mass Spectrometry (CEMS). Each sample consisted of approximately 0.5 - 1.0 kg of rock collected from single beds. The coarsest fractions were

targeted because they have a greater likelihood of containing abundant usable zircon. Care was taken to avoid veins, weathering rinds and other potential sources of alteration or contamination. Processing of the raw data generated by the mass spectrometer during LA-ICP-MS analysis was conducted using the *UPbGeochronology3* data reduction scheme of the Iolite v.3 software suite (Paton et al., 2010) within the IgorPro data and computation package. Individual ages were then filtered based on the concordance, $^{206}Pb/^{207}Pb$ and $^{206}Pb/^{238}U$ ratios, total U and Th concentrations, and the degree of uncertainty in the resulting calculated ages. Concordance refers to the level of agreement between the $^{207}Pb/^{235}U$ and $^{206}Pb/^{238}U$ ages calculated from a single grain. A concordance filter of 85% and a reverse concordance filter of 105% was used as the acceptable cutoff, typical of detrital applications (e.g. Gehrels, 2014). The Sri Lanka (SL) zircon standard was used as the primary reference material for all analyses presented in this study (TIMS age = 563.5 ± 2.3 Ma, 2σ; 518 ppm U, 68 ppm Th, $^{206}Pb/^{204}Pb$ = 18000; Gehrels et al., 2008). The zircon standard 91500 (ID-TIMS age = 1065 ± 5 Ma; Wiedenbeck et al., 1995) was used as the secondary reference material. For consistency and comparability all ages reported are based on the reduction scheme using SL as the primary reference material. During analysis, both reference materials were analyzed following ablation of every five unknowns.

The resulting filtered data is presented herein as normalized age-probability density plots which were created using the program *IsoPlot v.3*. Individual sample information, full geochronologic data tables, procedures for sample collection, preparation, interpretation, U-Pb concordia diagrams (Wetherill, 1956), and accompanying descriptions for each sample are provided in the Supplementary Materials section of this document. The entire U-Pb data collection and processing procedure was conducted under the advisement of Dr. David Barbeau from the University of South Carolina.

4.3 Whole Rock Volcanic Geochemistry

Magmas contain distinctive trace element compositions which can be used to differentiate between basalts erupted from different tectonic settings (e.g. Pearce, 1983). More specifically, the characteristic enrichments and depletions of trace elements within these magmas can be used to provide clues to identify the source and processes responsible for magma formation. For instance, enrichment in large ion lithophile elements (LILEs; e.g. Cs, Rb, K, Ba, Pb, Sr, Th) and depletion of high field strength elements (HFSEs; e.g. Nb, Zr, Ti, Ta, P) in arc basalts are the result of metasomatic processes between the subducting lithospheric slab and the overlying mantle wedge and are highly indicative are arc-related tectonic settings (e.g. Tatsumi, 2005). Similarly, the systematic chemical behavior of rare earth elements (REEs) makes them a highly effective tool for determining the tectonic setting in which mafic to intermediate igneous rocks may have formed and the various petrogenic and alteration processes that may have affected them (e.g. Hanson, 1980; Pearce and Cann, 1973; Winchester and Floyd, 1977; Bacon et al., 1997; and many others). REE cations systematically decrease in size with increasing atomic number (from La to Lu) the distribution coefficients and partitioning behavior of REEs, a product of charge and size of an ion relative to crystal lattice sites, also vary systematically (e.g. Blundy and Wood, 1994; Hanson, 1980; Davidson et al., 2013). As such, petrogenetic processes (i.e. partial melting, fractional crystallization, melt mixing) affect REE patterns based on systematically variable properties dictated by variations in ionic radius and the abundance of particular mineral phases capable of incorporating REEs into their structure.

Eleven samples of igneous rock from the Apoon Assemblage of the Doonerak fenster were analyzed for whole rock major, trace, and REE geochemical abundances. Samples were

prepared and powered in the rock preparation laboratory at West Virginia University using standard practices and analyzed by a professional commercial laboratory (Activation Laboratories, Ontario, CA - Analysis type: Whole Rock Analysis + ICP 4 Lithoresearch QUANT). Care was taken to avoid weathering rinds and obviously altered rock surfaces. All samples were treated with an aggressive fusion technique and then digested in an acid solution, which is required to totally dissolve the entire sample and adequately assess major oxides, refractory minerals, REEs, and other high field strength elements. Analysis was conducted by ICP-OES and ICP-MS. A full table of results, detection limits, and individual sample descriptions is provided in the Supplementary Materials section of this document.

This work expands on that of Moore (1987), who compared the Apoon volcanics to volcanic rocks of the northeast Brooks Range, and Julian and Oldow (1998), who suggested that the lithogeochemistry of rocks in the northeastern part of the Doonerak fenster was indicative of a magmatic arc complex along an active continental margin. Several of the basalt discrimination diagrams used by Julian and Oldow (1998) are presented alongside the new data from this study in order to allow for direct comparison. Neither previous study considered the full suite of trace and REE trends presented herein. The new REE data presented in this study is also presented alongside representative data from global databases to aid in the comparison of geochemical trends. The N-MORB, E-MORB, OIB, and depleted mantle chemistry of Sun and McDonough (1989), Salters and Stracke (2004), and McDonough and Sun (1995) respectively is provided to aid in comparison and qualitatively compare different source regions. Focus is given to variation (spider) diagrams of trace and REEs because rocks of the Apoon assemblage have experienced hydrothermal and/or low grade metamorphic conditions, which complicate the interpretation of trends based on major elements or those based on other fluid mobile elements. Trace elements,

particularly REEs, are relatively immobile under hydrothermal and low grade metamorphic conditions, making them a more reliable means to assess these particular rocks (e.g. McLennan, 1989). The primary goal of these geochemical analyses is to define the likely tectonic setting in which the Apoon rocks formed.

5. RESULTS

5.1 Field Relationships, sample collection, and lithologic characteristics

Figure 8 provides an updated geologic map of the area containing the locations of samples analyzed for whole rock geochemistry and detrital zircon geochronology. Note that most samples and field data come from an area which is approximately 17 km x 8.5 km and focused around the North Fork Koyukuk River; however, one sample (J1415) was provided by J. Strauss northeast of all the other samples. The field relationships mapped in direct proximity to that sample come from their observations and mapping (see Strauss et al., 2017). The nomenclature on this map generally follows that of Julian and Oldow (1998) and Strauss et al. (2017). Some contacts and structures are inferred from aerial and satellite imagery. Some contacts are projected onto this map from the east where Strauss et al. (2017) conducted field work.

One of the most important field relationships observed during the 2015 field season along the North Fork of the Koyukuk River was confirmation of the presence of the sub-Mississippian unconformity between rocks of the Ellesmerian Sequence and rocks of the Apoon assemblage within the Doonerak fenster (below the Amawk thrust). Along the North Fork of the Koyukuk River east of its confluence with Ernie Creek the river's flow direction changes from E-W to N-S. Just upstream of that bend in the river, rocks of the Lisburne Limestone are easily visible at

the field scale as a dip slope on the south side of the river valley. Figure 10 provides an annotated field photo with a view to the east along this strategic portion of the North Fork of the Koyukuk River. To the north (left) side of the image, rocks of the Devonian Hunt Fork formation (Endicott Mountains allochthon) are exposed among rolling tan-gray hills. This is the approximate location of sample 26DF15, which was collected for detrital zircon geochronology (next section). The south (right) side of the image shows the Ellesmerian Sequence, including the Lisburne Limestone and Kayak Shale (Doonerak Fenster), and the Ordovician to Silurian age rocks of the Apoon assemblage. This is the approximate location of sample 23DF15 (Kayak fm), which was also collected for detrital zircon analysis (next section). At this location, the Kayak Shale sits unconformably atop the Apoon assemblage. Elsewhere within the fenster, the Kekiktuk Conglomerate, stratigraphically below the Kayak Shale (see Fig. 4 & 5), is described as resting in direct unconformable contact with the Apoon assemblage (e.g. Dutro et al., 1976; Julian, 1989; Strauss et al., 2017). This implies some variation along strike of this important contact. That variability has not been acknowledged previously and is different from what is observed in the northeast Brooks Range and North Slope subsurface. The abrupt craggy edifices making resistant peaks to the right (south) side of the image are composed of the Apoon igneous rocks (Fig. 10).

Stereographic projections of poles to the dominant foliation, S_1, of various outcrops are provided in Figure 11 (A - D), which is organized based on lithology. Interior to the fenster, rocks of the Kayak Shale and Lisburne Limestone (Ellesmerian Sequence in Fig. 11 - C) have poles to bedding, S_0, that indicate planes which dip consistently to the north and northwest; however the underlying rocks of the Apoon assemblage do not follow the same orientation (Fig. 11 - D). The attitude of the Apoon units is significantly more variable. Immediately south of the

sub-Mississippian unconformity, the Apoon units dip to the south opposite those of the Ellesmerian Sequence. Yet, in close proximity the same units strike north-south and dip to the west (see Fig. 8). The relationship and angle between cleavage and bedding (where both were identified) did not remain consistent throughout the area, being near parallel to each other in some places and at a steep angle to each other in others, indicating that the primary bedding planes are folded. Rocks of the Hunt Fork Formation (northern portions of Fig. 8) generally dip to the west and northwest with rare southward dipping structures (Fig. 11 - A). The underlying Beaucoup Formation, which occupies the hanging wall of the Amawk Thrust, contains chaotically organized fabrics (Fig. 11 - B), but generally mimic the orientation of the overlying Hunt Fork Shale.

Some structural features observed in the field exist below the scale of the map in Figure 8 and are not immediately apparent from the aggregated structural data (Fig. 11 A - D). Specifically, two upright, open outcrop scale anticlines were observed along the west side of the North Fork Koyukuk River, north of Frigid Crags and south of Shushalch Creek, near sample location 43 in Figure 8. Both folds were observed within the Beaucoup Formation in the hanging wall of the Amawk thrust, about 2.5 km from each other (Fig. 12). It was clear that these two anticlines deformed bedding because the lithologies at their centers differed from those at their edges. The axial planes of each of these folds strike approximately east-west or northeast-southwest (Fig. 12) and dip to the south or southeast, broadly similar to Brookian deformational trends regionally.

The Apoon assemblage contains a diversity of complex structures and lithologies that are easily recognized at the outcrop scale. There are multiple field examples of the internal complexity of the Apoon assemblage, both lithologically and structurally (Fig. 13). Small folds

deforming bedding in multiple orientations, folds superimposed over a preexisting cleavage, and various brittle structures (i.e. small faults and joints) suggest that the Apoon Assemblage experienced multiple episodes of deformation, some of which likely predate that observed within the Endicott Mountains allochthon (the Brookian structures). Along Pyramid Creek (Fig. 8), small scale (0.5 m wide) isoclinally folded beds of sandstone are exposed on the ground along a pavement outcrop (Fig. 13 - A). These small folds bend gray slate and 3 - 10 cm thick sandy beds. They have approximately vertical axial planes parallel to the dominant cleavage, angular hinges, and are crosscut by occasional northwest dipping dolomitic veins. This is markedly different from the broad, nearly upright, open folds seen further up the Pyramid creek drainage (Fig. 13 - C). This other set includes folds that deform a pre-existing foliation within units of mostly slate. The folds are approximately 2 - 10 m wide with rounded hinges and a gentle plunge to the northwest (Fig. 13 - C). South of Pyramid Creek (Fig. 8) an en echelon array of veins define a small normal fault zone separating tuff from slate within the Apoon assemblage (Fig. 13 - B). The clastic portions of the Apoon assemblage (Fig. 13 - D, E, and F) are widely variable lithologiocally and include slates, tuffs, sandstones, and phyllites.

The volcanic/igneous rocks of the Apoon assemblage show a wide variety of textures and field relationships (Fig. 14 A - F). Some clearly intrusive contacts were observed along Pyramid Creek (Fig. 14 - A and B) where sills of andesite, crosscut by veins of quartz and calcite, intruded the gray slates and sandstones of the Apoon clastics (Pzc). South along Boreal Mountain, a large igneous edifice deflects the surrounding phyllitic rocks and contains basaltic-andesite with large laths of plagioclase visible to the unaided eye (Fig. 14 - D). In contrast, the region north of Pyramid Creek is dominated by fine grained basaltic greenstone and only minor slates and clastics (Fig. 14 - F). Along Bombardment Creek, basaltic pillows form a massive (15

- 20 m tall) cliff (Fig. 14 - C). The same area contains out-of-place blocks of brecciated greenstone, which resembles a flow top igneous breccia (Fig. 14 - E).

The downstream portions of Bombardment Creek transect the Ellesmerian Sequence and expose gently folded limestone beds among the Kayak Shale and massive beautifully folded gray Lisburne Limestone high above the creek (Fig. 15). Rare crinoids were observed within the Kayak Shale (Fig. 15 - B). North of Pyramid Creek, along strike of Bombardment Creek, the Lisburne Limestone forms a massive slope south of the North Fork Koyukuk River and exposed bone gray micritic limestone with large black chert nodules (Fig. 15 - C and D).

In the northernmost part of the map area (Fig. 8), the Devonian Hunt Fork Shale outcrops among rolling tan-gray hills north of the North Fork Koyukuk River (Fig. 16). In this area the Hunt Fork dips consistently to the north and northwest; however older published maps suggest that its attitude changes to southeastward dipping strata just north of this study area (Fig 8; Dillon et al., 1986). At the outcrop scale, the Hunt Fork contains tan to brown-black shale and slate interbedded with brown fine grained sandstone and quartzite as well as rare lenses of brown limestone (Fig. 16 - C and D). To the west of the confluence between Ernie Creek and the North Fork Koyukuk River and to south of Shushalluk Creek, the Hunt Fork passes conformably up section into the Noatak Sandstone and Kanayut Conglomerate (Fig. 16 -A and B). The Noatak Sandstone was poorly expressed within a mostly covered interval; however the overlying Kanayut Conglomerate was present as a massive quartz-chert pebble conglomerate within interbedded sandstones (Fig 16 - A). Aerial and satellite imagery was used to supplement field observations and produce the contact relationship seen in Figure 8. This is the approximate location of sample 41DF15 (Kanayut Conglomerate), which was collected for detrital zircon analysis (next section).

The following section contains observations and data from samples collected for detrital geochronology and whole rock major and trace element geochemistry. These data are presented within Figures 17 - 22. All analyzed sample information is presented within the supplementary materials along with information on other samples collected, but not analyzed, during this study. This document focus on samples used for detrital zircon geochronology (six samples) and whole rock volcanic geochemistry (eleven samples), other samples (45 in total) are appropriate for other analyses. These may include assessment of deformational fabrics, Ar-Ar dating of detrital and potentially authigenic white mica along cleavage planes, and laser raman spectroscopy of carbonaceous material (forthcoming thesis by Greg Hammond will address estimates of maximum paleotemperature based on this technique). All samples could benefit from more detailed petrographic analysis, as this was only conducted on a preliminary basis for most samples in the course of the current project.

5.2 Detrital Zircon Geochronology

Six clastic samples (Figs. 8) were collected from the vicinity of the North Fork Koyukuk River in the Gates of the Arctic National Park, AK for laser ablation analysis and detrital zircon geochronology. Samples presented here are organized based on their sampling locations and respective formations. For instance, samples 05DF15 and 23DF15 (Fig. 8) represent the Apoon Assemblage and Kayak Formation respectively. These two samples come from the interior of the Doonerak fenster, definitively below the Amawk thrust. Samples 43DF15 and J1415 (Fig. 8) represent the Beaucoup Formation and come from the complicated northern margin of the fenster, where field relationships and contacts are difficult to decipher and there may be complication by faulted slivers of Apoon, EMA, and/or Hammond Terrane rocks. Samples

41DF15 and 26DF15 (Fig. 8) represent the Hunt Fork Shale and Kanayut Conglomerate respectively and come from the Endicott Mountains allochthon, north of and definitively above the Amawk thrust. The following sections contain details regarding the detrital zircon geochronology of the samples outlined above. All geochronologic data presented in Figures 18-23 and Figures 29-32 contain U-Pb analyses that have met the necessary filtering conditions outlined in the methods section based on concordance and abundance of various U, Th, and Pb isotopes and isotope ratios (e.g. Gehrels, 2014; more details provided in the Supplemental Materials section).

Fenster Interior: Apoon Assemblage and Kayak Shale

Sample 05DF15 is an impure lithic sandstone collected from the Apoon assemblage along a ridge south of Pyramid Creek and to the east of the North Fork Koyukuk River (Fig. 8; 67.861869 N, -150.787034 W). In hand sample and thin section it is poorly sorted and contains subrounded grains of quartz and K-feldspar, masses of microcrystalline quartz, minor chert fragments, and angular volcanic lithic fragments with clasts reaching an approximate maximum size of 0.6 mm (Fig. 17 - A and B). Detrital zircon spectra from 05DF15 (Fig. 18) are based on 96 successful zircon analyses. The maximum depositional age for 05DF15, calculated as a weighted mean of the six youngest zircon grains that fall within error of each other, is 452 ± 13 Ma (MSWD = 0.76). Probability density plots from sample 05DF15 (Fig. 18) show a dominant unimodal peak centered on 504 Ma. Other minor detrital populations are present at 601, 764, 1153 - 1370, 1455 - 1565, 1764 - 1942, 2308, 2500 - 2624, and 2683 - 2875 Ma.

Sample 23DF15 is a sandstone of the Ellesmerian sequence (Kayak Fm.), which was collected from the south side of the North Fork Koyukuk River between its confluence with Ernie Creek and Bombardment Creek (Fig. 8; 67.907896 N, -150.752165 W). It is a moderately sorted sandstone (Fig. 17 - E and F) containing subrounded to angular monocrystalline and polycrystalline quartz grains, with some grains showing undulose, or wavy, extinction within a fine dark matrix. It also sporadically contains throughgoing bands of mica which appear to define cleavage planes and extend along the boundary of some grains (Fig. 17 - F). Detrital spectra from 23DF15 (Fig. 19) are based on 108 successful zircon analyses. The maximum depositional age for 23DF15, calculated as a weighted mean of the six youngest zircon grains that fall within error of each other, is 385.6 ± 8.9 Ma (MSWD $= 0.70$). Probability density plots from sample 23DF15 (Fig. 19) show a dominant polymodal peak centered on 405 and 441 Ma. Other detrital populations are present at 573, 773, 931, 980 - 1250, 1310 - 1470, 1710 - 2160, 2260 - 2410, and 2460 - 2660 Ma.

Fenster Margin: Beaucoup Formation

Sample J1415 is a lithic/conglomeratic sandstone of the Beaucoup Formation, which was collected from an area approximately 10 miles east of the other samples. It was collected by J. Strauss from the east side of the North Fork Koyukuk River, north of the headwaters of Saint Patrick's Creek (Fig. 8; 67.938861 N, -150.427833 W). In hand sample, J1415 contained stretched grains of chert and quartz within a noticeable pervasive fabric. In thin section it contains many small thoroughgoing fractures and veins among subrounded clasts of quartz, plagioclase, with rare mica and opaques (Fig. 17 - I and J). Detrital zircon spectra from J1415

(Fig. 20) are based on 121 successful zircon analyses. The maximum depositional age for J1415, calculated as a weighted mean of the six youngest zircon grains that fall within error of each other, is 360.1 ± 7.4 Ma (MSWD = 0.117). Probability density plots from sample J1415 (Fig. 20) show a dominant unimodal peak centered around 426 Ma. Other detrital populations are present at 360, 507, 835 - 1000, 1203 - 1520, 1610 - 1924, 2373, 2475, 2601 - 2724, 2843, and 3179 - 3280 Ma.

Sample 43DF15 (Fig. 17 - G and H) is a slightly sheared lithic sandstone probably of the Beaucoup Formation (see discussion section), which was collected from the west banks of the North Fork Koyukuk River, south of the confluence with Ernie Creek (Fig. 8; 67.889526 N, -150.935793 W). This unit was mapped as part of the Hunt Fork formation in the field by Dillon et al., (1986) and rests near the Beaucoup - Hunt Fork contact, as drawn in this study. 43DF15 is a fine grained sandstone containing subrounded clasts of quartz and feldspar (Fig. 17 - G and H). It also contains obvious thoroughgoing bands of mica, partitioned onto cleavage planes. The sample was not collected oriented spatially, but grains appear to have rotated slightly within this pervasive banded framework, indicating some component of shear. Detrital zircon spectra from 43DF15 (Fig. 21) are based on 126 successful zircon analyses. The maximum depositional age for 43DF15, calculated as a weighted mean of the six youngest zircon grains that fall within error of each other, is 397.1 ± 6.4 Ma (MSWD = 0.17). A single anomalously young grain (340.4 ± 14 Ma) was not included in this calculation because it does not fall within error of the other youngest grains. Despite careful steps taken to avoid contamination, it is possible that this single grain is exotic to this sample. Therefore, no interpretations were made based on the age of this single grain. It is presented here and within the data tables because there was no impartial means by which to exclude it based on concordance, isotope ratios, or isotope abundances. Probability

density plots from sample 43DF15 show a dominant unimodal peak centered around 420 Ma. Other detrital populations are present at 506, 548, 646, 702, 875, 995-1240, 1600-1830, and 2760 Ma.

Endicott Mountains Allochthon: Hunt Fork and Kanayut Formations

Sample 26DF15 (Fig. 17 - C and D) is a sandstone of the Hunt Fork formation, which was collected from the north side of the North Fork Koyukuk River between its confluence with Ernie Creek and Bombardment Creek (Fig. 8; 67.933120 N, -150.778276 W). Sample 26DF15 was collected from a sandy fraction interbedded among the tan-gray shales/slates of the Hunt Fork. It is a fine grained sandstone containing rounded and subrounded grains of quartz, potassium feldspar, plagioclase, and opaques (Fig. 17 - C and D). Detrital zircon spectra from 26DF15 (Fig. 22) are based on 86 successful zircon analyses. The maximum depositional age for 26DF15, calculated as a weighted mean of the six youngest zircon grains that fall within error of each other, is 372 ± 12 Ma (MSWD = 0.17; Fig. 22). Probability density plots from sample 26DF15 (Fig. 21) show a dominant unimodal peak centered on 429 Ma. Other detrital populations are present at 372, 570, 630, 930 - 1100, 1240 - 1370, 1600 - 2175, and 2375 - 2730 Ma.

Sample 41DF15 is a lithic/conglomeratic sandstone of the Kanayut Formation, which was collected upslope of Shusaluk Creek, to the northwest of the confluence between Ernie Creek and the North Fork Koyukuk River (Fig. 8; 67.918660 N, -150.929762 W). In the field it was collected from a large 10 m x 10 m bounder near the top of the slope. This was done because the

terrain became impassible, but large in place blocks of Kanayut were visible just upslope from where this sample was collected. It is a quartz and chert pebble rich conglomerate with some potassium feldspar and well-rounded clasts held within a sandy matrix (Fig. 16 - A). Detrital spectra from 41DF15 (Fig. 23) are based on 127 successful zircon analyses. The maximum depositional age for 41DF15, calculated as a weighted mean of the three youngest zircon grains that fall within error of each other, is 339 ± 17 Ma (MSWD = 0.19). Three anomalously young grains (shaded gray in Fig. 23) which did not fall within error of each other were not included in calculation of the maximum depositional age (265.2 ± 11 Ma, 283.9 ± 11 Ma, 305 ± 15 Ma). Probability density plots from sample 41DF15 (Fig. 23) show a dominant unimodal peak centered around 428 Ma. Other detrital populations are present at 339, 364, 600, 721, 960, 1120, 1800 - 2000, and 2510 Ma.

5.3 Whole Rock Volcanic Geochemistry

The geochemical trends of volcanic rocks can be used to provide information on the tectonic setting in which they formed (e.g. Pearce, 1983; Tatsumi, 2005). Eleven igneous rock samples from the Apoon assemblage were analyzed for major, trace, and rare-earth element (REE) compositions. The geochemical data presented here is the first to include REE abundances from the Apoon assemblage and complements the work of Julian and Oldow (1998).

Major element data from are shown in the Supplemental Materials section. Data reports from Activation Laboratories (Ontario, CA) are included as well as the loss on ignition (LOI), the volatile abundance driven off during sample fusion. All of the major element abundances were recalculated to 100% without volatiles (H_2O or CO_2) for all pertinent figures and calculations. This was done so that all major element plots compare samples on the same

anhydrous basis, but the raw data is given in the Supplementary Materials section. Not all samples from this study have geochemical compositions that are suitable for use in all of the geochemical plots (i.e. basalt discrimination diagrams were only applied to samples with suitable major element compositions). The samples that contained SiO_2 (wt %) and $CaO + MgO$ (wt %) abundances which prevent them from being classified as basalts or basaltic-andesites by the system of Pearce and Cann (1973) were not included in the basalt discrimination diagrams, but they were included in trace and rare-earth element variation diagrams. These high silica samples include 03DF15 (59.32% SiO_2 norm.), 11DF15 (62.16% SiO_2 norm.), 13DF15 (57.91% SiO_2 norm.), and 33DF15 (60.51% SiO_2 norm.). Among these, sample 33DF15 was distinct due to its ophitic to subophitic texture in thin section and large laths of plagioclase, as such this sample could not be classified as a basalt. Because all samples have experienced hydrothermal alteration and low grade regional metamorphism, emphasis is given to trace and rare-earth element geochemical trends, which are typically less susceptible to alteration than the major elements. As such, fluid-mobile elements (e.g. LILE) are used with precaution.

For comparison, representative basalt samples are presented alongside geochemical analyses in all trace and REE geochemical plots. These include island arc basalts (IABs; Sun and McDonough, 1989), normal and enriched mid ocean ridge basalts (NMORBs and EMORBs; Sun and McDonough, 1989), and ocean island basalts (OIBs; Nye and Reid, 1984).

Basic Classification - Major Elements and Thin Sections

Figure 24 is a total alkali - silica diagram, comparing the abundance of SiO_2 (wt %) and $CaO + MgO$ (wt %) after Le Maitre et al., (2002). The dotted line represents the boundary

between alkaline and subalkaline compositions. The fields marked by solid lines denote IUGS classification of volcanic rock type based on the comparison of these major elements. In general, the Apoon Assemblage contains a diverse suite of igneous rock compositions, spanning ~45 to 64 wt% SiO_2 (Fig. 24). All of the collected samples (n = 11) from the Apoon Assemblage are classified as subalkaline basalts, basaltic-andesites, and andesites. Although two samples plot within the trachy-andesite field, they are still classified as subalkaline.

The five low SiO_2 samples (e.g. ~45-52 wt% SiO_2; 01DF15, 08DF15, 25DF15, 32DF15, and 38DF15) are plotted together (Fig. 26A and 27A). Similarly, the moderate-to-high silica samples (e.g. ~55- 63 wt% SiO_2; 03DF15, 11DF15, 13DF15, 21DF15, 24DF15, and 33DF15), are grouped together in the subsequent variation diagrams (Fig. 26B and 27B). Comparing these classifications to the spatial distribution of these samples (Fig. 8), highlights no discernable trends related to location within the fenster. South of Pyramid Creek sporadic dikes and sills crosscut clastics, including lithic sandstones and phyllites. In areas north of Pyramid Creek, the clastics are less abundant and massive outcrops of flows and pillows are found along Bombardment Creek. These textural and lithologic variations are visible sample-to-sample but the range of major element compositions observed does not follow any discernible spatial or lithologic pattern.

The igneous rock samples of the Apoon assemblage show wide variability in their textures and mineralogical character, ranging from ophitic/subophitic (Fig. 25 - A and B) to glassy and mildly vesicular (Fig. 25 - G, H, I and J). A mild pock-marked, texture was found on some plagioclase laths within sample 33DF15 (Fig. 25 - A and B) is not concentrated on the edge of grains and appears to muddle grain interiors, possibly as a result of some process during crystallization (trapping fluids or gasses). The thin sections also provide some corroborating

evidence of hydrothermal alteration. Many samples (e.g. 38DF15 and 01DF15) showed partial to

extensive replacement of plagioclase feldspar by carbonate. Birefringent carbonate was

ubiquitous across multiple samples, an example of which is visible in Figure 25 C and D. The

birefringent carbonate and replacement of plagioclase is direct evidence for the alteration of

primary mineral phases and suggests that some geochemical trends, especially major element

trends, may have been affected by secondary alteration. Because many of the Apoon Assemblage

rocks show evidence of hydrothermal alteration, fluid-mobile elements (e.g. LILE) are used with

caution. However, these elements, along with other fluid-immobile trace elements (HFSE and

REE) are evaluated in the next section. Greater emphasis is placed on the HFSE and REE

elements. These are viewed alongside the fluid-mobile elements (LILE) for completeness and to

better characterize geochemical trends within the collected rocks.

Variation/Spider Diagrams - Trace and Rare Earth Element Trends

Figure 26 (Trace element; NMORB normalized) and Figure 27 (REE; chondrite

normalized) are variation diagrams for the Apoon Assemblage whole rock geochemical samples,

based on the normalization and plotting scheme of Sun and McDonough (1989). Each of these

figures (Fig. 26 and 27) separates the five low SiO_2 samples (A - top frame) from the moderate

to high SiO_2 samples (B -middle frame) and provides normal mid-ocean ridge basalt (NMORB),

enriched mid-ocean ridge basalt (EMORB), ocean island basalt (OIB), and island arc basalt

(IAB) chemistries (Sun and McDonough, 1989; Nye and Reid, 1986) for comparison (C - bottom

frame). The raw geochemical data used to generate these variation diagrams is provided in the

Supplementary Materials section of this document.

The horizontal axes of Figure 26, the NMORB-normalized trace element variation diagram, lists a series of trace elements organized based on their compatibility within common mineral structures (compatibility increasing to the right). The low SiO_2 samples (01DF15, 08DF15, 25DF15, 32DF15, and 38DF15; Fig 26 A) show a range of chemical trends, but all show enrichment among large ion lithophile elements (LILEs - e.g. Cs, Rb, Ba, Th) with values ranging from 30 to 110 times the concentration found in a NMORB. Some low SiO_2 samples show depletion among the high field strength elements (HFSEs - e.g. Nb, P, Zr, Ti) particularly samples 01DF15, 32DF15, and 38DF15.

The high SiO_2 samples (Fig. 26 B) show some similar trends. All six high SiO_2 samples (~55- 63 wt% SiO_2) display a negative Nb anomaly, meaning the concentration of Nb is less than would be expected from the values of adjacent trace elements on the plot. This is accompanied by depletion among other HFSEs (Ti and Zr) in samples 03DF15, 11DF15, and 33DF15. The negative Nb anomaly is particularly prevalent in samples 03DF15, 11DF15, 13DF15, 21DF15, and 24DF15. Depletion of Rb, Nb, P, and Zr all occur within the IAB representative sample. Among the most compatible trace elements (Y, Yb, Lu), all eleven samples show nearly flat trace element patterns, similar to the patterns of NMORBs and EMORBS.

The NMORB-normalized chemistry of rocks from the Apoon assemblage show similarities to the patterns observed within island arc basalts (IABs) and mid-ocean ridge basalts (MORBs). Specifically, the high-silica Apoon Assemblage samples contains LILE enrichments and HFSE depletions similar to IAB patterns world-wide (Fig. 26; e.g 03DF15, 11DF15,

13DF15, 21DF15, 33DF15, 25DF15). Similarly, some of the low-silica Apoon samples display similarities to MORB trends (Fig. 26; e.g. 01DF15, 08DF15, 25DF15, 32DF15, 38DF15). These are characterized by flat-lying patterns in compatible trace elements in MORB-normalized plots (e.g. Nd, Sm, Eu, Dy, Yb, Lu). No samples showed significant similarity to OIB patterns on NMORB-normalized trace element plots.

Rock/Chondrite

Chondrite-normalized rare earth element (REEs) variation diagrams are a special subset of trace element variation diagrams which capitalize on the unique behavior of the Lanthanide series of elements (La -Lu). Because the Lanthanides systematically decrease in atomic radius with increasing atomic number (La $\rightarrow$ Lu), their partition coefficients and partitioning behavior in igneous systems also vary systematically. Similar to Figure 26, low SiO_2 samples are plotted in the top frame (Fig. 27 A) and followed by the high SiO_2 samples (Fig. 27 B) and representative basalt samples (the same used previously; Fig. 27 C). All composition are normalized to the composition of a normal chondritic meteorite based on the values of Sun and McDonough (1989). Light rare earth elements (LREEs) refers to La, Ce, Pr, Nd. Middle rare earth elements (MREEs) refers to Sm, Eu, Gd, Tb, Dy, and Ho. Heavy rare earth elements (HREEs) refers to Er, Tm, Tb, and Lu.

The chondrite normalized REE variation diagrams from the Apoon assemblage show a wide range of patterns. In general, the low SiO_2 samples display an array of LREE enrichments. Specifically, sample 01DF15 shows a clear enrichment in LREE abundances, while sample 08DF15 shows a dramatically lower LREE abundances. The other low SiO2 samples (e.g

25DF15, 32DF15, and 38F15) have relatively flat REE patterns with LREE to HREE (right side of Fig. 27) abundances approximately 20-30x chondrite. For example, sample 38DF15 shows near parity among the REEs, meaning the abundance of each REE is similar to the others when normalized to chondritic compositions generating a relatively flat pattern. Its pattern most closely resembles that of the EMORB, which has very mild enrichment among LREEs and approximant parity across the MREEs and HREEs.

The high SiO_2 samples all show enrichment of the LREEs relative to the MREEs and HREEs. The LREEs in these samples range from ~20 to ~110 times the amount expected in chondritic meteorites. All high SiO_2 samples show flat patterns among the HREEs, similar to the patterns of both NMORBs and EMORBs. Five samples show anomalously low concentrations of Eu as compared to its adjacent REEs (38DF15, 33DF15, 24DF15, and 13DF15), a feature commonly attributed to the fractionation of plagioclase (see Section 6; discussion). Two samples (03DF15, 11DF15) show LREE and MREE patterns which resemble the composition of OIBs, but they have considerably different HREE patterns compared to OIB. One difference is the slight positive Eu anomaly within the OIB sample, which is noticeably different from the minor negative Eu anomaly within 03DF15 and 11DF15. These samples show similarities to both OIBs and highly LREE enriched IABs. Three samples (13DF15, 21DF15, and 24DF15) show LREE and MREE patterns which most closely resemble the chemistry of IABs.

Ti - V ratios

The Ti-V diagram of Shervais (1982) capitalizes on variation in the behavior of Ti and V as a product of differences in their partition coefficients. Because V is found in both reduced (V

3+) and oxidized states (V 4+, and V 5+) within magmas and Ti is not (only exists as Ti 4+), the proportion of V:Ti can serve as a proxy for the oxygen activity and fractional crystallization processes, which took place in a magma at the time of eruption. Shervais (1982) related this to the tectonic environment of eruption. Because Ti and V are generally immobile under hydrothermal alteration and intermediate metamorphic conditions, this method allows determination of tectonic setting from ancient rocks.

Figure 28 shows the Ti - V diagram of Shervais (1982) with data from the Apoon assemblage superimposed. The gray area marks the field of data from Julian and Oldow (1998) for comparison. Samples from this study plot within the island arc tholeiite and back arc basin MORB fields, and show considerable compositional overlap with the data from Julian and Oldow (1998). Only those samples which classified as basalts and basaltic andesites were included in this figure because the complexities of more highly evolved magmas can affect the proportion of Ti and V by other means (as per Shervais, 1982).

6. DISCUSSION

6.1 Field Relations and Overview

The Apoon assemblage has been tentatively related to a volcanic arc setting for four decades based on sparse and incomplete data (Dutro et al., 1976; Mull et al., 1987; Julian, 1989; Julian and Oldow, 1998). The relative inaccessibility and complicated field relationships within the Doonerak fenster have prevented conclusive determination of the tectonic setting in which the Apoon assemblage formed. Only small portions of the fenster have been studied in any

appreciable detail and its stratigraphic and structural architecture is complex and difficult to decipher. One goal of this research was to provide evidence to help constrain the setting in which the Apoon assemblage formed and test the possibility that rocks exposed in the Doonerak fenster are the remnant of an island arc complex, which could be related to the suture between Laurentian and non-Laurentian portions of Arctic Alaska. We also aimed to better understand the provenance of the Apoon assemblage and Ellesmerian Sequence within the fenster relative to the rocks of the Endicott Mountains allochthon and Hammond subterrane, which structurally overlie the fenster within the Brooks Range. The data presented in section 5 provides new insight into the origins of these sequences and, when placed in the context of other recent regional studies, corroborates the interpretation that the Apoon assemblage is the remnant of an island arc complex. The new data also highlights significant outstanding issues concerning the structure and stratigraphy of the Apoon assemblage and some regional relationships.

The updated geologic map and cross section of the North Fork Koyukuk River along the northern margin of the Doonerak fenster in the central Brooks Range (Fig. 5, 8 and 9) make several alterations from previous interpretations. Some notable changes include (1) treatment of the Apoon igneous sequence, Pzv, as two different units - Pzv intrusives and Pzv flows, which are mapped collectively with Pza in keeping with Strauss et al. (2017), (2) the extension of Pzp, the Apoon phyllitic unit, to the east along strike of where it was mapped by Strauss et al. (2017) in the southernmost portions of the map area, (3) the presence of an inferred thrust fault in the southern region to accommodate juxtaposition of Pzp against Pzv intrusives and Pzc, the Apoon clastics, (4) the grouping of several small discontinuous map units of Brosge and Reiser (1960, 1971) and Dillon et al., (1986) into the Beaucoup Formation along the northern margin of the fenster in the hanging wall of the Awawk thrust, (5) the differentiation of the Kayak and

Lisburne Formations along the southern banks of the North Fork Koyukuk, and (6) extension of the Hunt Fork - Endicott Group contact south of Shushalluk Creek in the northwest portion of the map area based on recognition of the Noatak and Kanayuk formations in that location.

Data from six samples of sandstone analyzed for detrital zircon geochronology from the vicinity of the North Fork Koyukuk River in the Gates of the Arctic National Park are summarized in Figure 29. Placing this data into context requires consideration of potential source regions, which may have contributed primary igneous and metamorphic zircon grains as detritus and potential sources of recycled detrital grains. Detrital spectra from particular regional map units allows for comparison to data from the same formations elsewhere and comparison to regionally associated units from elsewhere in the circum-Arctic. Unpublished detrital geochronologic data from elsewhere in the central Brooks Range was provided by E. L. Miller (Stanford) and V. Pease (U. of Stockholm) for comparison to relatively proximal portions of the Brooks Range (Fig. 30). These data come from the John River, an area also within the Gates of the Arctic National Park, but about 50 km west of the North Fork Koyukuk River. The John River transect samples include some of the same stratigraphy, the Beaucoup and Hunt Fork formations, but come from the Endicott Mountains allochthon and Hammond subterrane and also contain the Sillyasheen formation of the Hammond subterrane. Other detrital zircon data from the Apoon assemblage, Ellesmerian Sequence, and Trembly Creek phyllite (Fig. 31) allow for direct comparison of map units in the vicinity of the North Fork Koyukuk, within the Doonerak fenster from Strauss et al. (2017). These provide the most direct comparison to associated strata from within and near the Doonerak fenster. Lastly, a suite of detrital spectra from elsewhere in the Arctic (Fig. 32; NE Brooks Range, Canadian Arctic, and Svalbard) allow for comparison of regional trends in provenance.

6.2 The Beaucoup and Hunt Fork Formations: Hanging wall of the Awawk Thrust

The Beaucoup Formation and Hunt Fork Shale are widespread Late Devonian units of conglomerate, shale, slate, sandstone, and siltstone that are ubiquitous across much of the Brooks Range (e.g. Tailleur et al., 1967; Dutro et al., 1979; Moore et al., 1994). Their heterogeneity in terms of lithostratigraphy and provenance, although recognized, is poorly defined. Along the northern margin of the Doonerak fenster near the North Fork Koyukuk River, discontinuous units of sandstone, sheared green-purple conglomerate, wacke, shale, and slate have been assigned to both of these units by previous mappers (Dillon et al., 1986; Brosge and Reiser, 1961 and 1971). Herein, we define the contact where the fissile gray-tan shales/slates of the Hunt Fork become the dominant lithology (Fig. 8). This ascribes the complicated package of interbedded and folded conglomerates, wacke and sandstones to the Beaucoup Formation. What is herein defined as the Beaucoup also includes the well-foliated, sheared green-purple quartz and chert pebble conglomerate found near the confluence of the North Fork Koyukuk River and Ernie Creek (Fig. 8 and 16; previous section).

Some previous workers have also suggested that these units along the northern margin of the Doonerak fenster might fit better into formations of the Hammond Terrane particularly the Trembley Creek phyllite, which is recognized along the southern margin of the fenster (Strauss et al., 2017) and could have continuity to its northern side; however that assertion is not well borne out in the new data. Samples 43DF15 and J1415 both come from this complicated border zone in the hanging wall of the Amawk thrust. Sample J1415 is a sheared green-purple conglomerate definitively from the Beaucoup Formation; however, 43DF15 was a dark lithic

sandstone found in close proximity to the thinly bedded brown slates of the Hunt Fork Shale. In the field 43DF15 could arguably be assigned to either the Hunt Fork or the Beaucoup although it is most similar to the Beaucoup Formation. This ambiguity complicates interpretation of its unique detrital zircon spectrum (Fig. 31 and 21), which bears similarities to the other Beaucoup sample (J1415) and the Hunt Fork sample (26DF15); however, it is largely dissimilar to the Trembley Creek phyllite (Fig. 5) sample from Strauss et al. (2017), which completely lacks the otherwise prominent 440 Ma centered population in the other samples and has a greater abundance of 800 - 550 Ma zircons and other Precambrian populations.

Comparing these detrital zircon spectra highlights several similarities and differences between various formations. In regard to the calculated maximum depositional ages, none of these three formations produce anomalously young maximum depositional ages; however, it is curious that the youngest detritus within 26DF15 (Hunt Fork; Fig 22) is actually older than the youngest detritus within J1415 (Beaucoup; Fig. 20) because the Beaucoup is stratigraphically below the Hunt Fork (see Fig. 5). Both produce Late Devonian maximum depositional ages which fall within error of each other and are in concert with the stratigraphic age of both these formations. The fact that their maximum depositional ages fall within error of each other, prevents any major claims based solely on this; however, sample 43DF15 generates a maximum depositional age of 397.1 ± 6.4 Ma (Early Devonian) and therefore has a distinct detrital signature, and could be older than both J1415 and 26DF15. It is important to state explicitly that this does not necessarily mean 43DF15 is Early Devonian in depositional age, just that the youngest detrital zircon it contains are Early Devonian. It could still have been deposited in the Late Devonian, consistent with the Beaucoup stratigraphic age. 43DF15 also contains a minor

peak at 506 Ma, similar to one seen within J1415 (Beaucoup Formation), which is the same age as the dominant unimodal peak within sample 05DF15 (Apoon assemblage).

When considered relative to the Hunt Fork, Sillyasheen, and Beaucoup Formations of the John River transect (Fig. 30), sample 43DF15 bears similarities to all three, but more closely resembles the Beaucoup Formation than the Hunk Fork Shale based on the position of its prominent Caledonian population and the presence of some 800 – 550 Ma (Timanian) zircons. Ultimately the detrital spectra and lithologic characteristics of 43DF15 are more similar to the Beaucoup Formation, and it is therefore included within the Beaucoup Formation rather than the Hunt Fork Shale.

It is important to note another significant aspect of 43DF15, which makes it similar to the Trembley Creek phyllite in some respects. Figure 31 compares the samples of this study to those from Strauss et al. (2017). Strauss et al. (2017) analyzed one sample from the Trembley Creek phyllite of the Hammond subterrane from the southern margin of the Doonerak fenster. Interestingly, this sample contained a prominent population centered on 504 Ma, the exact same age as the major population found in 05DF15 (Apoon Assemblage). The Trembley Creek phyllite sample also contains a significant population centered on 635 Ma, a Timanian age, and accessory populations consistent with various Proterozoic detritus common to Laurentian rocks. Notice that sample 43DF15 contains a distinct population of 550 - 800 Ma zircon, which is also present within the Trembley Creek phyllite and is rare among other samples (Fig. 31; some rare grains of this age are present within the Endicott Group of this study and of Strauss et al., 2017). Detrital spectra of that age could be the result of detritus from the Timanian orogen of northern Baltica (see Fig. 2). This indicates that both 43DF15 (Beaucoup) and the Trembley Creek phyllite likely received some portion of their detritus from the Timanian orogen.

That said, the dominant population within 43DF15, a Caledonian age peak centered on 420 Ma, contains the vast majority of zircon from that sample. The complete lack of this population within the Trembley Creek phyllite indicates that these cannot possibly be from the same formation. While they may both contain some Timanian detritus, they are not from the same formation. The detrital zircon spectrum of sample 43DF15 is most similar to the Beaucoup Formation (see section 6.3 and 7 for more on the relationship to the Trembley Creek sample and the Timanian orogeny).

6.3 The Apoon Assemblage and the Endicott Group

Sample 05DF15 was collected from the volcaniclastic portion of the Apoon assemblage (Pzc of Julian and Oldow, 1998) south of Pyramid Creek and contains a dominantly unimodal detrital zircon spectrum (Fig. 18). A prominent peak centered on 504 Ma (Cambrian) contains ~75% of the zircon analyzed from this sample. The youngest grains from 05DF15 generate a maximum depositional age of 452 ± 13 Ma (Ordovician). Detrital populations of this same age appear as minor constituents in several other samples, J1415 and 43DF15, potentially indicating that minor amounts of Apoon detritus were recycled into the Beaucoup Formation or that the Beaucoup Formation received some portion of its detritus from the same regions as the Apoon itself.

Several interesting characteristics emerge when 05DF15 (Apoon; Fig 18) is compared to the detrital samples of Strauss et al. (2017) (Fig. 31). First, none of the Apoon samples from their study contain the same unimodal population (504 Ma centered population). Instead, their samples contain prominent peaks centered on ~440 Ma, ~ 475 Ma, ~483 Ma, or ~493 Ma. Their

aggregated Apoon Assemblage spectrum (Fig. 31 - B) has a prominent peak centered on ~480 Ma, noticeably younger than 05DF15's major population at 504 Ma. The samples they collected from the Apoon Assemblage Pzc unit, approximately along strike 05DF15, contain the same minor accessory peaks as 05DF15; however, they lack the 504 Ma population and instead contain younger (Ordovician-Silurian) major populations. One sample contained major populations both younger and older than that observed in 05DF15 (475 Ma and 540 Ma), but it still lacked detritus similar in age to the 504 Ma peak. Within the Apoon Assemblage phyllitic unit, Pzp, they recorded two samples. One contained a 440 Ma population and a complete lack of other detritus. The second contained a dominant population centered on 493 Ma (~80% of the sample) with minor populations at 570 Ma and 429 Ma.

When 05DF15 is considered in conjunction with all the samples from Strauss et al. (2017), the nomenclature of Julian and Oldow (1998) is brought into question. While their subdivisions of the Apoon assemblage are useful inasmuch as they provide helpful lithostratigraphic divisions of the broader succession, they cannot be clearly defined in terms of their age relationships. Julian and Oldow (1998) acknowledged that these units could overlap in age, but this results in the grouping of units in the field, which vary in age by up to 50 my and potentially over simplifies complex relationships. Despite their shortcomings, these subdivisions remain the most useful and practical subdivisions of the Apoon assemblage currently available and Figure 8 carries this nomenclature into the north-central portion of the fenster, in keeping with Strauss et al. (2017) to the east. This study only analyzed the detrital spectrum from one Apoon sample, 05DF15. Strauss et al. (2017) analyzed only five. The spectra of 05DF15 is markedly different from any of those five samples. This highlights the significant shortcomings in our current divisions of the Apoon assemblage. The full diversity of Apoon clastics has not

been sufficiently described. Future work should focus on analyzing a broader suite of Apoon siliciclastics to better define the range of ages present and to provide more useful subdivisions. As it currently stands, multiple non-age-equivalent map units are likely grouped together, misrepresenting the complexities of the Apoon Assemblage in both structure and stratigraphy.

Finally, apart from a greater abundance of Grenville and other Proterozoic detritus, the Endicott Group spectra of Strauss et al. (2017) are very similar to the Kayak and Kanayut curves from samples 23DF15 and 41DF15 respectively (Fig. 31 - A). Strauss et al. (2017) only sampled the Endicott Group within the Doonerak fenster. The similarity to sample 41DF15, which comes from the Endicott Group (Kanayut Formation) of the Endicott Mountains allochthon, implies that by the time these units were deposited (Mississippian) the Endicott Group of the Doonerak fenster and the Endicott Group of the Endicott Mountains allochthon were receiving detritus from similar areas. Recall that the rocks of the Endicott Mountains allochthon did not achieve their current structural position, in fault contact above the rocks of the Doonerak fenster, until the Mesozoic Brookian orogeny. Therefore, by Mississippian time rocks of the Endicott Mountains allochthon and those unconformably atop the Apoon assemblage were likely being deposited in the same broad system, prior to emplacement of the Endicott Mountains allochthon.

6.4 Circum-Arctic Comparisons and Paleotectonic Setting of the Apoon Assemblage

Understanding the similarities and differences between the detrital zircon spectra of rocks of the Doonerak fenster relative to other rocks in the Brooks Range is important for correlation of widely distributed map units. It does little, however, to help elucidate connections to other regions of the circum Arctic, which is necessary to inform paleogeographic models. Figure 33

illustrates two possible paleogeographic reconstructions of circum-Arctic terranes during the late

Ordovician (~450 Ma), at the approximate time of deposition of the Apoon siliciclastics (sample

05DF15 maximum depositional age 452 ± 13 Ma). Two lines of evidence from this study can be

used to evaluate such models and potentially help discriminate between them: (1) the comparison

of detrital spectra to regional sediment sources and (2) the use of the whole rock geochemical

data to help determine the paleotectonic setting in which the Apoon assemblage formed.

Limited evidence has been used to suggest that the Apoon assemblage formed in an arc

setting for several decades (see section 3), but the data was inconclusive and did not provide

exclusive determination of the Apoon's paleotectonic setting (e.g. Julian and Oldow, 1998). The

new whole rock geochemical data herein provides an independent line of evidence to help

determine the tectonic setting in which the Apoon Assemblage volcanics formed and can be

compared to previous work to either corroborate or refute the assertion that the package formed

as part of an island arc. Recall that at least some of the Apoon igneous rocks were dated to

between 520 ± 17 Ma and 373 ± 17 Ma by K-Ar and Ar-Ar analysis of hornblende in mafic

dikes crosscutting the Pzc unit (Dutro et al., 1976), therefore the reconstructions of Figure 33

represent a time when the Apoon volcanic units were still likely forming. Therefore the

geochemistry of these volcanic units can be used to assess the validity of these paleogeographic

reconstructions.

Trace element geochemistry is only useful for determining the tectonic environment in

which a rock formed if we make some assumptions about the geological processes which control

the distribution of trace elements in different tectonic settings. Some such processes are well

understood and their effects on trace element distribution in magmas is well defined; however,

the inherently incomplete nature of our understanding of chemical behavior of magmas

introduces uncertainty into deciphering the geological processes capable of generating any given trace element distribution. That said, several fundamental processes must be considered to determine which trace elements and trace element ratios provide the most reliable information about the environment in which an igneous rock formed. All rocks exposed to hydrothermal and metamorphic conditions have experienced some amount of element mobility. As such, high field strength elements (HFSEs), such as, Zr, Hf, Ti, Nb, Ta, and P (Pearce, 1983) which are immobile up to moderate metamorphic conditions are more reliable than their low field strength counterparts. Other elements are also commonly immobile (Co, Ni, V and Cr), but the degree of mobility of all elements is complicated by particular mineral phases capable of incorporating them and various fluid controls (Humphries, 1984). A special case of element mobility occurs in subduction zones, where dehydration of the subducted oceanic slab causes metasomatic reactions which mobilize some elements (Sr, K, Rb, Ba, Th, Ce, P, and Sm) which may be immobile under other conditions (Pearce, 1983; Tatsumi, 2005). This affects the composition of both the magma expelled from arc volcanoes, derived from the overlying mantle wedge, and the residual components of the slab. In terms of this study, which provides relatively little complementary evidence to understand how particular volcanic rocks are related to each other in the field, it is difficult to know if different samples are part of the same cogenetic suite or if they come from different sources entirely. Regardless, we must consider the affect any petrological process would have on the trace element distribution of both a partial melt and a residual solid.

The major element geochemistry of all rocks analyzed from the Apoon assemblage characterize them as part of the sub-alkaline series and define them as various basalts, basaltic-andesites, andesites, and minor trachyandesites based on their proportions of silica to total alkalis (SiO$_2$ to Na$_2$O+K$_2$O) after Le Maitre et al. (2002). While this simple classification helps

illustrate the range of rock types present, it does not help assign them to a particular tectonic environment, because basalts and andesites are common to multiple tectonic settings.

The NMORB normalized trace element diagrams (Fig. 26) highlight enrichment in highly incompatible trace elements, especially in the samples with the greatest abundance of SiO_2. Large ion lithophile elements (LILEs; e.g. Cs, Rb, Ba, Th) are enriched to between 50 and 1000 times the composition of a NMORB in the high SiO_2 samples. Those same elements are enriched, but to a lesser extent, in the low SiO_2 samples. Nearly all samples show depletion among HFSEs (e.g. Nb, P, Zr, and Ti), especially in Nb. Such depletion in HFSEs is characteristic of magmas from arc settings because HFSEs can be left within the down-going slab as other trace elements are liberated during dehydration and incorporated into the overlying mantle wedge, ultimately being incorporated into the magma of arc volcanoes (e.g. Tatsumi, 2005). Conversely, the patterns of the most compatible trace elements (e.g. Y, Yb, Lu) are similar to normal and enriched MORBs across all samples (flat lying patterns to the right side of Fig. 26).

On the whole, the Apoon Assemblage volcanic rocks cover a wide range of REE geochemical trends, even among samples with similar SiO_2 abundances, which classify as the same rock type based on their total alkali-silica compositions (Fig. 24). Samples 01DF15 and 08DF15 both classify as basalts based on their total alkali-silica abundances and come from relatively proximal locations within the field area south of Pyramid Creek (Fig. 8). Despite these similarities, these samples (01DF15 and 08DF15) have entirely different REE patterns (Fig. 27 - A). 08DF15 is depleted in the LREEs relative to the MREEs and HREEs, while 01DF15 is enriched in the LREEs relative to the MREEs and HREEs. These two samples are indistinguishable in terms of their textures, basic minerology, and major element compositions,

so these REE differences cannot be explained as a product of differences in rock type. Such variation in REE trends among otherwise similar rocks could be explained by small degrees of partial melting, which would preferentially liberate LREEs into the melt phase. Ultimately this could result in the residue and the melt phase forming two different rocks with mirrored REE patterns, as seen in 01DF15 and 08DF15. That said, because there is no age constraint on either of these samples and their field relationships are ambiguous it is not possible to determine if these two samples are in fact genetically related. The same geochemical trends could result from the melting of two different initial sources.

The high SiO2 samples (Fig. 27 - B) are all highly enriched in LREEs (03DF15, 11DF15, and 33DF15) relative to the MREEs and HREEs, ranging from 20 to 110 times the composition of a normal chondrite. Samples 03DF15 and 11DF15 (Fig. 27 - B) have geochemical trends and relative abundances of LREEs, MREEs, and HREEs that most closely resemble the ocean-island basalt (OIB) representative sample (Fig. 27 - C). Other high SiO_2 samples demonstrate some direct similarities to island arc volcanic rocks (IAB representative basalt in Fig. 27 - C) especially among the LREEs and MREEs in samples 13DF15, 21DF15, and 24DF15 (Fig. 27 - B).

Eight of the eleven samples also show a negative Eu anomaly - depletion of Eu relative to its adjacent REEs (Sm and Gd). Europium anomalies are controlled by the precipitation of feldspars from the melt because divalent Eu is easily incorporated into plagioclase, whereas other REEs (trivalent) are incompatible within the structure of feldspars. A melt can attain a negative Eu anomaly, as seen in many Apoon igneous samples, by the removal of feldspar by fractional crystallization or by the partial melting of a rock in which feldspar, laden with Eu, is retained in the source. At least one sample (25DF15) has a positive (rather than a negative) Eu anomaly,

which could result from the exact opposite scenario, if that sample were derived from a rock with abundant feldspar laden with Eu. As before, without age constraints and better defined field relationships it is not possible to confidently know if these samples are genetically related, but it is at least conceivable that 25DF15 (positive Eu anomaly) represents the residue from which the other samples (with negative Eu anomalies) might have been derived by partial melting. This further highlights the great range in REE geochemical trends found within igneous rocks of the Apoon Assemblage and suggests that the tectonic setting in which these rocks formed must be capable of producing a sufficiently wide range of geochemical trends. As a general rule, volcanic arcs and subduction zones are more capable of producing such a wide range in trace and REE trends than other tectonic settings (e.g. Bacon et al., 1997; Tatsumi, 2005).

Another high SiO_2 sample, 33DF15 (Fig. 27 - B), is also best explained through formation in an arc setting. Although 33DF15 has an overall higher REE pattern, meaning all REE occur in greater abundances than in the other samples, this could be explained by very small partial melts or considerable amounts of fractional crystallization. The overall shape of 33DF15's REE pattern is still consistent with that of the island arc basalt (IAB; Fig. 27 - C) representative sample, potentially indicating a wet and oxidized setting where plagioclase is not strongly crystallized (small Eu anomaly).

The depletions in high field strength elements (HFSEs) observed within the NMORB normalized diagram also suggests formation within an island arc setting. HFSEs are often retained within particular mineral structures and often not incorporated into the overlying mantle wedge along subductions zones, leading to a relative lack of some HFSEs in the magma of arc volcanoes as compared to the abundance of other trace elements. Niobium (Nb) is particularly useful in this regard because its abundance is not often controlled by the presence of any

particular mineral phase that might preferentially incorporate it, so if Nb is depleted relative to other trace elements it is best explained by formation in a subduction zone related tectonic setting, where Nb can be sequestered within the down going slab. Highly prevalent negative Nb anomalies occur within eight of the eleven samples analyzed from the Apoon Assemblage, further suggesting formation within an island arc tectonic setting.

Placing this information into context alongside the Ti:V ratios of the Apoon samples (Fig. 28) begins to highlight the strong likelihood that the igneous portions of the Apoon assemblage are likely derived from a subduction-related tectonic setting. Fig. 28 suggests formation within either an arc setting or a mixed back arc basin setting based on the proportion of Ti:V within these rocks, which occurs as a result of the oxygen activity and fractional crystallization processes within a magma chamber (Shervais, 1982). This in conjunction with the trace and REE data, further corroborates the formation of the Apoon in an arc setting.

It remains difficult to differentiate between the potential of either an island arc or a continental arc based on these chemical trends alone; however, the clean unimodal detrital zircon populations from Apoon Assemblage sample 05DF15 indicates that most detritus was contributed from a proximal source and that only a minor proportion came from some continental margin. This supports the idea that these rocks formed, at least initially, in a relatively isolated paleogeographic setting, which is more consistent with an island arc rather than a continental one. Additionally, some features within the Apoon rocks indicate subaqueous extrusion of magma during their formation (pillow basalts along Bombardment Creek; Fig. 15). This potential arc system could have been influenced by dry asthenosphere magmas, which could help form the MORB like geochemical trends, or by the subduction of non-typical oceanic crust (e.g. an ocean island or seamount), which could result in some of the ocean-island basalt like

geochemical trends. Those complexities cannot be determined from this data alone, but the diversity among the trace and rare earth elements seen within the Apoon assemblage is best explained by its formation within an island arc setting.

Other geochemical and isotopic evidence corroborates an island arc interpretation for the oridin of the Apoon Assemblage. Strauss et al. (2017) conducted U-Pb analysis on a set of igneous zircon from a leucogabbro within the Apoon assemblage in order to corroborate previous dating of the volcanic units (Fig. 6). The age Strauss et al. (2017) found fell within the range of previously published ages (462 ± 8 Ma; Ordovician); however they also conducted Hf isotopic analysis on the zircon grains and calculated highly positive ε Hf values (ε Hf = + 13), which suggest a distinct lack of crustal assimilation and corroborate the idea of these rocks having formed in an island arc setting. This strongly suggests that the rocks of the Apoon Assemblage had limited crustal influence, at least from ancient continental crust. Additionally, they found similar ε Hf values within their Ordovician age detrital populations from the Apoon Pzc unit. Again, this suggests that these clastics were receiving detritus from a highly juvenile source. Collectively, this data and the geochemical data presented herein indicate conclusively that the Apoon assemblage formed as part of an island arc complex, which could have persisted for tens of millions of years based on the range of depositional ages found from the Apoon assemblage, but more data is needed to fully address that.

We have demonstrated that sample 05DF15 contains a prominent unimodal detrital zircon population centered on 504 Ma (Cambrian; Fig. 29) and has a maximum depositional age of 452 ± 13 Ma (Ordovician). Strauss et al. (2017) demonstrated that detrital spectra from other samples of the Apoon assemblage contain prominent youngest peaks centered on ~ 475 Ma, 478, 483, 429, and 440 Ma (Fig. 31). This alone indicates that the Apoon assemblage was deposited

within a long lived depocenter, which must have persisted for 40 - 50 my. Apoon samples from Strauss et al. (2017) contain diagnostic accessory peaks (980 - 1200 Ma; 1300 -1500 Ma, 1600 - 1800 Ma, 2600 - 2800 Ma) that are suggestive of detritus from the Laurentian margin (Grenville, Pinwarian, Superior craton, ect.).

Additionally, a sample of the overlying Kayak Formation (23DF15) from this study and the Endicott Group of Strauss et al. (2017) contain prominent Caledonian age peaks centered on ~ 420 Ma (Fig. 31). Recall that sample 43DF15 (max depositional age 397.1 ± 6.4 Ma), which was assigned to the Beaucoup Formation, contains a prominent unimodal Caledonian age peak and significant amounts of Timanian age detritus (Fig. 21). This means that between the time of deposition of the youngest Apoon sample known (~ 420 Ma max depositional age; J1427 of Strauss et al. (2017)) and deposition of sample 43DF15 sedimentary provenance changed in several ways. There was an increase in the amount of Timanian detritus and the appearance of Caledonian age spectra all alongside typical Laurenitan spectra (Grenville, ect.). This change in provenance occurred between the deposition of these units; however, because the Beaucoup sample (43DF15) could have been transported a great distance during Brookian thrusting it is difficult to know how to fit this into a paleogeographic context.

Elsewhere in the Arctic, along the Varanger Peninsula (Fig. 1 and 2) of the northern Baltic states, Caledonian and Timaninan rocks are sutured together (e.g. Gee and Pease, 2004 and references therein). The coexistence of Timanian and Caledonian age detritus within 43DF15 (Beaucoup Formation), indicates that there may be continuity of this suture on the Alaskan side of the Arctic.

Caledonian age (Laurentian side) and Timanian age (Russian side) detritus is similarly ubiquitous across much, though not all, of the circum-Arctic and allows for comparison to the

units from this study (Fig. 33). Zircon between ~ 990 - 820 Ma from the Clarence River Group of the NE Brooks Range (Johnson et al., 2016) are mostly absent from samples collected along the North Fork of the Koyukuk River except for minimal sporadic grains. Tentative links between rocks of Doonerak and those of the northeast Brooks Range have been discussed for several decades (e.g. Moore, 1987; Moore et al., 1994; 1997) because broadly coeval mafic volcanic rocks of the Whale Mountain area (Fig. 1 and 2) have similar chemistry to those at Doonerak (Moore, 1987) and are similarly enigmatic. Zircon of this ~990 - 820 Ma range are not common however, and are thought to be related to the collapse of the Grenville orogen, related to rocks in the Central Gneiss Belt of Ontario, CA (Ketchum et al., 1998), the East Greenland Caledonides (Kalsbeek et al., 2000; Watt et al., 2000), the Canadian Arctic and Svalbard. The presence of these in the northeast Brooks Range and general lack of them in the Apoon samples (and others) at Doonerak suggests differences in the sediment pathways between Doonerak and the Whale Mountain area (Fig. 1 and 2).

Early Neoproterozoic (1000 – 541 Ma) magmatic rocks have also contributed detritus to the peri-Laurentian terranes of the Canadian Arctic and Greenland, including Pearya (e.g. Trettin, 1987) and Svalbard (e.g. Gee et al., 1995; Johansson et al., 2004, 2005). Connections between Pearya, Svalbard and possibly the northeast Brooks Range are apparent (Fig 33), but the same cannot be said for the Apoon assemblage rocks of Doonerak. The prominent peak of the Apoon sample (05DF15) is slightly older than those associated with most other locales and generally lacks the accessory peaks which draw links to Svalbard, Pearya, and the Clements Markham Belt of Ellesmere Island (Canadian Arctic) (See Fig 1. for locations). This implies that while 05DF15 was being deposited (452 ± 13 Ma) there were only limited similarities in the sediment pathways between these landmasses. That said 05DF15 does contain some older

accessory peaks which link it to the Laurentian margin to some degree. Yet, the age of 05DF15's major peak (504 Ma) is rare among Laurentian rocks. Regarding the paleogeographic implications, there is admittedly limited data to support or refute either model proposed in Figure 33; however, the general dissimilarities between the detrital spectra of the Apoon as compared to those of Pearya, Ellesmere Island, northwest Svalbard, and southwest Svalbard more closely support Model A "Peri-Baltica" over Model B "Peri-Laurentian."

The unimodal Apoon sample from this study (05DF15) suggests that a geographically isolated island arc existed during the Cambrian and generated significant amounts of detritus, which was deposited to form some of the older Apoon siliciclastics. The increasing proportion of Laurentian affinity detritus within younger Apoon samples from Strauss et al. (2017; Fig. 31) indicates that this arc progressively approached the continental margin of Laurentia. All of the Devonian and Mississippian age rocks from this study (Beaucoup Fm., Hunt Fork Shale, Kayak Shale, Kanayut Conglomerate) contain prominent, generally unimodal, Caledonian age peaks within their detrital zircon spectra, which is evidence for an accretionary event. Some samples from this study, including the younger Mississippian age rocks (Kayak Shale, Kanayut Conglomerate), contain both Caledonian and Timanian detritus (both sides of the orogen) and likely reflect a post accretionary overlap assemblage. The Trembley Creek phyllite sample of Strauss et al. (2017) mostly lacks the Caledonian age peak, which could be explained by derivation from the passive margin side of this orogen.

7. CONCLUSIONS

This study aimed to provide evidence which would place the Doonerak fenster into greater context. One goal was to determine the tectonic setting in which the Apoon assemblage

of the Doonerak fenster formed. Whole rock volcanic geochemistry, including trace and rare earth elements, was applied to igneous rocks of the Apoon assemblage and provides clear evidence for formation within a subduction zone related tectonic setting, likely an island arc. Another goal of this study was to constrain the sedimentological links between rocks of the Doonerak fenster and the Endicott Mountains allochton. Detrital zircon geochronology was applied to the Apoon Assemblage and Kayak Formation within the Doonerak fenster and to the Endicott Group of the Endicott Mountains allochthon. These data highlighted a major change in provenance from the Apoon assemblage (05DF15) to the overlying Carboniferous rocks of the Ellesmerian Sequence and showed the coexistence of detritus from the Caledonian (Laurentian) and Timanian (Baltican) orogens. Together these data help constrain the origins of the Apoon assemblage and highlight the Doonerak fenster as a probable location for the boundary between Laurentian and non-Laurentian rocks within Arctic Alaska. Several new conclusions (below) can be drawn from these data:

- The Apoon assemblage likely formed along a subduction zone as part of an island arc complex. HFSE depletions and enrichment among LREEs and MREEs suggest formation along an island arc. Although there is a considerable amount of geochemical variability within the Apoon Assemblage, many of the analyzed rocks contain chemistries similar to patterns observed within IAB and MORB world-wide. An arc interpretation is also supported by the Hf isotopic data of Strauss et al. (2017).
- Caledonian age detritus was the dominant source of clastic material for all units except the Apoon assemblage, suggesting that the Doonerak arc initially formed in a different and relatively isolated paleogeographic setting, fed by a proximal arc. The near complete

lack of detritus from other sources (i.e. minimal presence of zircon from other populations; general lack of Grenville and other Laurentian sources) within 05DF15 indicates it formed in this isolated setting, where most detritus feeding 05DF15 was proximal. This change in provenance among the overlying units is evidence for an accretionary event which occurred between the time of deposition for sample 05DF15 (Apoon; 452 ± 13 Ma) and the other clastic samples of this study, all of which contain ~ 420 Ma centered populations (Caledonian detritus).

- The Apoon volcaniclastics were deposited in a long lived (50 my +) depocenter based on the range of depositional ages from the Apoon assemblage.

- Portions of the Apoon assemblage received detritus from similar source regions as the Beaucoup Formation and Trembley Creek phyllite, both of which contain a 504 Ma peak, identical to the dominant peak in the Apoon assemblage. The Cambrian detritus of the Endicott Mountains allochthon and Hammond subterrane could be recycled from the Apoon Assemblage.

- Similarities between the detrital spectra of the Endicott Group interior and exterior to the fenster indicate shared provenance for the Endicott Mountains allochthon and Doonerak regions by Mississippian time.

- The presence of Timanian age detritus (800 – 550 Ma; Baltican) alongside Caledonia detritus (~ 420 Ma; Laurentian) in some samples (e.g. 43DF15) indicates the juxtaposition of Timanian (Baltican) and Caledonian (Laurentian) source regions in Arctic Alaska by late Devonian to Mississippian time. This likely represents a post accretionary assemblage, deposited after the amalgamation Laurentian and non-Laurentian terranes.

- Cumulative detrital zircon spectra indicate significant dissimilarities between rocks of the Apoon assemblage and those of the Canadian Arctic and Svalbard during deposition of sample 05DF15 (Apoon), further supporting the idea that this sample was deposited in an isolated paleogeographic setting (Max Depositional Age = 452 ± 13 Ma).

- Based on the data presented here, the Apoon Assemblage likely initially formed in an isolated island arc setting. This arc progressively approached and eventually docked onto the northwest margin of Laurentian in the early Paleozoic, juxtaposing Laurentian and non-Laurentian terranes within Arctic Alaska. Accretion was complete by late Devonian-to-Mississippian time leading to post assembly overlap assemblages containing both Caledonian (Laurentian) and Timanian (Baltican) age detritus, which reflect both sides of the orogen.

SUPPLEMENTARY MATERIALS \ APPENDIX

NOTE ON THE NOMENCLATURE OF SAMPLE DESCRIPTIONS/NAMES

Reconnaissance scale mapping of the Wiseman Quadrangle by Dillon et al. (1986) and Brosge and Reiser (1960 & 1971) are the most current and comprehensive geological maps in the vicinity of the Doonerak fenster in the central Brooks Range. Some detailed mapping and stratigraphic studies were conducted in the eastern part of the fenster by Julian (1989) and Strauss et al., (2017). Additional regional work by Mull et al. (1987) and Moore (1987) add further complexity to the nomenclature of major rock units making the comparison of results increasingly difficult. For these reasons and to increase comparability, I utilized on the mapping and unit descriptions of the most recent published work from Doonerak - Strauss et al. (2017). This nomenclature recycles the nomenclature of Julian (1989) and Julian and Oldow (1998) for the lower Paleozoic volcanic rocks of the Doonerak fenster (Apoon assemblage) but otherwise generally remains consistent with Dillon et al., (1986). Even so, it is important to acknowledge the difficulty of defining precise unit boundaries in an area of poorly constrained stratigraphic relations. The samples from this study can be generally divided into those from the Endicott Mountains allochthon (above the Amawk thrust), those from the Doonerak fenster but above the regionally recognizable pre-Mississippian unconformity (Ellesmerian Sequence), and those from the Doonerak fenster and below the major unconformity (Apoon assemblage). The sample summary table (below) includes the sample locations and types of analysis pertaining to the various samples. It also shows samples available for potential future analysis.

NOTE ON DETRITAL ZIRCON SAMPLE PREPARATION

Zircon-rich separates were acquired from whole rock samples by mechanical disaggregation and by density and magnetic differentiation of the resulting rock powders in the

rock preparation lab at West Virginia University. This procedure was adapted from the standardized protocol used by the Arizona LaserChron Center and other laser ablation labs (e.g. e.g. Gehrels, 2014).

Samples were disaggregated to < ~250 µm particle sizes using a jaw crusher (Bico Braun Chipmunk) and disc mill (Bico Braun UA Pulverizer). After each crushing or pulverizing step, all material finer than 250 µm was removed from further disaggregation via standard U.S. series sieves (No. 60 - opening .0098 in; 250 µm). Sieves were thoroughly cleaned before and after each sample using an air compressor, fine brush, and alcohol wash. Each sieve was visually inspected prior to use to ensure no foreign material was added to the separate.

The disaggregated rock powders were then separated based on their hydrodynamic characteristics (mainly density) using a shaking water table (MD Mineral Technologies MK2 Gemini). The most dense sample grains, those that entered the most distant three of seven receptacles attached to the water table, proceeded to further processing. Less dense material which entered the upper four receptacles was examined, dried, and archived when found to be absent of zircon.

The densest grains were then separated by their magnetic properties. First a hand magnet was used to remove highly magnetic material (mostly iron filings incorporated during crushing and pulverizing). Samples were then progressively separated according to magnetic susceptibility when exposed to an electromagnet within an L-1 Frantz isodynamic magnetic separator operating at a vertical angle of 15 degrees. Paramagnetic grains were removed from the sample in ~0.25 ampere increments up to ~1.5 amperes, and archived progressively. Nonmagnetic fractions at ~1.5 amperes were retained for further processing.

The nonmagnetic dense mineral fractions were then combined with a lithium polytungstate solution (LPT; density = 2.85 ± 0.02 g/mL) in a ~50 mL glass funnel fixed with a gasket and rotatable valve at the base. Each sample was agitated and allowed to settle for approximately 45 min within the LPT, until grains could be observed within distinct floating and sunken fractions with an intervening clear heavy liquid zone between them. The gasket at the base of the funnel was then briefly opened to allow the dense mineral fraction to fall into a second glass funnel fixed with filter paper. Dense separates were then washed repeatedly using deionized water, sonicated, and dried before proceeding to further processing. The lighter mineral fraction was similarly treated, washed repeatedly, inspected to confirm the absence of zircon, and archived.

The nonmagnetic mineral separates denser than LPT proceeded to further heavy liquid processing. The densest grains from previous steps were combined with a methylene iodide solution (MEI; density = 3.3 ± 0.02 g/mL) in glass constriction tubes, inserted into test tubes following the procedure of Dumitru and Stockli (1998). Grains were left to settle within the MEI filled constriction tubes for ~ 1 hour. Lighter grains were removed by inserting a needle into the opening of the constriction tube and removing the constriction tube with forceps. The lighter grains were then transferred to filter paper, washed repeatedly with acetone, transferred to a vile and archived. The denser mineral fraction was then transferred to a separate funnel with filter paper, repeatedly washed with acetone, sonicated, washed again, and dried in a low temperature oven. The final dense zircon-rich mineral separate was inspected to assess the proportion of zircon. Those samples found to contain significant amounts of pyrite progressed to further processing. Those samples found to be sufficiently zircon-rich without significant amounts of other dense nonmagnetic mineral grains progressed to sample mounting.

Pyrite rich samples were placed within glass beakers, warmed over a hot plate and agitated with a magnetic stirrer while submerged in a 20% nitric acid solution in order to dissolve the pyrite (~25 min). Samples were then washed repeatedly, sonicated, dried and transferred to a new vial. The final zircon rich mineral separate progressed to sample mounting steps.

To avoid the biases related to the selection of individual grains, each sample's resulting zircon-rich separate was simply poured onto double-sided tape attached to a hard glass tile within the bounds of a 1" diameter Buehler circular ring form. Any un-adhered grains were then poured off to yield a representative mounted subset. Samples were again visually inspected to ensure that the resulting mounted aliquot was zircon-rich. Obvious grains of non-zircon high-density nonmagnetic minerals (e.g. pyrite, barite, apatite) were removed from the mount by hand using tweezers. Approximately 300 individual zircon grains were mounted in this manner for each sample.

Grain mounts were then constructed using Buehler Epo-Thin epoxy resin and hardener (Buehler #20-8142-016 & #20-8140-032). Epoxy resin was mixed with hardener at a ratio of 100:39 and poured over top the grains within the 1" diameter Buehler ring form and allowed to harden for 48 hours. Mounts were then removed from the glass tile and sanded using progressively finer wet sandpaper - standard 2500 grit paper followed by 9 micron and 5 micron film paper (Precision Surfaces PSI-1609-6 and PSI-1605-6). Sanding progressed until grains were polished between ⅓ - ½ way into the surface of most grains without removing the smallest grains. Mounts were inspected under the microscope between each sanding step. When found to be sufficiently well sanded, mounts were finally polished using a solution of 1 micron gamma

alumina Buehler micropolish B on a Buehler MINIMET auto-polisher, sonicated, dried, and stored in clean sample containers until LA-ICP-MS analysis.

NOTE ON LASER-ABLATION MASS-SPECTROMETRY

Detrital-zircon U-Pb geochronologic analysis was performed at the University of South Carolina's Center for Elemental Mass Spectrometry (CEMS) by laser-ablation high-resolution single-collector inductively coupled plasma mass-spectrometry (LA-HR-SC-ICP-MS) in 2 different sample runs during December of 2015 (23DF15 & 26DF15) and May of 2016 (05DF15, 41DF15, 43DF15 & J1415).

Grain ablation was conducted using a PhotonMachines Analyte G2 193 nm (deep ultraviolet) ArF exciplex laser operating with a 25 µm diameter spot aimed at the center of individual sample zircons, "unknowns," and reference zircons "standards." Reference zircon standards come from natural zircons of well-constrained and known ages determined by U-Pb isotope dilution thermal ionizonation mass-spectrometry (ID-TIMS). All zircon grains were mounted in 1" polished epoxy resin-filled ring forms and contained within a nine-hole stage held within a HelEx sample cell. Unknown zircons were randomly selected, shot by the laser and ablated in batches of five unknown grains each. Natural reference "standard" zircons were analyzed after each set of five unknown grains. The method of sequentially shooting five unknowns followed by standards is referred to as the "standard-unknown bracketing" approach and is used to correct for instrumental drift age-offset, and down-hole elemental fractionation as the laser ablates (e.g. Gehrels, 2014). Instrumental drift and down-hole fractionation both introduce uncertainties in age accuracy and precision (e.g. Gehrels, 2014) as compared to data

collected by ID-TIMS; however, this is offset by the larger datasets used it detrital provenance studies such as this one.

For the purposes is of this study the Sri Lanka (SL) zircon standard was used as the primary reference material (TIMS age = 563.5 ± 2.3 Ma, 2σ; 518 ppm U, 68 ppm Th, $^{206}Pb/^{204}Pb$ = 18000; Gehrels et al., 2008). The zircon standard 91500 (ID-TIMS age = 1065 ± 5 Ma; Wiedenbeck et al., 1995) was used as the secondary reference material. For consistency and comparability all ages reported are based on the reduction scheme using SL as the primary reference material. During analysis, both reference materials were ablated following ablation of every five unknowns.

Ablated material was transported in He carrier gas flowing from internal and external HelEx sample cell mass flow controllers toward the torch of the mass spectrometer. Entering the mass spectrometer, the carrier gas mixed with Ar sample gas in a mixing chamber before flowing into the dry plasma torch of the Thermo ELEMENT2 high resolution single collector mass spectrometer, where the ablatant passed through the plasma and was ionized. A portion of the ionized material then passed through the sample and skimmer cones into the vacuum of the mass spectrometer where it could be analysed and discriminated using the ELEMENT2's double-focusing magnetic sector field mass analyzer.

Before each analysis, the entire LA-HR-SC-ICP-MS system was manually adjusted to maximize signal and performance using the NIST 612 synthetic glass standard (Hollocher and Ruiz, 1995). Manual tuning included adjusting the torch position as well as sample and carrier gas flow rates while attempting to minimize oxide formation. Analysis of unknown and reference zircons involved the collection of signal intensity data for a set of masses (202, 204, 206, 207, 208, 232, and 238) using the ion counting feature of the ELEMENT2. The mass of 235 was

found by dividing the signal intensity of 238 by 137.88 (Nier, 1939 a&b; Nier et al., 1941). During analysis, laser ablation of "unknown" and "standard" zircons was preceded by 5 seconds of background data collection and followed by approximately 15 seconds for signal washout and data recording. In this manner, between 50 and 75 standard and unknown grains could be measured per hour, including time for periodic manual laser focusing and selection of spot locations.

NOTE ON DETRITAL ZIRCON DATA REDUCTION AND PROCESSING

Processing of the raw data generated by the mass spectrometer was conducted using the *UPbGeochronology3* data reduction scheme of the Iolite v.3 software package (Paton et al., 2010) within the IgorPro data and computation package.

Processing began with the import of individual .FIN2 files acquired from analysis of each unknown or reference zircon and its associated baseline and washout signals into the time-constrained reference frame of the IgorPro environment. Following data import, integration windows for baseline and ablatant signals were selected automatically by trimming 5 sec respectively from the start and end of each data file for baseline integrations, and 15 sec respectively from the start and end of each data file for ablation signals. In addition to removing the baseline signal for the ablatant signal, the latter data trimming removes any surface contamination incorporated into the mount surface during grinding, polishing and storage. Small offsets in analytical start times caused by operator error or computational delays in compiling prior analyses' data occasionally yielded inaccurately auto-selected integration windows; the ablation of epoxy in insufficiently ground zircons and/or small zircons drilled through during standard ablation durations yielded similarly inappropriate windows. Adjustment of these windows was achieved by manual grain-by-grain data inspection, as was the elimination of

analyses of grains known not to be zircon (e.g., by very low U signals, etc.). In the case of the former, care was taken to ensure that the start time of each ablatant integration window was spatially equivalent to those of grains with auto-selected windows in order to optimize the accuracy of down-hole fraction correction models.

Following data import, selection, and inspection of integration windows, Iolite-based data reduction involved: (1) subtraction of background signals from an automatic (best-fit: see Paton et al. 2010) interpolation model; (2) determination of an appropriate downhole-fractionation correction model by separately stacking the ^{206}Pb/^{238}U, ^{207}Pb/^{235}U and ^{208}Pb/^{232}Th downhole ratios for each of the primary reference zircon analyses, calculating best-fit exponential curves to those stacked datasets, and applying the resulting models to transform the isotopic ratios of analyzed 'unknown' zircons, ideally to optimize ratio steadiness; (3) estimation and correction of instrumental age-offsets and drift by comparison of determined (raw) and accepted (i.e., ID-TIMS) isotopic ratios of the primary reference zircon; and (4) calculation of final ages and values, including (a) propagated uncertainties determined from analyses of the primary reference zircon as pseudo-secondary standards, progressively removing them individually from the dataset, reprocessing the data, and calculating uncertainty, and (b) error correlations using the IgorPro StatsCorrelation function. See Paton et al. (2010) for further clarification and discussion of methods of Iolite data reduction of U-Pb zircon data.
