CHAPTER 1

General introduction

Introduction

The nucleus is defined by the nuclear envelope (NE), which is composed of an outer and inner nuclear membrane (ONM, INM, respectively) interrupted by nuclear pore complexes (NPC)¹ (Figure 1). The ONM, continuous with and functionally related to the endoplasmic reticulum (ER)², is separated from the distinct INM by a luminal space. The INM and ONM converge at sites of incorporated NPCs, which are homogeneously spread across the NE and regulate nuclear import and export of macromolecules. Furthermore, the nucleoplasmic side of the INM is coated by the nuclear lamina, a layer of intertwined intermediate filament A-type (Lamin A, C) and B-type lamins (Lamin B1, B2), membrane proteins anchoring the lamina to the NE (including Emerin, LAP2, LBR) and proteins that modulate and interact with peripherally localized chromatin (including BAF, HP1)³ (Figure 1). The discovery of a mutation in the LMNA gene, that encodes for lamin A and C, as the cause of the autosomal dominant Emery-Dreifuss muscular dystrophy⁴ merely a decade ago, launched numerous research studies investigating the role of A-type lamins in human disease. Since then, 11 distinct phenotypes have been associated with LMNA mutations, including several types of muscular dystrophies, lipodystrophies, cardiomyopathies, neurological disorders and premature aging syndromes.⁵ This broad range of LMNA related diseases, commonly referred to as laminopathies, suggests that A-type lamins play a pivotal role in diverse biological systems.

The nuclear lamina are important for maintaining nuclear integrity. Lamin fibers are assembled by head-to-tail polymerization of lamin dimers, and loss or mutation of lamin A causes dramatic structural changes that make nuclei less capable to tolerate mechanical strain and result in increased cell death.⁶⁻⁷ Furthermore, A-type lamins are involved in cell differentiation. Dominant negative lamin A mutants block myoblast differentiation⁸ and progerin, a lamin A mutant associated with the premature ageing disease HGPS (Hutchinson-Gilford Progeria Syndrome), inhibits adipogenesis and favors osteogenic stem cell differentiation.⁹ In addition, lamins regulate the expression of gene pathways by interacting with numerous transcription factors.¹⁰⁻¹² Finally, lamins are crucial for chromatin organization as loss of A-type lamins results in thinning or loss of peripheral heterochromatin¹³ and various LMNA mutations modify

Figure 1. Schematic cartoon of various proposed interactions of lamins with inner nuclear membrane (INM) proteins, the nuclear pore complex (NPC), chromatin and various other nucleoplasmic factors. Lamins are located both underneath the INM in a thick layer, as within the nucleoplasm. Lamin A is synthesized in the endoplasmic reticulum (ER) as a precursor (prelamin A), which is farnesylated and processed by Face1 to release mature lamin A. LAP2 β , Emerin and Man1 are localized in the INM and capable of interacting with barrier-to- autointegration factor (BAF) with their LEM domain. The lamin B receptor (LBR) interacts with lamins as well as with heterochromatic protein 1 (HP1). INM localized SUN proteins and outer nuclear membrane (ONM) localized nesprin proteins interconnect the nuclear lamina to the cytoskeletal intermediate filaments and actin fibers. Furthermore lamins interact with PCNA, and the transcription factors Rb and cFOS.

chromatin structure and localization as well.¹⁴⁻¹⁵ Although progress has been made in understanding molecular functions of A-type lamins, many aspects still remain elusive.

The nuclear lamina are important for maintaining nuclear integrity. Lamin fibers are assembled by head-to-tail polymerization of lamin dimers, and loss or mutation of lamin A causes dramatic structural changes that make nuclei less capable to tolerate mechanical strain and result in increased cell death⁶⁻⁷. Furthermore, A-type lamins are involved in cell differentiation. Dominant negative lamin A mutants block myoblast differentiation⁸ and progerin, a lamin A mutant associated with the premature ageing disease HGPS (Hutchinson-Gilford Progeria Syndrome), inhibits adipogenesis and favors osteogenic stem cell differentiation⁹. In addition, lamins regulate the expression of gene

pathways by interacting with numerous transcription factors¹⁰⁻¹². Finally, lamins are crucial for chromatin organization as loss of A-type lamins results in thinning or loss of peripheral heterochromatin¹³ and various LMNA mutations modify chromatin structure and localization as well¹⁴⁻¹⁵. Although progress has been made in understanding molecular functions of A-type lamins, many aspects still remain elusive.

First, it remains uncertain whether differentiation defects are common amongst tissues affected by laminopathies. LMNA mouse models have mainly been used to study tissue defects in the young adult mice, thereby potentially missing defects in tissue differentiation, which occurs especially during early post-natal development. A common role of lamin A in tissue differentiation is suggested by the observations that lamin A expression highly correlates with the level of differentiation. Lamin A expression is turned on during the embryonic developmental stage of tissue differentiation¹⁶⁻¹⁷ and in stem cells lamin A is only expressed after differentiation induced loss of pluripotency¹⁸. Furthermore loss of lamin A expression correlates with poor histological differentiation of primary gastric carcinomas¹⁹.

A second question to be answered is how A-type lamins regulate chromatin organization. The findings that A-type lamins interact in vitro with DNA and histones²⁰⁻²¹ and B-type lamins bind chromatin in vivo²², led to the hypothesis that A-type lamins regulate chromatin organization by direct in vivo interaction with chromatin. Such chromatin organization could be important to regulate gene expression, as genes occupy preferred subnuclear positions in relation to their transcriptional status²³. A peripheral localization of many loci is associated with a transcriptionally inactive state, and several repressed loci relocate towards the nucleus' interior upon activation²⁴.

Finally, the major enigma in laminopathies is how mutations in one gene can cause so many phenotypic diversity. It is hypothesized that lamin A mutations affect specific lamina protein- and chromatin-interactions, thereby giving rise to laminopathy specific defects. In line with this hypothesis, Dunnigan familial partial lipodystrophy (FPLD) associated lamin A mutations specifically disrupt interaction with the adipogenic transcription factor Srebp1¹⁰. Moreover, expression of a premature ageing associated lamin A mutant, E145K,

mislocalizes telomeres due to erroneous lamina interaction¹⁵. The low amount of studies identifying protein or chromatin interactions specifically interrupted by LMNA mutations indicates how challenging this quest is. This is mainly due to technological restrictions, as the number of applicable techniques is limited due to the insoluble nature of nuclear lamina, and those assays that can be used typically are biased or only identify a small subset of interactors. Furthermore, most assays identify general lamin interactors and do not enrich for those interactors specifically affected by LMNA mutations. These limitations prevent unbiased identification and comparison of wildtype and mutant lamin A protein and chromatin interactions in a proteome- and genome-wide fashion. Such complete mapping would help to clarify the exact function of lamin A in diverse biological processes and may provide disease mechanisms for specific laminopathies.

Aim of thesis

The overall aim of this thesis is to identify molecular mechanisms underlying laminopathies. Specifically the role of LMNA and the effect of LMNA mutations were studied in the context of disruption of protein- or chromatin interactions, chromatin organization and early postnatal tissue differentiation.

Based on this aim we defined the following goals:

- Map protein interactions of A-type lamins in a proteome-wide unbiased approach.
- Map chromatin interactions of A-type lamins in a genome-wide unbiased approach.
- Identify laminopathy-related changes in these chromatin- and protein-interactomes.
- Identify a molecular disease mechanism for a laminopathy based on these changes.
- Determine the biological relevance of A-type lamin chromatin interactions on chromatin organization and gene expression
- Determine the biological relevance of A-type lamins in tissue differentiation during early post-natal development.

A detailed review on technological approaches to identify lamina protein and chromatin interactions is presented in Chapter 2. The identification of protein interactors of lamin A and progerin, the HGPS associated lamin A mutant, is summarized in Chapter 3. The identification of lamin A and progerin chromatin interactions and the biological relevance of these interactions in chromatin organization and gene expression is revealed in Chapter 4. Chapter 5 describes a novel disease mechanism for HGPS. The biological relevance of A-type lamins in early postnatal tissue differentiation is described in Chapter 6. The results obtained in these studies and their implications are discussed in chapter 7.

CHAPTER 2

Mapping of protein- and chromatin- interactions at the nuclear lamina

Based on: Kubben N, Voncken J, Misteli T. *Nucleus*. 2010

Abstract

The nuclear envelope and lamina define the nuclear periphery and are implicated in many nuclear processes, including chromatin organization, transcription and DNA replication. Mutations in lamin A proteins, major components of the lamina, interfere with these functions and cause a set of phenotypically diverse diseases referred to as laminopathies. The phenotypic diversity of laminopathies is thought to be the result of alterations in specific protein- and chromatin interactions due to lamin A mutations. Systematic identification of lamin A-protein and -chromatin interactions will be critical to uncover the molecular etiology of laminopathies. Here we summarize and critically discuss recent technology to analyze lamina protein- and chromatin interactions.

Introduction

The nuclear periphery is marked by the nuclear envelope (NE), which is composed of an outer and inner nuclear membrane (ONM, INM, respectively) interrupted by nuclear pore complexes (NPC).¹ The nuclear lamina lines the NE and consists of a large collection of proteins, most prominently the intermediate filament A-type (Lamin A, C) and B-type lamins (Lamin B1, B2), INM proteins anchoring the lamina to the NE (including Emerin, MAN1, LAP2, Nesprin) and proteins that modulate and interact with chromatin such as BAF, HP1 and histone deacetylase 3 (Figure 1).²

Mutations in the lamina's major constituent, particularly the A-type lamins, cause a diverse set of human diseases collectively referred to as laminopathies; these include several types of muscular dystrophies, lipodystrophies, cardiomyopathies, neurological disorders and premature aging syndromes.³ The phenotypic diversity of laminopathies is hypothesized to be caused by lamin A mutations affecting specific lamina protein- and chromatin-interactions, thereby compromising nuclear integrity, higher-order chromatin organization, gene expression and/or various other nuclear processes.⁴ In line with this notion are the observations that Dunnigan familial partial lipodystrophy (FPLD)-associated lamin A mutations specifically disrupt interaction with the adipogenic transcription factor *Srebp1*⁵ and that failure of progerin, a lamin A mutant that causes premature aging, to interact with the NURD chromatin remodeling complex contributes to loss of peripheral heterochromatin, a hallmark of the premature aging disorder Hutchinson-Gilford Progeria Syndrome (HGPS).⁶ Another progeria-associated lamin A mutation, E145K, leads to aberrant interaction of the lamina with telomeres.⁷

A key challenge in the field of lamin biology is to identify all protein and chromatin interactions at the nuclear periphery. Over the past years, several approaches have been developed and applied in order to systematically map the complete spectrum of lamina protein- and chromatin-interactions. Such approaches are crucial to elucidate the biological function of the lamina and pinpoint molecular defects for specific laminopathies. In this review we provide an overview of current technology aimed at identifying

protein- and chromatin-interactions at the lamina. We focus on proteome- and genome-wide unbiased approaches, with particular emphasis on technical advantages and potential pitfalls in the context of subsequent mass spectrometry⁸⁻⁹, high-throughput microscopy and mass sequencing analysis.¹⁰ The methods discussed each with its strengths and weaknesses are all complementary but they all contribute to increasing our knowledge of function of lamins and the nuclear periphery.

Protein-interactions

Visual Screens

A basic approach to identify lamina proteins is by visual inspection of the localization of candidate proteins. In visual screens putative lamina proteins are expressed using specific tags and their localization, depending on the tag, is then detected either using live cell imaging or indirect immunofluorescence. The use of fluorescent or other epitope tags has made it possible to systematically visualize the localization of a large number of putative lamina proteins and lamin-interacting proteins by high-throughput microscopy. The most commonly used tags are GFP and Myc. The foremost advantage of visual screens is the instant registration of dynamic or abnormal changes in subcellular protein-complex localization in the context of changed cell physiology or protein mutation, respectively (Table 1). Capture of such dynamic behavior has been successfully applied¹¹ to the study of the nuclear lamina; lamin A interactions with Rb, c-FOS and SMAD2 occur only under specified conditions, like proliferation, differentiation and TGF β stimulation.¹²⁻¹³ Sensitivity, specificity and spatial resolution in cell-based imaging are somewhat confounded by the necessity to co-stain for relevant subcellular domains as well as low cellular abundance of NE proteins.¹⁴⁻¹⁷ Bioinformatic approaches can assist in visual screens by selecting for predicted membrane proteins¹⁸ localized at the NE.¹⁹

A powerful and more sophisticated approach of a visual screen to identify novel lamin interaction partners is the use of GFP-fusion protein libraries. In this approach

collections of GFP-tagged fusion proteins are expressed, screened by high-throughput microscopy for subcellular localization, and clones of interest are subsequently sequenced to determine the identity of the expressed protein. Rolls et al. successfully applied a heterologous promoter-driven GFP-fusion library to screen 40,000 clones and test in an unbiased fashion whether they localized to the nuclear periphery.²⁰ In doing so they discovered the NE membrane protein Nurim, a six-transmembrane spanning INM protein with potential isoprenylcysteine carboxymethyltransferase enzymatic activity for Caax-motifs.²⁰⁻²¹ A drawback of protein overexpression is possible mis-localization of the fusion protein; there is an obvious need for analysis of the effect of protein expression levels on its localization and the validation of each hit by analysis of the endogenous protein.^{15, 22} A key advantage of visual screens is that interactors which may associate with the small, but significant pool of lamin components present in the nucleoplasm, can be distinguished from those that interact with the peripheral pool of lamins. In a more physiologically relevant approach, Bickmore and colleagues identified the NE associated protein Lyric/AEG-1, an apoptosis and cell growth implicated transcriptional regulator, by using gene trapping to insert 1350 reporters into active genes.^{11, 23} In this approach, endogenously expressed genes were spliced onto a genomically integrated LacZ cassette, which allowed visualization of the resulting fusion proteins by X-gal staining and β -galactosidase immunohistochemistry.¹¹ Although such visual screens are becoming increasingly feasible, they are relatively labor intensive and slow.

Biochemical Fractionation

NE proteins are highly lipophilic and lamina proteins are strongly resistant to high concentrations of salts and detergents. These biochemical characteristics are exploited in fractionation studies to separate NE and lamina proteins from other subnuclear domains. Such isolation drastically increases the frequency of detecting NE and lamina proteins by unbiased biochemical methods e.g. mass spectrometry (MS) (Table 1). Combined with recent MS advances in complex protein mixture analysis^{9, 24}, such fractionation studies have the potential to contribute significantly to the identification of the full lamin proteome. As MS analysis itself cannot distinguish lamina proteins from contaminants, fraction purity is crucial.

Figure 1. A schematic view of lamina and lamina-interacting protein fractions purified by various techniques. The nuclear periphery consists of an inner nuclear membrane (INM), outer nuclear membrane (ONM), and is connected to the endoplasmic reticulum (ER). Salt solubilizes (left) weakly attached lamina proteins, but not the nuclear lamina. Detergents preferentially dissolve membrane proteins that are not anchored in the detergent resistant lamina.^{28, 66} Chaotropes and alkaline extraction generate an insoluble fraction mainly consisting of integral membrane proteins.⁶⁶ Immunoprecipitations (right) with an antibody directed against lamin A/C, using mild lysis conditions (for example 0.1% NP-40, 250 mM NaCl¹²), preferentially dissolve and precipitate nucleosoluble A-type lamins and protein interactors.³⁵ For a lamin A OST pull-down assay⁴⁶, cross-linking, indicated by crosses, captures protein-protein and protein-chromatin interactions, and allows solubilization of the total lamin A/C pool while preserving interactions.

Various assays have been developed to fractionate NE and lamina proteome subsets, each with a specific trade-off between obtained purity and amount of background proteins.

Protein Correlation Profiling (PCP) was developed to determine subcellular protein localization in crude extracts, separated by rate-zonal centrifugation into fractions which are subsequently analyzed by MS analysis (Table 1).²⁵ In essence, the technology relies on co-detection of proteins known to reside in the organelle of interest and novel proteins.²⁵ The main advantage of PCP is its ability to detect multiple co-segregating proteins in a complex mixture without the need to fully isolate and highly purify subcellular fractions. However, PCP comes at a price: as many subcellular domains are only partially separated by centrifugation, non-specific interactors co-purify and separation of true interactors relies strongly on computational analysis. Follow-up studies to characterize the properties of identified proteins are imperative. Although PCP analysis has not been applied yet to distinguish and define nuclear lamina/envelope proteins domains, the fact that differences in rate-zonal resolving properties have previously been used to purify NE fractions²⁶, makes PCP a promising technique to identify NE and lamina proteins.

In comparison to PCP, differential extraction assays use more highly purified fractions for MS analysis and consequently reduce non-specific co-purification (Table 1). In general, biochemical fractionation of the NE starts with isolation of nuclei, removal of non-NE membrane fractions by centrifugation and digestion of chromatin to remove nucleoplasmic contents. Crude NE and lamina fractions are subsequently extracted in salt, detergent, and chaotrope or alkaline buffers to further remove different types of proteins. Salt preferentially dissolves chromatin-bound proteins and other non-membrane, weakly attached lamina proteins, but not lamina proteins (Figure 1). Detergents (Octyl glucoside, Trx-100, Empigen BB) mimic the lipid bilayer environment and particularly dissolve membrane-associated proteins, except those that are anchored to the detergent resistant lamina (Figure 1). In this manner Cronshaw et al. successfully identified 6 novel NPC components, among which ALADIN, the gene mutated in the triple-A or Allgrove syndrome.²⁷ Chaotropes (urea, thiourea) and alkalines (NaOH) are used to solubilize cytoskeletal, chromatin and lamina components, while leaving integral transmembrane proteins

embedded in the insoluble membrane fraction (Figure 1). As such lamina and lamina anchored INM/NE proteins are extracted by combined application of salt and detergent (Figure 1; 29-30), whereas integral INM-ONM- and ER-membrane proteins are purified by chaotrope or alkaline extraction (Figure 1).

Despite increased sample purity by applying differential extractions, these fractionation studies are still hampered by co-purification of non-specific interactors, in particular from the peripheral ER, which is continuous with the ONM and therefore difficult to separate from the NE and lamina. To further reduce false positive hits, Dreger et al. compared salt, detergent and chaotrope/alkaline extractions, and were able to screen out ER contaminants in chaotrope/alkaline resistant fractions.²⁸ This strategy identified 19 previously unknown and putative integral INM proteins, including Unc84a (Sun1), LUMA and two LAP2 isoforms.²⁸ A disadvantage of this comparative approach is that selection is based on the assumption that all INM and lamina proteins have similar biochemical extraction characteristics. However, several lamina anchored INM proteins, like emerin, LBR and LAP1, behave biochemically very different in detergent or chaotrope-based extraction.²⁸

In an extension of purification methods, subtractive approaches can be used to filter out ER residing proteins. In these methods proteins identified in non-NE/lamina fractions, thus enriched for background, are subtracted from proteins detected in differential NE/lamina extracts. Schirmer and colleagues used microsomal membrane fractions as a source of background proteins, as these ER-rich fractions are easily obtained and can be prepared free of nuclear membranes.²⁹ By combining differential fractionation and subtractive proteomics, they identified 67 previously unidentified NE transmembrane proteins. The disadvantage of using a reference background source is that proteins that reside in both the ER and NE, like AEG-1/Lyric, Sec13 and Torsin A, are inadvertently discarded.³⁰⁻³² This is a serious concern, since it is now estimated that one third of cellular proteins have multiple organellar localizations.²⁵

Affinity purification

An alternative approach to identifying lamina interactions is affinity purification. In these approaches a protein of interest is epitope tagged and the bait protein is affinity purified using antibodies against the tag (Table 1). Affinity purification can identify and distinguish bound protein complexes from each other by co-elution and MS analysis. Such gradual elution was used for example to separate emerin-interacting RNA processing, signaling and chromatin remodeling complexes.³³ In addition, it is possible to study interactions in the context of posttranslational modifications by using specific antibodies directed against them, for example phosphorylation-dependent LBR-p32/p34³⁴, lamin A-Rb and -Smad2¹² interactions. In contrast to biochemical fractionation, in which fractions are generated under denaturing conditions, the main challenge in affinity purification assays is to extract as many NE and lamina proteins while leaving protein interactions intact. Overly stringent solubilization dissolves many proteins at the cost of disrupting complexes, while excessively mild conditions do not dissolve all relevant interactors. Various strategies have been applied to find a good balance for this trade-off.

In classic immunoprecipitations (IPs) solubilization conditions are optimized for the protein of interest (Table 1). Low amounts of detergents and salt preferentially solubilize nucleoplasmic pools of proteins (Figure 1), as described to exist for lamin A³⁵, and were mainly applied to study easily extractable, weakly bound NE interactors (Smad2, PP2A, Rb, Ubc9, hnRNP1, EGF1, SREBP1; See Table 2)^{5, 12, 36-38}. Increasing amounts of detergents, salts and the solvent glycerol³⁹ successfully solubilize protein complexes of well-anchored NE and lamina components (LAP2 β , Emerin, Nesprin2, Lamin B; Table 2), although sometimes at the cost of disrupting interactions (LaminA/B1/B2 - LAP2 β)⁴⁰ (Table 2). Highly stringent conditions were applied when studying NPC proteins as they were assumed to be highly stable structures (Table 2).⁴¹⁻⁴³ Even though NPCs apparently better withstand stringent extraction, increased stringency of washing buffers disrupts interactions (Table 2).⁴¹ An additional disadvantage to be accounted for is that lysis buffers also can affect the antibody/epitope-interaction. Various groups therefore prefer to dilute buffer compositions after initial lysis, which combines increased solubilization with the ability of protein complexes to reassemble and antibodies to bind under sequential

milder conditions. This strategy was used to identify unknown interactors for BAF and Emerin (Table 2).^{33, 44} Other limitations of antibody-based methods include the unavailability of IP-suited antibodies³⁶, antibodies that recognize multiple epitopes (MAN1 antiserum)³⁶, antibodies that cross-react undesirably with non-mature forms of a protein (prelamin A versus lamin A)³⁸ or even disrupt protein interactions (laminA/B2 - LAP2 β).⁴⁰

To avoid the use of antibodies, precipitations can be performed using bacterially expressed and purified baits, conjugated to beads prior to incubation with solubilized protein extracts. Fusing the bait to an epitope tag contributes to high quality purification of the bait, and efficient precipitation of interactors from protein extracts (Table 1). This approach was combined with mild lysis, for BAF and emerin interactors^{33, 44}, or more stringent buffers for lamin-LAP2 β and -nesprin 2 interactions (Table 2).^{40, 45} In accordance with mild solubilization, identified BAF and emerin interactors represented many proteins that also reside outside the nuclear periphery (PARP, HP1gamma, RBBP4,7).^{40, 45} Another advantage of using a bait is the ability to pinpoint interactions to relevant protein domains, as the bait does not have to be incorporated *in vivo* and therefore cannot mislocalize, as described to occur for LAP2 β constructs.⁴⁰ The main disadvantages of IPs using a bait is that solubilization issues still remain and interactions formed *in vitro* do not necessarily occur *in vivo*.

A major step forward in overcoming solubilization problems is the OneSTrEP (OST) pull-down assay^{6, 46}, which combines the use of a biotin resembling OST-tag⁴⁷⁻⁴⁸ with mild cross-linking of cells prior to solubilization (Table 1). Cross-linking allows extraction of the total lamin A/C pool⁴⁶ (Figure 1) while leaving protein interactions intact. The OST-tagged protein and its interactors can then be highly efficiently precipitated under denaturing conditions using a high-affinity, engineered streptavidin analogue (Table 2). Stringent washes reduce background, especially relevant for A-type lamins, known to be “sticky” proteins and reported to precipitate in negative pull-down controls as well.⁴⁴ The main advantages of the OST pull-down are that it can be used to identify a full *in vivo* interactome of a protein regardless of its subnuclear position, detect the effect mutations have on these interactions and identify weak interactors. OST pull-downs have been used to compare protein interactions for lamin A and progerin, an HGPS causing

lamin A mutant, and detected a decreased interaction for progerin with NPC components.⁴⁴ The main disadvantages of this approach is that it is not possible to study endogenous proteins and that cross-linking does not allow gradual elution and thereby separation of interacting protein complexes (Table 1).

Yeast Two-Hybrid

An interesting alternative to affinity purifications is yeast two-hybrid (Y2H) (Table 1), in which a direct interaction between a DNA-binding domain fused bait and a co-expressed transcriptional activating domain fused prey allows growth under restrictive conditions. When the primary interest is to identify weak and direct interactors Y2H is useful as bait and prey are expressed by strong exogenous promoters, protein solubilization is not required and weak interactions are sufficient to allow restrictive growth. The focus on direct protein interactions, which might best reflect the core activities of the protein of interest, restricts the mapping of a complete interactome. Protein fragments can easily be used as bait since they don't have to be incorporated *in vivo*, and have been applied to describe interactions between the specific domains of the nuclear envelope proteins Otefin, Lamin A, Nesprin2 and.^{45, 49-50} The benefit of choosing the exact bait composition can further be exploited by choosing domains involved in disease mechanisms, like the 50 amino acid deleted region in progerin, shown in a Y2H screen to interact with the NURD chromatin remodeling complex component Rbbp4.⁶ Disadvantages of Y2H assays are the lack of information on protein complex composition, the inability to study posttranslational modifications and the large amount of false positives identified. The large amount of background can be caused by endogenous transcriptional activity of bait or prey proteins, as reported for cFOS domains used to map lamin A interaction¹³, bait or prey proteins affecting yeast growth under restrictive conditions, and the fact that investigated interactions may never occur *in vivo* (Table 1). In addition, Y2H approaches for lamin proteins are particularly difficult since expression of lamin-fusion proteins in *S. Cerevisiae* has detrimental effects on the organism.

Chromatin-interactions

In addition to protein-protein interactions, the importance of interactions between chromatin and the lamina is increasingly appreciated. In particular, many lamin proteins are now known to directly or indirectly interact with chromatin and chromatin defects are a hallmark of several laminopathies.⁵¹⁻

⁵³ These observations have catalyzed the development of unbiased screening techniques for chromatin interactions at the NE. A broad distinction can be made between assays using affinity purification and those based on enzymatic activity (Figure 2, Table 3).

Affinity based approaches: ChIP & OST pull-down

Chromatin-protein interactions are most commonly interrogated using chromatin-immunoprecipitation (ChIP) methods. In this approach, a protein of interest is cross-linked to chromatin and immunoprecipitated using a specific antibody against the protein. The DNA is then identified either by targeted PCR methods or by genome-wide microarray or sequencing approaches. The major difference between conventional IPs and ChIP is the addition of a cross-linking step prior to solubilization of intact protein-chromatin complexes. Cross-linking provides the advantage of combining ultra-sonication and stringent lysis, to shear DNA and dissolve NE proteins (Figure 2), with good preservation of protein-chromatin interactions (Table 3). Just as for classic IPs, lysis buffers still need to be attuned to the strength of the epitope-antigen interaction. For this reason, initial ChIP studies were performed on Myc-tagged NPC proteins in *S. Cerevisiae*⁵⁴, as NPCs are easily dissolved in the absence of nuclear lamina and high quality ChIP-suited Myc antibodies are commercially available. For the INM protein Src1, a MAN1 resembling protein, interactions with (sub)telomeric regions were identified in yeast using a high affinity protA-system.⁵⁵⁻⁵⁶ Silver et al. used endogenous Nup93 in HeLa cells by dialyzing the initial lysis buffer to a milder variant prior to incubation with antibodies.⁵⁷ The foremost advantage of using antibodies is the ability to study endogenous proteins and chromatin interactions in the context of posttranslational modifications (Table 3).

A modification of the classical ChIP approach is the use of the OneSTrEP tag (OST) pull-down which enables high affinity precipitation of OST-tagged proteins under denaturing conditions completely dissolving A-type lamins,

Figure 2. Schematic overview of techniques to identify chromatin interactions, which are categorized in enzymatic- and affinity-based approaches. For DamID⁵⁹ a DNA adenine methyltransferase (Dam) tag (ball on stick) is fused to the protein of interest and adenylates (star) bound chromatin *in vivo*, enabling *in vitro* selective DpnI (scissor) restriction and subsequent amplification of restricted chromatin by ligation mediated PCR (LMPCR). For *in vivo* chromatin endogenous cleavage (ChEC)⁶⁴ a protein of interest is fused to a micrococcal nuclease (MNase) tag, which introduces DNA double strand breaks (scissors) upon introduction of calcium chloride to weakly permeabilized cells. Due to the mild permeabilization of cells prior to addition of calcium chloride for activation, the MNase digestion step is indicated as being partially *in vitro* and *in vivo*. Restricted DNA is amplified by LMPCR. For chromatin immunocleavage (ChIC)⁶⁴ cells are cross-linked (crosses). *In vitro*, MNase-conjugated antibody interacts with the epitope of interest and induces DNA breaks enabling LMPCR amplification of cleaved chromatin. For chromatin immunoprecipitation (ChIP) chromatin-protein interactions are cross-linked and chromatin is randomly sheared, typically by ultrasonication, (lightning arrow and stripes). Antibodies are used to precipitate the endogenous protein of interest with the help of antibody binding beads (big ball). In a OneSTrEP (OST) pull-down a OST-tagged protein is expressed.⁵⁸ Cells are cross-linked and ultrasonicated. The OST-protein is highly efficiently precipitated by a streptactin matrix (big square).

comparable to the use of OST tags used for pull-down of proteins (Table 3).^{46, 58} The OST pull-down for identification of chromatin interactions is highly similar to that for detecting protein interactions, and only includes slight changes in sonication and washing conditions.^{46, 58} Although OST pull-downs have the advantage of easy solubilization and high affinity pull-down without the use of antibodies, which in the case of lamin A have not been ideal in ChIP experiments, a limitation is the inability to directly study endogenous proteins and posttranslational modifications (Table 3).

Enzymatic activity based approaches: DamID, In vivo ChEC, ChIC

DamID is an enzyme-based method for the *in vivo* mapping of chromatin-protein interactions. In DamID a protein of interest is fused to a DNA adenine methyltransferase (Dam) and expressed. Upon binding of the fusion protein to chromatin, the Dam activity marks in the vicinity bound chromatin by methylation, thereby enabling selective DpnI restriction *in vitro*. The marked sites can then be identified by targeted PCR or, more commonly, by genome-wide microarray analysis and deep-sequencing⁵⁹ (Figure 2). The main advantage of using a tag that enzymatically marks DNA is that only isolation of DNA, not of intact protein/chromatin complexes, is required, thus eliminating any issues related to interaction stability. In addition, there is no need for cross-linking, thereby avoiding potential fixation artifacts. These characteristics made DamID the first technique to characterize and compare chromatin interactions for the relative insoluble lamin B and emerin proteins in a genome-wide fashion and resulted in the characterization of lamin associated domains (LADs) which define regions of the genome that preferentially interact with the lamina.⁵⁹⁻⁶⁰ Disadvantages of DamID include the inability to study posttranslational modifications, a slightly reduced resolution

compared to alternative assays and potential interference of the tag with protein localization or functioning (Table 3).⁶¹ In addition, since DamID relies on the expression of an enzymatically active fusion protein, it monitors chromatin interactions over a relative long period of time (app. 24 hours) and therefore is less useful to detect rapid interaction changes and dynamic reorganization of chromatin. Due to the DNA binding activities and high enzymatic activity of Dam, tagged proteins can only be expressed in trace

amounts in order to prevent saturation of non-targeted DNA methylation.⁶² This makes it not possible to study chromatin interactions in a dosage dependent manner, which could be relevant for diseases in which phenotypes are dependent on the amount of protein, such as HGPS.⁶³

An alternative method to measure protein-chromatin interactions is ChEC (chromatin endogenous cleavage). In this approach, micrococcal nuclease (MNase) is fused to a protein of interest and expressed. The fusion protein is recruited to its endogenous sites on chromatin where the MNase introduces double strand breaks at nuclease hypersensitive sites (HS).⁶⁴⁻⁶⁵ The MNase tag remains inactive under physiological Ca^{2+} concentrations, which provides the ability to selectively turn its activity on *in vivo* by addition of calcium chloride to mildly permeabilized cells. Cleaved chromatin can either be directly used to map HS sites by indirect end-labeling and Southern blotting, or is first selectively amplified by ligation-mediated PCR prior to genome-wide microarray analysis and deep-sequencing (Figure 2).⁶⁴ Laemmli and colleagues used this approach to map chromatin interactions of the nuclear pore complex protein Nup2 and found that Nup2-gene promoter interactions typically are an early event of gene activation and are independent of transcription.⁶⁴ Control over MNase activity and relative short times needed for

digestion make this assay suitable for detection of rapid changes in interactions. The major strength of *in vivo* ChEC is that there is no need to dissolve intact protein/chromatin complexes and information on chromatin structure is obtained by mapping HS (Table 3). In comparison to DamID higher expression levels of MNase-tagged proteins can be used, although at very high expression levels background issues were reported.⁶⁵ ChEC can also be modified to study posttranslational modifications as the MNase tag can also be conjugated to an antibody of interest. This *in vitro* method is referred to as chromatin immunocleavage (ChIC). In ChIC cross-linked cells are lysed and incubated with MNase-coupled antibodies that bind to the epitope of interest after induction of DNA cleavage by Ca^{2+} (Figure 2). ChIC is a hybrid between affinity- and enzyme-based approaches in that it uses cross-linking and antibodies, but does not need to fully dissolve and precipitate intact protein-chromatin complexes due to the use of enzymatic activity, which specifically marks bound DNA (Table 3).

Concluding remarks

The characterization of structural and other functional components in the nuclear lamina is vital for our understanding of higher-order chromatin organization, transcription, DNA replication and various other nuclear processes. Recent development of powerful techniques to map protein and chromatin interactions have begun to reveal these roles.

Several approaches to identify the interaction network at the nuclear periphery are now available. These methods are all complementary and each has its own usefulness and limitations. Ideally, one would map the interactions of proteins and chromatin using multiple, complementary techniques. At present this is practically often not feasible, however, as interaction-detection methods are improved, it should become possible to interrogate interactions by multiple means. For now, the choice of method often relies on the particular question to be addressed. When it is important to identify multiple sub-cellular localizations of a protein, visual screens are the best option. Biochemical fractionation studies best assist in revealing a full proteome. A more detailed impression of an individual protein's interactome can be obtained by classic IPs to study endogenous proteins, by OST pull-down to identify weak and relative insoluble proteins, and by IPs using a bait to distinguish individual protein complexes. Mapping interactions of direct and weak interactors to protein domains can best be done by Y2H. For DNA interactions a careful choice has to be made between the need for studying endogenous proteins and posttranslational modifications (ChIP, ChIC), obtaining extra information on chromatin structure (*In vivo* ChEC, ChIC), full protein solubilization and obtaining an instant snapshot of interactions (OST pull-down), or not dissolving protein/chromatin complexes and capturing interactions over a longer period of time (DamID).

Even though the overlap between various chromatin techniques is slightly bigger than for protein techniques, in both fields a combinatorial or comparative use of techniques, as well as the target proteins they are applied on, will lead to more reliable results and provide a better understanding of the NE. These methods are becoming increasingly routinely used in many laboratories and is no doubt that proteome and

genome-wide mapping method and screening for mutation-induced interaction changes will play a key role in unraveling nuclear lamina function and laminopathy disease mechanism.

CHAPTER 3

Identification of differential protein interactors of lamin A and progerin

Based on: Kubben N, Voncken J, Demmers J, Calis C, van Almen G, Pinto Y, Misteli T. *Nucleus*. 2010

Abstract

The nuclear lamina is an interconnected meshwork of intermediate filament proteins underlying the nuclear envelope. The lamina is an important regulator of nuclear structural integrity as well as various nuclear processes, including transcription, DNA replication and chromatin remodeling. The major components of the lamina are A-type and B-type lamins. Mutations in lamins impair lamina functions and cause a set of highly tissue-specific diseases collectively referred to as laminopathies. The phenotypic diversity amongst laminopathies is hypothesized to be caused by mutations affecting specific protein interactions, possibly in a tissue-specific manner. Current technologies to identify interaction partners of lamin A and its mutants are hampered by the insoluble nature of lamin components. To overcome the limitations of current technologies, we developed and applied a novel, unbiased approach to identify lamin A-interacting proteins. This approach involves expression of the high-affinity OneSTrEP-tag, precipitation of lamin-protein complexes after reversible protein cross-linking and subsequent protein identification by mass spectrometry. We used this approach to identify in mouse embryonic fibroblasts and cardiac myocyte Nk1TA_g cell lines proteins that interact with lamin A and its mutant isoform progerin, which causes the premature aging disorder Hutchinson-Gilford Progeria Syndrome (HGPS). We identified a total of 313 lamina-interacting proteins, including several novel lamin A interactors, and we characterize a set of 35 proteins which preferentially interact with lamin A or progerin.

Introduction

The nuclear lamina lines the nuclear envelope (NE), which is composed of an outer and inner nuclear membrane (ONM, INM,) interrupted by nuclear pore complexes (NPC).¹ The lamina is a proteinaceous structure consisting of the intermediate filament A-type (somatic: lamin A, AΔ10, C; germ cell specific: C2) and B-type lamins (somatic: lamin B1, B2; germ cell specific: B3), integral membrane proteins anchoring the lamina to the NE including LAP2, Emerin, Lamin B receptor, MAN1, and proteins involved in a variety of nuclear processes including DNA replication, chromatin remodeling, cell cycle progression and signal transduction.² Mutations in lamins or other lamina proteins can impair specific functions or interfere with the structural integrity of the nucleus.³ Mutations in lamin components cause various human diseases referred to as laminopathies and include several types of muscular dystrophies, lipodystrophies, cardiomyopathies, neurological disorders and premature aging syndromes.²

One model for the tissue-specificity and phenotypic diversity among laminopathies is the notion that mutations which cause laminopathies lead to differential interactions of mutant lamins with their associated proteins.² In support, several mutations in the carboxy-terminus of lamin A that lead to Emery-Dreifuss muscular dystrophy (EDMD) or dilated cardiomyopathy 1A (CMD1A) impair a direct binding of lamin A to emerin.⁴ In addition, progerin, the lamin A isoform that causes the premature aging disease Hutchinson-Gilford Progeria Syndrome (HGPS), is unable to interact with several members of the NURD chromatin remodeling complex, thereby contributing to HGPS characteristic chromatin defects.⁵ Although these observations suggest a role for differential protein interactions in the tissue-specificity of laminopathies, they are circumstantial. Systematic mapping of the complete spectrum of wild-type and mutant lamin A interacting proteins is required to test this disease model. Such approaches will also clarify the function of lamin A in biological processes and may contribute to the identification of targetable pathways relevant to specific laminopathies.

Experimental approaches to identify lamin interacting proteins are severely hampered by the unique biochemical properties of the nuclear lamina, which is classically defined as a non-ionic detergent, salt and nuclease

insoluble peripheral nuclear structure.¹ Solubilization of the lamina by ultrasonication and high concentrations of ionic- or chaotropic detergents inevitably results in disruption of intact lamin-protein complexes, impeding analysis by precipitation methods. Various alternative strategies have been applied to circumvent these technical problems, including immunoprecipitation (IP) with partial solubilization under mild conditions, IP using harsh solubilization conditions followed by *in vitro* protein complex re-assembly under mild conditions, mass spectrometry (MS) analysis of differential extractions from isolated whole nuclear membrane fractions, and yeast two-hybrid, GST-pull-downs and other techniques which do not need protein complex solubilization.⁶⁻¹² Each technology has its specific drawbacks including low recovery, high false positive rates and non-physiological conditions.

Here we have developed and applied a novel method to identify wild-type and mutant lamin A interacting proteins. This approach is unbiased and overcomes many of the limitations of current methods to identify lamin A-interacting proteins. Our approach consists of expression of lamin A tagged with a OneSTrEP biotin analogue tag followed by isolation of intact lamin-protein complexes after protein cross-linking for 5 minutes using 1% formaldehyde. Direct and indirect interaction partners are identified by sensitive MS after a highly specific streptactin matrix precipitation. Using this approach we identify 313 lamina-interacting proteins including numerous novel candidates, and proteins that appear to associate preferentially with either wildtype lamin A (8 candidates, including *Nup153*, *Nup98* and *Translocated promoter region*) or progerin (27 candidates, including *Paired related homeobox 1*, *Proliferating cell nuclear antigen* and *Pinin*).

Materials & Methods

Cell lines and culture

A lentiviral expression plasmid for N-terminal OneSTrEP tagged progerin (OST-P) was created by PCR amplification of lamin A, omitting amino acids 609-658 using the previously described pCDH MCSNard OST-A plasmid as template.⁵ Forward and reverse primers, containing a BamHI and EcoRI

restriction site, were used for subsequent ligation of the PCR product in BamHI/EcoRI digested pCDH MCSNard OST-A plasmid. For the cloning of pCDH MCSNard OST-Lamin C (OST-C), lamin C was PCR amplified from the previously described pBabe purox HA-Lamin C plasmid, adding an in frame 5' Sall and a 3' EcoRI site, which were used for ligation into equally digested pCDH MCSNard OST-A plasmid.¹³ Lentivirus was produced in 293 FT cells (Invitrogen, Carlsbad, USA) co-transfected with pCDHblast MCSNard OST-A, OST-P or OST-C in combination with pSPAX and pMD2.G vectors (Trono Lab). The mouse cardiac myocyte cell line Nk1TAG, human osteosarcoma cell (U2OS), as well as mouse embryonic fibroblasts (MEFs) of wildtype (LMNA^{+/+}) and LMNA knock-out (LMNA^{-/-}) embryos were infected with various concentrations of lentivirus and 48 hours post infection selected with blasticidin.¹⁴⁻¹⁵ Infected cells with OST-tagged lamin protein amounts comparable to endogenous lamin protein levels were further cultured and grown in Dulbecco's modified Eagle's/F-12 media (for Nk1TAG cells) or Dulbecco's modified eagle medium (for U2OS and MEFs) both supplemented with 2mM L-glutamine, 10mM non-essential amino acids, 110 mg/l pyruvate, 10% fetal bovine serum and antibiotics in a humidified atmosphere at 37°C and 5% CO₂. Nk1TAG cells were plated on 12.5 µg/ml fibronectin and 0.1% gelatin coated plates.

Immunofluorescence

For immunofluorescence microscopy LMNA^{-/-} MEFs infected with control, OST-A or OST-P lentivirus were grown on 0.1% gelatin/PBS solution coated multi-wells glass slides (MP Biomedicals). After fixation (4% paraformaldehyde/PBS; 15 min), cells were permeabilized (0.5% Triton X-100/PBS; 5 min), blocked (1% BSA, 1% sucrose in milliQ; 1 hour) and incubated for one hour with appropriate primary antibodies (α -LMNA/C, Sc-7292, Mouse, Santa Cruz, detects OST-tagged and endogenous human, but not mouse, lamin A, Lamin C and Progerin; α -emerin, Cl.4G5, mouse, Leica; α -HP1 γ , mab3450, Chemicon, Temecula, USA ; α -LAP2, kind gift from K. Wilson, raised against residues 1-187 of human LAP2, and suitable for detection of all LAP2 isoforms). Primary antibodies were detected with an Alexa Fluor 488 chromophore labeled secondary antibody (Invitrogen). Cells were mounted in Vectashield containing 10g/ml DAPI and observed on a Nikon E800 microscope. Quantitative microscopy measurements were

performed as previously described.¹⁶⁻¹⁷ Exposure times and acquisition settings were established at the beginning of the experiment and kept constant for all samples. The average nuclear intensity of total LAP2 (all isoforms included) and HP1 γ minus average background signal was measured for at least 200 cells per sample in duplicate using Metamorph software (Molecular Devices). The criteria to define cells with reduced levels of chromatin proteins were previously described.¹⁶⁻¹⁷

OneSTrEP-lamin A farnesylation and proliferative effects

To determine whether OST-A was correctly farnesylated U2OS cells expressing OST-A and C at endogenous levels were treated with indicated concentrations of Atorvastatin (10 mM stock dissolved in DMSO was further diluted in cell culture medium) for 48 hours. Samples were harvested in Laemmle Sample Buffer and further analyzed by western blotting. Proliferative effects of OST-tagged lamin A/C were determined with the MTS assay, as described elsewhere.¹³ LMNA^{-/-} MEFs infected with empty control or OST-A and C were seeded at 1000 cells per well in 96 wells plates.¹⁵ 62 hours post attachment 20 ml 2 mg/ml 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium (Promega CellTiter 96w AQueous MTS) and 1 ml 0.92 mg/ml phenazine methosulfate (Merck) was added for 3 hours. The tetrazolium is reduced by the living cells into a colored formazan product, which absorbance was measured at 490 nm and is directional proportional to the cell number. Statistical analysis was performed by Student's t-test.

OneSTrEP pull-down assay and mass spectrometry

U2OS, Nk1TAg and MEF cell lines were grown until confluency in 150 mm dishes. Plates were left for several minutes at ambient temperature before protein complexes were mildly cross-linked by direct addition of formaldehyde to the culturing medium to a final concentration of 1% (10 minutes, ambient temperature). The cross-linking reaction was stopped by addition of glycine (125 μ M final conc.) and gentle shaking for 5 minutes at ambient temperature. Fixed cells were scraped in PBS, pelleted, dissolved in ice-cold SDS lysis buffer (1% SDS, 10 mM EDTA, 50 mM Tris pH 8.1), snap frozen in dry ice once, thawed, left for 30 minutes on ice and finally sonicated for 2 times 30 seconds at 10 μ m amplitude using a tip sonicator.

Endogenous biotinylated proteins were blocked by addition of avidin (10 µg/ml). As the affinity of avidin for biotin is much higher than for the OneStrEP epitope, OST-tagged lamin pull-downs will not be impaired by the addition of avidin.¹⁸ A small sample aliquot was taken, de-cross-linked for 6 hours at 65°C in the presence of 200mM NaCl and 30 µg/ml RNAase A, after which the genomic DNA concentration was determined with a Qiagen PCR clean-up kit (Qiagen). Next, protein samples were diluted in SDS lysis buffer to contain equal amounts of genomic DNA (typically 200µg genomic DNA/pull-down for MS purposes) and subsequently diluted in CHIP dilution buffer (0.1% SDS, 1.1% Triton X-100, 1.2 mM EDTA, 17 mM Tris pH 8.1, 170 mM NaCl) to reach a final concentration of 0.2% SDS, 0.1% Triton X-100, 2mM EDTA, 20 mM Tris.HCl pH 8.1, 150 mM NaCl. Both SDS lysis buffer and CHIP dilution buffer were supplemented with 2 mM sodiummorthovanadate and protease inhibitors (Boehringer Mannheim). Undissolved fractions were discarded after a 10 minute centrifugation step (16,000 g) at 4 degrees and a small sample of the supernatant (i.e. input fraction) was stored for further analysis. CHIP dilution buffer pre-washed Strep-Tactin Matrix (IBATagnology) was added and OST-lamin/protein complexes were bound by overnight end-over-end rotation. Strep-Tactin matrix was pelleted by centrifugation and the supernatant (i.e. depleted fraction) was stored, while the pellet was washed four times with OST stringent wash buffer (2M NaCl, 2% Trx-100, 500 mM LiCl, 0.1% SDS, 1% Sodium Deoxycholate, 20 mM Tris pH 8.1, 2mM EDTA) and twice with CHIP dilution buffer. LiCl was included to improve the effective removal of non-specific interactors by the presence of different types of salts. Pelleted protein-chromatin complexes (pull-down fraction), input and depleted fractions were de-cross-linked by boiling for 20 minutes at 95°C in Laemmli Sample Buffer.

For pull-down verification purposes samples were analyzed by western blot (see below). For mass spectrometry (MS) pull-down fractions were separated on NuPage Novex Bis-Tris 4-20% gradient gels (Invitrogen) and stained with Coomassie Brilliant Blue (CBB). For CBB staining gels were first fixed for minimally 2 hours in solution 1 (50% v/v ethanol, 2% v/v phosphoric acid), washed 3x30 minutes in distilled water, incubated for 1 hour in solution 2 (34% v/v methanol, 17% w/v ammonium sulphate, 2% v/v phosphoric acid) and finally stained with CBB-G (0.66% w/v in distilled water) until desired staining intensity was reached (1-3 days). Gels were

stored in distilled water and transported for subsequent MS analysis at the Erasmus MC Proteomics Center (Rotterdam, The Netherlands). Gel lanes were cut and subjected to in-gel digestion with trypsin (Promega), essentially as described previously.¹⁹ Polypeptides were identified on an LQT Orbitrap hybrid mass spectrometer (ThermoFischer), coupled to an 1100 series capillary liquid chromatography system (Agilent Technologies) as described elsewhere.²⁰ Data analysis was performed using a Mascot based search algorithm (version 2.2; MatrixScience).²⁰

Mass spectrometry data analysis

In order to compare MS results of various samples, all retrieved GI and IPI protein identifiers were converted to *Mus Musculus* and *Homo Sapiens* Entrez identifiers, using the Database for Annotation, Visualization, and Integrated Discovery (DAVID), BioDBNet (<http://biodbnet.abcc.ncifcrf.gov/db/db2db.php>), Clone/Gene ID converter and g:profiler databases.²¹⁻²⁴ For identifiers that could not be converted to Entrez identifier with these databases, the top hit with matching Entrez ID of a protein blast search (<http://blast.ncbi.nlm.nih.gov>) using a PSI-Blast algorithm was used. This created one list of all MS identified proteins in our study, which was used for alignment of individual MS sample results using excel software with a DigDB plugin (<http://www.digdb.com/>). To select true lamin interactors, several selection criteria were sequentially applied. First, proteins needed to be detected at high levels, i.e. average OST-A mascot score above 100, with the average calculated only in OST-A samples in which the protein was detected. Second, proteins were required to be detected at levels minimally 3-fold less in background pull-downs (based on average mascot scores, calculated as described for previous criterion). Third, keratin proteins and proteins with gene ontology (GO) codes for mitochondria and ribosome, which are all considered non-lamin A interacting proteins, were excluded. In order to compare OST-A and OST-P pull-down results in LMNA^{-/-} and LMNA^{+/+} MEFs these selection criteria were first applied to identify lamina interactors, independent of cell line and OST-A or OST-P construct. Amongst this protein set of lamina interacting proteins, differential interactors were selected by several additional criteria. Proteins were only included if in either cell line the overall average mascot score (including samples in which

no protein fragment was detected for calculation of the average) of OST-A or OST-P was above 100 and more than 3-fold larger than background pull-down overall average mascot scores. Next, proteins were required to have a ratio of OST-P over OST-A overall average mascot scores above 3.0 or below 0.33 in either LMNA^{-/-} or LMNA^{+/+} MEFs;. The final inclusion criterion was that this ratio was similar directed (both above or below 1.0) in both cell lines. Mascot scores were considered semi-quantitative only, and were used to distinguish proteins that might either have higher affinity for lamin A or progerin (or associated proteins) or were expressed more abundantly in OST-A versus OST-P cells. Whether these candidates bound lamins directly or indirectly was not revealed by this method.

GO analysis for indicated proteins subsets were performed separately for GO categories “cellular components level 5” (CC), “biological process all” (BP) and “molecular function all” (MF) using *Mus Musculus* Entrez Identifiers as input values and standard DAVID settings for functional annotation clustering, listing significant clusters by most significant GO term.²²⁻²³ GO analysis was performed against a random protein background consisting of all known *Mus Musculus* Entrez identifiers, or a set of previously identified nuclear envelope proteins.^{6, 10} To identify enrichment of protein complexes a clustering analysis was performed with DAVID against the reactome database, using *Homo Sapiens* Entrez gene identifiers.

Plasmid transfection

For verification of differential interactors U2OS Ctrl, OST-A and OST-P expressing cells were plated at 80% confluency in 10mm-dishes and FuGENE transfected with previously described expression plasmids for Myc-Nup98, Myc-Nup153, GFP-Nup107, GFP-Tpr and Myc-Prx1 (Kindly provided by respectively Günter Blobel, Brian Burke, Thomas Schwartz, Larry Gerace and Peter Lloyd Jones).²⁵⁻²⁹ 32 hours after transfection cells were harvested for a OST pull-down assay.

Western blot

Western blots were performed essentially as described elsewhere.⁵ SDS-PAGE Laemmli sample buffer was added to protein samples from various stages of the OST-pull-down (input, depleted, pull-down) and heated for 20

minutes at 95°C to de-cross-link and denature proteins. Equal amounts of protein extract were loaded and run on NuPage Novex Bis-Tris 4-20% gradient gels (Invitrogen, Carlsbad, USA), blotted on immobilon-PVDF membrane (Millipore, Billerica, USA), blocked 1 hour in 5% bovine serum albumin /TBS-T (20 mM Tris-HCl pH 7.5, 150 mM NaCl and 0.1% Tween 20). The blocked membrane was incubated at 4°C overnight in block buffer diluted primary antibodies. The following antibodies were used: α -LaminA/C (Sc6215, Goat, Santa Cruz; detects endogenous Lamin A and C, OST-A, OST-C and OST-P), α -LaminA/C (Sc7293, mouse, Santa Cruz; detects only endogenous Lamin A and C, and not OST-A, OST-C or OST-P), α -LAP2 (Y-20, Sc19783, Goat, Santa Cruz; detects all LAP2 isoforms), α -GFP (Ab6673, Goat, Abcam), α -Onestrep (2-1507-001, mouse, IBATagnology), α -c-Myc (MS-139-P, mouse, Labvision), α -Emerin (Cl.4G5, mouse, Leica), α -Beta-Actin (Cl.AC15, A-5441, mouse, Sigma), α -Trim28 (A300-767A, rabbit, Bethyl Laboratories), α -Ku70 (Ab10878, rabbit, Abcam). After incubation with appropriate secondary HRP-labeled secondary antibodies immunoluminescence was detected with an ECL Western Blotting detection system from Amersham. Intensity of signals were quantified using ImageJ software and statistically analyzed with a Student's t-test.

Results

Characterization of OneSTrEP tagged A-type lamins

To ensure protein purification with high affinity and specificity, we made use of a modified version of the well-characterized streptavidin/biotin system.³⁰⁻³¹ A-type lamins were tagged with the OneSTrEP (OST) tag (Figure S1), and expressed at endogenous levels in human osteosarcoma (U2OS), mouse myocyte Nk1Tag or mouse embryonic fibroblasts (MEFs) from LMNA^{+/+} or LMNA^{-/-} cells (Figure 1A).¹⁴ The OST-tag is a biotin analogue, but offers the advantage of binding with high specificity and affinity ($K_d=1\mu\text{M}$) to the streptavidin analogue Strep-Tactin matrix.¹⁸ In addition, the OST-tag is relatively small (3kDa) compared to other epitope tags typically used for MS purposes, thus reducing the likelihood of interference with protein function. To test for physiological functionality of OST-tagged A-type lamins, we first

Figure 1. Characterization of OneStrEP tagged A-type lamins. (A) Western blot of endogenous and tagged A-type lamin in OneStrEP-tagged lamin A (OST-A), lamin C (OST-C), progerin (OST-P) or control virus-infected mouse cardiac NkITAg myocytes, human osteosarcoma U2OS cells, and mouse embryonic fibroblasts (MEFs) from wildtype (LMNA^{+/+}) or LMNA knock-out (LMNA^{-/-}) embryos. The following antibodies were used: α -LaminA/C (Sc6215, Goat, Santa Cruz; detects endogenous Lamin A and C, OST-A, OST-C and OST-P) and α -Beta-Actin (Cl.AC15, A-5441, mouse, Sigma). **(B)** Western blot of endogenous and OST-tagged lamin A, lamin C and prelamin A in U2OS cells infected with OST-A or OST-C and treated for 48 hours with indicated concentrations of atorvastatin, an inhibitor of lamin A farnesylation. The following antibodies were used: α -LaminA/C (Sc7293, mouse, Santa Cruz; detects only endogenous Lamin A and C, and not OST-A, OST-C or OST-P) and α -Onestrep (2-1507-001, mouse, IBATagnology). **(C)** Immunofluorescence staining of OST-A, OST-P and control infected LMNA^{-/-} MEFs for A-type lamins (LMNA) and emerin. DNA was stained with DAPI. The following antibodies were used: α -LMNA/C (Sc-7292, Mouse, Santa Cruz, detects OST-tagged human Lamin A and Progerin, but no endogenous murine lamins), α -emerin (Cl.4G5, mouse, Leica). **(D)** MTS ((3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium)) assay to quantify relative cell number 62 hours after attachment of equal cell numbers of control or OST-A/C infected LMNA^{-/-} MEFs. An asterisk indicates a significant difference ($p < 0.05$) between control and OST-A/C infected cells.

determined whether OST-tagged lamin A (OST-A) was farnesylated correctly in U2OS cells. Normally mature lamin A is formed after cleavage of the farnesylated C-terminal *Caax* motif in prelamin A by *Zmpste24*.³² Atorvastatin inhibits the synthesis of farnesyl pyrophosphate and thereby impairs farnesylation and processing of prelamin A to mature lamin A.³³ The farnesylation of both OST-A and endogenous lamin A in U2OS cells was inhibited similarly by increasing concentrations of atorvastatin (Figure 1B). OST-tagged and wildtype lamin C do not contain a *Caax* motif and remained unaffected by atorvastatin (Figure 1B).

Next, we visualized the localization of OST-A and OST-tagged progerin (OST-P) in A-type lamin knock-out (LMNA^{-/-}) MEFs (Figure 1C).¹⁵ As expected, both OST-A and OST-P were detected at the nuclear rim. In contrast to OST-A, OST-P generated distortions in of the nuclear lamina identical to those seen in HGPS patient cells (Figure 1C).¹⁶ Furthermore, expression of OST-P leads to a decrease of total LAP2 (all isoforms included) and HP1 γ protein levels in the nucleus (Figure S2) as observed as well in HGPS and progerin-expressing fibroblast.¹⁷ OST-A expression further restores correct localization of endogenous emerin in LMNA^{-/-} MEFs to the NE (Figure 1C).³⁴ This capacity was reduced after 3 days in culture for OST-P (Figure 1C). Finally, combined expression of OST-A and OST-C inhibited cell proliferation, in line with previously reported endogenous lamin knock-down and HA-tagged lamin A and C overexpression studies (Figure 1D).¹³ Taken together, these data demonstrate that OST-tagged A-type lamins recapitulate endogenous lamin farnesylation, subcellular localization and dominant functions.

OneSTrEP pull-down assay

To isolate lamin A-associated proteins we used mild reversible cross-linking (5 minutes, 1% formaldehyde) to capture protein/protein and protein/DNA complexes (Figure 2A). Cross-linking enabled us to extensively solubilize A-type lamins by using vigorous sonication in combination with high percentage ionic detergent (1% SDS; Figure 2B). Solubilized protein complexes were diluted to comparable amounts of starting material, by correcting sample volumes to reach equal genomic DNA concentrations, (Figure 2A) and OST-tagged lamins were precipitated using Strep-Tactin matrix, a high-affinity streptavidin analogue.³⁰⁻³¹ Precipitated lamin-protein

Figure 2. OneSTREP pull-down assay. (A) Schematic overview of the OST pull-down protocol for cells infected with control and OST-tagged lamin, with the input, depleted and pull-down fraction indicated in bold. Depending on the purpose of the experiment proteins separated on SDS-Page gels were stained with Coomassie Brilliant Blue (CBB) (for mass spectrometry), or immunoblotted for verification of individual candidates. **(B)** U2OS cells were fixed in 1% formaldehyde, sonicated in SDS lysis buffer and further diluted in CHIP dilution buffer as described in Materials and Methods. Total protein extracts were spun down, separating the solubilized fraction (i.e. supernatant) and the insoluble fraction (i.e. pellet, twice washed with PBS). Total, insolubilized and solubilized fractions were compared for endogenous lamin A/C protein levels by western blot. The following antibody was used: α -LaminA/C (Sc6215, Goat, Santa Cruz; detects endogenous Lamin A and C). **(C)** Western blot of U2OS OST-A/C cell extracts (1% formaldehyde vs. no fixation) dissolved in Laemmli sample buffer (no heating vs. 20 minutes at 95°C) before loading on SDS-PAGE gels. The following antibodies were used: α -LAP2 (Y-20, Sc19783, Goat, Santa Cruz; LAP2 β isoform depicted) and α -Onestrep (2-1507-001, mouse, IBATagnology). **(D)** Western blot of endogenous lamin A/C and Lap2 β after cross-linking with 1% formaldehyde in U2OS cells infected with control or OST-A/C virus. The following antibodies were used: α -LAP2 (Y-20, Sc19783, Goat, Santa Cruz; LAP2 β isoform depicted), α -LaminA/C (Sc7293, mouse, Santa Cruz; detects only endogenous Lamin A and C, and not OST-A or OST-C) and α -Onestrep (2-1507-001, mouse, IBATagnology). **(E)** Western blot of OST-pull-down for lamin-A/protein complexes solubilized in SDS lysis buffer with increasing sonication strength (from 12x1 sec at 5 μ m amplitude, +; to 6x5sec at 10 μ m amplitude, +++). The following antibodies were used: α -LAP2 (Y-20, Sc19783, Goat, Santa Cruz; LAP2 β isoform depicted) and α -Onestrep (2-1507-001, mouse, IBATagnology).

epitope masking on western blot without detectable protein degradation (Figure 2C). Cross-linking was crucial for co-precipitation of lamin complexes were eluted and de-crosslinked under conditions (20 minutes at 95°C in Laemmli Sample Buffer) that fully reversed crosslink-induced interactors, as omitting this step resulted in loss of the known OST-A/C interaction partners wildtype lamin A/C and LAP2 β in purified protein complexes (Figure 2D).³⁵⁻³⁶ Increasing sonication strength drastically improved retrieval of the lamin A interacting partner LAP2 β (Figure 2E). These findings demonstrate that the OST-tag/Strep-Tactin pull-down approach is able to recover lamin A protein complexes after temporal cross-linking and solubilization.

Identification of lamin A interacting proteins

To identify and characterize lamin A-interacting proteins OST pull-downs were performed on murine cardiac myocyte Nk1TAG cells expressing OST-A at endogenous levels or a control virus lacking the lamin A transgene. Co-purified proteins were size-separated and retrieved from SDS-PAGE gels and analyzed by MS (Figure 3A). In total 5,162 unique peptide fragments corresponding to 649 individual proteins were detected in two independent experiments (Figure 3A). We reduced the list of potential interactors by stringent restrictive analysis (i.e. mascot score cut-off, minimum fold over background and filtering out non-essential peptides; see Materials and Methods; Figure 3A) to 60 proteins. The set of identified proteins contains several known lamin A interactors including *Lamin B*, *Lap2 β* , *Emerin*, *MAN1*, *Sun1* and 2, as well as the muscle specific interactor *Syne-2* (Figure 3A, Table S1).³⁷ About half of our candidate lamin A interactors were identified in two previous NE proteome studies which had identified proteins in an INM/lumen/ONM⁶ fraction or an INM/lamina/nucleoplasmic fraction¹⁰, respectively, in other cell types.^{6,10}

We identified 29 novel lamin A interactors (Table S1). These include proteins implicated in muscle differentiation (*Luc1-like*, *Serpine1 mRNA binding protein*), transcription factors (*Strap*, *Similar to calponin 3*), DNA repair (*Ku70*) and heterochromatin maintenance (*Trim28*).³⁸⁻⁴³ Several known (*Emerin*, *Lap2 β*) as well as previously unidentified lamin A interactors (*Trim28*, *Ku70*) were chosen for validation of the MS data by targeted co-precipitation. *Trim28* and *Ku70* were specifically chosen as they represented

Figure 3. Identification of lamin A interacting proteins. (A) Overview of the selection criteria for identification of lamin A interacting proteins from raw mass spectrometry data. Control and OST-A pull-down average mascot scores for several lamin A interactors identified in NkITAg cells are depicted (Underlined proteins are verified in figure 3B). (B) Western blot indicating protein levels of mass spectrometry identified lamin A-interactors (endogenous *lamin A/C*, *Lap2 β* , *Emerin*, *Trim28* and *Ku70*) precipitated in NkITAg cells infected with control or OST-A virus. The following antibodies were used: α -Onestrep (2-1507-001, mouse, IBATagnology), α -LaminA/C (Sc7293, mouse, Santa Cruz; detects only endogenous Lamin A and C, and not OST-A), α -LAP2 (Y-20, Sc19783, Goat, Santa Cruz; LAP2 β isoform depicted), α -Emerin (Cl.4G5, mouse, Leica), α -Trim28 (A300-767A, rabbit, Bethyl Laboratories) and α -Ku70 (Ab10878, rabbit, Abcam). (C) GO analysis of identified lamin A interactors. GO analysis was performed separately for the GO categories “cellular components” (CC), “biological process” (BP), “molecular function” (MF) and compared against a random protein set.²²⁻²³ The number of lamin A interacting proteins identified within a specific GO category versus the total amount of annotated lamin A interacting proteins is indicated next to the significantly enriched GO categories ($p < 1 \times 10^{-3}$ indicated by asterisk; statistical tests include using a kappa statistic measurement and is further described elsewhere).⁷¹

the two proteins that were closest to the selection cut-off and therefore were most likely to represent false positives. OST-A co-precipitated considerable amounts of endogenous *Lamin A/C*, *Lap2b*, *Emerin*, as well as *Trim28* and *Ku70* (Figure 3B). In contrast no interactions were observed in control pull-downs from cells only expressing OST (Figure 3B). In comparison to *Lap2b* and *Emerin*, *Ku70* and *Trim28* appear to be weaker interactors of OST-A (Figure 3B). In addition to *Lap2b* we identified interactions of lamin A with *Lap2α*, γ , δ and ϵ isoforms in U2OS cells by OST pull-down and immunoblotting (Figure S3). Taken together these data demonstrate that the OST pull-down/MS assay and bioinformatical selection criteria can be used for identification of lamin A interacting proteins.

Functional annotation of lamin A interacting proteins

To globally characterize the identified lamin A interactors, we performed a GO analysis to describe the subcellular localization (CC, cellular component), biological processes (BP) and molecular functions (MF) of identified interactors (Figure 3C). As expected, compared to random proteins lamin A interactors were 22-fold enriched for ‘nuclear envelope’ components ($p=5.0 \times 10^{-12}$; Figure 3C, TableS2), and to a lesser extent for other subcellular compartments. The interactors are enriched in the functional groups of ‘NE organization’ ($p=2.5 \times 10^{-4}$), actomyosin structure organization ($p=9.9 \times 10^{-3}$), and protein transport ($p=5.6 \times 10^{-6}$), with a preferential molecular function of ‘nucleotide binding’ ($p=5.5 \times 10^{-4}$). The GO analysis had high similarity to the previously identified proteins in the NE proteome (Table S2).^{6,10}

Identification of preferential lamin A or progerin interactors

We next applied the OST pull-down method to identify proteins that bind exclusively to lamin A or progerin as well as interactors that bind to both proteins with different affinity. To this end, we expressed control virus, OST-A or OST-P in LMNA^{-/-} or LMNA^{+/+} MEFs at endogenous levels (Figure 1A). OST pull-downs were performed in duplicate in all cell lines. In total we detected 54,939 unique peptide fragments in all OST and control pull-downs, corresponding to 2804 different proteins (Figure 4A). Using similar selection criteria as validated for the NkITAg OST-A pull-down (mascot score

Figure 4. Identification of preferential lamin A/progerin interacting proteins. (A) Overview of the selection criteria applied to identify preferential lamin A/progerin interacting proteins (See also Material and Methods). **(B)** Verification of lamin A and progerin preferential interactors in U2OS cells transfected with GFP-Nup107, GFP-Tpr, Myc-Nup98, Myc-Nup153 or Myc-Prx1. OST pull-down was performed in U2OS cells infected with control, OST-A or OST-P virus. The following antibodies were used: α -LaminA/C (Sc6215, Goat, Santa Cruz; detects endogenous Lamin A and C, OST-A, and OST-P), α -Emerin (Cl.4G5, mouse, Leica), α -c-Myc (MS-139-P, mouse, Labvision) and α -GFP (Ab6673, Goat, Abcam). **(C)** Quantification of western blot protein levels in OST-A and OST-P pull-down fractions (average \pm standard deviation) corrected for input signal intensity. Relative protein levels for OST-A pull-down fractions were set arbitrarily at 1. Protein levels identified by western blot in OST-P pull-down fractions (Figure 4B) are indicated. Asterisks indicate a significant ($p < 0.05$; Student's T test) difference between OST-A and OST-P pull-down fraction.

cut-off, minimum fold over background and filtering out non-essential peptides; see Materials and Methods) we defined 274 lamina-interacting proteins, 209 in LMNA^{-/-} MEFs and 111 in LMNA^{+/+} MEFs, of which 46 proteins were identified as interactors in both cell lines. Of these 274 interactors 150 proteins interacted with lamin A and 170 with progerin (Table S5). The relatively low number of interactors identified in both LMNA^{+/+} and ^{-/-} cells may be due to the very high stringency used in identifying interactors or may be due to differential effects of lamin A expression in a wild-type or null background. As many of the identified lamin A interactors were also detected by MS at levels just below inclusion criteria in progerin pull-down samples and vice versa, we used additional criteria to identify preferential interactors (minimal fold difference between OST-A and OST-P mascot scores and similarity of results in MEFs^{-/-} and MEFs^{+/+}; see Materials and Methods; Figure 4A). 110 proteins interacted with both lamin A and progerin and applying these criteria resulted in a final selection of 35 proteins candidates that preferentially interact with either wildtype lamin A (8 candidates, including *Nup153*, *Nup98* and *Translocated promoter region*) or progerin (27 candidates, including Paired related homeobox 1 (*Prx1*), *Proliferating cell nuclear antigen (Pcna)* and *Pinin*).

To validate preferential interactors we performed OST pull-downs in U2OS cells expressing control virus, OST-A or OST-P at endogenous levels (Figure 4B) and transiently expressed several potential differential interactors (Myc-tagged *Nup98*, *Nup153*, *Prx1* and GFP-tagged *Tpr*). In support of the pull-down results, we found weaker interaction of OST-P with *Nup98*, *Nup153* and *Tpr* (all $p < 0.05$, Figure 4B and C). The NPC protein *Nup107* also showed reduced, albeit statistically not significant, binding to OST-P. *Prx1* was confirmed to have increased, but not unique, affinity for OST-P ($p < 0.05$, Figure 4B and C). Finally, immunoblot detection confirmed the predicted interaction of endogenous emerin with OST-tagged lamin A and progerin ($p > 0.05$, Figure 4B and C). These data show that lamin A and progerin have distinct protein-interactions that can be identified by OST pull-down assays.

Functional analysis of preferential lamin A or progerin interactors

A GO-signature comparison of 150 identified lamin A-associated proteins and 170 progerin-associated proteins, shows that both protein sets were

Preferential lamin A/progerin interacting proteins were identified amongst all lamin A and progerin interactors in LMNA^{-/-} and LMNA^{+/+} MEFs according to standard selection criteria (see Materials and Methods). Overall average mascot scores for individual pull-downs are indicated, as well as whether proteins were identified in two previous NE proteome studies (see grey shaded column) which had identified proteins in an INM/lumen/ONM⁶ fraction or an INM/lamina/nucleoplasmic fraction¹⁰. Hashes indicate proteins GO-annotated as 'Extracellular region'.

over 50-fold enriched for INM and nuclear lamina proteins, are preferentially involved in NE organization, mRNA and protein transport and enriched for proteins with GTP binding capacity (Figure S4, Table S3). Lamin A interactors were preferentially enriched ($p < 1 \times 10^{-4}$) in NPC-related nucleocytoplasmic and protein transport proteins and to a lesser extent ($1 \times 10^{-2} < p < 1 \times 10^{-3}$) in proteins of the NE, the cytoskeleton and ECM ('sarcomere' and 'PDGF binding' GO-terms). Progerin interactors showed enrichment for endoplasmic reticulum (ER) membrane proteins involved in protein folding and processing ('cell redox homeostasis', 'intramolecular oxidoreductase' and 'signal peptidase processing' GO-terms) as well as proteins involved in chromatin organization (mainly histone 1 and 2A variants). ER-localized A-type lamin interacting proteins were preferentially membrane-associated (43 out of 46) and not luminal localized (3 out of 46). To further assess the functional context of lamin A and progerin interactors we used the Reactome protein interaction database, which contains maps of known protein complexes, as a reference.⁴⁴ This analysis showed that 10 proteins of the 26S proteasome complex were identified as progerin interactors (Figure S4, Table S3). These GO and Reactome profiles for lamin A and progerin interactors resemble those found in the previously identified NE proteome (Table S3).

GO-analysis of the 35 preferential lamin A/progerin interactors showed enrichment of NE proteins, proteins involved in RNA metabolism ('ncRNA metabolic transport' and 'RNA metabolic process' GO terms), general protein transport components, including members of the NPC ('Ran binding protein 2' Reactome term) and proteins with GTPase activity (All $p < 1 \times 10^{-2}$; Figure 5A, 5B, Table S2).⁴⁴ NPC lamin-interacting proteins were preferentially located at the nucleoplasmic site of the NPC (Figure 5C), of which a vast majority showed an overall diminished interaction with progerin in both LMNA^{-/-} and LMNA^{+/+} MEFs, including 3 proteins identified in our assay as preferential lamin A interactors (*Tpr*, *Nup98*, *Nup153*; Figure 5C, Table 1).

Figure 5. Functional annotation of preferential lamin A/progerin interactors. (A) GO profile of preferential interactors specified for “cellular components” (CC), “biological process” (BP), “molecular function” (MF) GO categories. Representation of protein complexes was analyzed using the Reactome database (R)⁴⁴. Significant categories based on comparison are indicated by asterisks ($p < 1 \times 10^{-3}$; random proteins used as background; statistical tests include a kappa statistic measurement as described elsewhere⁷¹), as well as the number of proteins within the specific category out of the total number of annotated preferential interactors. **(B)** Overview of GO annotated lamin A/progerin preferential interactors in significant categories. Individual categories are marked A-F and correspond to figure 5A. **(C)** Schematic illustration of the nuclear pore complex (NPC) indicating the location of lamin A-interacting NPC proteins identified by mass spectrometry analysis (underlined).⁷² Identified interactors preferentially localize in the nuclear basket (*Nup153*, *Tpr*), nuclear ring (*Nup50*, *Nup98*) or scaffold (*Nup-93*, -107, -133, -155, -160 and -205). *Nup98* has been described to localize in both the nuclear basket as well as the NPC central channel. Asterisks indicate proteins identified to preferentially interact with lamin A. Hashes indicate proteins with MS data indicative of diminished interaction with progerin as well (similar direction change for ratio OST-P/OST-A overall average mascot ratio’s in both MEF LMNA^{-/-} and MEF LMNA^{+/+}).

Discussion

The systematic mapping of lamin A interaction partners is currently hampered by the insoluble nature of lamina proteins. We have developed and applied a novel pull-down approach based on the One-STrEP tag to identify *in vivo* A-type lamin interactors, of which a subset interacts preferentially with lamin A compared to its mutant isoform progerin. To isolate lamin-associated protein complexes we took advantage of the OneSTrEP-tag/Strep-Tactin matrix system, an engineered version of the strongest non-covalent biological interaction known (biotin/streptavidin).^{18, 45} We first verified that the addition of a 3 kDa small OST-tag to lamin A recapitulated endogenous lamin A as judged by farnesylation, subnuclear localization, emerin NE localization and cell proliferative effects. Lamin interactors were identified, by subsequent solubilization of the majority of A-type lamins, high affinity precipitation of OST-tagged lamins, high stringency washes of precipitated protein complexes, important as lamins have a propensity to non-specifically interact with other proteins, and a highly restrictive selection based on MS results.⁴⁶ We identify a large number of known direct A-type lamin interactors (including *Emerin*, *Ubc9*, *LAP2 α* , *LAP1 β* , *LMNB1*, *Rbbp7*), as well as known indirect interactors (including Nesprin/Syne-1, Nesprin/Syne-2; HP1 γ /*CBX3*, HP1 α /*CBX5*, *MAN1*), therefore directly validating our approach.^{5, 12, 47-52} Our approach is able to identify physical associations which occur via multiple hierarchical interactions as indicated by the identification TorsinA, which is indirectly connected to the lamina via Nesprins and Sun proteins.⁵² The identification and verification of two previously unidentified lamin A interactors (*Trim28* and *Ku70*) that met the inclusion criteria justifies the applied selection threshold. Comparative analysis with two published NE proteomes further validates the OST approach.^{6, 10} Although these studies differ in their starting materials with one using isolated nuclear envelopes and the other isolated lamina preparations, they identify a significant part of the NE proteome, including laminar proteins, and therefore are considered of value for a cross-comparison. About half of the OST pull-down identified lamin A interactors in Nk1TAG cells were identified in these previous studies and the GO signature of our hits highly resembles that of NE proteins identified in these analyses.^{6, 10}

Our OST pull-down method differs from previously published approaches. First, in comparison to approaches that biochemically fractionate nuclear membranes or the lamina, we specifically precipitate lamin A interactors, regardless of their subcellular localization. Secondly, the inclusion of a cross-linking step preserves short-lived lamin-protein interactions and thereby contributes to detection of identified transient and indirect interactors. Thirdly, we use a highly sensitive and stringent MS analysis approach. Our validation indicates a low level of false positives. However, we cannot formally rule out that a small percentage of identified hits reflect non-specific interactions. Especially various extracellular matrix (ECM) identified interactors and proteins involved in Golgi related vesicle trafficking might reflect non-specific interactions. ER proteins form a group of identified interactors that have been considered background in previous NE proteomic studies.¹⁰ Although this exclusion is correct for luminal ER proteins, which are not directly accessible to lamins, membrane-associated ER proteins could reflect bona fide interactors of OST-tagged lamins involved in protein folding and processing during their synthesis and post-translational modification or diffuse from the ER to the continuous INM and anchor to the lamina.⁵³ In accordance with this, our data indicate that almost all identified A-type lamin interactors residing in the ER are membrane-associated and not luminal.

Our method combines beneficial aspects of several methods used to identify protein-content of and interactions at the nuclear lamina. IP studies have the advantage of enriching for the interactome of a protein of interest and the ability to analyze the impact of mutations on protein interactions, but are hampered by the need to solubilize intact NE protein complexes.⁵⁴ In contrast, differential extraction from isolated whole nuclear membrane fractions permits disruption of protein complexes prior to MS analysis, but identifies general protein composition at a subnuclear level based on similarity of proteins in biochemical characteristics.^{6, 8, 10} Yeast two-hybrid screens allow comparison of protein interactions for wild-type and mutated protein fragments without solubilization, but have the drawback of high false positive-rates and non-physiological conditions.⁵⁵⁻⁵⁷ The OST pull-down approach combines advantages of identifying and comparing the interactome for a wild-type and mutated protein of interest with a low false positive rate under physiological conditions, with complete extraction of

intact lamina protein complexes. These unique characteristics complement current technology to identify lamin A interactors.

We identified both interactors of lamin A and of progerin and compared their GO profiles. Differences in profiles indicate a loss of interactions of progerin with the cytoskeleton in comparison to lamin A, in agreement with reported disruption of nuclear-cytoskeletal coupling by progerin.⁵⁸ Furthermore, GO analysis suggests a preferential interaction of progerin with protein folding and processing enzymes as well as proteasome complex members. This observation is intriguing in the light of the reported degradation in HGPS patient cells of a large set of nuclear proteins, particularly chromatin-associated proteins.^{5, 16} To further investigate differences between lamin A- and progerin-interacting proteins we identified preferential interactors by comparing OST pull-downs in both LMNA^{-/-} MEFs, in the absence of endogenous lamin A/C which could mask distinct interactions due to dimerization with progerin, as well as biological more relevant LMNA^{+/+} MEFs.³⁶ Several identified distinct lamin A/progerin interactors preferentially possessed GTPase activity and others were involved in RNA metabolism or nucleocytoplasmic transport.

We found reduced interaction of *Nup153* with progerin compared to wild-type lamin A. *Nup153* anchors NPCs to the nuclear lamina and directly interacts with *Tpr*, which is involved in formation of NPC-associated heterochromatin exclusion zones.⁵⁹⁻⁶¹ Interestingly, HGPS is associated with peripheral loss of heterochromatin and clustering of *Nup153* and other NPC proteins.⁶²⁻⁶³ A diminished interaction between OST-P and *Nup153* could explain a loss of NPC anchoring to the nuclear lamina, as well as clustering and defective NPC-mediated nuclear import which have all been implicated in HGPS.⁶²⁻⁶³

We found an increased interaction of progerin with paired related homeobox 1 (*Prx1* or *Prrx1*), a transcriptional co-activator involved in skeletogenesis and vasculogenesis.^{28, 64} Loss of *Prx1* results in lethal vertebrae and craniofacial skeletal defects, while overexpression induces vascular smooth muscle cell (VSMC) proliferation and ECM remodeling by direct upregulation of tenascin C expression.^{28, 64} These phenotypes highly resemble HGPS etiology as *Zmpste24* knock-out mice, which serve as a

model system for HGPS, suffer from osteogenesis imperfecta, manifested in vertebrae and craniofacial bone fractures.⁶⁵ Furthermore progerin drastically downregulates tenascin C expression and progerin transgenic mice suffer from a progressive loss of VSMCs and changes in ECM composition.⁶⁶⁻⁶⁷ An increased interaction of progerin with *Prx1* could impair transcriptional activation of tenascin C and cause consecutive HGPS characteristic ECM, VSCM and bone related disorders.

A number of differential interactors link lamin A and progerin to previously reported abnormal cell biology in the context of *LMNA* mutations. We find an increased interaction of Proliferating cellular nuclear antigen (*Pcna*) with progerin. *Pcna*, as a replication fork processivity factor, regulates genomic replication and has been reported to redistribute upon introduction of progerin.⁶⁸ Several studies report abnormal proliferation in *LMNA* mutant cells.⁶⁹ *Pcna* is thought to become trapped in intranuclear mutant lamin aggregates, thereby ultimately blocking DNA replication and causing HGPS-associated DNA damage.^{63, 68} Of relevance in this context is also the identification of *Trim28* and *Ku70* as interaction partners of lamin A. Both are associated with DNA damage response and/or repair and *Trim28* is a reported interaction partner of heterochromatin protein 1.⁷⁰ While the contribution of these preferential interactions will need to be elucidated in targeted studies, the global identification of novel lamin A and progerin interactors using a novel pull-down method has generated several leads for studies of specific interaction partners of lamin A and its mutants with the goal of uncovering the molecular mechanisms of tissue-specific laminopathies.

Acknowledgements

We thank Günter Blobel, Brian Burke, Thomas Schwartz, Larry Gerace and Peter Lloyd Jones for kindly sharing expression plasmids. Thijs Konsten is thanked for his help in optimization of the OST pull-down assay. This research was supported in part by the Intramural Research Program of the National Institutes of Health (NIH), NCI, Center for Cancer Research, grants from the Dutch Heart Foundation, ZonMW and the EU-KP7 grant 'Inheritance'.

Supplemental Figures and Tables

Figure S1. Schematic overview of OneStrEP-tagged lamin constructs. Lamin A, C and progerin were tagged at their N-terminus by a OneStrEP-tag, consisting of two Strep-tag II epitopes (underlined), which interact with high affinity to Streptactin matrix, separated by a serine and alanine linker region. The chemical structure of a Strep-tag II epitope is further depicted. Mature OneStrEP-tagged lamin A (OST-A) is released after farnesylation of the C-terminal Caax-motif, cleavage of the -aax amino acids and subsequent carboxymethylation of the C-terminus, followed by an upstream cleavage by Zmpste24 in mice cells (indicated by scissor; Face-1 for human cell lines). Due to a loss of 50 amino acids (indicated as $\Delta 50$ aa.), including the Zmpste24 restriction site, OneStrEP-tagged progerin (OST-P) is only processed by farnesylation of the C-terminal Caax-motif, subsequent cleavage of the -aax amino acids and carboxymethylation of the C-terminus, and cannot be further cleaved by Zmpste24. OneStrEP-tagged lamin C (OST-C), contains a Lamin C-specific terminus, as well as the A-type lamins common coiled-coil rod domain and nuclear localization signal (NLS).

Figure S2. Progerin dependent loss of HP1 γ and LAP2 protein. Fluorescent detection of HP1 γ , LAP2 and DNA (DAPI) in human dermal fibroblasts (HDF) expressing an empty vector, OST-A or OST-P at endogenous lamin A levels. The nuclear intensity of total LAP2 (all isoforms included) and HP1 γ was determined as described in the Material and Methods, and average expression values are depicted in numbers. Distribution curves were tested to be different or comparable using a Kolmogorov-Smirnov statistical test. An asterisk indicates a significant ($p < 0.01$) difference between HDFs expressing OST-A or OST-P in comparison to empty vector (Ctrl) infected HDFs. The following antibodies were used: α -HP1 γ , mab3450, Chemicon, Temecula, USA ; α -LAP2, kind gift from K. Wilson, raised against residues 1-187 of human LAP2, and suitable for detection of all LAP2 isoforms).

Figure S3. Interactions between Lamin A and LAP2 isoforms. Western blot of a OneStREP pull-down performed on U2OS cells infected with OST-A and control virus. Input and pull-down fractions were immunoblotted with α -LaminA/C (Sc6215, Goat, Santa Cruz; detects endogenous Lamin A and C as well as OST-A) and α -LAP2 (Y-20, Sc19783, Goat, Santa Cruz; suitable for LAP2 $\alpha, \beta, \gamma, \delta, \epsilon$ and ζ detection). With the exception of LAP2 ζ , which could not be detected, all other isoforms were immunoblotted at their respective molecular weights.

Figure S4. GO analysis of lamin A and progerin interacting proteins identified in MEFs. Identified lamin A and progerin interacting proteins were analyzed separately for the GO categories “cellular components” (CC), “biological process” (BP), “molecular function” (MF), as well as the reactome (R) database. Significant categories were determined by standard statistical algorithms incorporated into the DAVID database (see Material & Methods) and are indicated by asterisks ($p < 10^{-3}$; random proteins used as background). Categories enriched for by either OST-A or OST-P are indicated by arrows.

Mascot scores for identified lamin A interacting proteins in Nk1Tag cells are listed. Furthermore it is indicated whether identified lamin A interactors were identified in two previous NE proteome studies (see grey shaded column) which had identified proteins in an INM/lumen/ONM6 fraction or an INM/lamina/nucleoplasmic fraction¹⁰. Hashes indicate proteins GO-annotated as 'Extracellular region'.

Identified lamin A interacting proteins in Nk1Tag cells and preferential lamin A/progerin interactors in MEFs, were analyzed separately for the GO categories "cellular components" (GO-CC), "biological process" (GO-BP), "molecular function" (GO-MF), as well as the Reactome (R) database. Categories are listed, together with the amount of proteins represented in the category compared to the total amount of annotated proteins. Enrichment factors are determined in comparison to random protein sets²¹⁻²² as well as NE proteins^{6, 10}, and p-values are indicated (p<1x10⁻³ indicated in bold) based on statistical algorithms incorporated into the DAVID database.⁶⁶

Identified lamin A and progerin interacting proteins in MEFs, as well as previously identified NE proteins were analyzed separately for the GO categories "cellular components" (GO-CC), "biological process" (GO-BP), "molecular function" (GO-MF), as well as the reactome (R) database.^{6, 10} Categories are listed together with the amount of proteins represented in the category versus to the total amount of annotated proteins, the enrichment factor compared to random protein sets²¹⁻²² and significance level. Significance p-values ($p < 1 \times 10^{-3}$; statistic testing includes kappa statistic measurement and is further described elsewhere⁶⁶) are indicated; non-significant values are underlined or blank in case no proteins were found within the respective GO-term.

CHAPTER 4

Identification lamin A- and progerin- interacting genome regions

Kubben N, Adriaens M, Voncken J,
Meuleman W, Pinto Y, Misteli T.

Abstract

Mutations in the A-type lamins A and C, both major components of the nuclear lamina, cause phenotypically diverse diseases collectively referred to as laminopathies. These diseases often involve defects in chromatin organization, however, it is unclear whether aberrant chromatin-lamin interactions contributes to disease. Here we have used an unbiased approach to comparatively map genome-wide interactions of gene promoters with lamin A and progerin, the mutated lamin A isoform in the premature aging disorder Hutchinson-Gilford Progeria Syndrome (HGPS). We find that lamin A-associated genes are predominantly silent or expressed at low levels. We identify multiple classes of common or uniquely lamin A- or progerin-associated genes. Loss of lamin-association is not sufficient for gene activation and does not determine peripheral gene localization. Progerin induces global changes in chromatin organization and leads to relocation of peripherally localized genes, but not necessarily to their activation. These observations provide insight into the role of lamin A in chromatin organization and demonstrate that progerin affect specific chromatin-lamina interactions.

Introduction

The nuclear envelope (NE) defines the boundary between the nucleus and the cytoplasm and is composed of an outer and inner nuclear membrane (ONM, INM, respectively), interrupted by nuclear pore complexes (NPC) ¹. The NE is lined by a proteinaceous network made up of lamin proteins. The nuclear lamins are intermediate filament proteins and are categorized in A-type lamins (lamin A, A Δ 10, C and C2), encoded by the LMNA gene, and B-type lamins (lamin B1, B2 and B3), encoded by the LMNB1 and LMNB2 genes, respectively ².

Mutations in A-type lamins cause a group of phenotypically diverse diseases, collectively referred to as laminopathies ³. They include several types of muscular dystrophies, lipodystrophies, cardiomyopathies, neurological disorders and premature ageing syndromes. A-type lamins are crucial in maintaining higher-order chromatin organization as loss of lamin A/C results in reduction or loss of heterochromatin at discrete regions close to the INM ⁴. Laminopathy-associated point mutations in lamin A/C often deregulate chromatin structure and organization, most dramatically in the premature aging disease Hutchinson-Gilford Progeria Syndrome (HGPS). The HGPS-associated mutant lamin A isoform progerin causes loss of heterochromatin and reduced mono- and tri-methylation of lysines 9 and 20 on histone 3 ⁵⁻⁶. Another progeria-related lamin A mutation, E145K, leads to alterations in pericentric chromatin, abnormal clustering of centromeres and mislocalization of telomeres ⁷. Loss of heterochromatin and mislocalization of HP1 β also occurs in mandibuloacral dysplasia (MAD) ⁸⁻⁹.

Several lines of evidence suggest that A-type lamins interact directly with chromatin *in vivo* and that these interactions are affected by LMNA mutations. First, structurally related B-type lamins directly bind histones H2A and H2B *in vitro* ¹⁰ and lamin B interacts with chromatin *in vivo* at discrete lamin-associated domains (LADs) which are characterized by low gene activity and demarcated by insulators ¹¹⁻¹³. Second, amino acids 396-430 of the human lamin A/C tail bind core histones *in vitro* ¹⁴. Third, the immunoglobulin domain of lamin A/C covalently binds 30 bp dimerized DNA fragments *in vitro* and the familial partial lipodystrophy (FPLD)-associated R483Q and -W mutations lower this affinity ¹⁵. Based on these findings it

was hypothesized that direct interaction of A-type lamins with chromatin is important for chromatin organization and gene regulation¹⁶. However to date it is unknown which chromatin regions directly interact with A-type lamins *in vivo*, and how loss or mutation of lamin A/C affects chromatin organization and gene expression.

To probe the role of the lamina in genome organization and gene expression we have conducted an unbiased and genome-wide mapping of gene promoters that interact with lamin A and/or progerin. We find that lamin A preferentially binds silent or lowly expressed genes. This association facilitates, but does not determine, peripheral localization and loss of the interaction is not sufficient for gene activation. Progerin differentially interacts with many of the lamin A-associated genes and the basal expression level of those and common interactors correlates with their relative subnuclear position. These data demonstrate a direct and distinct effect of lamin A and progerin on chromatin interaction and organization at the lamina.

Materials & Methods

Cell lines and culture

The lentiviral expression plasmid for N-terminal One-STrEP tagged lamin A (OST-A) is described¹⁷. An N-terminal One-STrEP tagged progerin (OST-P) lentiviral expression plasmid was created by lamin A PCR amplification omitting amino acids 609-658 using the pCDH MCSNard OST-A plasmid as a template and consequent ligation of the PCR product back into BamHI and EcoRI restriction sites. A lentiviral vector expressing shRNA directed against mouse lamin A/C (pSIHpuro-shRNA-mouseLMNA) was created by annealing 5'gatccGAGCTTGACTTCCAGAAGAACATtcaagagaATGTTCTTCTGGAAGTCAAGCTCtttttg3' and 5'aattcaaaaaGAGCTTGACTTCCAGAAGAACATtctcttgaaATGTTCTTCTGGAAGTCAAGCTCg 3' oligos and consequent ligation into BamHI and EcoRI restricted pSIH H1 plasmid (System Biosciences, Mountain View, USA). Lentivirus was produced by co-transfecting 293 FT cells (Invitrogen, Carlsbad, USA) with pSIHpuro-shRNA-mouseLMNA, pCDHblast MCSNard OST-A or OST-P in combination with pSPAX and pMD2.G vectors (a gift from D. Trono,

Lausanne, Switzerland). The mouse cardiac myocyte cell line NkITag¹⁸, as well as mouse embryonic fibroblasts of wild-type (WT) MEFs and LMNA knock-out (LMNA^{KO/-}) embryos⁴ were infected with various concentrations of lentivirus and 48 hours post infection selected with blasticidin. Infected cells with OST-A or OST-P protein expression levels comparable to endogenous lamin A were further cultured and grown in Dulbecco's modified Eagle's/F-12 media (for NkITag cells) or Dulbecco's modified eagle medium (for MEFs) both supplemented with 2mM L-glutamine, 10mM non-essential amino acids (NEAA), 110 mg/l pyruvate, 10% fetal bovine serum and antibiotics in a humidified atmosphere at 37°C at 5% CO₂. NkITag cells were plated on 12.5 µg/ml fibronectin and 0.1% gelatin coated plates.

Western blot

Western blots were performed essentially as described elsewhere¹⁷. Cells were lysed in SDS-PAGE Laemmli loading buffer and further denatured by heating for 5 min at 95°C. Equal amounts of cell lysates were loaded and run on NuPage Novex Bis-Tris 4-20% gradient gels (Invitrogen, Carlsbad, USA), blotted on immobilon-PVDF membrane (Millipore, Billerica, USA), blocked 1 hour in 5% bovine serum albumin /TBS-T (20 mM Tris-HCl pH 7.5, 150 mM NaCl and 0.1% Tween 20). The blocked membrane was incubated at 4°C overnight with primary antibodies (α -Lamin A/C, Sc6215, StCruz, Santa Cruz, USA; α -Beta Actin, A-5441, Sigma, St Louis, USA) in blocking buffer diluted. After incubation with appropriate secondary HRP-labeled secondary antibodies, immunoluminescence was detected with an ECL Western Blotting detection system (Amersham, Roosendaal, Netherlands). The intensity of signals was quantified using ImageJ software.

Immunofluorescence

For immunofluorescence microscopy, cells were grown on 0.1% gelatin/PBS solution coated multi-wells glass slides (MP Biomedicals, Solon, USA), fixed for 15 min in 4% paraformaldehyde/PBS, permeabilized with 0.5% Triton X-100 in PBS for 5 min, blocked for 30 minutes in block buffer (1% BSA, 1% sucrose in milliQ) and incubated for one hour at room temperature in appropriate primary antibodies (α -LMNA/C, Sc-7292, StCruz, Santa Cruz, USA) and for one hour with secondary antibodies labeled with the Alexa Fluor 488 or 568 chromophores (Invitrogen, Carlsbad, USA). Cells were

mounted using Vectashield containing 10g/ml DAPI and observed on a Nikon E800 microscope.

Chromatin Immunoprecipitation (ChIP)

NkITAg and MEF cell lines were grown in 150 mm dishes, formaldehyde fixed and lysed in SDS lysis buffer (1% SDS, 10 mM EDTA, 50 mM Tris pH 8.1). After sonication the SDS concentration was lowered 10-fold by adding ChIP dilution buffer (0.01% SDS, 1.1% Triton X-100, 1.2 mM EDTA, 17 mM Tris pH 8.1, 170 mM NaCl). Both SDS lysis buffer and ChIP dilution buffer were supplemented with 2 mM orthovanadate and protease inhibitors (Boehringer Mannheim, Indianapolis, USA). Undissolved fractions were discarded after a 10 minute 16,000 g centrifugation step at 4 degrees. ChIP dilution buffer pre-washed and herring sperm DNA coated Strep-Tactin Matrix (IBA BioTagnology, Göttingen, Germany) was added and samples were end-over-end rotated overnight at 4 degrees. The next day pelleted Strep-Tactin matrix was washed consequently with low salt buffer (0.1% SDS, 1% Triton X-100, 2 mM EDTA, 20 mM Tris pH 8.1, 150 mM NaCl), high salt buffer (0.1% SDS, 1% Triton X-100, 2 mM EDTA, 20 mM Tris pH 8.1, 500 mM NaCl), LiCl buffer (0.25 M LiCl, 1% Igepal-CA630, 1% deoxycholic acid, 1 mM EDTA, 10 mM Tris pH 8.1), OST stringent wash buffer (2M NaCl, 2% Trx-100, 500 mM LiCl, 0.1% SDS, 1% Sodium Deoxycholate, 20 mM Tris pH 8.1, 2mM EDTA) and TE buffer (10 mM Tris, 1mM EDTA pH 8.0). Precipitated protein-chromatin complexes were eluted at room temperature in fresh elution buffer (1% SDS and 0.1 M NaHCO₃). After de-cross-linking for 6 hours at 65°C in the presence of 200mM NaCl and 30 µg/ml RNAase A, DNA was purified using a Qiagen PCR clean-up kit (Qiagen, Hilden, Germany) and amplified according to Whole Genome Amplification kit instructions (Sigma, St. Louis, USA) for further analysis on promoter arrays.

ChIP-on-chip analysis

Amplified DNA fragments were hybridized to NimbleGen MM8 385K Refseq promoter arrays, tiling a region of 2000 bp downstream to 500 bp upstream for transcription start sites of ~19,000 Refseq genes, excluding chromosomes 20 to 22. NkITAg OST-A targets were identified based the combined data from 4 independent experiments. Two arrays were hybridized with Cy-3 labeled input DNA and Cy-5 labeled ChIPed DNA from

NkITAg cells. To correct for non-specific enrichment of DNA fragments ChIPs on cells transfected with an empty vector (Cy-3 labeled) served as a reference for ChIPs on OST-A expressing NkITAg cells (Cy-5 labeled) on two additional arrays. To identify differences in lamin A and progerin promoter association, data of 4 independent experiments were combined. Lamin A and progerin targets were identified independently in WT and LMNA^{KO/-} MEFs⁴ by hybridization of OST-A ChIPed DNA (Cy-5 labeled) against ChIPed DNA from empty vector infected cells (Cy-3 labeled), and hybridization of OST-P ChIPed DNA (Cy-5 labeled) against OST-A ChIPed DNA (Cy-3 labeled). Hybridization and data acquisition were performed in-house by NimbleGen according to standard procedures (Roche NimbleGen, Madison, USA).

To identify binding targets in the microarray data, we applied a between-array analysis approach in the statistical programming language R. This method compares all replicates and any negative controls directly at probe level, which is thereby expected to produce a statistically more robust set of potential targets compared to NimbleGen's standard within-array analysis method. Our approach is fully described elsewhere¹⁹. In short, a log-ratio between experimental and control samples are calculated separately for each array. Next, all probes are ordered according to genomic location and dichotomized using a threshold around twice the estimated standard deviation of the log-ratio. Probes with a log-ratio above this threshold are considered positive, those below negative. Next, for each array a sliding window of a variable number of base pairs is moved over all probes, calculating a detection p-value for the probes in each probe-window using a Yates corrected Chi-square test, to assess whether there are significantly more positive probes present than expected by chance. A promoter is significantly enriched when at least one probe-window shows significant enrichment in all experimental arrays for a particular condition and in none of any available arrays suitable as negative controls for that condition. To minimize false positives a detection p-value of 0.05 was used as the cut-off per array. OST-A- and OST-P associated gene promoters needed to be recognized as such independently in both WT and LMNA^{KO/-} MEFs, and are collectively referred to as MEF OST-A and OST-P ChIP targets.

Cluster analysis of identified lamin targets was essentially performed as described previously¹³. To test whether lamin targets were clustered, we

defined clusters as two or more adjacent lamin-associated genes not interrupted by non-target genes. Next, unclustered (cluster size=1 gene) and clustered (cluster size>1 gene) lamin targets for all chromosomes were compared by Fisher's exact test to randomly expected occurrences of gene clusters, determined in 10,000 simulations.

Gene ontology (GO) analysis was performed with the Database for Annotation, Visualization, and Integrated Discovery (DAVID) using standard settings for functional annotation clustering, listing significant clusters by most significant GO Biological Processes class²⁰⁻²¹. Average conservation plots were generated with Cis-regulatory Element Annotation System (CEAS) (<http://ceas.cbi.pku.edu.cn/submit.htm>)²², showing the level of conservation of the ChIP regions compared to the genomic background. MatInspector software and the Genomatix transcription factor motif database (www.genomatix.de) were used to identify enriched Transcription Factor Motifs (TFM) in target sites and target promoters²³.

Fluorescent In Situ Immunohybridization (FISH)

To produce probes for DNA FISH, bacterial artificial chromosomes (BACs, BACPAC Resources Center, Oakland, USA) were labeled by nick translations with dUTP conjugated with biotin or digoxigenin (Roche, Madison, USA) using the mouse BAC clones (Acpp, RP24-383K20; Sp100, RP24-235A6; OLFR681, RP24-324M2; OLFR1471, RP24-346K11; Eif2b, RP24-285P5; Fanca, RP24-157M4; Eef1a2, RP24-163K20; Kcnip2, RP24-337I2; Scn5a, RP23-103G4; Sdro, RP24-244F19; Cyp3a25, rp-23-332c3; Olfr804, rp24-167G2; Abpd, rp24-238I13; Defcr5, rp24-243I16; Daf2, RP24-154P21; Tcf21, RP23-93MI0; Trim30, RP23-312K22; Abcb10, RP24-361K8) as described²⁴⁻²⁵. Probes consisted of 150-300 ng of digoxigenin- and/or biotin-labeled probe DNA, 3 µg mouse COT1 DNA (Roche, Madison, USA) and 20 µg tRNA (Sigma, St Louis, USA) resuspended in 7 µl of hybridization mix (10% dextran sulfate, 50% formamide/2xSSC, and 1% Tween 20). Cells grown on glass slides were fixed in 4% PFA/PBS for 10 min, permeabilized for 20 min in 0.5% saponin/0.5% Triton X-100/PBS and incubated in 0.1 N HCl for 15 min with PBS washes between each step. After a 2x SSC wash, cells were equilibrated in 50% formamide/2xSSC. Nuclei and probes were denatured together at 85°C for 5 min and left to hybridize at 37°C overnight in a humidified

chamber. The next day, slides were washed three times with 50% formamide/2xSSC at 45°C for 5 min each and thrice with 1x SSC at 60°C for 5 min each. Next, the cells were placed in 0.05% Tween-20/4xSSC at room temperature to cool and blocked for 20 min in 3% BSA/0.05% Tween-20/4xSSC. For immunofluorescence of LMNB1 slides were incubated at room temperature for 45 minutes with 1:50 in block buffer diluted LMNB antibody (Sc-6217, Santa Cruz Biotechnology, Santa Cruz, USA). Next, detection antibodies (anti-dioxigenin-rhodamine; Roche, Madison, USA), fluorescein avidin DN (Vector Laboratories, Burlingame, USA) and Alexa Fluor 647 Donkey-anti-goat IgG (Invitrogen, Carlsbad, USA) diluted 1:200 in blocking solution were incubated with cells for one hour at 37°C. Slides were mounted in DAPI-containing Vectashield mounting medium after three 5-min washes in 0.05% Tween-20/4xSSC at 42°C.

FISH image acquisition and analysis

Cells were imaged with an IX70 microscope (Olympus) controlled by a Deltavision System (Applied Precision) with SoftWoRx 3.7.0 Release 13EL (Applied Precision) and fitted with a charge-coupled device camera (CoolSnap; Photometrics) using a 60x 1.4 oil objective lens (Olympus) and an auxiliary magnification of 1.5 using an optical step size of 0.2 μm . Typically, 25 focal sections were imaged covering the entire nucleus. Using SoftWoRx 3.7.0 Release 13EL (Applied Precision) FISH signals were detected and analyzed in the z section with the brightest signal intensity. The two brightest FISH signals were used for quantification and frequency of cells with minimally one FISH signal within 500 nm distance of (NkITAg experiments) or overlapping (MEF experiments) with LMNB staining were quantified. Minimally 150 nuclei were analyzed in duplicate per probe per cell line. Per probe quantification results were statistically tested between different cell lines using the chi-square test. To test whether the distribution of observed frequencies of cells with FISH signals at the NE for OST-Aunique, common OST-A&P and OST-Punique targets differ for different cell lines a Kruskal-Wallis One way analysis of variance by ranks was applied, using Dunn's method for pair-wise multiple comparisons. SigmaStat 3.1 software was used for statistical analysis. For all tests P-values <0.05 were considered significant.

RNA isolation and expression microarray

RNA was isolated using the RNAeasy minikit (Qiagen, Hilden, Germany) from MEF, cardiac myocyte Nk1TAG cells and cardiac left ventricles of a gene trap LMNA null mouse model (LMNA^{GT-/-}) (Kubben et al., in preparation). For whole transcriptome analyses RNA from 5 days old WT and LMNA^{GT-/-} mice (N=2 each) and from WT MEFs infected with a OST-A, OST-P or empty vector lentivirus (N=2 each) were isolated and hybridized to Nugo Mouse Affymetrix expression arrays and Affymetrix Mouse Gene 1.0 ST arrays, respectively. Intensity values after hybridization were normalized to the median signal intensity of the array. For individual genes differences in expression levels were statistically tested by a one way ANOVA. Expression heatmaps were generated with DNA Arraystar 3.0 Software (DNAStar, Madison, USA). Expression profiles between different cell lines were statistically analyzed by first testing for normality of distribution by a Kolmogorov-Smirnov test. P-values tested were all significant (p<0.05) hence expression values were not considered to be normally distributed. Consequently differences in expression values were tested with the non-parametric Mann-Whitney Rank Sum test between 2 groups, and the Kruskal-Wallis one-way analysis of variance for more than 2 groups. P-values below 0.05 were considered significant. Verification of microarray expression data by PCR cDNA was synthesized with the iScriptTM cDNA synthesis kit (BioRad, Hercules, USA). SYBR Green real-time quantitative PCR analysis was performed in experimental duplos with primers for Beta-Actin (FW 5'TGGAGCCTGTGTTCTATCCA3', Rev 5'TGGAGCCTGTGTTCTATCCA3'), PCNA (FW 5'AGGGTTGGTAGTTGTCGCTGTAG3', Rev 5'GGTCCCCGATTACAGAT3'), Sp100 (FW 5'AACGACGCAGAAAAAGAGGT3', Rev 5'GTGAATAACCGCCCTGTCTT3'), Cdk14 (FW 5'ACCAGGGCACCTCTAATCAC3', Rev 5'CTCTGGTGAACTGGAAGCA3'), OLF686 (FW 5'TGGATATCCCTTCCCTTCTG3', Rev 5'TGGAGCCTGTGTTCTATCCA3'), OLF826 (FW 5'ACTCGGGCTTAGGAAGATGA3', Rev 5'GGATCATGGCATAACAAGC3'), OLF1098 (FW 5'TGCTCTACATCGTTGGAGCTAT3', Rev 5'TGCAGAAATCCAGTGTGCTT3'), Defb28 (FW 5'TAGCTGTCTTGTGGTCTG3', Rev 5'CCAAGCCATAAAAGCAGGTT3'), Acpp (FW 5'CTGGGTCTTTTCCCTGTGT3', Rev 5'ACTCGGGCTTAGGAAGATGA3') and HPRT (FW 5'GCGTCGTGATTAGCGATGATGAAC3', Rev 5'CCTCCCATCTCCTTCATGACATCT3'). Differences in real-time PCR quantification were determined applying a student T-test with 0.05 significance level.

Figure 1. Genomic localization and characteristics of lamin-associated genes. (A) Identified ChIP-chip targets of OST-LMNA in Nk1TAG myocytes are plotted according to their genomic location. Chromosomes are depicted in a relative scale, which corrects for size differences between individual chromosomes. (B) Summary of a gene ontology (GO) analysis on identified lamin A-targets. Per GO category the amount of lamin A-associated genes, out of a total of 292 targets, enriched for is indicated, as well as the minimal amount of genes needed to reach a significance level of 0.05, based on statistical algorithms of the DAVID database described elsewhere 39.

Results

Identification of lamin A-associated genes

To map lamin A interacting chromatin regions genome-wide we stably expressed One-STrEP-tagged lamin A (OST-A) at endogenous levels in a murine myocyte Nk1TAG¹⁸ cell line²⁶. The One-STrEP (OST) tag is a modified version of the biotin-related 8 amino acid StrepII epitope, which binds with high affinity ($K_d = 1\mu\text{M}$) to Strep-Tactin Matrix, an engineered streptavidin analogue²⁷. OST-A has previously been characterized in detail and the OST-tag does not interfere with correct localization or function of lamin A at the

nuclear lamina (²⁶ also Figure S1A). To identify lamin A-associated genome regions, we performed chromatin immunoprecipitation (ChIP) using the Strep-Tactin matrix for highly selective binding to the OST tag²⁸⁻²⁹ (Materials and methods; Figure S2A). Recovered chromatin was hybridized to NimbleGen promoter tiling arrays covering 2,500 bp promoter regions flanking the transcriptional start site of ~ 19,000 annotated Refseq genes. Samples were run in duplicates and ChIPed DNA from empty vector infected cells, as well as input DNA from OST-A expressing cells, were used as

Figure 2. Subnuclear localization of lamin A-associated genes. (A) FISH on 4 lamin A targets (*AcpP*, *Sp100*, *Olfr681*, *Olfr1471*) and 2 non-targets (*Eif2b*, *Fanca*). The percentage of cells with at least one FISH signals near the nuclear lamina (overlapping or within 500 nm of lamin B) was measured. Typical examples of each scoring category are depicted for the lamin A target *Sp100* (green), and the non-target *Fanca* (red). **(B)** Quantification of FISH staining for lamin A targets and non-targets in NkITag cells infected with control shRNA, lamin A/C shRNA, OST-A or a control vector. Asterisks indicate a significant ($p < 0.05$; χ^2 test) change in peripheral positioning in comparison to control infected cells.

controls (Figure S2A). 292 lamin A-associated genes were identified, based on enrichment in four independent experiments and stringent statistical criteria¹⁹(Material and methods).

The 292 OST-A target genes localize to all chromosomes with the exception of the Y chromosome, which is absent in the female NkITag cell line (Figure 1A and S3). 27% of the 292 lamin A targets localize in gene clusters (defined

Figure 3. Expression profiles of lamin A-associated genes. (A) A genome-wide heatmap of RNA expression levels in cardiac left ventricle of wild-type (WT) and LMNA^{GT-/-} mice, which are functional knock-out for A-type lamins⁴⁰. (B) Average fold changes (±sd) of absolute linear RNA expression levels for lamin A targets and random gene sets upon loss of lamin A/C (WT vs. LMNA^{GT-/-} mice). Observed fold changes did not differ significantly from 1.0 ($p > 0.05$; Mann-Whitney U test). (C) Real-time quantitative PCR on 7 lamin A targets (*Sp100*, *Cdk4*, *Olfr826*, *olfr686*, *olfr1098*, *Defb28* and *Acpp*) and 2 non-targets (*B-Actin* and *Pcna*) in the presence and absence of lamin A/C shRNA in NkITag myocytes. Ct values (±sd) are indicated, and reversely correlate to RNA expression levels (approximately a 2-fold decrease in expression levels per increased Ct value of 1). Ct values were all corrected for the housekeeping gene GAPDH expression levels and determined in hexaplo, using equal amounts of starting material (100ng cDNA) for each reaction. The detection limit⁴¹ of quantitative PCR (Ct value of ~35) is indicated with a dotted line. Ct values did not differ significantly ($p > 0.05$; Students T-test) for all targets between NkITag cells infected with control and LMNA shRNA respectively.

as two or more adjacent genes), which is 5-fold higher ($p < 1.0 \times 10^{-4}$; Fisher's exact test) than expected for random gene association (Figure S4A and B). Gene ontology (GO) analysis identified 74 of the 292 target genes as involved in 'G protein coupled receptor signaling' pathways (Figure 1B), with the vast majority (N=55) belonging to the GO subcategory 'perception of smell' including 52 olfactory receptors (OLFR) and 3 vomeronasal receptors (VMNR). This frequency is significantly higher ($p < 1.0 \times 10^{-5}$) than would be expected based on random association, which would predict less than 30 of the 292 lamin A-associated genes to be involved in this GO category. Other significantly enriched GO categories included 'locomotion' (N=11/292, $p = 1.3 \times 10^{-2}$) and 'regulation of blood coagulation' (N=3/292, $p = 3.5 \times 10^{-2}$; Figure 1B).

Conservation plots using the Cis-regulatory Element Annotation System (CEAS) database ²² did not reveal significant sequence conservation of precipitated DNA fragments (Figure S5), arguing against the existence of a specific lamin A-binding sequence. Analysis of known transcription factor binding motifs (TFM) by MatInspector software ²³ revealed 42 of the 170 known TFM to be significantly enriched in OST-A-associated gene promoters in comparison to random promoter sequences ($p < 0.05$). The most highly enriched TFMs include those for the bromodomain and plant homeo domain transcription factor (BPTF, $p < 1.0 \times 10^{-4}$) family, the three-amino acid-loop extension (TALE, $p < 1.0 \times 10^{-4}$) and auto-immune regulator (AIRE, $p < 1.0 \times 10^{-4}$) TF families. These data demonstrate that A-type lamin interacting gene promoters preferentially localize in genomic clusters, lack unique consensus lamin A binding sequences but are enriched for several transcription factor binding motifs.

Nuclear localization of lamin A-associated genes

To assess the subnuclear localization of lamin A-associated genes and to validate the CHIP technique, the location of 4 lamin A targets and 2 non-targets in NkITAg cells were probed by DNA FISH. We measured the percentage of cells with at least one FISH signal within 500 nm of the nuclear periphery identified by lamin B (material and methods; Figure 2A) ³⁰.

For the randomly selected lamin A targets *Acpp*, *Sp100*, *Olfcr681* and *Olfcr1471* located on chromosomes 9, 1, 7, and 19, respectively, at least one allele localized to the periphery in 55, 45, 55 and 30%, respectively, of cells compared to 17 and 9% for the non-targets *Eif2b* and *Fanca* (Figure 2B). The difference between peripheral localization of lamin A targets and non-targets is statistically significant at $p < 0.001$ in a χ^2 test. Next we set out to probe the effects of loss of A-type lamins on the subnuclear localization of lamin A associated-genes by knocking-down lamin A/C using shRNA in Nk1TAG cells. Expression of lamin A/C shRNA resulted in over 90% knock-down for both lamin A and C proteins (Figure S1B). The peripheral localization of the lamin A target loci *Acpp*, *Sp100* and *OLFR681* decreased significantly to 35, 31 and 25% ($p < 0.01$, χ^2 test; Figure 2B). In contrast, the lamin-associated *OLFR1471* locus and the non-targets *Eif2b* and *Fanca* retained their subnuclear position ($p > 0.05$, χ^2 test; Figure 2B). In contrast, overexpression of OST-A at endogenous levels did not affect localization of lamin A-associated genes, with the exception of the lamin A target *OLFR681*, which showed increased localization to the nuclear lamina upon introduction of OST-A (from 46% to 63%, $p < 0.05$, χ^2 test). These findings support a role for lamin A in recruiting gene promoters to the nuclear periphery.

Expression profile of lamin A-associated genes

To obtain insights into the effect of lamin A/C and its loss on lamin A target genes in Nk1TAG cardiac myocytes, we analyzed the expression profiles of lamin A interacting genes using microarray expression profiles of neonatal cardiac tissues of WT and LMNA^{GT-/-} mice, a LMNA null model based on gene trap technology (Kubben et al., in preparation). Basal expression levels of lamin A-interacting genes are significantly lower compared to random gene sets ($\Delta \log_2 -1.28$, $p < 0.001$, Mann-Whitney U test; Figure 3A). Amongst the 292 lamin A-associated target genes, 238 genes were not expressed or expressed at very low levels (absolute linear expression value < 25 , which is 650-fold lower than the housekeeping gene GAPDH), 18 were expressed at low levels (linear expression value 25-100) and 36 had roughly average expression levels (linear expression value > 100).

Loss of A-type lamins in LMNA^{GT-/-} cardiac tissue significantly changed the transcriptional profile of 1136 genes (Kubben et al., in preparation). The average expression fold change (FC) of the 292 lamin A associated genes was similar to the FC observed in the total genome, and indicated no preferential effect of lamin A loss on the lamin A-associated genes (OST-A targets FC 1.03±0.12, p=0.604; Random genes FC 1.01±0.16, P=0.478, Mann-Whitney U test; Figure 3B). As these genes lose their association with the lamina (Figure 2B), absence of any effect on gene transcription argues that re-activation/expression is probably not dependent on interaction with lamin A or the lamina.

Microarray data were confirmed by quantitative real-time PCR on seven lamin A targets (*Sp100*, *Cdk14*, *Olfr826*, *Olfr686*, *Olfr1098*, *Defb28* and *Acpp*) and two non-targets (*B-actin*, *Pcna*) in NklTAG cardiac myocytes. All lamin A targets were expressed at low levels near the detection limit of the RT-PCR (C_t values in the range of 33-38), with the exception of *Sp100* (C_t values of 29), in contrast to the non-targets *B-actin* and *Pcna* (C_t values of 18-21; Figure 3C). Knock-down of lamin A/C did not result in significant changes in expression levels for the tested genes (p>0.05, Student's T-test) in accordance with the expression microarrays results. Combined, these findings support a role for lamin A in nuclear organization of chromatin through association with transcriptionally silent genes. Our data also suggest that loss of association of genes with A-type lamins is not sufficient for gene activation.

Identification of lamin-A and progerin associated genome regions

We next sought to identify genome regions which interact uniquely with lamin A, uniquely with progerin or with both. To this end OST tagged lamin A (OST-A) or progerin (OST-P) were expressed at endogenous levels in wild-type (WT) or LMNA knock-out (LMNA^{KO-/-}) MEFs. As previously shown, and in contrast to OST-A, OST-P expression leads to distortions of the nuclear lamina (Figure S1A) and global loss of LAP2 and HP1 γ nuclear levels²⁶ as observed in HGPS patient cells⁵. Lamin A-associated gene promoters were first identified by hybridizing ChIPed chromatin of WT or LMNA^{KO-/-} MEFs expressing OST-A against that of empty vector infected cells (Figure S2B).

Figure 4. Genomic localization and characteristics of common and differential lamin A- and progerin-associated genes. (A) Venn-diagram of lamin A- and progerin-interacting genes determined by ChIP-chip in MEF cells (See Material & Methods). Overlapping targets are referred to as common OST-A&P targets, while genes only interacting with lamin A or progerin, are named OST-A unique and OST-P unique targets respectively. (B) A genomic plot of OST-A unique, OST-P unique and common OST-A&P subsets of targets on chromosome 2 and 16. Boxes highlight examples of genomic areas containing gene targets from all 3 subsets (on chromosome 2), and regions that preferentially represent gene targets from one subclass (on chromosome 16). (C) Summary of gene ontology (GO) analysis on gene targets of all 3 subsets, indicating the GO class, the amount of genes (N) per total ChIP target genes in that GO class, the minimal amount of targets needed for a significance level of 0.05 and the p-value, based on statistical testing fully described previously³⁹. (D) ChIPed DNA fragments of all 3 subclasses were analyzed for the occurrence of 170 transcription factor motifs (TFM) (See Material & Methods). Common OST-A&P targets were shown to be enriched for 58 TFM, while all 170 TFM were normally represented in OST-Aunique and OST-P unique targets subsets.

Progerin-interacting gene promoters, as well as differences in lamin A and progerin-gene promoter interaction profiles, were then determined by comparing OST-P ChIPed chromatin with OST-A ChIPed chromatin as a control (Material and methods; Figure S2B). We identified 595 lamin A-associated gene promoters (defined as promoters interacting with OST-A in both WT and LMNA^{KO/-} MEFs) and 552 progerin-associated gene promoters (defined as promoters interacting with OST-P in both WT and LMNA^{KO/-} MEFs) (Figure 4A, S2B). A significant overlap was present for lamin A-interacting genes (n=595) between WT (N=1686) and LMNA^{KO/-} MEFs (N=840) ($p < 1 \times 10^{-3}$, χ^2 test), as well as for progerin-interacting genes (n=552) in WT (N=1214) and LMNA^{KO/-} MEFs (N=1642) ($p < 1 \times 10^{-3}$, χ^2 test). Lamin-associated genes identified in MEFs and Nk1TAG cells significantly overlapped as 23% of the 595 lamin A target genes, and 23% of the 552 progerin target genes identified in MEFs were also identified at the nuclear lamina in at least one CHIP-on-chip experiment in Nk1TAG cells as well ($p < 1 \times 10^{-3}$, χ^2 test).

Over two-thirds (N=402) of the identified lamin-associated genes in MEFs interacted with both lamin A and progerin, and will further be referred to as common OST-A&P targets (Figure 4A). 193 lamin A target genes interacted uniquely with lamin A (OST-A unique targets) and 150 target genes interacted specifically with progerin only and were not enriched in OST-A ChIP experiments in the absence of progerin (OST-P unique targets). Closer examination of the genomic localization reveals that 38% of the lamin A- as well as the progerin-associated genes occurs in clusters (varying in size from 2 to 11 adjacent genes), which is 5-fold more frequent than expected for random gene sets ($p < 1 \times 10^{-4}$; Fisher's exact test), and both sets of interactors overlap significantly ($p < 1 \times 10^{-10}$; Figure S4 C-F). Despite this genomic co-localization of lamin A- and progerin-associated genes, occasional genomic regions that preferentially bind to progerin or lamin A could be found, for instance on chromosome 16 (Figure 4B).

GO analysis identified 157 of the 402 common lamin A and progerin targets involved in 'G protein coupled receptor signaling' pathways (Figure 4C). This frequency is significantly higher ($p < 1.0 \times 10^{-5}$) than would be expected based on random association of genes, which predicts less than 42 of 402 associated genes to be involved in this GO category. Other GO categories

that were significantly enriched, include 'Defense response to bacteria' (12/402, $p=7.2 \times 10^{-5}$) and 'Response to pheromone' (11/402, $p=2.6 \times 10^{-5}$). The former category mainly consists of defensin and defensin-related cryptdin proteins, and the latter of vomeronasal receptors, which are also represented in the 'G protein coupled receptor signaling' GO class. In comparison to common OSTA&P targets, lamin A uniquely associated genes were significantly less enriched in the 'G protein coupled receptor signaling' category (27/193, $p=1.7 \times 10^{-2}$; Figure 4C), but instead were enriched in 'cation transport' (16/193, $p=7.4 \times 10^{-5}$), 'response to cytokine stimulus' (5/193, $p=1.8 \times 10^{-4}$) and 'regulation of hormone levels' (7/193, $p=1.2 \times 10^{-3}$). OST-P unique targets were enriched for 'G protein coupled receptor signaling' (27/150, $p=9.7 \times 10^{-4}$) and 'regulation of translation' (4/150, $p=3.9 \times 10^{-2}$). The enrichment of different GO families amongst OST-A, OST-P and OSTA&P targets suggests distinct preferential association of various gene groups with lamin A or progerin.

As for lamin A- and progerin-interacting genes, no consensus lamin binding sequence could be identified in any subclass of target genes (Figure S5). TFM analysis indicated enrichment of common lamin A/progerin-associated gene promoters for 58 TFMs ($p < 0.05$, Figure 4D, Table S2). Over half of these TFMs were also found enriched in lamin A targets within the Nk1Ag cardiac myocytes, including the 5 most significantly enriched TFs brain-5 (BRN5), serum responsive factor (SRF), octamer transcription factor 1 (Oct-1), bromodomain and plant homeo domain transcription factor (BPTF) and HOXC (all $p < 1 \times 10^{-5}$, Table S2). Lamin A unique and progerin unique targets contained TFM (170 analyzed) at similar frequencies as random promoter sequences ($p > 0.05$). Overall these data show that lamin A and progerin interact differently with chromatin, and that common and uniquely lamin A- or progerin-associated genes possess distinct features including their biological function and TFMs.

Subnuclear localization of common versus unique lamin A- and progerin-associated genes

To assess the subnuclear localization of common and unique lamin A- and progerin-associated genes, four randomly selected target genes for each subset (OST-A unique: *Eef1a2*, *Kcnp2*, *Scn5a*, *Sdro*; common OST-A&P:

Cyp3a25, *Olfr804*, *ABPD*, *Defcr5*; OST-P unique: *Daf2*, *Tcf21*, *Trim30*, *Abcb10*) were analyzed by FISH. Peripheral localization was assigned to FISH signals when at least one allele per cell overlapped with the nuclear periphery, defined by lamin B staining (Figure 5A). In WT MEFs cells infected with an empty vector, the non-target *E1f2b* only sporadically localized peripherally (1%), while for unique lamin A target genes the frequency of lamin B signal overlap varied from 4% (*Eef1a2*) to 29% (*Scn5a*), for progerin unique interacting genes from 2% (*Daf2*) to 23% (*Abcb10*) and for common targets frequencies were between 53% (*Cyp3a25*) and 65% (*ABPD*) (Figure 5B). Overall, these data indicate that common lamin A/progerin targets showed an overall significantly higher frequency of lamin B signal overlap (58% on average) than OST-A unique (17% average) and OST-P unique targets (16% average) (Figure 5B, Table S4; Pvalue<0.001, χ^2 test). This preferred peripheral localization of common lamin A/progerin-associated-genes was independent of the presence of endogenous A-type lamins as common interactors in empty vector infected LMNA^{KO/-} MEFs also more frequently overlapped with lamin B (47% average, range 43-54%), in comparison to lamin A (19% average, range 8-39%) and progerin (11% average, range 5-15%) uniquely associated genes (Table S4; Pvalue<0.001, χ^2 test).

Expressing OST-A at endogenous levels in LMNA^{KO/-} MEFs affected subnuclear positioning of unique lamin A targets, as *Eef1a2*, *Kcnp2* and *Scn5a*, but not *Sdro* showed increased peripheral localization (OST-A unique targets; p<0.05, χ^2 test; Figure 5B). In contrast all common lamin A/progerin interactors (*Cyp3a25*, *Olfr804*, *Abpd*, *Defcr5*) as well as progerin unique interactors (*Daf2*, *Tcf21*, *Trim30*, *Abcb10*) examined, were insensitive to higher levels of OST-A and did not change subnuclear positioning (all p>0.05, χ^2 test). In WT MEFs, introduction of OST-A significantly increased peripheral localization of the lamin A uniquely associated gene *Kcnp2*, but not of the other probed loci. These results suggest that the subnuclear positioning of uniquely lamin A-interacting genes is sensitive to the levels of lamin A, in contrast to genes which interact both with progerin or both lamin A and progerin.

Expression of OST-P at endogenous levels in LMNA^{KO/-} MEFs specifically influenced the peripheral positioning of the progerin uniquely-associated

Figure 5. Subnuclear positioning of common and differential lamin A- and progerin-associated genes. (A) FISH was performed on 4 loci per subset of ChIP targets (OST-Aunique: *Eef1a2*, *Kcnp2*, *Scn5a*, *Sdro*; common OST-A&P: *Cyp3a25*, *OLFR804*, *ABPD*, *Defcr5*; OST-Punique: *Daf2*, *Tcf21*, *Trim30*, *Abcb10*) as well as one non-target (*E1f2b*). An example is shown of the *Tcf21* gene in wild-type (WT) MEFs expressing OST-A, OST-P or an empty control vector. Signals (red) were scored to overlap with lamin B (blue) at the nuclear rim or not. **(B)** FISH quantification of the frequency of cells with minimally one FISH signal overlapping with lamin B, indicated for all ChIP targets in A-type lamin knock-out (LMNA^{KO/-}) MEFs and WT MEFs, expressing OST-A, OST-P or an empty control vector. Significant differences in localization with the corresponding empty vector control cells are indicated by an asterisk ($p < 0.05$; χ^2 test).

genes, as *Daf2* and *Tcf21* became more frequently peripherally localized (OST-P unique targets; $P < 0.05$, χ^2 test; Figure 5B). In addition, an opposite effect was observed for the lamin A unique interactor *Sdro*, which significantly lowered its peripheral localization in the presence of progerin ($p < 0.01$, χ^2 test; Figure 5B). All other investigated unique lamin A- and common lamin A/progerin-associated loci maintained their subnuclear position. Interestingly, the introduction of OST-P in a WT MEF background, similar to the situation found in heterozygous HGPS patients, increased

peripheral localization of the *Tcf21* progerin uniquely interacting gene, but none of the other loci tested, suggesting that the presence of progerin in a wild-type background may have gene-specific effects, but does not dramatically alter the location of genes globally.

For the lamin A unique interactors expression of OSTA in LMNA^{KO/-} MEFs increased the relative frequency of lamin B signal overlap by 54% on average, which is significantly ($p < 0.05$, Student's T-test; Table S3) different from the 17% decrease observed upon the introduction of progerin. In WT MEFs these differences were less pronounced, +38% upon lamin A and -13% upon progerin expression ($p = 0.08$, Student's T-test; Table S3). These results suggest that lamin A contributes significantly to the peripheral localization of lamin A-unique interactor sequences.

For uniquely progerin-associated genes, the increased peripheral localization upon the introduction of OST-A in LMNA^{KO/-} MEFs (+18% on average), was significantly less pronounced than upon the expression of OST-P (+83%; Table S4; $p < 0.05$, Student's T-test). In WT MEFs these differences, +10% and +106% upon lamin A or progerin expression, respectively, were borderline significant ($p = 0.09$, Student's T-test; Table S3).

Common targets on average did not change ($p > 0.05$) their peripheral positioning upon the addition of either OST-A or OST-P in either LMNA^{KO/-} MEFs (+11% OST-A; +11% OST-P) or WT MEFs (-1% OST-A; -3% OST-P). Overall, these data demonstrate that common lamin A/progerin interacting genes differ from unique interactors by an increased peripheral positioning, which is relatively insensible to nuclear lamin A or progerin protein levels. In contrast, unique lamin A and progerin targets can further be distinguished from each other in that they specifically increase their peripheral localization upon the expression of OST-A and OST-P respectively.

Global gene expression profiles of common versus unique lamin A- or progerin-associated genes

To examine the expression behavior of lamina-associated genes in response to overexpression of lamin A or progerin, we analyzed mRNA from WT MEFs transfected with OST-A, OST-P or an empty vector on expression arrays. As

previously observed in other systems³¹, introduction of progerin changed the global transcriptional profile significantly by up-regulating 468 genes and downregulating 702 genes ($p < 0.05$; Figure 6A). OST-A expression affected 1142 genes (571 up and 517 down) of which 379 targets were also affected by expression of OST-P.

When compared to empty vector controls, lamin A, progerin and common targets generally show lower basal expression levels than random sets of genes (\log_2 FC -1.9, $p < 1 \times 10^{-3}$, Mann-Whitney U-test; Figure 6B). In good agreement with their localization at the lamina, common targets were most repressed compared to random genes ($\Delta \log_2$ -2.6, $P < 1 \times 10^{-3}$, Kruskal-Wallis test) followed by lamin A unique targets (\log_2 -2.2 ; $P < 1 \times 10^{-3}$, Kruskal-Wallis test) and progerin unique targets (\log_2 -1.1; $p < 1 \times 10^{-3}$, Kruskal-Wallis test). mRNA levels of all three individual classes differ significantly from each other ($p < 1 \times 10^{-3}$, Kruskal-Wallis test). These basal expression levels of the subclasses did not change significantly upon OST-A or OST-P expression in WT MEFs ($p > 0.05$, Kruskal-Wallis Test; Figure 6C), suggesting that expression of lamin A or progerin is not sufficient to induce a global change in gene activity of lamina-associated genes. Overall, these data indicate that, independent of the presence of progerin, common lamin A/ progerin targets have lower basal expression levels than lamin A or progerin unique targets, which appear to partially escape the repressive effect of the NE.

Progerin-induced changes in gene expression of lamina-associated genes

To further probe the effect of progerin on lamina-associated genes, we analyzed individual ChIP targets whose expression were affected by the expression of progerin and not lamin A. 53 of 745 genes associated with lamin A and/or progerin display a significantly altered expression (Table S5) upon introduction of OST-A or OST-P into WT MEFs. 28 of 53 genes respond only to progerin and not lamin A (relative expression changes -27% to +63% for OST-P; Table S5), 16 change expression upon lamin A but not progerin introduction (-11 to +36% for OST-A; Table S5), and 9 genes respond to both progerin and lamin A, of which one (*Serpin1ad1*) shows an opposite response to both lamins (-13% for OST-A; +11% for OST-P), 3 are down-regulated equally by both lamins (*Fcer2a*, *Smarca5*, *AI747699*; range -4% to -

46% for OST-A or OST-P), 2 show decreased mRNA levels upon the expression of lamin A (*Hoxc11*- 4%, *Srp9* -17% for OST-A) and further decreased levels upon the introduction of OST-P (-13 and -26%, respectively), and the remaining 3 are down-regulated by progerin (*Cysltr1* -1%, *Abpg* -6% and *5730494M16Rik* -9% for OST-P) and more pronounced by

Figure 6. Expression profiles of common and differential lamin A- and progerin-associated genes. (A) A Venn diagram depicting the amount of genes which are deregulated ($p < 0.05$, Anova; no minimal fold change cut-off used) upon introduction of respectively OST-A or OST-P in WT MEFs. The amount of genes up(\uparrow)- and down(\downarrow)-regulated are indicated. **(B)** Expression heatmaps of lamin A/progerin unique and common targets and a random gene set. Expression levels are indicated for WT MEFs expressing OST-A, OST-P or an empty control vector. Common interactors have lower expression levels compared to lamin A and progerin unique interactors ($P < 0.001$; Kruskal-Wallis test). Unique interactors have lower basal expression levels compared to random genes ($p < 0.001$; Kruskal-Wallis test). **(C)** Average expression fold changes (FC) (\pm sd) are given for all 3 subsets of gene targets, comparing WT MEFs expressing OST-A or OST-P with empty vector cells and with each other. Fold changes are based on absolute linear expression values and all were insignificant ($p > 0.05$; Kruskal-Wallis test).

lamin A (-5, -8 and -15% respectively). Despite these significant changes, expression levels for 44 of 53 targets remain very low (absolute linear expression value 1-50, which is 325-fold lower than the housekeeping gene *GAPDH*). Four genes have moderate expression levels (50-100), and increase their expression levels either by either progerin (*B130050I23Rik* +20% and *Krtap5-1* +27% for OST-P), or lamin A (*Pnpla2* +17% for OST-A) or decrease expression by both lamins (*Srp9*, -17% for OST-A, -26% for OST-P). 5 genes were more highly expressed (>100), of which two change expression levels upon the expression of OST-P, but not OST-A (*Cmtm3* +19%, *Rpn2* +3% for OST-P), *5730494M16Rik* changes expression upon the introduction of OST-A (-5%), but not OST-P, and two genes are down-regulated by both lamins, of which *Smarca5* responds equally to both lamins (-44% for OST-A, -33% for OST-P) and *2700069A02Rik* is down-regulated more drastically by lamin A than progerin (-15% for OST-A, -9% for OST-P). Overall, these data identify novel lamina-associated genes whose expression is specifically deregulated by progerin, lamin A or both.

Discussion

The presence of chromatin defects in several laminopathies⁸ points to an important role for A-type lamins in chromatin organization. Recent findings¹⁶ indicate direct lamin A-chromatin interactions are critical for such chromatin organization and suggest that aberrant chromatin-lamin interactions may contribute to laminopathies. We here map genes which interact with lamin A or with the disease causing lamin A isoform progerin in a genome-wide, unbiased fashion. We find that lamin A preferentially binds to peripherally localized, genomically clustered and silent genes, and that chromatin interactions for progerin and lamin A are substantially different. Furthermore, we demonstrate that loss or gain of interaction with lamin A or progerin changes the nuclear position of many interacting genes, but *per se* is not sufficient to change gene expression levels of the interacting genes. We speculate, however, that altered gene location may predispose genes for subsequent aberrant regulation.

Recent studies using the DamID method to map lamin-interacting genome regions¹²⁻¹³ have revealed the importance of lamina-chromatin interactions

in chromatin organization and gene expression regulation by identifying sharply defined lamin-associated domains (LADs) across the genome ¹¹. LADs are preferentially localized in gene-poor, low expressed regions, yet they contain cell-type specifically silenced gene clusters ³². In agreement, using an independent approach we find that lamin A-associated genes are generally silent or very lowly expressed. Lamin A target genes also show preferential localization at the nuclear periphery compared to non-targets and are genomically clustered. Consistent with this, GO analysis reveals that lamin A-associated genes are enriched in gene groups such as sensory perception of smell and bacterial response which are not functional in the fibroblasts or cardiomyocytes analyzed here, and are hence expected to be transcriptionally silent in these cells ³³⁻³⁴. The presence of over 42 tissue and cell-type specific transcription factor binding motifs (TFMs) in lamin A-associated gene promoters further supports this notion. Other enriched TFMs, like RP58, may contribute to the transcriptional repressive environment of the NE by helping maintain condensed chromatin ³⁵⁻³⁶.

We identified targets which associate with lamin A or with progerin or with both. The former two classes of differential targets are distinguished from common targets by a number of characteristics: First, unique targets are less involved in cell-type specific biological processes and are not enriched for any of the 172 investigated TFM. Second, lamin A/progerin common target genes are more frequently co-localized with lamin B at the nuclear lamina than lamin A or progerin unique targets. Correspondingly, we find that the peripheral position of common targets is significantly less affected by overexpression of lamin A or progerin than that of unique targets. Finally, genome-wide expression profile analysis shows that regardless of the presence of progerin, basal expression levels of common lamin A and progerin targets are lower than those of lamin A or progerin-unique targets. These data are in good agreement with our FISH analysis and suggest that transcriptional silencing of common targets at the nuclear lamina is sustained, whereas unique targets partially escape interaction with the lamina under normal conditions, and are likely less influenced by repressive capacities of the NE. The observation that in the absence of progerin, uniquely lamin A-associated genes show significantly lower expression than progerin-specific interacting targets, which in this state do not interact with the lamina, further corroborates this notion.

To determine the importance of lamin-chromatin interactions in subnuclear positioning and regulation of gene expression, we applied FISH and expression array technology to lamin A loss- and gain-of-function cell models. RNAi-mediated knock-down of lamin A/C reveals substantial relocalization of lamin A target loci to the nuclear interior. Despite this relocalization, lamin A-associated genes remain overall more frequently localized at the NE compared to non-targets. The reverse experimental approach, in which we overexpressed lamin A in LMNA^{KO/-} MEFs, lead to the movement of several lamin A target genes to the nuclear periphery. Introduction of progerin in LMNA^{KO/-} MEFs increased the peripheral position of progerin unique targets and resulted in a repositioning of lamin A targets towards the nuclear interior. Combined, these findings support a facilitating role for A-type lamins in recruitment of silenced genes to the nuclear periphery. Interactions with additional nuclear lamina proteins, like emerin and lamin B, which are known chromatin interactors^{11, 13}, likely contribute to this functional nuclear organization.

A key outcome of our analyses is the notion that while localization of (silent) genes to the periphery is dependent on lamin A, dissociation from the lamina does not necessarily lead to their activation. We speculate that loss of lamina-association is only one of multiple steps required for gene activation. Consistent with this, the relocation of the CFTR locus due to activation and consequent internalization of neighboring genes by itself is insufficient for CFTR activation³⁷⁻³⁸. Furthermore, for olfactory receptors, which were identified as the most prominent group of lamin A targets, many additional steps necessary for stochastic activation have been described as well³⁴. It is possible that dissociation from the periphery renders the transcriptional status of these genes to “poised” and facilitates their activation by subsequent signals that may occur e.g. during differentiation. Extending these studies to differentiation models in which additional factors support gene activation of specific subsets of target genes are active will be important. The herein described identification of specific lamin A and/or progerin interacting genes provides a basis for further study of the role of lamina-chromatin dissociation in transcriptional activation and the etiology of laminopathies.

Supplemental Figures and Tables

Figure S1. Characteristics of cell lines expressing One-STREP tagged lamin A and progerin. (A) Immunofluorescent signal of lamin A/C indicating a preferred localization of OST-A and OST-P at the nuclear rim in *LMNA^{KO/-}* MEFs. DNA is stained with DAPI. **(B)** Western blot for B-actin and endogenous lamin A/C in *Nk1TAg* cells infected with control and *LMNA* shRNA.

Figure S2. Experimental workflow of lamin A and progerin One-STRIP pulldown. (A) Overview of the experimental procedures applied to determine lamin A interacting genes in NkITAG cells. The chromatin of formaldehyde cross-linked control vector and OST-A expressing NkITAG cells was sheared by sonication to an average length of 200-1000 base pairs. After determining the DNA concentration, samples were further diluted to contain equal concentrations of DNA. Strep-Tactin matrix was added to these input samples for overnight precipitation of OST-A. After removing unbound chromatin by high stringency washes, the pull-down fraction, as well as aliquots of input samples were de-cross-linked, and chromatin was isolated for subsequent amplification and labeling with Cy-3 and Cy-5. Indicated samples were hybridized on genome-wide promoter arrays, and an in-between array biostatistic analysis (See material & methods) was applied to identify lamin A associated gene promoters. **(B)** For the identification of lamin A and progerin associated gene promoters a similar technical procedure was applied on OST-A, OST-P and control vectors infected WT and LMNA^{KO/-} MEFs. OSTA- and OST-P associated gene promoters needed to be recognized as such independently in all arrays in both WT and LMNA^{KO/-} MEFs, and are collectively referred to as MEF OST-A and OST-P CHIP targets in this paper.

Figure S3. Genomic localization plots of all identified lamin A- and progerin-interacting genes. For each chromosome identified lamin A targets in Nk1Tag cells (bottom line) and lamin A unique interactors, progerin unique interactors and common interactors in MEFs (upper three lines) are plotted according to their genomic localization. A correction for absolute chromosome size has been applied, creating plots of equal length.

Figure S3 (Continued).

Figure S4. Cluster analysis of lamin A- and progerin-interacting genes. (A) Lamin A-associated genes in NkITAg cells were analyzed for their occurrence in gene clusters, defined as two or more lamin A targets being genomically located adjacent to each other without interruption of a non targets. The percentage of lamin A-associated targets represented in clusters is indicated, and compared by Fisher's exact test to randomly expected occurrences of gene clusters (asterisk $p < 1 \times 10^{-4}$). (B) Sizes of identified gene clusters for lamin A-associated genes in NkITAg are indicated by relative frequency. Targets can be divided in unclustered (cluster size=1 gene) and clustered (cluster size>1 gene). Comparable analysis was performed for lamin A-targets (C,D) and progerin-associated genes (E,F) in MEFs.

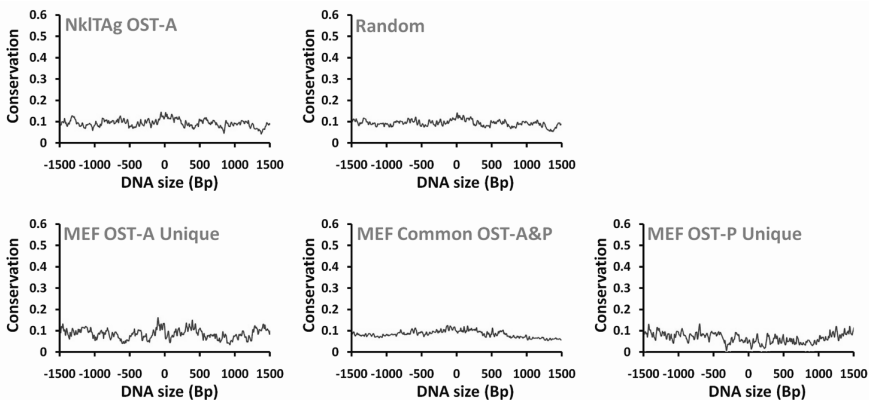

Figure S5. Genomic conservation plots of lamin A and/or progerin interactors. The CEAS database was used to create genomic conservation plots of ChIPed DNA fragments elongated at both ends to a total size of 3 kb, for lamin A unique, progerin unique and common interactors in MEFs as well as lamin A interactors in NkITAg. All conservation levels fluctuated around 0.1 and were comparable to random promoter sequences.

Table S2. Transcription Factor Motif (TFM) analysis of lamin A- and progerin-associated genes.

Results of the TFM analysis using MatInspector software and the Genomatix transcription factor motif database (www.genomatix.de) show the amount of TFM (N) identified in ChIPed DNA fragments and corresponding significance levels for 170 transcription factor families. Significant results are indicated in bold ($p < 0.05$; Statistical analysis described previously²³). Extra note: This list was shortened for publication purposes.

Table S3. Absolute and relative subnuclear positioning of common and unique lamin A/progerin-associated genes

Absolute Values		LMNA ^{ko/-} MEF			WT MEF		
		+Ctrl	+OST-A	+OST-P	+Ctrl	+OST-A	+OST-P
ChIP Targets	OST-A Unique	19%	26%	17%	17%	19%	15%
	Common OST-A&P	47%	52%	53%	58%	57%	55%
	OST-P unique	11%	13%	20%	16%	18%	23%
Relative Values		LMNA ^{ko/-} MEF			WT MEF		
		+Ctrl	+OST-A	+OST-P	+Ctrl	+OST-A	+OST-P
ChIP Targets	OST-A Unique	100%	159% ←*→	83%	100%	138% ←#→	87%
	Common OST-A&P	100%	111%	111%	100%	99%	97%
	OST-P unique	100%	118% ←*→	186%	100%	110% ←#→	206%

Legend: FISH quantifications (Figure 5B) of OST-Aunique (*Eef1a2*, *Kcnp2*, *Scn5a*, *Sdro*), common OST-A&P (*Cyp3a25*, *OLFR804*, *ABPD*, *Defcr5*) and OST-Punique targets (*Daf2*, *Tcf21*, *Trim30*, *Abcb10*) were averaged per subclass, to obtain absolute frequencies on lamin B signal overlap. Relative values were calculated by setting the frequency for each individual locus in empty virus infected cells to 100% and adjusting quantification results in the other cell lines accordingly. Asterisks and hashed indicate respectively significant ($p < 0.05$, Student's t-test) and borderline significant ($0.05 < p < 0.10$, Student's t-test) differences in lamin B overlap between OST-A and OST-P expressing cells.

Table S4. Overview of lamin A-associated genes in NkITAg myocytes that change expression levels.

Entrez Gene ID	Gene Abbreviation	Target Type	Expression WT	Expression LMNA ^{GT-/-}	FC LMNA ^{GT-/-} vs. WT	P-value

Note: Genes that were identified by ChIP technology to interact in MEFs with OST-A only, OST-P only or with both lamins and in addition significantly ($p < 0.05$, no fold-change criterion; Anova) changed their expression level either upon introduction of OST-A or OST-P in WT MEFs. Entrez gene ID, absolute linear expression values, fold changes and significance values between WT MEFs infected with empty virus (Ctrl), OST-A or OST-P are indicated.

CHAPTER 5

Ageing-related chromatin defects through loss of the NURD complex

Based on: Pegoraro G, Kubben N, Wickert U, Göhler H,
Hoffmann K, Misteli T. *Nat Cell Biol.* 2009 Oct; 11(10):1261-7

Abstract

Physiological and premature aging are characterized by multiple defects in chromatin structure and accumulation of persistent DNA damage. Here we identify the NURD remodeling complex as a key modulator of these aging-associated chromatin defects. We demonstrate loss of several NURD components during premature and normal aging and we find aging-associated reduction of HDAC1 activity. Silencing of individual NURD subunits recapitulates some chromatin defects associated with aging and we provide evidence that structural chromatin defects precede DNA damage accumulation. These results outline a molecular mechanism for chromatin defects during aging.

A hallmark of normal and premature aging are global changes in chromatin including loss of heterochromatin structure, altered patterns of histone modifications¹⁻⁴, loss of key heterochromatin proteins²⁻³, and increased levels of persistent DNA damage.⁵⁻⁶ To begin to elucidate the molecular mechanisms leading to these aging-related chromatin defects, we have taken advantage of the premature aging disorder Hutchinson-Gilford Progeria Syndrome (HGPS). This early childhood disease is caused by a recurrent de-novo point mutation in exon 11 of the lamin A/C gene (*LMNA*), which encodes for the intermediate filament proteins lamin A and lamin C, two of the key architectural proteins of the cell nucleus.⁷ The disease-causing mutation in *LMNA* leads to the production of a mutant form of lamin A, referred to as progerin, which lacks 50 aa near the C-terminus, and acts in a dominant negative fashion causing multiple cellular defects of physiological and accelerated-aging.^{1-2, 8-9} In particular, HGPS cells exhibit several chromatin defects which are also characteristic for physiological aging including loss of heterochromatin structure, loss of methylation at H3K9 and H3K27, down-regulation of the heterochromatin protein HP1, and increased transcription of pericentromeric Satellite III repeats (SatIII).^{2, 4} In addition, as normally aged cells, HGPS patient cells exhibit increased steady-state levels of DNA damage.^{3, 5}

To identify the molecular basis of aging-associated chromatin defects, we performed a yeast two hybrid screen using a C-terminal region of lamin A (aa 562-664) which overlaps with the region deleted in progerin (Fig. 1A). We identified the WD40 domain chromatin protein RBBP4 as a lamin A interactor in four independent experiments. None of the other lamin A fragments tested (aa 1-118, aa 416-568, aa 604-657) interacted with RBBP4 by two-hybrid analysis (data not shown). The interaction between RBBP4 and the aa 562-664 fragment of lamin A was confirmed by GST-pull down (Supplementary Fig. 1A). RBBP4 and RBBP7 are evolutionary conserved histone binding proteins.¹⁰ They are shared subunits of several multi-protein complexes involved in the establishment of heterochromatin including the Nucleosome Remodeling and Deacetylase (NURD) complex¹¹ and the Polycomb PRC2 complex.¹² RBBP4 is also the p48 subunit of the CAF-1 complex, which assembles chromatin upon DNA replication and DNA damage repair.¹³ In support of a physical interaction between lamin A and RBBP4/7, recombinant forms of both proteins bound in vitro to GST-lamin A

Fig. 1. Loss of RBBP4 and RBBP7 in progerin expressing cells. (A) Schematic representation of lamin A. The fragment used as a bait in the Y2H assay (aa 562-664) is underlined. (B) GST pulldown assays with recombinant GST-RBBP4/7 and in vitro transcribed and translated lamin A (aa 1-664) or progerin. (C) Crosslinked protein lysates were prepared from U2OS cells expressing One-Strep (OST)-tagged lamin A and then incubated with Streptactin beads. Input and pulled down material was probed by Western blot with antibodies against the indicated endogenous proteins. (D) Immunofluorescence staining on control and HGPS primary dermal fibroblasts with the indicated antibodies. DAPI, 4', 6'-diamidino-2-phenylindole. Quantitative analysis of fluorescence intensity signal in control and HGPS patient cells. The percentages of cells with reduced protein level are indicated. $N > 200$; values represent averages \pm S.D. from at least three experiments. Cells were analyzed around population doubling (PD) 25 in the RBBP4 experiments and around PD 20 in the RBBP7 experiments. Control cells were passage-matched to HGPS cells in each experiment. (E) Western blot of cell lysates prepared from control and HGPS dermal fibroblasts. (F) Immunofluorescence with indicated antibodies in wt fibroblasts that were either induced (on) or not induced (off) to express a GFP-tagged version of progerin. Arrowheads indicate cells with reduced levels of heterochromatin proteins. Scale bars: 10 μ m.

(1-664) and to a lesser extent to a C-terminal fragment (residues 390 – 646) (Fig. 1B; Supplementary Fig. 1B). Importantly, neither protein bound to GST-progerin which lacks residues 607-657 of mature lamin A (Fig. 1B). The *in vivo* interaction of RBBP4, and more weakly of RBBP7, with lamin A was confirmed by immunoprecipitation of endogenous RBBP4/7 by overexpressed One-Strep (OST)-tagged lamin A (Fig. 1C). These results identify the two histone chaperone proteins RBBP4 and 7 as lamin A interactors.

To ask whether RBBP4 and RBBP7 are involved in aging-associated chromatin defects, we probed their status in HGPS cells. Strikingly, a substantial fraction (48 +/- 2%) of HGPS patient cells showed reduced protein levels of RBBP4 when compared to passage- and age-matched controls from healthy donors by quantitative immunofluorescence microscopy as previously described (Fig. 1D, E).²⁻³ The protein level of RBBP7 was similarly reduced in HGPS patient cells (Fig. 1D, E). As previously observed for other nuclear defects in HGPS cells, the extent of reduction was variable amongst cells in the population, but its extent was similar to that observed in HGPS for several other nuclear proteins including all isoforms of the heterochromatin protein HP1. Furthermore, loss of RBBP4/7 occurred in the same cells that exhibited lower levels of HP1 pointing to global chromatin defects in those cells (Fig. 1D).² Reduction of RBBP4 and RBBP7 in HGPS skin fibroblasts relative to control cells was confirmed by Western blot analysis on total cell lysates (Fig 1E). Similar observations were made in several independent primary HGPS patient cell lines (data not shown) and, as observed for HP1 γ , the extent of RBBP4/7 reduction increased during cell passaging (data not shown; ref. ³⁻⁴). RBBP4 and RBBP7 down-regulation occurred at the protein level since similar levels of mRNAs were present in HGPS and control fibroblasts as determined by RT-PCR (Supplementary Fig. 2A). Consistent with the reduction of RBBP4/7, the levels of the centromeric protein CENP-A was reduced in HGPS cells (Supplementary Fig. 2B, 2C), in agreement with earlier observations demonstrating loss of CENP-A after concomitant siRNA silencing of RBBP4 and RBBP7.¹⁴

The loss of RBBP4 and RBBP7 was dependent on progerin. Upon controlled induction of a GFP-tagged version of progerin in immortalized wild-type skin fibroblasts using a tetracycline-dependent expression system⁶, RBBP4 and RBBP7 were almost completely lost within 4 days when compared with the uninduced control (Fig 1F). The control protein RAD52 was not affected by GFP-progerin expression (Fig. 1F). Conversely, elimination of progerin pre-mRNA from HGPS skin fibroblasts by a previously characterized RNA morpholino approach² rescued the levels of RBBP4 when compared to the same cells treated with a scrambled control oligonucleotide (Supplementary Fig. 2D). In addition, staining of HGPS primary fibroblasts with specific anti-progerin antibodies revealed that expression of progerin inversely correlated with RBBP4 levels in these cells (Supplementary Fig. 2E). Collectively, these results demonstrate loss of the histone chaperones RBBP4 and RBBP7 in HGPS cells in a progerin-dependent manner.

Given the role of RBBP4 and RBBP7 in various chromatin remodeling and assembly complexes, we hypothesized that their loss contributes to the changes in chromatin structure and elevated levels of DNA damage that occur during premature and normal aging. To directly test whether the absence of RBBP4/7 is sufficient to cause these defects, we analyzed the status of pericentromeric heterochromatin after siRNA-mediated knockdown of RBBP4 and RBBP7, either alone or in combination (Fig. 2). Efficient knockdown was confirmed by Western blotting (Supplementary Fig. 3A). As expected, cells treated with non-targeting control siRNA oligonucleotides displayed several bright foci of H3K9me3, corresponding to pericentromeric heterochromatin¹⁵, as confirmed by partial colocalization of these foci with CREST antibody which recognizes centromeric proteins (Fig. 2A). Upon simultaneous knock-down of RBBP4 and RBBP7 the focal accumulation of H3K9me3 was lost (Fig. 2A). Silencing of either RBBP4 or RBBP7 alone was not sufficient to cause heterochromatin alterations (Fig. 2A), most likely reflecting the functional overlap between these two highly similar proteins. In line with previous observations¹⁴ concomitant silencing of RBBP4 and RBBP7 led to loss of the centromeric protein CENP-A (Supplementary Fig. 3B). To further test whether RBBP4 and RBBP7 are involved in mediating the chromatin defects observed in HGPS cells, we probed the effect of loss of RBBP4 and RBBP7 on DNA SatIII repeat transcription by semi-quantitative RT-PCR (Fig. 2B).

SatIII repeats are normally maintained in a transcriptionally silent state but are activated in HGPS cells, most likely as a result of heterochromatin disruption.^{4, 16} As observed in HGPS cells, simultaneous silencing of RBBP4 and RBBP7 caused a significant increase in SatIII transcription compared to control siRNA treated cells (Fig. 2B).

To test whether loss of RBBP4 and RBBP7 is also sufficient to induce the increased levels of DNA damage present in HGPS cells, we probed RBBP4 and RBBP7 depleted cells for the presence of phosphorylated histone H2AX, a marker of DNA damage.¹⁷ Similar to cells from HGPS patients and aged individuals, the percentage of cells containing multiple prominent phospho-H2AX foci increased from 5% in control cells to more than 60% in cells depleted of RBBP4 and RBBP7 (Fig. 2C, D).³ The increase in endogenous DNA damage upon RBBP4/7 silencing was mirrored by an increased proportion of cells in S-phase as detected by FACS analysis (Supplementary Fig. 3C, D; $P < 0.01$ for HeLa cells, $P < 0.01$ for U2OS cells), in agreement with the accumulation in S-phase of late-passage HGPS cells (Supplementary Fig. 3E, $P < 0.01$). While the percentage of cells with aberrant chromatin structure in RNAi-treated cells was significantly increased 72 h after RNAi knockdown when compared to the control (Supplementary Fig. 4A), DNA damage only became evident at 120h (Supplementary Fig. 4B), suggesting the occurrence of structural chromatin defects prior to DNA damage. Similar results were obtained after reduction of RBBP4/7 levels by induced expression of progerin (Supplementary Fig. 5).

RBBP4 and RBBP7 are shared subunits of multiple protein complexes involved in chromatin metabolism, including the NURD complex and the PRC2 complex.¹¹⁻¹² In addition, RBBP4 is an integral subunit of the CAF-1 complex.¹³ To test which of these complexes mediates the aging-associated chromatin defects caused by RBBP4 and RBBP7 loss, we tested the status of other subunits of the NURD, CAF-1 and PRC2 complexes in HGPS cells (Fig. 3). Similar to RBBP4 and RBBP7, two additional subunits of the NURD complex, MTA3 and HDAC1, were largely lost from HGPS cells as judged by quantitative single-cell microscopy and Western blotting (Fig. 3A-C). Consistent with a possible regulatory role of lamin A on the NURD complex,

Fig. 2. Heterochromatin defects and increased DNA damage upon RBBP4 and RBBP7 silencing. (A) HeLa cells were transfected with the indicated combinations of siRNA for 144 hrs and processed for immunofluorescence staining with the indicated antibodies. (B) Semi-quantitative, strand specific RT-PCR analysis of SatIII G-rich transcripts in cells knocked down for the indicated gene. (C) Detection of DNA damage in knock-down cells using α -phospho-H2AX antibody. (D) Quantitative analysis of the percentage of p-H2AX positive cells (defined as containing more than 8 foci per cell). Values represent averages \pm S.D. from three experiments. $N > 200$. Scale bars: 10 μ m.

Fig 3. Loss of NURD subunits in HGPS cells. (A) Immunofluorescence staining of control and HGPS primary dermal fibroblasts with the indicated antibodies. **(B)** Quantitative analysis of the fluorescence intensity signal in control and HGPS cells. $N > 200$; Values represent averages \pm S.D. from three experiments. **(C)** Western blot with the indicated antibodies on total cell lysates prepared from dermal fibroblast from two unaffected individuals and two HGPS patients. **(D)** HDAC activity measured in total lysates or in HDAC1 immunoprecipitates prepared from primary fibroblasts. Values represent averages \pm S.D. from three experiments. Scale bar: 10 μ m.

HDAC1 physically interacted with lamin A *in vivo* as demonstrated by its immunoprecipitation with OST-lamin A (Supplementary Fig. 6A). In contrast, protein levels of p150 and EZH2, the catalytic subunit of the CAF-1 and the PRC2 complexes, respectively, were unaffected in HGPS cells (Fig. 3C). The p60 subunit of the CAF-1 complex was up-regulated in HGPS primary fibroblasts (Fig. 3C), likely as a consequence of persistent DNA damage.¹⁸ We conclude the NURD complex is lost from HGPS patient cells.

The loss of HDAC1 protein in HGPS cells pointed to the possibility that the observed chromatin defects are caused by loss of cellular HDAC1 deacetylase activity. To test this hypothesis we measured HDAC1 activity in HGPS patient cells. HDAC1 activity in total cell extracts and in HDAC1 immunoprecipitates prepared from HGPS patient cells was reduced by ~40% compared to matched control cells (Fig. 3D). To directly probe whether the NURD complex is responsible for the aging-associated chromatin defects, we individually knocked down the NURD subunits HDAC1, MTA3, CHD3 or CHD4 in HeLa cells (Supplementary Fig. 6B). In a manner similar to RBBP4/7 knock down, silencing of any subunit increased the percentage of cells lacking H3K9me3 and HP1 γ heterochromatin foci (Fig. 4A, B). Furthermore, shRNA mediated silencing of HDAC1, MTA3, CHD3 or CHD4 in primary human fibroblasts (Supplementary Fig. 6C, D) increased the percentage of cells containing phospho-H2AX positive foci to similar levels as observed in HGPS cells (Fig. 4C, D). These results demonstrate that HDAC1 activity is reduced in HGPS cells and that loss of NURD complex components is sufficient to recapitulate some aging-associated chromatin defects.

Since chromatin defects associated with HGPS also occur during physiological aging³, we finally probed the status of the NURD subunits in cells from normally aged individuals. Quantitative immunofluorescence microscopy analysis on cells obtained from two young donors (7 and 9 years, respectively) and passage-matched primary fibroblasts from two old donors (92 and 88 years, respectively), revealed significant differences in RBBP4, RBBP7, and HDAC1 protein levels (Fig 5A-C). Cell populations from old individuals consistently showed a 4-5 fold increase in the percentage of cells with reduced protein levels of RBBP4, RBBP7 and HDAC1 (Fig. 5D). At the single cell level, the extent of reduction of NURD components strictly

Fig. 4. Heterochromatin defects and increased DNA damage upon silencing of NURD subunits. (A) HeLa cells were transfected with the indicated siRNA for 96 hrs and processed for immunofluorescence staining with the indicated antibodies. Scale bar: 10 μ m. **(B)** Quantitation of the percentage of siRNA treated HeLa cells in which H3K9me3 or HP1 γ foci are absent. Values represent averages \pm S.D. from two experiments. Scale bar: 10 μ m.

correlated with each other and with HP1 γ levels, albeit less pronounced than that observed for HGPS cells as previously described³. In contrast to HGPS cells, no loss of CENP-A was detected in normally aged cells. We conclude that loss of the RBBP4, RBBP7, and HDAC1 subunits of NURD is not limited to premature aging but is also a feature of physiologically aged cells. Here we have identified the NURD chromatin remodeling complex as a mediator of aging-associated chromatin defects. We demonstrate reduction of several NURD subunits in cells from a progeroid syndrome and from normally aged individuals. Loss of any one of these components and reduction of HDAC1 activity is sufficient to recapitulate multiple aging-associated chromatin defects. The *in vivo* physical interaction of lamin A with RBBP4, RBBP7 and HDAC1 observed here, and previously suggested by biochemical fractionation¹⁹, points towards a regulatory role for the nuclear lamina in the function of the NURD complex in normal cells.

We find that loss of RBBP4/7 is dependent on the presence of progerin and is an early event in the appearance of aging-associated chromatin defects. Upon induction of progerin or upon knock-down of RBBP4 and RBBP7, changes to heterochromatin structure occur and are followed by accumulation of DNA damage. We suggest that loss of critical chromatin components RBBP4/7 is an upstream event in the formation of aging-associated chromatin defects. Loss of RBBP4/7 compromises the establishment and maintenance of histone modifications and higher order chromatin structure, possibly making chromatin more susceptible to DNA damage. The increase in DNA damage might be a consequence of higher susceptibility of the affected chromatin to damage or alternatively due to impaired DNA replication.²⁰ Interestingly, similar to the effects we observe upon silencing of RBBP4 and RBBP7, impairment of the H4K20 histone methyltransferase PR-Set7, which is necessary for proper H4K20 trimethylation associated with heterochromatin, interferes with DNA replication, arrests cells in S-phase and causes increased levels of DNA damage.²¹⁻²²

Our finding that multiple NURD components are lost in HGPS and normally aged cells suggests that the integrity of the NURD complex is compromised and its components are down-regulated during premature and physiological aging. Whether loss of these proteins occurs by activation of a specific

Fig 5. Loss of NURD subunits in physiological aging. (A), (B) and (C) Immunofluorescence microscopy of passage-matched primary dermal fibroblasts from healthy young (7 yrs and 9 yrs) or old (92 yrs and 88 yrs) donors were fixed and stained with the indicated antibodies. (D) Quantitative analysis of the fluorescence intensity signal measured in dermal fibroblasts from young and old individuals. $N > 200$; Values represent averages \pm S.D. from three experiments. Arrowheads indicate cells with reduced levels of heterochromatin proteins. Scale bars: 10 μ m.

protein degradation program or by interference with the normal homeostasis of the NURD protein complex remains to be determined. The involvement of a specific pathway is suggested by the fact that progerin affects the protein levels of several subunits of the NURD complex, but not of other RBBP4- or RBBP7-containing complexes, such as CAF-1 or PRC2. While we cannot rule out that the degradation mechanism of NURD components are distinct in HGPS cells and in normally aged cells, the fact that progerin is also expressed at low levels in cells from normally aged individuals is consistent with a conserved degradation mechanism.³ Overall, these results implicate declining NURD remodeling complex function in aging-associated chromatin defects and accumulation of DNA damage during aging.

Materials and Methods

Cell culture

Primary dermal fibroblast cell lines were obtained from the NIA and NIGMS collections of the Coriell Cell Repository (CCR), from the American Type Culture Collection (ATCC) or the Progeria Research Foundation (PRF). The cells from HGPS patients were AG01972 (Patient age 14 years, CCR, population doublings (PD) 20 at purchase), AG06297 (8 years, CCR, PD17), HGDAFN003 (2 years, PRF, PD7). Control cell lines were CRL-1474 (7 years, ATCC, PD19) GM00038 (9 years, CCR, PD17), AG05247 (88 years, CCR, PD15) and AG09602 (92 years, CCR, PD 12). Cells were used at PD's 19-27. WI-38 primary human fetal fibroblasts (3 month gestation fetus, ATCC, PD8) were used at PD's 10-18. All primary fibroblasts were grown in Minimum Essential Medium (MEM, Gibco), 15% FCS, 2mM L-glutamine, 100 U/ml penicillin and 100 µg/ml streptomycin at 37 °C in 5% CO₂. Growth and induction of immortalized, Tet-off human fibroblasts expressing GFP-Progerin was as previously described⁶. U2OS cells stably expressing One-Strep-Lamin A were maintained in McCoy's 5A medium (Gibco), 10% FCS, 2mM L-glutamine, 10 µg/ml blasticidin at 37 °C in 5% CO₂.

Plasmids

Plasmids expressing GST -RBBP4/7 were a kind gift of B. Stillman (Cold Spring Harbor, NY)¹⁰. Vectors for in vitro transcription and translation of lamin A and progerin were constructed as follows: an EcoRI/BamHI fragment containing the entire CDS of lamin A (1-664) or progerin was excised from either pEGFP-Lamin A or pEGFP-Lamin $\Delta 50$ ², respectively, and cloned into the pCDNA3.1 (-) vector (Invitrogen) cut with the same enzymes. pGBKT7-lamin A (390-646) was a kind gift of T. Dittmer (NCI/NIH, Maryland). N-terminal One-Strep tag (IBA BioTagnology, Göttingen, Germany) oligonucleotides (Sigma, Zwijndrecht, Netherlands) were cloned into BamHI and EcoRI sites of pBabe puro (Plasmid 1764, Addgene). The retroviral pBabe puro One-Strep-Lamin A plasmid was generated by inserting lamin A from the pBabe puro HA-Lamin A vector²³ into the Sall and EcoRI sites. In order to generate a lentiviral expression system a BamHI and EcoRI containing multiple cloning site was introduced in the pCDH1-MCS1-EF1-Puro vector (System BioSciences, Mountainview, California, USA), the puromycin cassette was replaced by a blasticidin cassette from the pLenti6/V5-GW/LacZ vector (Invitrogen, Carlsbad, California, USA) and the One-STREP-tagged lamin A from the pBabe puro One-Strep-Lamin A vector was ligated into the BamHI and EcoRI restriction sites, thereby generating the lentiviral pCDHblast MCSNard OST-Lamin A vector. The Yeast Two Hybrid screen was performed as described²⁴⁻²⁵

siRNA and shRNA constructs

siGenome SMART pool siRNA oligos against human RBBP4 and RBBP7 were purchased from Dharmacon-Thermo Scientific and transfected at 0 and 72h into Hela cells at 50 nM using Oligofectamine (Invitrogen) or Dharmafect1 (Dharmacon-Thermo), following the manufacturer instructions.

GIPZ lentiviral vectors expressing shRNAmir sequences targeted against human HDAC1, MTA3, CHD3 and CHD4 were purchased from Open Biosystems-Thermo Scientific (Waltham, MA) and virus produced in 293FT packaging cells (Invitrogen) using FUGENEHD (Roche), following the manufacturer's instructions. Target WI38 fibroblasts (~ 50% confluent) were incubated for 8 hrs with a 1:1 mix of filtered viral supernatant and MEM+15%FBS and in the presence of 6 µg/ml Polybrene (Sigma-Aldrich). A second round of infection with fresh lentiviral vector-containing supernatant was performed after 24 hrs. 48-72 hrs after the first round of infection, puromycin (2 µg/ml) was added to the medium to select shRNAmir expressing cells. Experiments were performed 6 days after the first round of infection.

GIPZ non-targeting sequence: 5'-TCTCGCTTGGGCGAGAGTAAG

Antibodies

The following antibodies were used in immunofluorescence, Western blotting and immunoprecipitation: α -HP1 γ mouse monoclonal (MAB3450, Chemicon), α -H3K9me3 rabbit polyclonal (4861, kindly provided by T. Jenuwein), α -RBBP4 mouse monoclonal (11G10, Abcam), α -RBBP4 rabbit polyclonal (ab1765, Abcam), α -RBBP7 rabbit polyclonal (ab3535, Abcam), α -RAD52 rabbit polyclonal (3425, Cell Signaling), α -p-H2AX mouse monoclonal (JBW301, Millipore), α -p-H2AX mouse monoclonal (2F3, Abcam), α -HDAC1 rabbit polyclonal (PA1-860, ABR), MTA3 rabbit polyclonal (A300-160A, Bethyl Laboratories), α -p150 CAF-1 mouse monoclonal SS1 and α -p60 CAF-1 mouse monoclonal SS53 (kind gifts of B. Stillman), α -EZH2 rabbit polyclonal (39103, Active Motif), α -CHD3 rabbit polyclonal (A301-219A, Bethyl Laboratories), α -CHD4 rabbit polyclonal (H-242, St. Cruz), α -CHD4 mouse monoclonal (91984, Genetex), α -Lamin A goat polyclonal (N-18, St. Cruz), α -progerin mouse monoclonal 13A4, (Alexis Biochemicals), α -centromeric proteins CREST human autoimmune serum (Antibodies Inc.), α -CENP-A mouse monoclonal (3-19, Abcam).

Immunofluorescence microscopy and image quantitation

Indirect immunofluorescence microscopy was performed as previously described². Quantitative microscopy measurements were performed as previously described²⁻³. For single cell analysis, at least 200 cells per sample were counted in triplicate and the error bars in the histograms represent the standard deviation.

Western blotting

Cells were rinsed in PBS and lysed in either 1X Laemmli SDS-PAGE loading buffer or, alternatively, in a buffer containing 150 mM NaCl, 20 mM Hepes pH 7.4, 0.5% NP40, 1mM EDTA, 10 mM β -Glycero-phosphate, 1 mM NaF, 1 mM Na_3VO_4 , Protease Inhibitors Cocktail SetIII (Calbiochem). Western blotting and immunodetection were performed as previously described ².

Recombinant proteins expression and in vitro binding assays

GST-fusion proteins were expressed in *E. coli* BL21(DE3)pLysS (Promega) and affinity purified on glutathione Sepharose beads (GE Healthcare). For *in vitro* binding assays, GST fusion proteins (1-5 μg) immobilized on glutathione Sepharose beads were pre-washed twice in NETN150 (20 mM Tris-HCl pH 7.5, 150 mM NaCl, 1mM EDTA, 0.5% NP40, 1 mM DTT), incubated 30 min at 4°C with Benzonase, washed once in NETN1000, blocked for 30 min in NETN150, 1 mg/ml BSA and then washed twice in NETN150. [³⁵S]-labelled proteins were generated by *in vitro* transcription/translation using a T7TNTQuick-rabbit reticulocyte lysate system (Promega). Equal amounts of *in vitro* translated, [³⁵S]-labelled proteins were incubated in a total volume of 50 μL of NETN150 with either GST or the appropriate GST fusion protein for 1 hr at 4°C in binding buffer. The beads were washed 6x with NETN150, boiled for 5 min in 1x SDS-PAGE Laemmli loading buffer, and resolved on a SDS-PAGE gel. The gel was dried and [³⁵S]-labelled proteins were visualized using a Storm 860 (Molecular Dynamics).

RNA extraction and RT-PCR

RNA was extracted from cells using the RNeasy Mini Kit (QIAGEN) following the manufacturer instructions. Residual contaminating genomic DNA was eliminated by treating the RNA with Turbo DNA-free DNase (Ambion). RBBP4 and RBBP7 mRNA levels in control and HGPS cells were measured by retrotranscribing 1 μg of RNA using random primers and the Mo-MuV RT enzyme included in the High Capacity Archive cDNA kit (Applied Biosystems) for 2 hr at 42 °C, after a denaturation step of 5 min at 65 °C. Equal volumes of cDNA were employed as template in a real-time Q-PCR reactions using iQ SYBR Green Supermix (Biorad) in a Biorad iCycler. Reaction conditions were: 3 min at 95 °C, 1 cycle; 20 sec at 95 °C, 30 sec at 56 °C, 41 cycles. Melting

curves of the amplified product were generated to verify that a single amplicon was generated. Primers :

RBBP4-6-Fw (5'-TCTGTTTGGGTCAGTTGCTG-3')

RBBP4-6-Rw (5'-AACTGAGTGGCTTGGTTTGG -3')

RBBP7-6-Fw (5'-CTGGCCACTCAGCTGTTGTA -3')

RBBP7-6-Rw (5'-AGGTGGTATTGGACCTGGTG -3').

All the values were normalized to the internal control Cyclophilin A gene: Cycl-Fw (5'-GTCAACCCACCGTGTCTT-3') and Cycl-Rw (5'-CTGCTGTCTTTGGGACCTTGT -3'). The G-rich strand of SatIII transcripts was retrotranscribed and PCR amplified as previously described²⁶.

HDAC1 immunoprecipitation and HDAC assays

CRL- 1474 and AG01972 primary fibroblasts were grown in 10 cm dishes to 70-90% confluency. Cells were rinsed in PBS and resuspended in Lysis buffer (300 mM NaCl, 50 mM Hepes pH 7.4, 0.5% NP40, 1 mM EDTA, 20% glycerol, 10 mM β -Glycero-phosphate, 1 mM NaF, 1 mM Na₃VO₄, Protease Inhibitors Cocktail SetIII (Calbiochem)). The cell lysate was incubated for 30 min at 4 °C on a rotating wheel and then centrifuged for 12 min at 12000 g. Total protein concentration of lysates was measured using the Bradford Assay reagent (Biorad). Equal quantities of protein lysate from different samples (1.5-2.0 mg) were diluted to 1 ml with Lysis buffer. Lysates were pre-cleared by incubation for 1hr at 4 °C with rabbit-preimmune serum and Protein A/G+ agarose (St. Cruz) and then incubated o/n at 4 °C with a α -HDAC1 rabbit polyclonal antibody. Immunocomplexes were captured by adding Protein A/G+ agarose. Beads were washed 5X in Lysis buffer and rinsed twice in HDAC assay buffer (see below). HDAC activity in total lysates and in HDAC1 immunoprecipitates was measured with the Fleur de Lys Fluorescent HDAC assay kit (Biomol) following the manufacturer instructions.

OneSTrEP-lamin A pulldown

U2OS cells stably expressing OneSTrEP-lamin A were grown in 150 mm dishes, fixed in formaldehyde and lysed in SDS lysis buffer (1% SDS, 10 mM EDTA, 50 mM Tris pH 8.1). After extensive sonication, the SDS concentration in the lysate was lowered 10-fold by addition of SDS dilution buffer (0.01% SDS, 1.1 % Triton X-100, 1.2 mM EDTA, 17 mM Tris pH 8.1, 170 mM NaCl).

Both SDS lysis buffer and SDS dilution buffer were supplemented with 2 mM orthovanadate and protease inhibitors (Boehringer Mannheim, Indianapolis, USA). Undissolved fractions were discarded after a 10 minute centrifugation step at 4 degrees at 10, 000xg. Streptactin Matrix (IBA BioTagnology, Göttingen, Germany) prewashed in SDS dilution buffer was added and samples were incubated on a rotating wheel o/n at 4 °C. Precipitated protein complexes were washed extensively, and eluted from the beads by incubation at 95 °C in 1X Laemmli SDS-PAGE loading buffer.

Acknowledgements

We would like to thank P. Scaffidi and A. Marcello for critical reading of the manuscript and P. Scaffidi for sharing data and providing numerous suggestions during the course of the experiments. Fluorescence imaging was performed with the assistance of T. Karpova at the NCI Fluorescence Imaging Microscopy Facility. FACS cell cycle acquisition and analysis was performed with the help of K. McKinnon at the NCI FACS facility. We would also like to thank T. Jenuwein, B. Stillman and T. Dittmer for providing reagents. We thank H. Herrmann and E. Wanker for their support with the Y2H screening and subsequent confirmation studies. G.P. was partly supported by postdoctoral fellowships from the Telethon Italy Foundation and the Italian Association for Cancer Research (AIRC). K.H. and H.G. were supported by The Deutsche Forschungsgemeinschaft (DFG, SFB 577, projects A4 and Z2). This work was supported by an Intramural Research Program of the NIH, NCI, Center for Cancer Research.

Abstract

A-type lamins are a major component of the nuclear lamina. Their expression is developmentally regulated and is absent during embryonic development until the onset of tissue differentiation and maturation. Mutations in the *LMNA* gene, which encodes the A-type lamins A and C, cause a set of phenotypically diverse diseases collectively called laminopathies. While adult *LMNA* null mice show various symptoms typically associated with laminopathies, the effect of loss of lamin A/C on early post-natal development is poorly understood. Here we developed a novel *LMNA* null mouse (*LMNA*^{GT-/-}) based on genetrap technology and analyzed its early post-natal development. We detect *LMNA* promoter activity in heart, liver, intestine and somites during early embryonic development. Loss of A-type lamins results in severe growth retardation and developmental defects of the heart, including impaired myocyte hypertrophy without functional cardiac defects, skeletal muscle hypotrophy, decreased amounts of subcutaneous adipose tissue and impaired *ex vivo* adipogenic differentiation. These defects cause death at 2 to 3 weeks *post partum* associated with muscle weakness and metabolic complications, but without the occurrence of dilated cardiomyopathy or an obvious progeroid phenotype. Our results indicate that defective early post-natal development critically contributes to the disease phenotypes in adult laminopathies.

Introduction

Nuclear lamins are intermediate filament proteins mainly localized in the nuclear lamina, a protein meshwork lining the nucleoplasmic face of the inner nuclear membrane. Lamins are classified as A-type or B-type. The A-type lamins consist of the three *LMNA* splicing isoforms lamin A, A Δ 10 and C. B-type lamins are encoded by the *LMNB1* and *B2* genes. Whereas B-type lamins are expressed in all mammalian cells throughout development, A-type lamin expression is developmentally regulated. Lamin A/C expression commences in the zygote but is lost at the morula stage¹⁻³. It is only at the beginning of tissue differentiation, in mouse at day E12.0, that lamin A/C expression restarts in myoblasts. In many other tissues, lamin A/C was reported to be absent until well after birth⁴⁻⁵. The notion of lamin A/C being expressed upon tissue differentiation is further strengthened by its absence in embryonic stem cells and its re-expression after loss of pluripotency markers upon neuronal or cardiac myocyte differentiation⁶. Similarly, embryonic carcinoma cells are devoid of lamin A/C in contrast to differentiated derivatives^{3, 7}. Loss of lamin A/C results in increased proliferation due to hyperphosphorylation of the retinoblastoma protein⁸ and correlates with poor histological differentiation and prognosis in primary gastric carcinomas⁹.

Mutations in A-type lamins cause a group of phenotypically diverse diseases, collectively called laminopathies. They include several types of muscular dystrophies, lipodystrophies, cardiomyopathies, neurological disorders and premature aging syndromes¹⁰. Several of the *LMNA* mutations affect cell differentiation. Mutations that lead to Dunnigan familial partial lipodystrophy (FPLD) interfere with the binding of lamin A to the adipocyte differentiation factor sterol element binding protein 1 (SREBP1) and impair adipocyte differentiation¹¹. In the premature aging disease Hutchinson-Gilford Progeria Syndrome (HGPS), the disease-causing lamin A mutant isoform progerin inhibits adipogenic differentiation and favors osteogenic differentiation of human mesenchymal stem cells via increased Notch signalling¹². To study the

role of lamin A/C in skeletal, cardiac and adipose tissue and to probe how *LMNA* mutations affect the functioning of these tissues in laminopathies, several lamin A/C mouse models have been created¹³. Tissue defects in these models mostly become manifest in young adult mice and are therefore mainly studied in weaned mice. As a consequence, little is known about the effect of loss of lamin A/C on early post-natal development or the contribution of defective development to laminopathies.

In this study we set out to probe the effects of loss of lamin A/C on early post-natal development as this is the period in which most tissue differentiation and maturation occurs. To this end, we created a novel *LMNA*^{GT/-} mouse model which combines loss of *LMNA* function with *LMNA*-controlled reporter gene expression. We demonstrate early activity of the *LMNA* promoter at day E11 during embryonic development in heart, liver, intestine and somites. Loss of lamin A/C results in growth retardation at 2 weeks *post partum*, with impaired post-natal hypertrophy of cardiac myocytes, skeletal muscle hypotrophy, decreased subcutaneous adipose tissue deposits, decreased adipogenic differentiation of MEFs and metabolic derangements. Ultimately these tissue differentiation and maturation defects are lethal before mice are weaned. These results demonstrate that lamin A/C is crucial in the early post-natal period and they provide novel insights into the physiological function of A-type lamins in the context of the developing animal.

Materials & Methods

Targeting of the LMNA gene

LMNA^{Gt(FHCRC-GT-S7-1F1)Sor} AK7.1 ES cells (strain of origin 129S4/SvJaeSor) containing a ROSAFARY Genetrap (GT) vector in the *LMNA* gene were obtained from the International Genetrap Consortium (www.genetrap.org). Chimaeric mice were created by ES cell injection into C57Bl/6 recipient blastocysts at the Transgenesis and gene

Targeting Unit Maastricht (Maastricht, The Netherlands). Resulting chimaeric males were bred to wildtype (WT) C57Bl/6 mice. Resulting heterozygous $LMNA^{GT}$ ($LMNA^{GT+/-}$) mice were interbred to achieve homozygosity ($LMNA^{GT-/-}$). For genotyping, PCR-primer pairs Fw (forward) 5'GACGGGTTGTTACTCGCTCAC3' and Rev (reverse) 5'CAGGTCAAATTCAGACGGCAA3' were used to selectively amplify GT; Fw 5'ACCATCTCCCCAGCCCTTAG3' and Rev 5'CAACATTCTGATTCTTTCTGC3' to detect the endogenous $LMNA$ gene. All studies involving animal experiments were approved by the Animal Care and Usage Committee of Maastricht University (Maastricht, The Netherlands) and the National Institutes of Health (NIH, Bethesda, USA) and were performed in accordance with regulations formulated in Dutch and US law on care and use of experimental animals.

Histology, Immunohistochemistry and Transmission Electron Microscopy (TEM)

$LMNA^{GT}$ mice were sacrificed by decapitation or cervical dislocation. Blood was removed from the vascular system by perfusing of 5 ml physiological buffered saline via the left ventricle (LV) of the heart; muscle relaxation was induced by a consecutive injection with 100 μ l of a 0.1N cadmium chloride solution. Tissues for histological analysis and immunohistochemistry were fixed for 4-6 hours in 4% paraformaldehyde, washed three times 5 minutes in PBS, stored overnight in 70% ethanol, embedded in paraffin and sectioned at 4 microns. Tissues sections were stained with haematoxylin eosin (H&E) and Picro Sirius Red (SR) as described before¹⁴. H&E staining was used for quantification of cardiac- and skeletal-myocyte cross sectional areas. Impaired post-natal hypertrophy was quantified by cardiac myocyte cross-sectional area (CSA) counts in LV myocytes opposite or adjacent to the septum. Tissues for RNA isolation were snap frozen in liquid nitrogen. Tissues for TEM analysis were fixed in 2.5% glutaraldehyde and further analysis was performed as previously described¹⁵. Whole-mount embryos were β -galactosidase stained as described¹⁶.

RNA isolation and microarray analysis

RNA was isolated from mouse embryonic fibroblasts (MEF) and LV of *LMNA*^{GT} mice using the RNeasy minikit (Qiagen, Hilden, Germany). For whole transcriptome analyses, RNA from LV's of 5 and 13 days old WT and *LMNA*^{GT-/-} mice (N=2 for each genotype and age) was isolated and hybridized to Nugo Mouse Affymetrix expression arrays. Intensity values after hybridization were normalized to the median signal intensity of the array. Enrichment of deregulated genes in specified biological pathways was tested using GENMAPP 2.1 software. For expression analysis by PCR cDNA was synthesized with the iScript™ cDNA synthesis kit (BioRad, Hercules, USA). SYBR Green real-time quantitative PCR analysis was performed with primers for ANF (Fw 5'ATTGACAGGATTGGAGCCCAGAGT3', Rev 5'TGACACACCACAAGGGCTTAGGAT3'), BNP (Fw 5'GTTTGGGCTGTAACGCACTGA3', Rev 5'GAAAGAGACCCAGGCAGAGTCA3'), Ki67 (Fw 5'TCAACAGCTGGTATGCCTAACAG3', Rev 5'TTCCAGTGGTCAAAGAGTCATTAGC3'), PCNA (Fw 5'AGGGTTGGTAGTTGTCGCTGTAG3', Rev 5'GGTCCCCGATTCACGAT3'), GAPDH (Fw 5'GGTGGACCTCATGGCCTACA3', Rev 5'CTCTCTTGCTCAGTGCCTTGCT3') and HPRT (Fw 5'GCGTCGTGATTAGCGATGATGAAC3', Rev 5'CCTCCATCTCCTTCATGACATCT3').

Echocardiography and electrocardiogram (ECG) analysis

WT, *LMNA*^{GT+/-} and *LMNA*^{GT-/-} cardiac functioning was monitored by serial echocardiography and ECG analysis at days 10, 13 and 17 *post partum* (PP10, PP13 and PP17). ECG analysis was performed under 2% isoflurane sedation; P wave, QRS and QT time were assessed using IDEEQ v1.7 software (Instrument Development Engineering & Evaluation, Maastricht University, The Netherlands). Echocardiography was performed under similar sedative conditions, with a 30MHz transducer on a Vevo770™ high-resolution *in vivo* micro-imaging system (VisualSonics B.V., Amsterdam, The Netherlands). LV parameters were obtained from M-mode recordings in the short axis-view. Fractional shortening (FS) was calculated using the formula: FS = 100x((Left Ventricle Inner Diameter in diastole – Left Ventricle Inner Diameter in systole)/Left Ventricle Inner diameter in diastole). To study the effects of α - and β -adrenergic receptors antagonists on *LMNA*^{GT-/-} cardiac

performance, labetalol was administered twice daily by subcutaneous interscapular injections at a dose of 10 mg/kg from day PP10 onward; ECG analysis was performed as indicated above at day PP13. To study the effects of *LMNA* heterozygosity on cardiac hypertrophy, echocardiography was performed as indicated above on 60-70 weeks old *LMNA*^{GT+/-} mice and WT controls. Furthermore 16-18 weeks old WT and *LMNA*^{GT+/-} mice were infused subcutaneously with 1.5 µg/g/day angiotensin II for 4 weeks by an osmotic minipump (Alzet osmotic minipumps, Cupertino, CA). Echocardiograms were made at 2 and 4 weeks after the start of the angiotensin II treatment.

Functional assessment of skeletal muscles.

Total quadriceps muscle weight were normalized to tibia length for all genotypes. Skeletal muscle strength was assessed by quantifying the capacity to hang upside down on a grid with use of both fore- and hind limbs. Time in seconds indicates the time from placing the raster upside down until the mouse dropped from the grid. Measurements on each genotype were performed in triplicate (n=4, PP15).

Adipocyte differentiation assay

MEFs were isolated from E12.0 *LMNA*^{GT-/-}, *LMNA*^{GT+/-} and WT embryos by digesting skin isolates for 20 min in 3 ml 0.05% trypsin at 37°C during which the solution was resuspended every 10 minutes. This was followed by addition of an equal volume of fresh trypsin solution and a 20 minute incubation step; this was repeated once and incubated for 5 additional minutes, after which a cell pellet was obtained by centrifugation and plated in Dulbecco's modified eagle medium (11360-070, Invitrogen, San Diego, USA) with 2mM L-glutamine, 10mM non-essential amino acids (NEAA), 110 mg/l pyruvate, 10% fetal bovine serum (FBS) and antibiotics. Passage 2 (P2) cells were seeded at 50% confluency in 6-wells plates for adipogenic differentiation and grown to confluency for 3 days. The medium was replaced and cells were left for 3 days on induction medium: hMSC basal medium (PT-3238, Lonza, Basel, Switzerland) with 2mM L-glutamine, 10mM NEAA, 110 mg/l pyruvate,

10% FBS, antibiotics, 10µg/ml insulin, 0.5 mM 3-isobutyl-1-methylxanthine (IBMX) and 1µM dexamethasone. After 3 days the medium was replaced by maintenance medium (similar to induction medium with omission of IBMX and dexamethasone) and left for 2 days. This 5 day cycle of induction and maintenance was repeated three times. Oil Red O staining and quantification after each cycle (6, 10 and 16 days post induction) were performed in triplicate as previously described ¹².

Metabolic characterization

To assess core body temperature, mice received an inter-intestinal temperature probe through a small abdominal incision directly after applying isoflurane anesthesia. Core body temperature was measured as soon as it reached a plateau phase (i.e. before ambient temperature decreased body temperatures). Subcutaneous adipose tissue deposits were determined by incising the skin along the sagittal axis, collecting and weighing subcutaneous adipose tissue in between the left fore- and hind leg. Subcutaneous adipose tissue weights were standardized by tibia length. For blood chemistry measurements, WT, *LMNA*^{GT+/-} and *LMNA*^{GT-/-} mice were intraperitoneally injected with 50 µl of a 500 Units/ml heparin solution as an anticoagulant before decapitation and collection of blood. For glucose, lactate and betahydroxybutyrate analysis the collected blood was mixed with equal amounts of 1M perchloric acid and centrifuged to obtain a supernatant fraction for further analysis ¹⁷. The acylcarnitine spectrum was determined by mass spectrometry on regular blood plasma as described ¹⁸. Urea, creatinine and creatinine kinase were determined on EDTA anticoagulated blood. For mitochondrial functioning LV samples were snap frozen in liquid nitrogen and used to determine catalytic activity of citrate synthase and individual oxidative phosphorylation complexes as described ¹⁹. Mitochondrial DNA copy numbers were assessed in LV cardiac muscle and quadriceps skeletal muscle ¹⁹.

Statistical analysis

Data are represented as average \pm SD. The data for each study group were compared using 2-way ANOVA or student's t-test where appropriate. Analyses were performed using the statistical package SPSS 11.0. $P < 0.05$ was considered to be statistically significant.

Results

Generation of a Lamin^{GT-/-} mouse

We created *LMNA* null mice by interruption of the endogenous lamin A/C locus by a promoter-trap construct, which introduces an in-frame *LMNA*- β geo fusion allele. The construct was inserted in second *LMNA* intron (Figure 1A). Lamin A/C transcripts (Figure 1B) and protein were undetectable in *LMNA*^{GT-/-} animals 15 days *post partum*. As expected, *LMNA*^{GT+/-} mice expressed approximately half the amount of lamin A and C mRNA (Figure 1B) and protein compared to WT controls. RT-PCR analysis confirmed the absence of randomly integrated GT vector sequences elsewhere in the genome, as well as the absence of alternative *LMNA* splicing products (data not shown).

The *LMNA*- β geo fusion protein is encoded by the first *LMNA* exon followed by β -galactosidase-neomycin cDNA (Figure 1A), which allows for direct visualization of *LMNA* promoter activity in *LMNA*^{GT+/-} and *LMNA*^{GT-/-} whole mounts and tissue sections. At E8.0 and E9.0, only *LMNA*^{GT+/-} placental tissue showed *LMNA* promoter activity (Figure 1C). At E11.0 the *LMNA* promoter was active in heart, liver, intestines and embryonic somites. Late in embryonic development (E18.0) *LMNA* promoter activity was observed macroscopically in all organs. Specificity of β -galactosidase signal was confirmed by staining adult *LMNA*^{GT+/-} mice, which showed absence of *LMNA* promoter activity in various cell types, as reported previously⁴ (data not shown).

At birth, genotypes were present in normal Mendelian ratios and no obvious macroscopic differences were detected between WT, $LMNA^{GT+/-}$ and $LMNA^{GT-/-}$ mice. At PP7, onset of initial growth retardation was observed in $LMNA^{GT-/-}$ mice, which was confirmed by decreased body weight (BW) (Figure 1D and E). $LMNA^{GT-/-}$ body weight peaked at PP13 and decreased slightly thereafter, leveling off at approximately half the BW of that of WT and $LMNA^{GT+/-}$ at PP16 (Figure 1E). Complete loss of lamin A/C due to insertion of the GT sequence was invariably lethal between PP16 and PP18 (Figure 1F). BW and survival curves of $LMNA^{GT+/-}$ mice were comparable to those of WT siblings. Grooming behavior and foraging appeared normal for all genotypes, and were only diminished for $LMNA^{GT-/-}$ mice at days PP16-PP18. $LMNA^{GT-/-}$ autopsy at PP17 revealed an increased amount of intra-intestinal gas, but did not reveal obvious differences in food content or GI tract histology. Pathological examination at PP15 revealed heart, skeletal muscle myocytes and adipose tissue abnormalities. $LMNA^{GT-/-}$ mice did not show overt abnormalities in stomach, intestines, liver, kidneys, spleen, thymus, thyroid, lung, bladder, pancreas and brain. No obvious indications of abnormal bone or dentation were observed (data not shown), in contrast to reports on other $LMNA$ mouse models¹³. Hence, we conclude that loss of lamin A/C leads to defects in early post-natal development and ultimately death.

Transcriptome analysis

To assess how loss of lamin A/C affects tissue differentiation and maturation, microarray expression analysis was performed on left ventricle (LV) cardiac tissue at PP5 and PP13. At PP5 expression of 671 genes changed more than 1.2 fold (199 up, 472 down) in $LMNA^{GT-/-}$ mice compared to WT siblings (Figure 2A and B). 28 of those genes were still misregulated at PP13, 3 of which in similar and 25 in opposite direction. In addition, 359 genes were more than 1.2 fold deregulated at PP13 (194 up, 165 down) while normally expressed at PP5 (Figure 2A and B). *Genmapp* analysis indicates that the deregulated genes are significantly

Figure 1. General phenotypical characterization of the $LMNA^{GT/-}$ murine model. (A) Overview of the ROSAFARY genetrap (GT) sequence insertion in the $LMNA$ gene. The GT consists of a splice acceptor (SA) containing β geo-reporter with a polyA signal (bpA) and a PGK promoter driven hygromycin antibiotics resistance cassette surrounded by FRT sites and harbouring a splice donor (SD) site. 5' and 3' ends of the GT sequence are demarcated by long terminal repeats (LTR). (B) Relative mRNA expression levels for full length lamin A, C and the $LMNA$ - β geo splicing product. Expression levels are normalized to HPRT mRNA levels. (C) $LMNA$ promoter activity is visualized by β -galactosidase staining in $LMNA^{GT/+}$ embryo's (E8.0, E9.0, E11.0 and E18.0). $LMNA^{GT/+}$ maternal placental tissue is indicated by an asterisk. (D) Macroscopic view of WT, $LMNA^{GT/+}$ and $LMNA^{GT/-}$ siblings 12 days post partum (PP12). (E) Body weight over time graph (PP2-PP18). Asterisks indicate a significant difference for $LMNA^{GT/-}$ opposed to $LMNA^{GT/+}$ and WT littermates (N=10, $P < 0.05$). (F) Survival curves for all three genotypes during the first 3 weeks post partum.

($P < 0.05$) over-represented in fatty acid beta oxidation (PP5), striated muscle contraction (PP5), electron transport chain (PP13), adipogenesis (PP13) and hypertrophy (PP13). The most highly deregulated genes included *Mybcp2*, *My6*, *Tnni1* (striated muscle contraction); *Hdac9*, *Gata4*, *Atf3* (hypertrophy); *Dci*, *Slc25a20* (fatty acid beta oxidation); *Cebpd*, *Nrip*, *Dlk* (adipogenesis) and *ATP5g2*, *Cox8a*, *Cox8b* (electron transport chain) (Figure 2C). These results indicate that loss of lamin A/C resulted in myogenic, adipogenic and metabolic defects during early post-natal stages of development.

Cardiac morphology phenotype

In keeping with transcriptome analysis, histological examination revealed that cardiac myocytes were smaller in the LV of *LMNA*^{GT-/-} mice compared to WT controls (PP13; Figure 3A). We examined cardiac hypertrophy by weighing LV as a function of time *post partum*. LV weight (LVW; normalized to tibia length) was decreased by 14% at PP11 and up to 47% at PP15 in *LMNA*^{GT-/-} mice compared to WT age-matched controls (PP11 2.2 ± 0.2 mg/mm *LMNA*^{GT-/-} vs. 2.6 ± 0.2 mg/mm WT $p < 0.05$; PP15 1.9 ± 0.3 mg/mm *LMNA*^{GT-/-} vs. 3.6 ± 0.3 mg/mm WT $p < 0.01$) (Figure 3B). Post-natal hypertrophy was significantly impaired at PP11 in homozygous GT animals: cross-sectional area (CSA) counts were nearly 2-fold reduced ($116 \pm 17 \mu\text{m}^2$ *LMNA*^{GT-/-} vs. $220 \pm 34 \mu\text{m}^2$ WT; Figure 3C $p < 0.01$), and reached a substantially lower maximum of $153 \pm 17 \mu\text{m}^2$ in *LMNA*^{GT-/-} mice vs $380 \pm 8 \mu\text{m}^2$ in WT siblings ($p < 0.001$). Real-time quantitative PCR analysis showed comparable expression levels of the proliferative markers *Ki67* and *PCNA* in the LV of all genotypes in early post-natal development and a general decrease in levels after birth ($p > 0.05$; Figure 3C). The cardiac hypertrophy markers *BNP* and *ANF* showed 10- to 100-fold upregulation in *LMNA*^{GT-/-} mice, at PP11 and PP13 and onwards, respectively ($p < 0.05$; Figure 3D). No cardiac myocyte degenerative areas, fibrosis or obvious abnormalities in interstitial spaces and Z-disc organization were observed (data not shown). These data show that A-type lamins are essential for normal post-natal cardiac hypertrophy.

Figure 2. Transcriptome analysis of the *LMNA*^{GT-/-} mouse. (A) mRNA expression levels of left ventricle cardiac tissue were analyzed by microarrays at PP5 and PP13. Scatter plots indicate logarithmic expression levels of mRNA of *LMNA*^{GT-/-} mice vs. WT littermates at both time points. Twofold up- and down regulation borders are indicated by straight lines within the scatter plots. **(B)** A Venn diagram of over 1.2 fold up- or down-regulated genes in the *LMNA*^{GT-/-} mice compared to WT siblings at PP5 and PP13. The number of genes and direction of change are indicated for all deregulated genes at PP5, PP13 and genes which are deregulated at both time points. **(C)** Heatmaps with mRNA expression levels of the most deregulated genes at PP5 and PP13 within the biological pathways striated muscle contraction, hypertrophy, fatty acid beta oxidation, adipogenesis and electron transport chain. WT expression levels for each gene were set at 1.0 (black color code). Relative differences in expression levels for *LMNA*^{GT-/-} mice are indicated as fold change values and color coded.

Figure 3. Post-natal cardiac hypertrophy in the *LMNA*^{GT-/-} mouse. (A) Haematoxylin and eosin (H&E) staining on left ventricle sections of WT and *LMNA*^{GT-/-} mice (PP13). (B) Bar graph indicating left ventricle weight (LVW) standardized by tibia length over time (PP5-PP18) for all three genotypes. (C) Bar graph with cardiac myocytes cross sectional area over time (PP2-PP18) for *LMNA*^{GT-/-} and WT siblings. (D) mRNA levels of proliferative markers *Ki67* and *PCNA* and hypertrophic markers *ANF* and *BNP*, standardized for GAPDH. Asterisks in figure 3 indicate significant differences for *LMNA*^{GT-/-} vs. both *LMNA*^{GT+/-} and WT values (N=5, P<0.05).

Cardiac function phenotype

To determine whether decreased cardiac hypertrophy results in compromised cardiac function, *LMNA*^{GT} mice were subjected to echocardiography and electrocardiography (ECG). Impaired post-natal hypertrophy was confirmed by lower relative LVW in *LMNA*^{GT-/-} mice (PP17: 2.1±0.3 mg/cm *LMNA*^{GT-/-} vs. 3.7±0.1 mg/cm WT p<0.01; Table 1). Nevertheless, fractional shortening (FS), which measures the fraction of LV diastolic dimension lost in systole, as an indicator for LV contractility,

* p<0.05 LMNA^{GT+/-} vs. both age-matched LMNA^{GT+/-} and WT values; # p<0.05 within the same genotype compared to the start of angiotensin II treatment. Abbreviations: IVSs=Intraventricular Septal Wall Thickness in systole, LVIDs=Left Ventricular Internal Dimension in systole, LVPWs=Left Ventricle Posterior Wall Thickness in systole, IVSd=Intraventricular Septal Wall Thickness in diastole, LVIDd=Left Ventricular Internal Dimension in diastole, LVPWd=Left Ventricle Posterior Wall Thickness in diastole, FS=Fractional Shortening.

was comparable in all 3 genotypes at days PP10, PP13 and PP17 (PP17: 31±7% *LMNA*^{GT^{-/-}}, 32±9% *LMNA*^{GT^{+/-}}, 32±8% WT). No signs of LV dilatation nor thinning of the LV wall were observed as all echocardiographic parameters appeared comparable for all genotypes (Table 1). ECG analysis, which captures electrical activity of the heart over time, did not reveal any differences in P wave duration (reflects atrial depolarization), QRS time (reflects ventricular depolarization), or QT time (prolonged QT time is a risk factor for ventricular tachyarrhythmias and sudden death). ECG analysis did reveal a significantly lower heart rate in *LMNA*^{GT^{-/-}} mice from day PP15 onwards (PP17: 279±34 bpm. *LMNA*^{GT^{-/-}} vs. 420±57 bpm. WT $p<0.05$). Decreasing cardiac workload by lowering blood pressure and decreasing heart rate was reported to be beneficial in dilated cardiomyopathy, which is observed in various *LMNA* mouse models^{13, 20}. We therefore assessed whether treatment with the α - and β -adrenergic antagonist labetalol had beneficial effects in *LMNA*^{GT^{-/-}} mice (Figure S1A). Labetalol increased QRS time in all genotypes ($p<0.05$). In contrast to WT and *LMNA*^{GT^{+/-}} mice, labetalol treatment significantly increased P time (from 23.7±2.6 ms to 29.8±3.2 ms; $P<0.05$) and lowered heart rate (396±51 bpm to 232±20 bpm; $p<0.05$) in *LMNA*^{GT^{-/-}} mice (Figure S1B). However, treatment with labetalol led to earlier post-natal death in *LMNA*^{GT^{-/-}} mice compared to *LMNA*^{GT^{+/-}} and WT siblings (Figure S1C).

To assess whether age-related physiological cardiac hypertrophy is subject to gene dosage effects 60-70 weeks old WT and *LMNA*^{GT^{+/-}} mice were subjected to echocardiography. Although the average FS was slightly decreased in *LMNA*^{GT^{+/-}} mice, this difference was not significant (23±7% *LMNA*^{GT^{+/-}} vs. 30±8% WT $p>0.05$; Table 1). Other cardiac parameters did not differ significantly. Similarly, angiotensin II treatment induced comparable levels of hypertrophy under acute pathological conditions in 16-18 weeks old *LMNA*^{GT^{+/-}} and WT mice, based on relative LVWs (*LMNA*^{GT^{+/-}} from 5.8±0.4 to 7.3±0.6 mg/cm $p<0.05$; WT from 6.1±0.5 to 7.9±0.6 mg/cm $p<0.05$). No signs of cardiac failure were observed as FS, other echocardiographic parameters and relative lung

weight were all comparable ($p > 0.05$; Table 1). Therefore, we conclude that partial loss of lamin A/C only slightly decreased LV weight without impairing the ability to respond structurally or functionally to increased load. Complete loss of lamin A/C impairs post-natal cardiac hypertrophy, lowers the heart rate moderately but does not cause any other direct functional abnormalities.

Skeletal muscle phenotype

Initial gross anatomical examination showed hunched posture and abnormal gait, characterized by splayed hind legs from day PP13 onwards in $LMNA^{GT-/-}$ mice. Histological examination revealed smaller quadriceps skeletal myocytes at day PP15 (Figure 4A). Based on transcriptome analysis and these initial findings we further assessed post-natal skeletal muscle development. Pathological findings were confirmed by quantification of the CSA of skeletal myocytes and the total quadriceps muscle weight (normalized to tibia length). Quadriceps muscle in $LMNA^{GT-/-}$ mice showed hypotrophy at PP15 (relative quadriceps weight 5.0 ± 0.5 mg/mm $LMNA^{GT-/-}$ vs. 7.1 ± 0.6 mg/mm WT $p < 0.05$) whereas they did not at PP9 (3.8 ± 0.95 mg/mm $LMNA^{GT-/-}$ vs. 4.7 ± 0.35 mg/mm WT $p > 0.05$; Figure 4B). Accordingly, myocyte CSA did not differ at PP9 (195 ± 100 μm^2 $LMNA^{GT-/-}$ vs. 259 ± 59 μm^2 WT $p > 0.05$), but was significantly lower at PP15 (270 ± 55 μm^2 $LMNA^{GT-/-}$ vs. 500 ± 50 μm^2 WT $p < 0.01$; Figure 4C). Consistent with these findings, $LMNA^{GT-/-}$ mice displayed reduced muscular strength (lag time dropping from grid: 0.9 ± 0.5 sec $LMNA^{GT-/-}$ vs. 6.7 ± 1.4 sec WT PP15; $p < 0.05$; Figure 4D). Histological analysis did not show any overt signs of fibrosis, as assessed by Sirius Red staining and Z-disc deorganization assessed by TEM (data not shown). These observations suggest that lamin A/C is important for maintaining skeletal muscle mass and strength.

Adipogenic Phenotype

As pathological findings included reduced subcutaneous adipose tissue at PP15 in $LMNA^{GT-/-}$ mice, we further investigated the role of lamin A/C

during early post-natal differentiation and maturation of adipose tissue. Subcutaneous adipose deposits at PP5 were comparable in weight for WT and $LMNA^{GT-/-}$ mice (weight corrected for tibia length: 0.38 ± 0.35 mg/mm $LMNA^{GT-/-}$ vs. 0.40 ± 0.17 mg/mm WT $p > 0.05$; Figure 5A). During early post-natal development both WT and $LMNA^{GT+/-}$ mice increase their subcutaneous fat storage (PP14 1.13 ± 0.17 mg/mm WT $p < 0.05$ compared to PP5), while this storage was severely impaired in $LMNA^{GT-/-}$ mice (PP14 0.62 ± 0.16 mg/mm, $p < 0.05$ compared to age-matched WT). Gonadal fat patches and subscapular brown adipose tissue were present in all genotypes and macroscopically showed no obvious mass reduction.

Figure 4. Post-natal skeletal muscle morphology and functioning in the $LMNA^{GT-/-}$ model. (A) Typical example of a haematoxylin and eosin (H&E) staining on quadriceps skeletal muscle sections of $LMNA^{GT-/-}$ and WT sibling (PP15). **(B)** Total quadriceps muscle weight normalized to tibia length assessed at PP9 and PP15 in $LMNA^{GT-/-}$, $LMNA^{GT+/-}$ and WT mice. **(C)** Quantification of the cross sectional area of quadriceps skeletal muscle myocytes for all 3 genotypes (PP9, PP15). **(D)** Assessment of skeletal muscle strength: time (in seconds) indicates the lag time until a mouse, hanging upside down, releases the grid; Asterisks in Figure 4 indicate significant differences for $LMNA^{GT-/-}$ vs. both $LMNA^{GT+/-}$ and WT values ($P < 0.05$; $n = 4$).

To directly investigate whether lack of subcutaneous adipose tissue could be caused by differentiation defects, E12.0 mouse embryonic fibroblasts (MEFs) were harvested from all 3 genotypes and adipogenic differentiation was induced *ex vivo*. Oil Red O lipid staining was substantially reduced upon complete loss of lamin A/C (0.284 ± 0.033 $LMNA^{GT-/-}$ vs. 0.615 ± 0.159 WT at 16 days post induction, $p < 0.05$; Figure 5B, C). These findings suggest that that loss of lamin A/C results in impaired adipogenic differentiation and decreased post-natal subcutaneous fat deposition.

Figure 5. Adipogenic capacity of the $LMNA^{GT-/-}$ murine model. (A) Quantification of 5 and 14 day old subcutaneous adipose tissue deposits normalized to tibia length (See Material & Methods). **(B)** Representative examples of Oil Red O staining at 16 days of differentiation for all genotypes. **(C)** Quantification of Oil Red O staining at 6, 10, and 16 days post induction. Asterisks in Figure 5 indicate significant differences for $LMNA^{GT-/-}$ vs. both $LMNA^{GT+/-}$ and WT values ($P < 0.05$; $n = 3$).

Metabolic Parameters

As loss of subcutaneous adipose tissue is expected to influence general metabolism, a metabolic fingerprint was taken at PP12 and PP16 by determining the status of carbohydrate, fat and protein metabolism. Glucose metabolism was determined by measuring blood levels of glucose (the major carbohydrate energy source for the glycolytic pathway), liver glycogen levels (energy storage) and serum lactate (a by-product of anaerobic metabolism). Only lactate levels were reduced at PP12 (1.41 ± 0.37 mM $LMNA^{GT-/-}$ vs. 2.01 ± 0.54 mM WT $p < 0.05$). Metabolic complications were observed at PP16 (Table 2) as $LMNA^{GT-/-}$ mice became hypoglycemic (1.88 ± 0.97 mM $LMNA^{GT-/-}$ vs. 5.40 ± 1.54 WT $p < 0.05$) while serum lactate levels remained normal. In further agreement with lowered blood glucose levels, glycogen deposits in the liver were undetectable in $LMNA^{GT-/-}$ mice at PP18 in contrast to WT and $LMNA^{GT+/-}$ mice (Figure S2).

Fat/Triglycerides metabolism was monitored by determining the acylcarnitine profiles (carnitine-coupled free fatty acid (FFA) substrates for β -oxidation) (18), and by measuring serum levels of the ketone body betahydroxybutyrate (by-product of fatty acid catabolism; alternative energy source during hypoglycemia). At PP12 most of these parameters were normal, with the exception of lowered C12 carnitine levels (0.08 ± 0.01 pmol/mg $LMNA^{GT-/-}$ vs. 0.013 ± 0.02 pmol/mg WT $p < 0.05$). Metabolic complications became apparent in $LMNA^{GT-/-}$ mice at PP16 (Table 2), as elevated levels of the ketone body betahydroxybutyrate (1.94 ± 0.18 mM $LMNA^{GT-/-}$ vs. triglycerides into fatty acids and ketone bodies. An elevated ratio of 1.26 ± 0.21 mM WT $p < 0.05$) indicate increased conversion of free carnitine to bound carnitine (0.72 ± 0.17 $LMNA^{GT-/-}$ vs. 0.038 ± 0.05 WT $p < 0.01$), C2 acetyl-carnitine (18.86 ± 1.90 pmol/mg $LMNA^{GT-/-}$ vs. 14.67 ± 1.73 pmol/mg WT $p < 0.05$) and C16 palmitoyl-carnitine (0.86 ± 0.13 pmol/mg $LMNA^{GT-/-}$ vs. 0.57 ± 0.15 pmol/mg WT $p < 0.05$) indicate increased FFA transport across the mitochondrial membrane.

A metabolic profile was determined on blood samples by assessing glucose, lactose, betahydroxybutyrate and various acylcarnitines levels at day PP12 and PP16. Body core temperature, creatinin, urea and creatin kinase levels were assessed at day PP9 and PP15. Asterisks indicate significant differences for LMNA^{GT-/-} vs. both LMNA^{GT+/-} and WT values (P<0.05).

As general markers for protein catabolism, creatin kinase, creatinin and ureum were determined. Blood creatin kinase levels (marker for muscle damage or wasting), were elevated at PP15 (1561 ± 287 U/L $LMNA^{GT-/-}$ vs. 667 ± 310 U/L WT $p < 0.05$), but not at PP9. However, urea and creatinin levels (indicators of protein breakdown and kidney functioning), did not differ significantly (urea: 11.1 ± 1.5 mmol/L $LMNA^{GT-/-}$ vs. 9.1 ± 1.7 mmol/L WT; creatinin: 8.2 ± 1.3 μ mol/L $LMNA^{GT-/-}$ vs. 9.7 ± 1.2 μ mol/L WT; PP15; $p > 0.05$). In addition to these metabolic parameters, core body temperature was lower both at PP9 (29.5 ± 0.9 °C $LMNA^{GT-/-}$ vs. 31.5 ± 2.0 °C WT $p < 0.05$) and PP15 (27.5 ± 0.8 °C $LMNA^{GT-/-}$ vs. 32.5 ± 1.0 °C WT $p < 0.01$).

As the metabolic fingerprint and the expression array analysis (Figure 2B) supported an abnormal metabolic phenotype, morphology and function of mitochondria was assessed. Transmission electron microscopy revealed no differences in mitochondrial morphology (Figure S3A). Mitochondrial DNA copy numbers were comparable in both heart and quadriceps skeletal muscle at PP15 ($p > 0.05$; Figure S3B). Electron transport chain subcomplex activities were determined in LV tissue at PP15 and were shown to be almost fully comparable between WT and $LMNA^{GT-/-}$ mice (Figure S3B). A slight elevation in the amount of mitochondria was observed, however (CS 1712 ± 307 $LMNA^{GT-/-}$ vs. 1508 ± 118 WT $p < 0.05$), and complex II activity was slightly, but significantly lowered (0.114 ± 0.00024 $LMNA^{GT-/-}$ vs. 0.122 ± 0.007 WT $p < 0.01$). These observations show the $LMNA^{GT-/-}$ mice become severely catabolic in the 3rd week *post partum*, without apparent abnormal mitochondrial function.

Discussion

Lamin A/C expression is developmentally regulated and has been specifically linked to early mesenchymal commitment⁴⁻⁶. Little is known, however, about the effect of A-type lamins in embryonic and early post-natal development. We have generated a novel $LMNA^{GT-/-}$ mouse model

and demonstrate that loss of A-type lamins results in defective post-natal differentiation and defective maturation of adipose-, cardiac- and skeletal muscle tissue.

For many essential organs in mice, differentiation and maturation start during embryonic development and continues throughout early post-natal development²¹⁻²³. Immunohistochemical studies revealed a diffuse lamin A/C protein staining in connective tissue and myoblasts at E11.0⁴⁻⁵. Lamin A/C protein levels increase until day E14.0 and lamin A/C protein was only detected in a few more tissues during embryonic development from this age onwards. Lamin A/C was reported to be absent in epithelia of lung, liver, kidney, intestine, heart and brain until well after birth. Using a β -galactosidase reporter gene in our *LMNA*^{GT/-} mouse model we here report *LMNA* promoter activation, coinciding with the onset of tissue differentiation (E11.0) in somites, heart, liver and intestines and widespread *LMNA* expression by the end of *in utero* development (E18.0). In good agreement, promoter activity of the lamin A processing enzyme *Zmpste24* in a GT mouse model partially mirrors the *LMNA* promoter activity described here¹⁶. It is conceivable that previous immunohistochemical studies may have been limited in their sensitivity and specificity toward e.g. potential embryonic *LMNA* splicing variants. The detection of *LMNA* promoter activity from the earliest stages of tissue differentiation onward supports the importance of lamin A/C in tissue differentiation and maturation. Although we cannot formally exclude discordant mRNA and protein synthesis, e.g. as a result of pre-/posttranslational regulation, our findings suggest that lamin A/C is expressed earlier than previously reported.

Despite apparently morphologically normal overall fetal development, the consequences of loss of lamin A/C becomes apparent during early post-natal development. By and large, *post partum* development in the absence of *LMNA* reveals no gross phenotypical abnormalities from PP1 until PP6. The growth of *LMNA*^{GT/-} mice is retarded from PP7 to PP12 compared to WT and *LMNA*^{GT+/-} siblings. We observe a prominent

abnormal post-natal cardiac development in $LMNA^{GT-/-}$ mice: whereas normal LV myocytes undergo post-natal hypertrophy upon cell cycle exit in the first week after birth ^{21, 24}, cardiac hypertrophy is severely impaired in $LMNA^{GT-/-}$ mice. The comparable *post partum* decrease in cardiac proliferative activity (*PCNA*, *Ki67*) between WT and $LMNA^{GT-/-}$ siblings suggests altered hypertrophy is not caused by an inability of myocytes to exit the cell cycle. Instead, elevated expression of the hypertrophic markers *ANF* and *BNP*, suggests that pro-hypertrophic signaling is increased in the absence of productive physiological cardiac hypertrophy. Finally, overall body growth ceases between PP13 and PP18 and BW decreases in $LMNA^{GT-/-}$ mice. During this stage, skeletal muscle display hypotrophy and a prominent catabolic phenotype is manifested, with reduced blood glucose (PP16), absent hepatic glycogen storage (PP18) and increased utilization of alternative energy sources (ketone bodies, FFA and muscle tissue; PP15-16). Although the direct cause of death is currently not clear, it most likely relates to a combination of muscle weakness and metabolic complications. Cardiac function appears not sufficiently impaired to explain premature death at this stage, but we cannot exclude the possibility that the short life-span of these mice prevents further development of cardiac malfunction. Decreased heart rate and core body temperature are typical side effects of a catabolic state. Both parameters decline in human anorexia nervosa patients as does blood pressure ²⁵. Progressive lowering of blood pressure and heart rate further deteriorates the condition during starvation ²⁶. This notion also provides an explanation for the detrimental effects of labetalol in $LMNA^{GT-/-}$ mice, which furthermore demonstrates that in the end-stage increased sympathetic activity prolongs survival to some extent, possible by its effects on overall metabolism. Although it is unclear at this stage whether muscular wasting contributes to the abnormal metabolic state of $LMNA^{GT-/-}$ mice, the impaired adipogenic capacity upon loss of lamin A/C provides a direct etiological connection to the defective energy metabolism.

The $LMNA^{GT/-}$ mouse complements previously established $LMNA$ murine models. Using a conventional gene targeting strategy, Stewart and colleagues created a functional $LMNA$ knock-out mouse ($LMNA^{KO/-}$) which displays growth retardation starting 2-3 weeks *post partum*, followed by skeletal abnormalities, decreased subcutaneous adipose deposits, cardiac dilatation and, ultimately at 6-8 weeks *post partum*, life-threatening impaired cardiac function²⁷⁻²⁹. Considering the onset and progression of these symptoms over time, the overall phenotype of the $LMNA^{KO/-}$ animals is comparatively milder than that of $LMNA^{GT/-}$ mice. A possible explanation for the hypomorphic phenotype in $LMNA^{KO/-}$ mice is the difference in targeting strategy between the models. In the contrast to the $LMNA^{GT/-}$ mouse, where a GT sequence is introduced at the $LMNA$'s second intron, in the $LMNA^{KO/-}$ mouse the $LMNA$ gene is disrupted in exon 8. Northern blot analysis revealed expression of faster migrating $LMNA$ mRNAs, possibly indicative of truncated but potentially functional N-terminal $LMNA$ gene products in $LMNA^{KO/-}$ mice²⁹. In the $LMNA^{GT/-}$ mouse no partial $LMNA$ splicing products were detected at the mRNA level besides the $LMNA$ - β -geo fusion protein. This synthetic gene-product does not induce obvious phenotypic defects as $LMNA^{GT+/-}$ mice were phenotypically indistinguishable from WT mice in all tested assays. Interestingly, the use of genetrap approaches was associated with more dramatic phenotypes compared to conventional gene targeting strategies including the lamin A processing enzyme *Zmpste24* loss-of function mouse models^{16, 30}. Besides the targeting strategy, phenotypes may be affected by genetic background, as identical mutated $LMNA$ gene products give rise to different laminopathies in humans³¹. In comparison to other $LMNA$ mutant mice, lethality in the $LMNA^{GT/-}$ model occurs much earlier, and, notably, in the absence of cardiac functional defects and HGPS related bone abnormalities and hair loss¹³. Cardiac hypertropic defects may not have had sufficient time to progress to heart failure in our model, as other tissue defects dominate during post-natal development.

The combined observations presented here show that the *LMNA*^{GT-/-} mouse model is the most severe lamin A/C mouse model to date and, relevantly, our results show that loss of lamin A/C induces severe and widespread defects in post-natal tissue maturation. This leads to an early post-natal and fully penetrant lethal phenotype, which is conceivably due to combined muscle weakness and metabolic complications, and occurs in the absence of a dilated cardiomyopathy or obvious progeroid phenotype. This novel *LMNA* mouse provides new opportunities to dissect the molecular and cellular mechanisms underlying the role of lamin A/C in early post-natal development.

Figure S1. Cardiac effects of α - and β -adrenergic receptor antagonist treatment in $LMNA^{GT}$ mice. (A) Labetalol inhibits sympathetic activity by antagonizing α - and β -adrenergic receptors, thereby suppressing sympathetic stimulation of heart rate and vasoconstriction. Arrows and T-shaped ends indicate respectively stimulatory and inhibitory actions. **(B)** ECG analysis indicating heart rate, P time, QRS duration and QT time 3 days after the start of subcutaneous labetalol or control injections in all genotypes (See Materials & Methods). Asterisks in this figure indicate significant ($P < 0.05$; $n = 5$) differences between labetalol and control injections within the same genotype. **(C)** Survival curve for $LMNA^{GT/-}$ mice treated from PP10 onward with labetalol or control injections (dashed lines) versus survival curves for labetalol treated $LMNA^{GT/+}$ and WT siblings (straight lines).

Figure S2. Post-natal hepatic glycogen storage in $LMNA^{GT/-}$ mice. Formalin fixed liver sections were Periodic Acid Schiff (PAS) stained to visualize glycogen deposits in a light purple/pink color. $LMNA^{GT/-}$ mice show absence of glycogen deposits at all ages investigated, whereas WT and $LMNA^{GT+/-}$ livers glycogen is detectable at day PP18.

Figure S3. Mitochondrial morphology and functioning in $LMNA^{GT-/-}$ mice. (A) Transmission Electron Microscopy pictures of left ventricle cardiac tissue at day PP15 WT and $LMNA^{GT-/-}$ mice, showing cardiac muscle fiber and Z-disc orientation, and (in close-up) a typical example of a mitochondrion. **(B)** Mitochondrial DNA copy numbers in both quadriceps skeletal and cardiac muscle as determined at PP15 by RT-PCR. Asterisks indicate significant differences for WT and $LMNA^{GT-/-}$ values ($P < 0.05$).

CHAPTER 7

General Discussion

A-type lamins define the nuclear lamina and are key architectural proteins of the cell nucleus involved in various nuclear processes including transcription, DNA replication, DNA repair and cell signaling.¹ Mutations in the *LMNA* gene, encoding for A-type lamins A and C, are associated with 11 different diseases including muscular dystrophies, lipodystrophies, neuropathies and premature aging syndromes.² The phenotypic diversity amongst these diseases, referred to as laminopathies, is hypothesized to be caused by mutation specific changes in lamin A protein- and chromatin interactions. Technological limitations hamper obtaining experimental evidence for a direct interaction of lamin A with chromatin *in vivo*, as well as mapping lamin A protein interactors in a proteome wide fashion. In this thesis novel techniques have been implemented to map lamin A-protein and -chromatin interactions in an unbiased approach, to identify differences in these interactomes for a progeria associated lamin A mutant and to study the biological relevance of *LMNA* mutations in the context of chromatin organization and early postnatal differentiation.

Lamin A protein- and chromatin-interactions

Experimental approaches to identify lamin interactors are severely hampered by the biochemical properties of the nuclear lamina, classically defined as a non-ionic detergent, salt and nuclease insoluble peripheral nuclear structure³ (See Chapter 2). This insoluble character impedes immunoprecipitation (IP) studies, as solubilization by high concentrations of detergents disrupts protein- and chromatin interactions and hampers antigen-epitope binding. Alternative assays that do not depend on solubilization of intact complexes have been used instead, but suffer from specific drawbacks including low recovery, high false positives and non-physiological conditions (Chapter 2). We therefore developed and applied a novel approach to identify lamin A-interacting proteins and chromatin. To map the full spectrum of both types of interactors we tagged lamin A with the biotin resembling OneSTrEP (OST) tag and expressed OST-tagged lamin A (OST-A) at endogenous levels in murine cells (Chapter 3 and 4). OST-A recapitulated endogenous lamin A in terms of prelamin A processing, subnuclear localization, attachment of *Emerin* to the nuclear envelope (NE) and cell proliferative effects (Chapter 3 and 4). A mild cross-linking prior to

OST precipitation enabled full solubilization and isolation of intact lamin A bound protein- and chromatin complexes. Although cross-linking is already commonly applied in chromatin immunoprecipitations (ChIP), it's combination with mass spectrometry (MS) is more recent⁴ and limited due to the enormous complexity of cross-linking reaction mixtures.⁵ To circumvent cross-linking induced artifacts we reverted cross-linking by extensive heating prior to analysis by mass spectrometry (MS; for protein interactions) or microarray technology (for DNA interactions). By OST pulldown we identified a total of 225 lamin A interacting proteins (Chapter 2) and 782 lamin A associated genes (Chapter 3).

We probed for the reliability of MS identified protein interactors by verifying several lamin A interactions with OST pulldown and western blot, including *Ku70* and *Trim28*, two previously unknown interactors that were just above the cut-off of our stringent inclusion criteria. Both proteins interacted weakly but significantly with lamin A (Chapter 3). In addition, a comparative analysis with published data⁶⁻⁷ confirmed that our method reproducibly and reliably co-purified lamin A protein interactors. Half of the identified lamin A interactors were previously identified as NE components⁶⁻⁷ and their gene ontology (GO) signature highly resembles those of the NE proteome, including functions in NE structural organization, chromatin assembly and nuclear cytoplasmic transport via the nuclear pore complex (NPC) (Chapter 3). Observed GO differences with studies that biochemically purify and extract the NE, includes detection of interactions that are predicted to be short-lived (*Zmpste24*, proteasomes), as well as interactors involved in protein folding, processing and vesicle trafficking (Chapter 3). These differences are expected to occur due to preservation of temporal interactions by cross-linking and precipitation of the total lamin A pool by OST pulldown, including endoplasmic reticulum (ER) localized partially unfolded or unprocessed lamin A. In addition, ER localized proteins can as well diffuse to the continuous INM and anchor to the lamina.⁸ OST pulldown technology was furthermore used to confirm yeast two-hybrid (Y2H) (Chapter 2) discovered novel interactions of the lamin A carboxy-terminus (amino acids 562-664) with *Rbbp4*, *Rbbp7* and *HDAC1*, all members of the nucleosome remodeling and deacetylase (NURD) complex (Chapter 5). *Rbbp4* is also a subunit of the CAF-1 complex, which assembles chromatin during DNA replication and DNA damage repair⁹, and together with *Rbbp7*

part of the Polycomb PRC2 complex.¹⁰ The NURD, CAF-1 and PRC2 complex are all involved in establishment of heterochromatin.⁹⁻¹² *Trim28* is associated with the Polycomb PRC1 complex (unpublished data) and involved in similar processes.¹³⁻¹⁴ Together with the observations that the nuclear periphery mostly contains heterochromatin and various *LMNA* mutations are associated with heterochromatin defects and DNA damage¹⁵⁻¹⁶, these findings suggest that A-type lamins are crucial in maintaining higher-order chromatin organization.

In line with this, we identified in total 782 gene promoters that directly interact with lamin A by OST pulldown (Chapter 4). All examined lamin A targets preferentially localize at the nuclear periphery compared to non-targets, are genomically clustered and transcriptionally silenced (Chapter 4). Consistent with this, GO analysis revealed that lamin A-associated genes are typically involved in highly specified biological pathways, including the perception of smell and defensive responses to bacteria. Most likely proteins of both pathways, typically expressed by neurons and neutrophils respectively¹⁷⁻¹⁸, are not functional in fibroblast and cardiac myocytes used in our screen and hence expected to be transcriptionally silent. The presence of over 42 tissue and cell type specific transcription factor binding motifs (TFMs) in lamin A associated gene promoters further supports this notion (Chapter 4). Our findings are in keeping with DamID (Chapter 2) detected lamin B/gene interactions, which revealed sharply defined lamin-associated domains (LADs) across the genome¹⁹, typically gene poor and low expressed regions, yet containing cell-type specific silenced gene clusters as well.²⁰ To determine how crucial A-type lamin chromatin interaction is in peripheral positioning and regulation of gene expression, we monitored spatial positioning and gene expression upon RNAi-mediated knock-down of lamin A/C (Chapter 4). Upon lamin depletion target loci relocalize substantially to the nuclear interior, yet remain more frequently localized at the NE compared to non-targets. These findings were confirmed in a reversed approach, lamin A overexpression in *LMNA* knock-out (KO) MEFs, which showed increased peripheral localization for several lamin targets (Chapter 4). This supports a facilitating role for A-type lamins in recruitment of silenced genes to the nuclear periphery. Interactions with additional chromatin interacting nuclear lamina proteins, like emerin and Lamin B, contribute to this functional nuclear organization.^{19, 21} Unchanged global

expression levels for lamin A targets in a LMNA loss-of-function model, the lamin A gene trap (LMNA^{GT-/-}) mouse (Chapter 6), argues that an escape from the repressive NE environment *per se* is not sufficient for gene activation. Most likely, loss of lamina-association is one of the multiple steps towards gene activation. Consistent with this, the CFTR locus' relocation due to activation and consequent internalization of neighboring genes by itself is insufficient for CFTR activation.²²⁻²³ For the olfactory receptor lamin A targets many additional steps necessary for stochastic activation have been described as well.¹⁸

Progeria related changes in protein- and chromatin-interactions

Hutchinson-Gilford Progeria Syndrome (HGPS) is a premature ageing disease hallmarked by global changes in chromatin, including loss of heterochromatin structure, altered patterns of histone modification, loss of key heterochromatic proteins and increased levels of persistent DNA damage.^{15-16, 24-25} To elucidate the molecular mechanisms leading to Hutchinson-Gilford Progeria Syndrome (HGPS) we compared protein- and chromatin-interactions for lamin A and progerin, an HGPS causing lamin A mutant lacking 50 amino acids near the carboxy-terminus. OST tagged progerin recapitulated HGPS characteristic distortions of the nuclear lamina and global loss of LAP2 and HP1 γ nuclear levels¹⁶ (Chapter 3 and 4).

Of the identified 150 lamin A and 170 progerin interactors in MEFs, 35 proteins either had an increased affinity for lamin A (8 targets) or progerin (26 targets). These preferential interactors included proteins with GTPase activity and were involved in RNA metabolism or nucleocytoplasmic transport, including several NPC members (*Nup98*, *Nup153*, *Tpr*). *Nup153* anchors NPCs to the nuclear lamina²⁶⁻²⁷ and directly interacts with *Tpr*, which is involved in formation of NPC associated heterochromatin exclusion zones.²⁸ A diminished interaction between progerin and *Nup153* could explain a loss of NPC anchoring to the nuclear lamina²⁶, subsequent NPC clustering and defective NPC mediated nuclear import, all associated with HGPS.^{27, 29-30} We also detected an increased interaction of progerin with paired related homeobox1 (*Prx1*), a transcriptional co-activator involved in skeletogenesis and vasculogenesis.³¹⁻³² *Prx1* induces vascular smooth muscle cell proliferation and extracellular matrix (ECM) modeling by direct

upregulation of tenascin C expression.³¹⁻³² Loss of *Prx1* manifests itself in vertebrae and craniofacial skeletal defects, including absence of the mandible's zygomatic arches.³² These phenotypes highly resemble defects observed in progeria related mouse models, which suffer from osteogenesis imperfecta related fractures in vertebrae and mandible's zygomatic arch³³ as well as tenascin C mediated progressive loss of vascular smooth muscle cells and ECM composition changes.³⁴⁻³⁵ Due to the mapping of protein interactions (Chapter 3) many more candidates potentially involved in HGPS aetiology are on the shelf and await confirmation and further investigation. An interesting candidate would be proliferating cellular nuclear antigen (*Pcna*). *Pcna* regulates initiation of genomic DNA replication, which is hypothesized to be disturbed in HGPS by trapping of *Pcna* in intranuclear lamin aggregates, thereby contributing to premature ageing associated DNA damage.^{24, 36} This hypothesis is in line with the increased interaction of *Pcna* with progerin observed by OST pulldown (Chapter 3).

In a second approach to identify a molecular basis for premature aging-associated chromatin defects, we probed for progerin interaction of the Y2H identified and OST pulldown confirmed novel lamin A interactors *Rbbp4* and *Rbbp7* (Chapter 5). For the Y2H assay a carboxy terminal lamin A fragment (amino acids 562-664) was used that includes the 50 amino acids deleted in progerin (amino acids 607-657). Both NURD complex subunits interacted with lamin A but not with progerin, and showed reduced protein levels during normal and premature ageing (Chapter 5). This loss occurred in the same cells that showed HGPS characteristic global chromatin defects, including HP1 loss, loss of H3K9 tri-methylation¹⁵⁻¹⁶, increased transcription of pericentromeric satellite III repeats³⁷ and increased levels of phosphorylated H2AX²⁵, indicative of DNA double strand breaks (Chapter 5). A global loss of NURD components preceded the occurrence of persistent DNA damage. RNAi-mediated knock-down of both *Rbbp4* and *Rbbp7* was sufficient to recapitulate these HGPS chromatin defects. Other subunits of the NURD complex were also downregulated in old individuals and HGPS patients and a knock-down of several of these subunits caused HGPS-associated chromatin defects as well. These findings demonstrate how loss of several NURD components occurs during premature and normal ageing and contributes to structural chromatin defects ultimately leading up to the accumulation of DNA damage. The observed DNA damage might be a

consequence of increased susceptibility of the affected chromatin to damage or, alternatively, might be caused by impaired DNA replication.³⁸

To probe for other mechanisms through which progerin can affect chromatin organization we compared direct chromatin interactions for lamin A and progerin (Chapter 4). By OST-pulldown we identified 3 subclasses of chromatin interactors: those that interact with both lamin A and progerin (common targets) and those interacting with only lamin A or progerin (differential targets). We identified several characteristics that distinguish these groups. Differentially interacting genes were least involved in cell-type specific biological processes and not enriched for any transcription factor binding motif, in contrast to common targets (Chapter 4). Furthermore, lamin A/progerin commonly bound genes colocalized more frequently at the nuclear lamina, and this positioning was significantly less affected by addition of lamin A or progerin in comparison to differential interactors. Finally, genome-wide expression profiles show that, regardless of the presence of progerin, expression levels of common targets are lower than for genes that bind either lamin A or progerin. Unique interactors are still lower expressed compared to random genes though (Chapter 4). Overall this suggests that common targets are kept silent at the nuclear lamina, whereas differential interactors partially escape laminar interactions and are less likely to be influenced by repressive capacities. The observation that, in the absence of progerin, lamin A uniquely associated genes show significantly less expression than progerin uniquely interacting targets, which in this state do not interact with the lamina, further corroborates this notion. Introduction of progerin in LMNA^{KO/-} MEFs increased the peripheral position of several progerin unique targets. Upon the introduction of progerin induced changes in chromatin organization and spatial positioning were insufficient to change expression levels of common or unique targets in wild-type MEFs. Most likely the absence of such effects is due to the presence of endogenous A-type lamins which partially counteract internalization of unique lamin A interactors and repositioning towards the nuclear rim for progerin unique targets. In line with this, spatial repositioning effects in wild-type MEFs were much less pronounced compared to LMNA^{KO/-} MEFs (Chapter 4). A second factor contributing, as mentioned before, is the lack of additional factors needed for gene

activation, which have been demonstrated to change gene interactions for B-type lamins²¹ and induce expression of cell-type specific gene clusters.²⁰

Biological relevance of A-type lamins in postnatal tissue differentiation

The revealed interaction of the nuclear lamina with highly specialized and cell-type specific silenced genes (Chapter 4) and with cell-fate regulating chromatin remodeling proteins (NURD³⁹, *Trim28*⁴⁰; Chapter 3 and 5) suggests a role for A-type lamins in cell differentiation. This notion is further corroborated by the finding that lamin A/C expression is absent during embryonic development until the onset of tissue differentiation and maturation⁴¹⁻⁴² and in stem cells lamin A is only expressed after differentiation induced loss of pluripotency⁴³. Furthermore, several *LMNA* mutations interfere with adipogenic and osteogenic differentiation.⁴⁴⁻⁴⁵ In order to determine the biological relevance for A-type lamins in differentiation we developed and used a novel *LMNA* gene trap (*LMNA*^{GT/-}) mouse model for *LMNA* loss-of-function (Chapter 6) in studying tissue differentiation defects during early postnatal development.

The gene trap enabled us to detect *LMNA* promoter activity during embryonic development by β -galactosidase staining. *LMNA* was strongly stained for near the beginning of embryonic tissue differentiation (E11.0) in somites, heart, liver and intestines (Chapter 6). At the end of intra-uterine development (E18.0) *LMNA* promoter activity was macroscopically visible in all tissues. The detection of *LMNA* promoter activity from the very early beginning of tissue differentiation onward supports the importance of lamin A/C in tissue differentiation and maturation. Our findings are in contrast to previous studies, which are unable to detect lamin A/C protein in many tissues until well after birth by immunohistochemistry (IHC).⁴¹⁻⁴² Although we can't strictly exclude a discrepancy between mRNA production and protein expression (e.g. pre-/posttranslational regulation), the data presented here suggest that reported IHC studies may have been hampered by relative insensitivity of antisera used, or inability to detect potential embryonic *LMNA* splicing variants. In support of our observations, promoter activity of the lamin A processing enzyme *Zmpste24* in a GT mouse model resembles the *LMNA* promoter described in Chapter 6.⁴⁶

Table 1. LMNA mouse models

Mouse Model	Lethality	Onset Diminished growth	Muscle								Bone	Metabolic	Other							
			Heart					Skel. Muscle Dystrophy	Vascular smooth muscle loss	Craniofacial Defects				Loss of bone density	Growth plate dysplasia	Diminished Subc. Fat	Absence subcut. Fat	Hypoglycemic	Hair loss	Kyphosis
			Chamber Dilatation	Impaired Hypertrophy	Fibrosis	Conduction defects	Decreased Fractional short.													
LMNA ^{GT-/-}	Day 16-18	Day 7	N	Y	N	N	N	Y	?	N	N	N	Y	N	Y	N	Y			
LMNA L530P KI*	2½-6 weeks	Day 5-10	N	Y	Y	?	N	Y	?	Y	Y	?	N	Y	?	Y	Y			
Progerin KI **	3-4 weeks	?	?	?	?	?	N	?	?	Y	Y	?	N	Y	?	Y	Y			
LMNA ^{KO-/-}	6-8 weeks	2-3 weeks	Y	Y	Y	Y	Y	Y	?	N	N	?	N	Y	Y	N	Y			
LMNA N195K KI	2½-4 months	4 weeks	Y	N	Y	Y	Y	Y	?	?	?	?	N	N	?	?	?			
Zmpste24 ^{GT-/-}	2-7 months	4-5 weeks	Y	N	Y	?	?	Y	?	Y	Y	Y	N	Y	?	Y	Y			
Zmpste24 ^{KO-/-}	6-7 months	3 weeks	N	N	N	?	?	Y	?	Y	Y	N	Y	N	N	Y	Y			
LMNA H222P KI	4-13 months	?	Y	N	Y	Y	Y	Y	?	?	?	?	N	N	Y	?	?			
Progerin TG	Unaffected	Unaffected	N	N	N	?	?	N	Y	N	N	?	N	N	?	N	N			

Legend: Y= Defect is present, N=Defect is absent, ?=It is not reported whether defect is present, KO=knock-out, KI=knock-in, TG=Transgene, GT=Gene trap; * LMNA transcripts lack either exon 9 or 9-12 due to a splicing anomaly. Lamin C absent, lamin A reduced levels;** Transgenic allele only produces progerin, no lamin A or C

Though no morphological defects were observed during embryonic development, the more pronounced the effect of loss of lamin A/C became manifest during early postnatal development. LMNA^{GT-/-} mice uniformly died within 3 weeks after birth with clear adipose, cardiac and skeletal muscle tissue defects (Chapter 6). Cardiac myocyte hypertrophy was impaired despite increased expression of hypertrophic markers. No cardiac functional defects were observed (Chapter 6). The increased expression of hypertrophy markers, which do not induce but mainly signify cardiac hypertrophy⁴⁷, suggests that pro-hypertrophic signaling pathways may be increased in an attempt to induce the desired physiological hypertrophy. Skeletal muscles were hypotrophic and in addition LMNA^{GT-/-} mice displayed an impaired body growth, decreased subcutaneous adipose tissue and a catabolic blood profile several days before the occurrence of death. Metabolic defects can

in part be explained due to a reduced adipogenic capacity, as adipogenic differentiation was found to be impaired *in vitro* (Chapter 6). This is in line with *LMNA* mutations affecting adipogenic differentiation.⁴⁴⁻⁴⁵ It remains unclear whether observed muscle wasting contributes to the abnormal metabolic state of *LMNA*^{GT/-} mice. Although an exact cause of death could not be pinpointed, death is likely due to a combination of muscle weakness and metabolic complications.

Observed tissue differentiation and maturation defects of the *LMNA*^{GT/-} mouse complement previously established *LMNA* murine models (Table 1). Stewart and colleagues created a functional *LMNA* knock-out (*LMNA*^{KO/-}) mouse⁵⁻⁷ which displays growth retardation starting 2-3 weeks *post partum*, followed in time by skeletal abnormalities, decreased subcutaneous adipose deposits, cardiac dilatation and ultimately at 6-8 weeks *post partum* life-threatening impaired cardiac functioning⁵⁻⁷ (See Table 1). This phenotype is comparatively milder than for the *LMNA*^{GT/-} mice considering onset and progression of symptoms over time (Chapter 6). A potential explanation for this discrepancy could be the place at which the *LMNA* gene was genetically modified. In *LMNA*^{GT/-} mouse a GT sequence is introduced after lamin A's first exon, while the *LMNA* gene is targeted at the 3' end in the *LMNA*^{KO/-} mouse. The latter is more likely to permit expression of shorter but potentially functional partial *LMNA* products from the 5' end of the gene. Northern blot assays indeed showed faster migrating 10-fold lower expressed *LMNA* mRNA products in *LMNA*^{KO/-} mice⁷. No shortened *LMNA* products were detected however at protein level⁷, possibly due to the absence of an AB recognizable epitope. Interestingly, the use of GT sequences has been reported to cause more drastic phenotypes compared to conventional gene targeting strategies in *Zmpste24* loss-of function mouse models as well^{3, 9} (Table 1). Besides the chosen gene targeting strategy, phenotypes might be prone to differences in genetic background, as identical *LMNA* amino acid changes have been reported to give rise to different laminopathies in humans.¹⁴ The phenotype of the *LMNA*^{GT/-} mouse differs from existing dominant negative *LMNA* models, by a much earlier time at which lethality occurs and by the absence of cardiac functional defects and progeria related bone abnormalities and hair loss (Table 1). The absence of ageing related derangements can be explained by the fact that these are especially caused by dominant gain-of-function lamin A mutants,

like progerin¹⁵ and the L530P mutation induced aberrant splicing products², while the LMNA^{GT-/-} is a loss-of-function model system.

Future research directions

Many questions regarding the molecular mechanisms behind HGPS and other laminopathies still remain unanswered. For example, it is unknown which mechanisms are involved in the loss of proteins from the NURD complex and how altered chromatin modifications result in persistent DNA damage. The involvement of a specific pathway in loss of NURD complex members is suggested by the fact that progerin affects protein levels of several subunits of the NURD complex, but not of the other complexes, such as the CAF-1 or PRC2, that also contain *Rbbp4* and *Rbbp7*. Increased DNA damage might simply be a consequence of increased susceptibility due to globally affected chromatin structure, or be caused by specific nuclear processes like DNA replication as elsewhere postulated.¹⁶ An experimental approach to identify common pathways involved in HGPS related loss of NURD components and DNA damage, is to identify and compare protein interactomes for several HGPS related mutations and define common derangements compared to wild-type lamin A. Such an approach assumes that defective lamin-protein interactions are the basis for HGPS aetiology. An even more unbiased way to define primary molecular defects in HGPS aetiology is to detect targets whose knock-down can rescue an HGPS phenotype. Developing a fluorescent HGPS-phenotype read-out enables pursuing this goal by high-throughput genome-wide RNAi screening combined with automated fluorescent microscopy .

In the context of protein- and chromatin-interactions an interesting question to address, is whether the presence of progerin also does affect the interactomes of wild-type lamin A or simply exerts dominant negative effects by interacting itself with different proteins and chromatin regions. In addition, it remains elusive to which regions outside of gene promoters A-type lamins interact. Upgrading OST pulldown studies by novel ChIP sequencing technology and comparing OST-lamin A interactomes in the absence and presence of untagged progerin can provide answers herein. The relevance of changes in chromatin interactions in the context of gene

expression can further be studied in differentiation models that possess relevant sequential factors necessary for gene activation. A long term exciting project would be to compare protein- and chromatin-interactions between various tissues and disease stages by creating a OST-A knock-in mouse, especially relevant as laminopathies are highly tissue-specific and NE proteomes vary drastically amongst tissues.¹⁷

Conclusions

The research in this thesis has started to unravel the role of A-type lamins and the effect of *LMNA* mutations in the context of disruption of protein- or chromatin interactions, chromatin organization and early postnatal tissue differentiation. Combined, our findings demonstrate that A-type lamins are important for chromatin organization by directly interacting with chromatin, thereby facilitating a peripheral localization of highly cell-type specific silenced genes (Chapter 4). We expect these interactions to be part of a transcriptional memory system for differentiation specific gene programs, as has been described for B-type lamins¹⁸⁻¹⁹. Adipogenic, skeletal- and cardiac muscle tissue early postnatal differentiation and maturation defects upon loss of A-type lamins are in line with this (Chapter 6). An HGPS causing *LMNA* mutation specifically modifies chromatin- and protein-interactions (Chapter 3 and 5) and thereby contributes to aging-related disruption of NPC organization (Chapter 3), heterochromatin defects and DNA damage (Chapter 5). Our findings herein provide a relevant basis for ongoing research determining defective pathways that precede and are caused by observed chromatin defects. Furthermore, the molecular toolbox developed within this thesis can be used to systematically map chromatin- and protein interactions for various *LMNA* mutations in order to identify novel disease mechanisms and, in time, develop possible cures for various laminopathies.

The nuclear periphery is marked by the nuclear envelope (NE), which is composed of an outer and inner nuclear membrane (ONM, INM, respectively) interrupted by nuclear pore complexes (NPC). The nuclear lamina lines the NE and consists amongst others of the intermediate filament A-type (Lamin A, C) and B-type lamins (Lamin B1, B2), INM proteins anchoring the lamina to the NE and proteins interacting with chromatin and modifying its structure. Mutations in A type lamins, encoded by the *LMNA* gene, cause several human diseases collectively referred to as laminopathies, which include several types of muscular dystrophies, lipodystrophies, cardiomyopathies, neurological disorders and premature aging syndromes. At the basis for this thesis lies the major enigma how mutations in one gene can cause so much phenotypic diversity (Chapter 1). The working hypothesis of this thesis is that *LMNA* mutations affect specific lamina protein- and chromatin-interactions, thereby giving rise to laminopathy specific defects.

Chapter 2 describes the most commonly used tools to study lamina protein- and chromatin interactions and discusses the advantages and disadvantages inherent to each method. At the beginning of this thesis' research, *in vivo* interactions of A-type lamins with chromatin were hypothesized yet remained to be experimentally proven, and methodologies to identify protein interactions were severely hampered by the salt- and detergent-insoluble properties of the nuclear lamina. These biochemical properties forced researchers to make a trade-off between the degree of solubilization of lamina proteins and the amount of interactions potentially disrupted by used lysis conditions. Alternative assays circumventing this technical problem each have their specific drawbacks. In order to overcome limitations of available methods we developed a novel approach, the OneSTrEP (OST) pulldown, to study protein- and chromatin-interactions in a unbiased proteome- and genome-wide fashion. This technique consists of expressing lamin A tagged by a biotin resembling OST epitope, high affinity precipitation of fully solubilized but intact OST-lamin A complexes, and subsequent analysis of the isolated complexes for protein by mass spectrometry (MS) and for DNA by array technology.

We used this approach to identify proteins that interact with lamin A and its mutant isoform progerin, which causes the premature aging disorder

Hutchinson-Gilford Progeria Syndrome (HGPS) (Chapter 3). We identified 150 lamin A and 170 progerin-interacting proteins, including novel lamina interactors. Lamin A interactors are preferentially involved in NE structural organization, chromatin assembly and nuclear cytoplasmic transport via the NPC. Of the lamin A and progerin interactors 35 proteins preferentially bound to either lamin A or progerin. These differential interactors included several transcription factors, proteins with GTPase activity, and proteins involved RNA metabolism or nucleocytoplasmic transport, including several NPC members. The global identification of novel lamin A and progerin interactors has generated several leads for studies of specific interaction partners of lamin A and its mutants with the goal of uncovering the molecular mechanisms of tissue-specific laminopathies.

Next, we mapped genome-wide chromatin interactions of A-type lamins and identified 595 lamin A- and 552 progerin-associated gene promoters (Chapter 4). We find that lamin A preferentially binds peripherally localized, silent genes. This association facilitates, but does not determine, peripheral localization and loss of the interaction is not sufficient for gene activation. Further analysis identified multiple classes of common or uniquely lamin A- or progerin-associated genes. Basal expression of the unique categories correlates to their relative subnuclear location. Changes in subnuclear position upon introduction of progerin are insufficient to change basal expression levels. These observations demonstrate that lamin A and progerin differently directly affect chromatin-lamina organization and that loss of peripheral localization and lamin association of endogenous gene loci is insufficient for their activation.

In order to identify a molecular basis for premature ageing characteristic defects in chromatin structure and accumulation of persistent DNA damage, we performed a yeast two-hybrid screen to identify differential lamin A/progerin interactors (Chapter 5). The nucleosome remodeling and deacetylase (NURD) complex subunits *Rbbp4* and *Rbbp7* were found to interact with lamin A, but not with progerin, and showed reduced protein levels during normal and premature ageing. Furthermore, the activity of histone deacetylase 1 (HDAC1), another component of the NURD complex, was reduced with aging. Silencing of individual NURD subunits recapitulated aging associated chromatin defects, which preceded the occurrence of

persistent DNA damage. These findings demonstrate that loss of several NURD components occurs during premature and normal ageing and contributes to structural chromatin defects ultimately leading up to the accumulation of DNA damage.

Next, we probed for the biological relevance of A-type lamins in early post-natal tissue differentiation and maturation, relevant as LMNA expression is reversely correlated to the degree of differentiation and several LMNA mutations induce differentiation defects. To this end, we created a novel LMNA gene trap (LMNA^{GT/-}) mouse model which combines loss of LMNA function with LMNA-controlled reporter gene expression (Chapter 6). We demonstrate early activity of the LMNA promoter during the beginning of embryonic tissue differentiation in heart, liver and somites. The loss of lamin A/C results in growth retardation at 2 weeks *post partum*, with impaired postnatal hypertrophy of cardiac myocytes, skeletal muscle hypotrophy, decreased subcutaneous adipose tissue deposits, decreased adipogenic differentiation of mouse embryonic fibroblasts and metabolic derangements. Ultimately these tissue differentiation and maturation defects are lethal before mice are weaned. These results demonstrate that lamin A/C is crucial in the early post-natal period and provides novel insights into the physiological function of A-type lamins in the context of the developing animal.

The significance of the results and their interrelationship are discussed in Chapter 7. The research in this thesis has started to unravel the role of lamin A and the effect of LMNA mutations in the context of disruption of protein- and chromatin interactions, chromatin organization and early postnatal tissue differentiation. These findings provide a solid foundation for ongoing research to determine disease mechanisms and ultimately potential cures for laminopathies.

Samenvatting

De nucleaire periferie wordt begrensd door de nucleaire envelop, die bestaat uit een buitenste en binnenste nucleair membraan, onderbroken door nucleaire porie complexen (NPC). De nucleaire lamina liggen aan de binnenkant van de nucleaire envelop en bestaan onder andere uit de intermediaire filamenten A- (lamine A, C) en B-type lamines (lamine B1, B2), eiwitten van het binnenste nucleaire membraan die de lamina verankeren in de nucleaire envelop, en eiwitten die binden aan chromatine en de chromatine structuur modifieren. Mutaties in A-type lamines, geëncodeerd door het *LMNA* gen, veroorzaken verschillende humane ziektes, tezamen laminopathieën genoemd, waaronder enkele vormen van spierdystrofie, lipodystrofie, cardiomyopathie, neurologische afwijkingen en versnelde verouderings syndromen. Ten grondslag aan deze thesis ligt het centrale vraagstuk hoe mutaties in één gen zo'n grote phenotypische variëteit kunnen veroorzaken (Hoofdstuk 1). De werkhypothese van deze thesis is dat *LMNA* mutaties specifieke eiwit- en chromatine-interacties met de lamina beïnvloeden, en daardoor laminopathie specifieke defecten worden veroorzaakt.

Hoofdstuk 2 beschrijft de meest voorkomende technieken die gebruikt worden om eiwit- en chromatine-interacties met de lamina te bestuderen, en bediscussieert de voor- en nadelen inherent aan elke methode. Aan het begin van het onderzoek uit deze thesis werden *in vivo* interacties van A-type lamines met chromatine gehypothetiseerd, maar moesten nog experimenteel bewezen worden. Methodologieën om eiwit interacties te identificeren waren sterk belemmerd door de zout- en detergentia-onoplosbare eigenschappen van de nucleaire lamina. Deze biochemische karakteristieken dwongen onderzoekers om een balans te vinden tussen de mate waarin eiwitten van de lamina in oplossing worden gebracht en de hoeveelheid interacties die mogelijk onderbroken worden door de gebruikte lysis condities. Alternatieve methodes om deze technische problemen te omzeilen hebben elk specifieke nadelen. Om de gebreken van bestaande methodes te boven te komen, hebben we een nieuwe techniek ontwikkeld, de OneSTrEP (OST) pull-down, om eiwit- en chromatine-interacties op een onbevooroordeelde manier proteoom en genoom-wijd te kunnen bestuderen. Deze techniek bestaat uit het expresseren van lamine A gelabeld met een op biotine lijkende OST epitoom, hoge affiniteits purificatie van volledig opgeloste maar intacte OST-lamine A complexen, en

daarop volgende analyse van geïsoleerde complexen voor eiwitten met massa spectrometry en voor DNA met array technologie.

We hebben deze techniek gebruikt om eiwitten die binden aan lamine A en progerine, een lamine A mutant die de versnelde verouderings ziekte Hutchinson-Gilford Progeria Syndroom (HGPS) veroorzaakt, te identificeren (Hoofdstuk 3). We detecteerden 150 lamine A en 170 progerine-bindende eiwitten, waaronder nieuw interactors van de nucleaire lamina. Lamine A interactors zijn bij voorkeur betrokken in structurele organisatie van de nucleaire envelop, chromatine assemblage en nucleair cytoplasmatisch transport via de NPC. Van de geïdentificeerde lamine A- en progerine-bindende eiwitten, binden 35 bij voorkeur danwel lamine A of progerine. Deze differentiël bindende eiwitten bestaan o.a. uit transcriptie factoren, eiwitten met GTPase activiteit en eiwitten betrokken bij RNA metabolisme of nucleocytoplasmair transport. De identificatie van nieuwe lamine A- en progerine-interactors levert verschillende aanknopingspunten op voor studies naar specifieke interactie partners van wild-type en mutant lamine A, met als doel het ontrafelen van moleculaire mechanismes van weefsel-specifieke laminopathieën.

Vervolgens hebben we genoom-wijd chromatine interacties van A-type lamines gemapt en identificeerden 595 lamine A- en 552 progerine-geassocieerde gen promoters (Hoofdstuk 4). We hebben vastgesteld dat lamine A bij voorkeur perifeer gelocaliseerde, inactieve genen bindt. Deze associatie faciliteert, maar is niet bepalend voor perifere localisatie en verlies van de binding is onvoldoende voor transcriptionele activatie van genen. Verdere analyse leidde tot een onderscheid in gemeenschappelijke en unieke lamine A- of progerine-bindende genen. Basale expressie van de unieke categorieën correleert met hun relatieve subnucleaire localisatie. Deze observaties demonstreren dat lamine A en progerine op directe en verschillende wijze chromatine-lamina organisatie beïnvloeden en dat verlies van perifere localisatie en lamine-associatie van endogene gen loci onvoldoende is voor transcriptionele activatie.

Om de moleculaire basis voor premature verouderingsziekte karakteristieke defecten in chromatine structuur en accumulatie van persistente DNA schade te identificeren, hebben we een yeast two-hybrid

screening uitgevoerd om differentiële lamine A/progerine interactors te identificeren (Hoofdstuk 5). *Rbbp4* en *Rbbp7*, onderdelen van het chromatine nucleosome remodelerings en deacetylase (NURD) complex, binden lamine A, maar niet progerine, en vertonen verlaagde eiwit niveaus tijdens normale en premature veroudering. Bovendien is de activiteit van histon deacetylase 1 (HDAC1), een andere component van het NURD complex, verminderd met veroudering. Inactivatie van verschillende NURD complex eiwitten recapituleerde verouderings geassocieerde chromatine defecten, die voorafgingen aan het ontstaan van persistente DNA schade. Deze bevindingen laten zien dat verlies van diverse NURD complex componenten plaatsvindt tijdens premature en normale veroudering en bijdraagt aan structurele chromatine defecten, uiteindelijk leidend tot de accumulatie van DNA schade.

Tot slot hebben we de biologische relevantie van A-type lamines in vroege postnatale weefsel differentiatie en maturatie onderzocht, relevant omdat *LMNA* expressie omgekeer evenredig is met de mate van differentiatie en verschillende *LMNA* mutaties differentiatie defecten induceren. Met dat doel voor ogen hebben we een nieuw 'LMNA gene trap' (*LMNA*^{GT-/-}) muismodel gecreëerd, dat het verlies van *LMNA* functie combineert met een *LMNA*-gestuurde reporter gen expressie (Hoofdstuk 6). We tonen vroege activiteit van de *LMNA* promotor tijdens het begin van embryonale differentiatie in hart, lever en somieten. Het verlies van lamine A/C resulteert in groei retardatie 2 weken postnataal, met verzwakte postnatale hypertrophy van cardiale myocyten, skeletspier hypotrofie, verminderde subcutane voorraden van adipos weefsel, verminderde adipogene differentiatie van muis embryonale fibroblasten en metabole afwijkingen. Het eindresultaat van deze weefsel differentiatie en maturatie defecten is letaliteit, nog voordat muizen gespeend zijn. Deze resultaten bewijzen dat lamine A/C cruciaal is in de vroege postnatale ontwikkeling en leveren nieuwe inzichten in de fysiologische functie van A-type lamines in de context van het ontwikkelende dier.

De significantie van de resultaten en hun onderlinge relatie worden bediscussieerd in Hoofdstuk 7. Het onderzoek in deze thesis is begonnen met het ontrafelen van de rol van lamine A en de effecten van *LMNA* mutaties in de context van het verbreken van eiwit- en chromatine-

interacties, chromatine organisatie en vroege postnatale weefsel differentiatie. Deze bevindingen leveren een solide fundament voor voortgaand onderzoek ter bepaling van ziekte mechanismes en, als ultiem doel, mogelijke genezing van laminopathieën.

During the presentation of my university diploma my then supervisor and current co-promoter, Willem, speeched about how he had to discover for every new student which buttons to push in order to make them improve. He concluded that most times when he was about to push one of my buttons, I already had beaten him to it. Although one might conclude from this that I prefer to be in control of things, which I won't deny, the far more important interpretation, in my belief, is that I am fortunate to be surrounded by colleagues, friends and family who set many good examples for me to follow. It is my pleasure to put my appreciation for all of them here in words.

Dr. Voncken, Willem: You use your high analytical capacity and enthusiasm not only for scientific experiments but also to further motivate people around you. This demonstrates that you do not only have a passion for science but also for the people around you. You are a man of principles and live up to your promises, which was nicely demonstrated at my PhD job interview, where I answered the only two asked questions in the negative: "Do you live by yourself?"; "Would you like to spent a long time abroad to do research?". You promised Yigal to change my point of view on these matters and, somehow, did. Thank you for that!

Dr. Misteli, Tom: You set an example for me in the way you manage a laboratory and approach science. For both, with the greatest of ease and engagement, you have the ability to eliminate the unnecessary so that the necessary may speak. Even though I am only beginning to understand how to do that, I'm already enthusiastic about finding out much more about it, and am looking forward to working together the coming years. This will also provide me with the oportunity to convince you that age does not matter when attending a Tina Turner concert!

Prof. Dr. Pinto, Yigal: During our weekly meetings you complemented Willem's enthusiasm for basic science, with your emphasis on the clinical importance of research. Even though by times it was difficult for me to steer a middle course between the both of you, I've learned a lot from it. Becoming a self-dependent scientist most of all requires being able to make your own mistakes and learn from them. Your balance between taking action and 'laissez-faire' allowed me to do that.

Prof. Dr. Crijns, Harry: Even though our encounters over the past years were brief, you always exuded genuine interest in what I was doing. I'm indebted to you for the financial support of my change-over to the NIH. Furthermore I am grateful to you, Prof. Dr. Steijlen and Prof. Dr. Post for taking place in the thesis assessment committee.

My paranymphs. Geert, soon to become Dr. Tweezerman, side-by-side we infiltrated the Cardio lab with basic lamin research, and it is with great delight I look back at that period. Fortunately, you were not intimidated enough by my attempt to make you do a small dance on your university graduation, and soon after became a PhD-colleague and good friend. I admire your optimism and learned a lot from that positive perspective. Your Brabantian humor is widely appreciated and inimitable. I'll strive to introduce its concept within the US borders. A quick reminder to refresh your MMP-oriented brain: everything is about lamins (until I start working on another topic)! The best of luck with your upcoming PhD defense. Melissa, we met during our study and after that always remained each others proximity. Not only did we learn from each other by sharing joys and sorrows, but also from our linguistic differences. It made me superior to Wikipedia in knowledge about the meaning of frou-frou! I am thankful for our friendship, your support as a paranymph during my thesis defense, and hope you'll find your niche in Milan and further career.

Fellow Cardio-ers: Gonda, you took on a lot of work for my PhD studies, especially regarding the LMNA genetrapp mouse and the ever memorable million dollar mouse. Thereby your contribution was crucial for the realization of this thesis, and I am very thankful to you for that and all the nice moments we had while working on these projects. Chapter 6 is yours! Joost, your social attitude was crucial for the Cardio atmosphere. Blanche's and Mark's PhD movies capture that spirit brilliantly. Going together to the Dutch-German Joint Cardiology meetings, the Keystone Symposium with a detour through Denver would not have been as much fun without you. Good luck with your thesis defense! Rudy, Mr. Duitsers, your attempts to put my world upside-down, figuratively sometimes literally, were effective and are greatly appreciated. One question remains open: Who finished first in Nice? Oh well ...we both have our answer to that question. The best of

luck with your new job. Stephane, even though the focus of my projects was on the cell nucleus, you broadened that narrow perspective with enthusiasm by getting me acquainted with the world of matricellular proteins. Thank you for that! Rick, your timing of saying “Out of sight, out of mind” is unrivaled. With that witticism you make colleagues quickly feel comfortable at the lab and open up socially. I am thankful for that and your support in giving guidance to students. Wouter, your experience as a technician is rapidly growing, and makes you an important factor within the lab. Your humor can be as dry as Geert’s, and personally I still can’t stop smiling when thinking back at your ‘Darth Vader’ joke. Blanche, your talent especially shows in the critical questions you ask during meetings, your ability to go around with many different personalities, networking qualities, and the skill to carefully build up a scientific career next to a family. You thereby set an example for me. M.A.R.K., no one can carry out Brabantian pride and joviality as much as you. You earned me my nickname, introduced the concept of intense clown, and took the preliminary work on you for introducing a new hazard label on fixative bottles “Dangerous in combination with extreme Italian shoes”. It is now waiting for a safety sign to be put on you: “Contagious humor”. Thank you for your help with the animal work and good luck with your new job! Arie, you introduced me and many colleagues into the world of micro-arrays, which soon gave you the honorable nickname of “micro-Arie”. Your knowledge was vital for this thesis, especially Chapter 6. Esther, you have vision as you realized well before I did, that I should go abroad to do science. It is re-assuring having seen you walk the same path and the other way around as well successfully. My door is open for more predictions! Viola, you recently changed your work- and life-style completely by making a change-over to South America. I admire the noble intentions behind that choice. Jop, my predecessor in the lamin research. Is performing large-scale experiments a necessity in lamin research or is it simply an ingrained habit of the both of us? I wish you all the best in your further career. Anke, Inge and Wino: It is good to see/hear how you all are in your element at the AMC. I wish you all the best. Suzanne, Veronica, Mirjam and Kim: Thanks for all your support! The department of Cardiology’s secretaries: Miriam, Bianca, and especially Barbara, thank you very much for making everything run smoothly from an organizational point of view. Barbara, I realize that lately I’ve come short on delivering you new stories to read in the train, hopefully I made it up to you with this thesis!

Not to be overlooked are the many Cardio-interns who each have contributed their fair share to this thesis over the past years. Lieke, Thijs, Rayna and Cynthia: With the best of intentions I've asked a lot of dedication from you, and I am very thankful to have had the opportunity to learn from all of you about the ins and outs of guiding students. Frank, you are spreading out the Cardio spirit across university. Good luck with that! Kevin, the English dictionary does not contain the word 'Sjeng'. They should introduce it with a picture of you next to it! A special word of thanks goes to Chantal. Your fanaticism in learning, discovering and working amazed me. With that attitude I'm positive that you will not only do great in science, but also in many other things you wish to accomplish in life. It is my absolute pleasure to reward your hard work with two co-authorships.

Just as there is no true South Limburg without the idyllic Munstergeleen there is no heart-related research without Molecular Genetics. When I started working at the Cardiology department, I often found myself walking up the stairs to the fifth floor subconsciously. Is that epigenetic imprinting? It is with much pleasure I look back at my internship at Molgen and the close association afterwards. Hanneke, you thought me the basics of the molecular biology; not only techniques, but also your mantra "All shall be well", which is a helpful motivation when experiments fail. I'm looking forward to giving you a tour through Washington, and you expanding my extraordinary limited knowledge about Baltimore! Frank, your optimism only has one setting, maximal. Even when having to withstand all my whistling you had a smile on your face; impressive! Peggy, you have extended the proportions of your experiments beyond science, considering your latest project: The Prickaerts Palace. Even though we have never directly worked in the same lab, it instantly felt like we did when we met, thanks to the pleasant chats. I enjoy the get-togethers with Hanneke, Frank and you, and hope they will continue! Vivian, a model of diligence. Not often do I see someone who works as accurate and organized as you do. I've learned a lot from your example and am thankful for your help on the animal work. Regarding the LMNA genetrapped mice I also want to thank Marjon, who contributed her expertise to help solving unanswered questions. Iris and Céline, thank you for your contribution to the nice atmosphere during my Molgen internship. Claudia, we got thrown in at the

deep end together. You are always friendly and willing to help out, thank you for that.

The warm welcome I received when coming to the NIH in Bethesda, was not only due to the subtropical climate, but especially due to the many great colleagues and friends. The pleasant atmosphere you all helped creating was crucial in making my experience abroad to a success. Not only did it make me learn a lot inside the lab, it also created many valuable experiences outside of the lab, allowing me to grow as a person. I am looking forward seeing you all again and continue working with you for the next years! In random order: Karen, you are a caring, ever-social and thereby central factor within the lab. Furthermore a guard (or is it occupier?) of my lab bench and worthy sparring partner in sarcasm. The latter I only show when feeling really comfortable around someone, so consider the blank pages within this thesis and other sarcasm as a great compliment for you in disguise! Christine, that same disguise applies on the many German-related jokes which are very hard for me to hold in around you. You are a hard-working, bright and cheerful bench mate, who furthermore has the virtue of not gossiping but always pointing out the positive aspects of people around you. I admire that. Nico, even though our characters are fairly opposite, we not only respect those differences, it even served as a breeding ground for many joyful adventures experienced together. How can I forget the evening we cooked risotto with almost forgetting the rice, the after midnight goulash, the visit to Baltimore, baseball lessons with a broomstick, pursuing a police/robber-chase in NYC, your well meant step-by-step guidance later that night at the crashed birthday party and our endless discussions on where to cross the road and how to walk back to Melvern Drive. You always took me in tow on your pursuit of liveliness throughout D.C. and I am very thankful to you for making me grow as a person by that. You only created one fear response in me, which becomes evident when I hear this sentence: "Don't worry!". We should work on that when I visit you in Buenos Aires. Alex, you have never-ending optimism. As only to be expected from a true Frenchman you came up with a very original way to transport wine glasses. I'll never forget your farewell drinks at the Harp & Fiddle. Thank you for getting me acquainted with animal work at the NIH, and I wish you the best of luck with further setting up your own lab in Lyon. Gianluca, an Italian gentleman of wide

reading and in addition a modest person. Those are great qualities! You provided me with the opportunity to work together on a revision experiment of your research project, by far the most appealing chapter of this thesis. Thank you for that! Nisha, always smiling and a very social person. You once told me I was absorbing the cooking-skills going on in your kitchen as a sponge. I hope to be able to do that sometime again in the near future, since the Indian cuisine has so many mysteries to me. Vassilis, your semi-grumpy remarks are funny, Malaka! You have the true Greek spirit of knowing what great dishes Hellas harbors, and together we also found out how to prepare some of them, with use of every single piece of kitchen equipment and some furniture (I remember eggplant being put in vases). Your big-heartedness nicely showed when one of those evenings you looked after me by telling me to leave the cooking to you and go talk to Uli, also seeing to it that I did. I look back at those 'Greek' evenings with much joy and hope we can experience some more. Reini, the artistic free-spirited Spanish influence of the lab. Whenever I think I have been to most of the interesting places in Bethesda and D.C., it is only that I have to hear you talking about the city and realize there are so many more interesting places I still have to go discover within the city. You published an excellent scientific paper recently, and I am sure there are more to follow! Beck, you always seem to introduce me with concepts I did not know before; a random selection: block parties, your own-mixed herbal drink, Tom Yum soup, using rosewater in cakes, a werewolves card-game, old P.T.T. jackets in the U.S., 4th of July celebration with fireworks. You do that in an open/hospitable way, which I like! Steve, you are not only making things run smoothly at the lab, but also update me during tissue culture on American musical history, which I still have to learn a lot about. I like the twinkle in your eyes, when you start talking about BBQ'ing with a spirit that almost makes it feel like a form of art! That is a true Chef's way of talking about cooking, and it makes me enthusiastic (and hungry) every time. Travis, you interpret 'translational science' in your own way, by experimenting with yeast to bake bread. Despite your hard work you remain mellow, which makes you a very approachable person. I hope all the yeast-work will result in nice data for you! Sarah, always polite; the continuous force on the 'progeria drug targets screening'-project. It is nice to have you as a colleague and I'm keeping my fingers crossed for an effective compound to roll out of the screening. Ty, can do the magic tricks with computers, to make happen what others

suspect is possible, but have no idea about how to effectuate it. Such knowledge is not only impressive, it is vital in making large scientific adventures to a success. Saying Paola, immediately makes the word talent come to my mind. Your fanaticism in discovering, connecting untied ends and doing experiments sets a standard for the lab to strive for. I admire that greatly, and am looking forward to working with your support on the RNAi screening project. Patricia, our paths only crossed shortly at the end of my stay, I wish you all the best. Simon, an LRBGE/CBGE hybrid, superior to me in organization drive. Although I know you don't agree with me on the latter, I'll stick to the argument that sorting pens by color, thickness of the tip and many other unknown criteria, beats sorting bottles with chemical solutions into a few labeled categories. You are always up for a good exchange of sarcastic remarks, and unique were the men's nights, formerly known as date-night's. I wanted to say unforgettable but changed that to unique, because there seem to be some gaps or fuzzy moments in my memory. What I do remember are the new-and-improved flambéed chicken oven-dish, the watermelon to go with that, jello dessert, special ice-tea and an exhaustive lord-of-the-rings marathon. We had quite a good bad influence on each other, thank you for that! Good luck with your (carefully planned) career! And then one men's night there was not only Rambo but also lady Gaga. Pilar, you are always up for liveliness accompanied by a catchy laugh. A mentor in American slang, guide from New Jersey's White Castle, Applebee's to excellent Filipino food, and colleague who has exchanged the U.S. for Europe. I wish you all the best in your PhD! Keren, always in a good mood, very friendly and with an open personality. You generated strange habits in me, not only was I intrigued by how your lunch looked like, since you always took the effort to cook your own food and frequently let me try a bit; I also found myself automatically checking whether you were in the Opera room when passing by, because I liked stopping by for a chitchat. I'll miss that. I wish you all the best!

Next, there are many people outside of the departments mentioned above, who I would like to acknowledge. To start with the Toxicology department, the place where I got acquainted with scientific work during my studies. Agnes, I like to thank you for your moral support throughout the years, which you always give with trust in me and without judging me. I enjoy how all those years after my internship we still remain in good contact and

witness important steps in each other's life's. I'll do my best to keep feeding your longing for the U.S. with new stories! I wish you and Tim a happy, harmonious and joyful togetherness for life. Guido, you once said that self-critique is the most difficult thing to give. Although it didn't make it to my final eleven propositions, that statement always appealed very much to me. Thank you for your guidance during my period at Toxicology. From the department of BigCat: Michiel, you have performed a great deal of work on the ChIP project, and always proved a very helpful, enthusiastic and a reliable colleague in analyzing the data that were generated. It is a pleasure to reward that work in a co-authorship, and I hope we can further collaborate on future projects! Next, continuing to Population Genetics, I would like to thank An and Bianca, as well as Kees from the Erasmus Medical Center, for their help on the mitochondrial characterization of the LMNA genetrapp mouse. Since the phenotype of that mice is mysterious the project soon became an inter-departmental one, and I would also like to take this opportunity to thank Hans for the electron microscopy analysis, and Ben, Jacques, Peter, Agnieszka, Helma, Nicole for their help and guidance in the animal work. A special word of thanks also for Paulien, Richard and Hub, from the central animal facility, who always were willing and helpful to create good logistics for these experiments. From the AMC, Ronald and Sander: you received me in an open and spontaneous way when I asked to collaborate on the LMNA genetrapp mouse. Metabolomics is a fully unknown territory for me and your help in analyzing the metabolic phenotype was crucial for Chapter 6. Jeroen, our collaboration on the mass spectrometry analysis of lamin protein-interactions is the foundation of Chapter 3. I appreciate your help on this, and hope to extend together on this project in the future. Lastly, Andrea, I appreciate how we always could exchange our thoughts, frustrations and hopes on the ChIP experiments. Even though the places where we got to meet each other are a bit out of the ordinary (the MolGen corridor, a pub in Washington, a wedding, a housewarming party), I always enjoy whenever we bumped into each other and I experience your and Sofia's warm- and open-mindedness.

Mijn laatste stelling geeft aan dat het belangrijk is om afstand te kunnen nemen van de wetenschap, en de zwemclub staat daarbij al jarenlang voorop. Waar in de wetenschap geleerden gedreven leren, is er de wetenschap dat Watervrienden-geleerden leren drijven. Dat brengt altijd

heel veel plezier met zich mee, zeker als dat drijven wordt uitgebreid tot zwemmen, even bijkomen van de geleverde inspanning, kletsen aan het einde van de baan, aan de kant, de douches, het kleedlokaal, het sporterscafé en op BBQ's. Graag wil ik dan ook Roel, Theo, Michel, Dion, Ansel, John, Kim, Carla, Claudy, Bianca, Linda, Emma en Francoise van Baan 4/5 en andere Watervrienden bedanken voor deze gezelligheid. Dat er nog veel mooie 'strijd' om, en vooral uitreikingen van (troost)prijzen mogen volgen! Roel, je hebt altijd het hart op de tong, hetgeen ik waardeer, net als de avonden waarop wij over het bovenstaande eindeloos na kunnen kletsen. Veel geluk voor jou en Samira!

Dennis, stelling tien heeft alles te maken met zelfreflectie en dit durven te delen met anderen. Jij kunt dat, hetgeen onder andere blijkt uit het dankwoord van je scriptie. Dat brengt me tot stelling negen: je pretendeert niet, maar bent iemand: een goed luisteraar, bij tijd en wijle filosoof, en bovenal een zeer goede vriend! Het blijft alleen eeuwig zonde dat je nu juist uit Stein komt. Roy, Jaap, Jan, Robbert en Laurens, ondanks dat we allemaal druk bezig zijn met onze levens op te bouwen door het hele (buiten)land, is er toch ook altijd tijd om weer terug bij elkaar te komen, en al onze belevenissen te delen met elkaar. Dat voelt vertrouwd en doet ook veel deugd. Dank jullie voor deze vriendschap!

Ulrike, Miss Punt, enjoying the simple things simply together is what I cherish most. I am greatly indebted to you for making me understand that sometimes not trying to understand, but to feel, feels ... beautiful. Remember this one-liner: in whatever two places we will be, we will come into line.

Pieter, dat het mogelijk is moleculair biomedisch onderzoek te doen zonder p53 direct erbij te betrekken blijkt uit dit proefschrift. Biomedisch onderzoek doen zonder jouw betrokkenheid is echter lastiger. Al van jongs af aan hebben we een goede *band* en sta je altijd klaar om bij te springen daar waar *hulp* nodig is (P.S.: in het cursief de Engelstalige essentie van je huidig beroep ;)). Dit boekje is daarom ook een beetje van jou! Pap en mam, hoe ouder ik word hoe meer ik begin te begrijpen dat jong geleerd, oud gedaan is. Als ik probeer de essentie van een goede opvoeding te verwoorden, dan is dat het aanleren van een zelf-lerend vermogen. Dat

vermogen maakt dat je niet hoeft te lijken, maar bepaalt wie je bent en daar zelfverzekerd in bent (stelling 9 en 10). Zelf-lerend vermogen is niets anders dan het voor jezelf kunnen indrukken van de juiste knoppen, en daarmee staat het grootste compliment voor de opvoeding die jullie mij hebben gegeven reeds vermeld in de eerste alinea van dit dankwoord. Mijn dank is groot voor jullie niet aflatende steun! Naast dat jong geleerd, oud gedaan is, geldt voor mijn opvoeding ook dat jong gedaan, oud geleerd is: Jullie hebben mij ooit als kind wijsgemaakt dat bij drie littekens op mijn hoofd ik Professor zou worden. Hierbij in ieder geval een stapje in die richting!

Curriculum Vitae

Nard Kubben was born December 18th, 1981 in Geleen. He attended the Graaf Huyn College in Geleen, where he graduated in 2000. The same year, he started to study Health Sciences at Maastricht University. In his fourth year, he performed an internship at the department of Molecular Genetics on the effects of 'Mitogen-activated protein kinase'-induced phosphorylation on Polycomb Group localization, which he was nationally awarded for with the Unilever Research Price in 2005. After graduation in Biological Health Sciences in 2004, he started his PhD at the department of Cardiology at Maastricht University with a focus on the identification of nuclear lamina protein- and chromatin-interactions and their respective roles in laminopathies. In 2007 he won the poster prize at the 5th Dutch German joint meeting of molecular cardiology groups. In the last year of his PhD he continued his work at the National Institutes of Health (NIH) in Bethesda (USA) and was rewarded with a fellows award for research excellence in 2009. He will continue his work on laminopathy disease mechanisms by starting a post-doctoral training at the NIH.

ER	Endoplasmic reticulum
FC	Fold change
FFA	Free fatty acids
FPLD	Dunnigan familial partial lipodystrophy
FS	Fractional shortening
GAPDH	Glyceraldehyde 3-phosphate dehydrogenase
GO	Gene ontology
GPC3	Glypican
GT	Gene trap
H&E	Hematoxylin and eosin
HDAC1	Histone deacetylase 1
HE	Heterozygous
HGPS	Hutchinson-Gilford Progeria syndrome
HPRT	Hypoxanthine-guanine phosphoribosyl transferase
IBMX	3-isobutyl-1-methylxantine

IFN γ	Interferon gamma
IHC	Immunohistochemistry
INM	Inner nuclear membrane
IP	Immunoprecipitation
IVSd	Intraventricular septal wall thickness in diastole
IVSs	Intraventricular septal wall thickness in systole
KI	Knock-in
KO	Knock-out
LAD	Lamin-associated domain
LMNA ^{-/-}	Homozygous LMNA knock-out
LMNA ^{+/+}	LMNA wild-type
LMNA ^{GT-/-}	Homozygous LMNA genetrap
LMNA ^{GT+/-}	Heterozygous LMNA genetrap
LMNA ^{KO-/-}	Homozygous LMNA knock-out
LSB	Laemmli sample buffer
LV	Left ventricle
LVIDd	Left ventricular internal dimension in diastole
LVIDs	Left ventricular Internal dimension in systole
LVPWd	Left ventricle posterior wall thickness in diastole
LVPWs	Left ventricle posterior wall thickness in systole
LVW	Left ventricle weight
MAD	Mandibuloacral dysplasia
MEF	Mouse embryonic fibroblast
MS	Mass spectrometry
NE	Nuclear envelope
NPC	Nuclear pore complex
NURD	Nucleosome remodeling and deacetylase
NUSAP1	Nucleolar and spindle associated protein 1
OCT-1	Octamer transcription factor 1
OLFR	Olfactory receptor
ONM	Outer nuclear membrane
OST	OneSTrEP
OST-A	OneSTrEP tagged lamin A
OST-C	OneSTrEP tagged lamin C
OST-P	OneSTrEP tagged progerin
PAS	Periodic acid shiff

Pcna	Proliferating cellular nuclear antigen
PCP	Protein correlation profiling
PHD	Plant homeo domain
PP	Post partum
Prx1	Paired related (mesoderm) homeobox 1
RP58	Repressor protein with a predicted molecular mass of 58 kDa
SDS	Sodium dodecyl sulfate
SR	Picro Sirius Red
Srebp1	Adipocyte differentiation factor sterol element binding protein 1
SRF	Serum responsive factor
TALE	Three-amino acid-loop extension
TEM	Transmission electron microscopy
TF	Transcription factor
TFM	Transcription factor binding motif
Tpr	Translocated promoter region
VMNR	Vomeronasal receptor
VSMC	Vascular smooth muscle cell
WT	Wild-type
Y2H	Yeast two-hybrid

Chapter 3; Figure 1

Human Dermal Fibroblast

Chapter 3; Figure S2

Chapter 4; Figure S1

Chapter 6; Figure S2

Let us try to teach generosity and altruism, because we are born selfish.

- Richard Dawkins -
