Abstract

Primary objective: To determine whether patients with stroke who have a good functional outcome show awareness of memory functioning and whether over- and under-estimation of memory performance are differentially related to neuropsychological performance.

Research design: Prospective cohort study.

Methods and procedures: The Barrow Neurological Institute Screen for Higher Cerebral Functions and a brief neuropsychological assessment were used to evaluate language, orientation, attention, visuospatial problem-solving, perception, reasoning, executive functioning, memory, affect and awareness of memory functioning. As for the latter, the patient's estimate of memory functioning was compared with his or her actual memory performance. Patients were divided into three groups: good-estimators (estimated performance = actual performance), over-estimators (estimated performance > actual performance) and under-estimators (estimated performance < actual performance).

Main outcomes and results: In total, 54 patients with stroke were included, of whom 27 patients were classified as good-estimators, 19 as over-estimators and eight as under-estimators. Compared to good-estimators, over-estimators had significantly lower scores for all cognitive domains. Under-estimators had significantly poorer affect compared to good-estimators.

Conclusions: These preliminary results suggest that over- and under-estimation of memory functioning can be observed in patients with stroke who have a good functional outcome and that they may reflect distinct underlying neuropsychological processes.

Introduction

Impaired awareness of deficits is a frequently observed phenomenon in patients with stroke that may lead to poor outcome [1–4]. It manifests itself as diminished insight of a specific deficit in sensory, perceptual, motor, behavioural or cognitive functioning [5]. Awareness deficits have been mostly studied in rehabilitation settings and consequently usually include patients with stroke who have considerable disabilities. However, impaired awareness of functioning may also be present in patients with stroke who have a good functional outcome (i.e. those who show no immediate significant motor, sensory or linguistic symptoms). Despite enduring cognitive and emotional impairments, these patients with 'mild' stroke are often discharged home within days and are usually not referred to a rehabilitation programme or other forms of follow-up care [6–9]. Impaired awareness in these

patients may lead to a failure to seek help for their cognitive and emotional impairments and consequently they may not receive the treatment that they need. All patients with stroke who have a good functional outcome should, therefore, be assessed by a neuropsychologist to screen for cognitive and emotional impairments and awareness deficits. Short screening procedures would be helpful to assess all patients with stroke. A neuropsychological screening instrument that is unique in its measurement of the patient's awareness of memory functioning and that also evaluates affect and cognitive functioning is the Barrow Neurological Institute Screen for Higher Cerebral Functions (BNIS) [10].

The BNIS awareness domain uses a performance-based discrepancy method to assess awareness of memory functioning. When using this method, the patient's opinion or estimation of his functioning is compared to an objective standard. The level of the awareness deficit is then based on the discrepancy between both measures. In the BNIS, the patient is asked to predict his memory performance in recalling words from a list. The patient's prediction is subsequently compared to the actual number of words he was able to recall [11]. The performance-based discrepancy

method can be used to classify patients into one of the following awareness groups: good-estimators (subjective performance = objective performance), over-estimators (subjective performance > objective performance) and under-estimators (subjective performance < objective performance) [12]. Previous studies suggested that the latter two awareness groups reflect different neuropsychological processes. Under-estimating cognitive performance has, for example, been associated with depressive symptoms in patients with multiple sclerosis [13, 14]. Also, Sawchyn et al. [15] proposed an association between an under-estimation of performance and more emotional distress in patients with traumatic brain injury. Over-estimation of cognitive performance, however, has been associated with more cognitive impairments in patients with epilepsy [16] and multiple sclerosis [13].

The current study investigated whether patients with stroke who have a good functional outcome have intact awareness, over-estimation or under-estimation of memory functioning on the BNIS. Furthermore, it was examined whether over- and under-estimators differ in cognition and affect, i.e. in their performance on the other BNIS domains and on a brief neuropsychological assessment (NPA).

Methods

Patients and procedure

This study was a prospective cohort study. For this paper, secondary analyses were done. Data were used from patients from two outpatient clinics and one inpatient clinic, between August 2009 and May 2011. Patients were included if they had suffered from stroke (<12 months); who had sufficient command of the Dutch language; and who had good functional outcome in terms of a Barthel Index [17] score ≥ 19 points.

A total of 54 patients with stroke were included in this study. Of this group, 46.3% of patients had an ischaemic stroke; 11.1% a haemorrhagic stroke; and 42.6% a subarachnoid haemorrhage (SAH). The mean time between diagnosis and assessment was 15.0 weeks (SD = 12.8). In Table I the sample characteristics are presented.

The Barrow Neurological Institute Screen (BNIS) for higher cerebral functions [10] was administered as part of a routine procedure following stroke. All patients completed the BNIS and the brief NPA in the same session with half of all patients starting with the NPA and the other half starting with the BNIS. The study was conducted according to the Code of Conduct for Medical Research of the Council of the Dutch Federation of Medical Scientific Societies. At these clinics, all patients are informed that their files can be used anonymously for research purposes, unless they object. A review procedure by a medical ethics committee is not needed for use of anonymous routinely collected data.

Materials

Barthel Index

The Barthel Index is a measure of functional independence [17]. It contains 10 items about basic self-care and mobility (e.g. washing, transfers). Its total score has a 0–20 range. Higher scores indicate more functional independence.

Table I. Sample characteristics and comparison of characteristics for awareness sub-groups.

^dn = 52 (one missing value in the good-estimator and over-estimator sub-group).

In accordance with other studies, this study used ≥ 19 points as a cut-off value for functional independence [18, 19].

Barrow Neurological Institute Screen for Higher Cerebral Functions (BNIS)

The BNIS [10] is a cognitive screening instrument that includes a pre-screening and a screening phase. The pre-screening is based on three domains: arousal–alertness, basic language abilities and co-operation, which are scored on a 3-point rating scale. The pre-screening is based on observations by the experimenter. For each of the three items patients have to attain a score of at least 2 in order to proceed to the screening phase. These three pre-screening items contribute to the BNIS total score. The BNIS screening part contains 27 items in seven domains: language, orientation, attention and concentration, visuospatial problem-solving, memory, awareness and affect. The awareness domain is based on evaluation by the patient. The patient is read three words and asked to repeat them. Subsequently, the patient is asked to estimate how many words he or she will recall after ~5–10 minutes: 0, 1, 2 or all 3. The patient's estimation is compared

to the actual number of recalled words. The other BNIS domains on cognition and affect are described in detail elsewhere [8, 10].

Items are summed to obtain domain scores and a total BNIS score. The total BNIS score has a 0–50 range. Higher scores indicate better functioning. Interpretation of impaired cognitive performance is based on a cut-off value of <47 for patients ≤ 55 years and <43 for patients >55 years [10]. Previous studies have reported good psychometric properties for the BNIS in patients with brain injury [8, 10, 20–26]. The BNIS takes 10–15 minutes to administer [10].

Neuropsychological assessment (NPA)

The brief NPA consisted of a core battery that was administered to all patients. Since the cognitive screening was part of standard care, additional neuropsychological tests varied depending on, for instance, cognitive complaints reported by the patient. The core battery consisted of six conventional neuropsychological tests. The Star Cancellation Test (SCT) [27] was used to assess perception. Language performance was assessed with the Boston Naming Test (BNT) [28] short form. The Rey Auditory Verbal Learning Test (RAVLT) [29] was used to assess verbal memory. The Trail Making Test Part A (TMT-A) [30] was used to evaluate attention. Abstract reasoning was determined with Raven's Advanced Progressive Matrices (RAPM) [31] short form. To assess executive functioning, the Stroop Colour and Word Test [32] was used. For the current study the variable of interest was the Stroop interference score which was calculated with the following formula: $(\text{card 3} - ((\text{card 1} + \text{card 2})/2))$. The neuropsychological tests are described in more detail elsewhere [33].

Statistical analysis

The BNIS awareness score was used to divide the patients into three sub-groups: good-estimators (estimated number of recalled words = number of words actually recalled); over-estimators (estimated number of recalled words > number of words actually recalled) and under-estimators (estimated number of recalled words < number of words actually recalled). Descriptive statistics were used to describe characteristics of the total stroke population and the sub-groups. Non-parametric statistics (Chi-square tests, Mann Whitney *U*-tests, Kruskal-Wallis tests, Fisher's exact tests) were used to compare the sub-groups regarding demographic (gender, age, education) and injury (type of stroke, stroke location, time post-stroke) characteristics. The differences between the sub-groups regarding BNIS domain scores and NPA scores were investigated by means of Kruskal-Wallis tests and Mann-Whitney *U*-tests. Data were analysed using SPSS version 21.0. Alpha was set at 0.05.

Results

Patients

A total of 54 patients with stroke who had a good functional outcome were included. All patients passed the BNIS pre-screening. Based on their BNIS awareness score, 27 patients were classified as good-estimators. An equally large group of

^aGood-estimators (estimated performance = actual performance); over-estimators (estimated performance > actual performance); under-estimators (estimated performance < actual performance).

patients showed awareness deficits: 19 patients were classified as over-estimators and eight patients were under-estimators. In Table II, the difference between the estimated number of recalled words and the number of words actually recalled is shown for the three groups.

The sub-groups were compared regarding their demographic and injury characteristics. There were no significant differences between the three sub-groups regarding age ($\chi^2 = 3.185$, $p = 0.203$) and gender (under- vs. over-estimators $p = 0.415$; under- vs. good-estimators $p = 0.433$; over- vs. good-estimators $\chi^2 = 0.016$, $p = 0.901$). There was a significant difference in education (under- vs. over-estimators $p = 0.616$; under- vs. good-estimators $p = 0.419$; over- vs. good-estimators $\chi^2 = 5.148$, $p = 0.023$). There were significantly more high educated patients in the good-estimator group (48.1%) than in the over-estimator group (15.8%). Regarding injury characteristics, no significant between-group differences were found regarding time post-stroke ($\chi^2 = 3.540$, $p = 0.170$); type of stroke (infarction or sub-arachnoid haemorrhage) (under- vs. over-estimators $p = 1.00$; under- vs. good-estimators $p = 1.00$; over- vs. good-estimators $\chi^2 = 0.034$, $p = 0.853$); stroke location (left or right) (under- vs. over-estimators $p = 0.335$; under- vs. good-estimators $p = 0.649$; over- vs. good-estimators $p = 0.702$).

Awareness and neuropsychological performance

Scores on the BNIS and NPA for the three groups are displayed in Table III. There were significant between-group differences for all BNIS domains, the BNIS total score and all cognitive tests of the NPA except for RAVLT delayed recognition ($\chi^2 = 2.709$, $p = 0.258$). In total, 44.4% of good-estimators, 75.0% of under-estimators and 89.5% of over-estimators scored below the BNIS cut-off for impairment on the BNIS total score (<47 for patients ≤ 55 years; <43 for patients >55 years [10]). Compared to good-estimators, over-estimators had significantly poorer performance for the BNIS domains orientation ($U = 116.0$, $z = -4.09$, $p = 0.000$); attention ($U = 120.0$, $z = -3.21$, $p = 0.001$); visuospatial problem-solving ($U = 128.5$, $z = -2.99$, $p = 0.003$); memory ($U = 36.5$, $z = -4.99$, $p = 0.000$); the BNIS total score ($U = 40.5$, $z = -4.84$, $p = 0.000$); the Stroop Colour and Word Test ($U = 104.0$, $z = -3.22$, $p = 0.001$); TMT-A ($U = 103.5$, $z = -3.42$, $p = 0.001$); Boston Naming Test ($U = 120.0$, $z = 3.05$, $p = 0.002$); RAPM ($U = 88.0$,

$z = -3.80$, $p = 0.000$); RAVLT immediate ($U = 132.5$, $z = -2.77$, $p = 0.006$) and delayed ($U = 120.5$, $z = -3.05$, $p = 0.002$) recall; and Star Cancellation Test ($U = 172.5$, $z = -2.31$, $p = 0.021$). Under-estimators had significantly lower scores for the BNIS affect domain compared to good-estimators ($U = 46.5$, $z = -2.75$, $p = 0.006$). The under-estimators did not significantly differ from the good estimators on any of the cognitive tests.

Discussion

The results of this exploratory study suggest that impaired awareness of memory functioning is not limited to patients with stroke who have considerable disabilities, but can also be observed in patients with stroke who have a good functional outcome. Half of the patients in this study over-estimated or under-estimated their memory functioning. The results further show that, compared to good-estimators, over-estimators had poorer cognitive functioning and under-estimators had poorer affect.

These findings suggest that over-estimation and under-estimation of memory functioning are related to different neuropsychological mechanisms. These findings are in line with previous studies and with cognitive theories of awareness. Giovagnoli [16] and Carone et al. [13], for example, suggested that impaired awareness is a specific cognitive impairment directly resulting from brain damage and they already reported an association between over-estimation of cognitive performance and cognitive impairments in patients with brain injury [13, 16].

Under-estimation, however, may be related to psychological or emotional functioning. Patients who under-estimated their memory performance had poorer affect than good-estimators. The vast majority of under-estimators did

not obtain full credit for the affect domain. These results suggest that an under-estimation of performance is associated with an emotional component. This is supported by previous studies in which emotional factors such as depression and emotional distress were related to an under-estimation of cognitive performance [13–15].

If different mechanisms underlie over-estimation and under-estimation of functioning, then, in clinical practice it is important to distinguish between patients who over-estimate and patients who under-estimate their cognitive performance. These two groups may need other interventions. Patients with stroke who over-estimate their memory performance may, for example, engage in activities that they are not capable of performing. These patients may benefit from psycho-education concerning their deficits and from interventions aimed at increasing awareness such as feedback interventions [34]. In contrast, patients who under-estimate their memory performance may needlessly avoid activities that they are perfectly capable of doing. These patients may need some kind of cognitive behaviour therapy first to decrease their fears and anxiety [35].

Some limitations of this study should be noted. First, it included a small, convenience sample of patients with heterogeneous diagnoses. In particular, the under-estimator group had a small sample size. Second, it is possible that good-estimators, under-estimators and over-estimators differed in the type, location and volume of stroke lesions. Previous studies suggested a strong association between impaired awareness and right-hemisphere lesions that involve cortical (insular, temporal and parietal lobes) and subcortical structures (thalamus, basal ganglia) [4]. Although this study did not find significant between-group differences regarding stroke location (left, right), it is possible that, in this study, the good-estimators more often had lacunar, less strategic or

smaller volume lesions than the under- or over-estimators and, consequently, better neuropsychological performance. Since further topography of the strokes was not available, the authors were not able to control for these factors. Second, the over-estimators were lower educated than the good-estimators. However, solely including high educated patients ($n = 18$) or solely including low educated patients ($n = 36$) yielded similar results. Low-educated over-estimators had significantly lower cognitive performance compared to good-estimators. High educated over-estimators had significantly lower cognitive performance compared to high educated good-estimators and high educated under-estimators had significantly poorer affect than high educated good-estimators. A third limitation is that no other emotional assessments other than the BNIS affect domain were used to confirm that under-estimating is associated with some kind of emotional problems. Last, the differentiation between good-estimators, over-estimators, and under-estimators was based on a single awareness score with a small score range (0–3). In 59% of incorrect estimations, estimated and actual performance differed by only 1 point. Also, the small score range may have caused a ceiling effect and, thus, a possible lack of sensitivity for more subtle awareness problems. Furthermore, mis-estimations of memory functioning are also found in healthy persons and, therefore, do not necessarily imply impaired awareness [10, 36]. With respect to the BNIS, ~35% of healthy persons mis-estimated their memory functioning in previous studies [10]. Hence, an over- or under-estimation of performance needs confirmation by a comprehensive neuropsychological assessment to diagnose impaired awareness. Further research is needed to evaluate the sensitivity of the BNIS awareness domain for detecting awareness problems and to determine whether these findings are specific to patients with stroke or that similar associations are present in healthy controls as well.

In conclusion, the preliminary results of this study suggest that impaired awareness of memory functioning can be observed in patients with stroke who have a good functional outcome. Results further seem to suggest that under- and over-estimation of memory performance reflect different neuropsychological processes. Further studies with larger samples and other measures are needed to confirm these results and to determine whether patients with poor memory awareness are also impaired on the more general domain of awareness.

Declaration of interest

This project is part of the research programme Cognitive Rehabilitation which is funded by the National Initiative on Brain and Cognition in the Netherlands (NWO number 056-11-014). The authors report no conflicts of interest.
