## ABSTRACT

**Context.** The most primitive metal-poor stars are important for studying the conditions of the early galaxy and are also relevant to big bang nucleosynthesis.

**Aims.** Our objective is to find the brightest ( $V < 14$ ) most metal-poor stars.

**Methods.** Candidates were selected using a new method, which is based on the mismatch between spectral types derived from colors and observed spectral types. They were observed first at low resolution with EFOSC2 at the NTT to obtain an initial set of stellar parameters. The most promising candidate, 2MASS J18082002–5104378 ( $V = 11.9$ ), was observed at high resolution ( $R = 50\,000$ ) with UVES at the VLT, and a standard abundance analysis was performed.

**Results.** We found that 2MASS J18082002–5104378 is an ultra metal-poor star with stellar parameters  $T_{\text{eff}} = 5440$  K,  $\log g = 3.0$  dex,  $v_t = 1.5$  km s<sup>-1</sup>,  $[\text{Fe}/\text{H}] = -4.1$  dex. The star has  $[\text{C}/\text{Fe}] < +0.9$  in a 1D analysis, or  $[\text{C}/\text{Fe}] \lesssim +0.5$  if 3D effects are considered; its abundance pattern is typical of normal (non-CEMP) ultra metal-poor stars. Interestingly, the star has a binary companion.

**Conclusions.** 2MASS J1808–5104 is the brightest ( $V = 11.9$ ) metal-poor star of its category, and it could be studied further with even higher S/N spectroscopy to determine additional chemical abundances, thus providing important constraints to the early chemical evolution of our Galaxy.

**Key words.** stars: abundances – stars: Population II – stars: individual (2MASS J18082002–5104378)

## 1. Introduction

The quest for the most metal-poor stars is one of the most active fields in astronomy. Efforts to discover metal-deficient stars have been in place for several decades. Previous surveys have found a number of them, which are important for studying the early stages of our Galaxy (e.g., Bond 1980; Bessell & Norris 1984; Beers et al. 1985, 1992; Cohen et al. 2004; Frebel et al. 2005; Fulbright et al. 2010; Placco et al. 2011; Caffau et al. 2011; Aoki et al. 2013; Yong et al. 2013; Keller et al. 2014; Frebel et al. 2015).

The ultra metal-poor stars ( $[\text{Fe}/\text{H}] < -4$ , UMP) are key to studying the products ejected by the first massive stars (Population III) that polluted the early Galaxy (e.g., Frebel et al. 2015). At such low metallicities, the spectral lines are weak, therefore it is highly desirable to find relatively bright metal-poor stars, so that detailed abundance analyses can be performed.

Most of the previous and ongoing surveys focus on finding new faint metal-poor stars, but their faintness means that they are harder to observe at high spectral resolution. Neverthe-

less, some bright extremely metal-poor stars remain to be discovered, as shown by the bright ( $V = 9.1$ ) star BD+44°493, identified by Ito et al. (2009) as an extremely metal-poor star with  $[\text{Fe}/\text{H}] = -3.7$ . This star is bright enough not only for high resolution optical spectroscopy but also for ultraviolet observations with the Hubble Space Telescope, as shown in a recent work by Placco et al. (2014). Based on the lack of molecular absorption in the mid infrared, another recent work has identified a large number of bright ( $V < 14$ ) metal-poor stars (Schlaufman & Casey 2014).

We have developed a new method that aims to find bright metal-poor stars with  $V < 14$ , in particular those with  $V < 12$ , for which high S/N high resolution spectra can be obtained in large telescopes. In this letter we report the first bright UMP star found in our survey, 2MASS J18082002–5104378 (hereafter 2MASS J1808–5104), a 11.9-magnitude star with  $[\text{Fe}/\text{H}] = -4.07$ .

## 2. Sample selection and observations

Our metal-poor candidates were found using an ingenious new method. Metal-poor stars are usually misclassified in most spectral classification surveys, such as in the case of the two stars (HD 19445 and HD 140283) for which a significant metal defi-

<sup>★</sup> Based on observations obtained at the European Southern Observatory (ESO) Very Large Telescope (VLT, observing program 293.D-5036) and New Technology Telescope (NTT, observing programs 091.D-0292 and 092.D-0308).

ciency was discovered for the first time by Chamberlain & Aller (1951). As noticed by the authors, these two stars are classified as A-type stars, but actually they were much cooler than stars of spectral type A. The reason for this mismatch was their low metal abundance, currently known to be  $[\text{Fe}/\text{H}] \sim -2$  (e.g., Korn et al. 2003; Zhang & Zhao 2005; Nissen et al. 2007; Ramírez et al. 2013).

We quantified the difference between the expected spectral type based on effective temperatures and their actual spectral classification using a sample of about 7,000 stars for which effective temperatures ( $T_{\text{eff}}$ ), metallicities, and spectral classification are available in the updated catalog of stellar parameters described in Ramírez & Meléndez (2005a). Each spectral subclass was assigned a numeric spectral type ST: ST = 0 for M9, ST = 9 for a M0 star, and so on (ST = 10 for K9, etc.). For example, the difference between F0 (ST=39) and G1 (ST=28) is  $\Delta\text{ST} = 11$ . We calibrated ST with  $T_{\text{eff}}$  for dwarf (ST =  $52.65 \ln(T_{\text{eff}}) - 429.0$ ) and giant (ST =  $42.10 \ln(T_{\text{eff}}) - 336.4$ ) stars, so that ST can be obtained based on  $T_{\text{eff}}$ . As expected from their effective temperatures, we find that the most metal-poor stars have the largest difference ( $\Delta\text{ST}$ ) between their observed spectral types.

We applied our technique to three large catalogs of spectral classifications (Nesterov et al. 1995; Wright et al. 2003; Skiff 2010). We cross-matched those three catalogs to APASS<sup>1</sup> and 2MASS photometry (Cutri et al. 2003), finding 40055, 195495, and 145441 matches, respectively. Using that photometry we estimated effective temperatures using color- $T_{\text{eff}}$  calibrations (Ramírez & Meléndez 2005b; Casagrande et al. 2010). We then selected stars with the largest differences ( $\Delta\text{ST} > 10$ ) as the most promising metal-poor candidates. About two thousand metal-poor candidates were selected for follow-up medium-resolution spectroscopy. Most of them have  $8.5 < V < 14.0$ , which is therefore adequate for an initial characterization of their stellar parameters with medium-resolution spectroscopy at small and medium-size telescopes and for follow up of the most interesting candidates using high S/N, high-resolution spectroscopy at medium-size and large telescopes.

Most medium-resolution spectra were acquired with the EFOSC2 spectrograph (grism #7) on the NTT telescope at the ESO La Silla Observatory. Additional medium-resolution spectra have been acquired with the 1.6-m telescope at the Observatorio Pico dos Dias in Brazil and with the 2.1-m Otto Struve telescope at the McDonald Observatory in the USA. The spectra were reduced with IRAF, following standard procedures (bias subtraction, flat fielding, sky subtraction, extraction of the spectrum, wavelength calibration).

The stellar parameters of the medium-resolution spectra were estimated using a modified version of the SEGUE Stellar Parameter Pipeline (e.g., Beers et al. 2014). The analysis revealed that 2MASS J1808–5104 was probably a subgiant with  $[\text{Fe}/\text{H}] \sim -4$ , so we selected this star for high-resolution follow-up spectroscopy. Observations were acquired with the UVES spectrograph at the VLT telescope (program 293.D-5036) at a resolving power  $R = 50,000$ . We used the dichroic #1 with the cross disperser #2 in the blue (330-450nm) and the cross disperser #3 in the red (480-680nm). Three exposures of 1800 s were obtained adding to a total exposure time of 1h30m. The high-resolution spectra were reduced using the UVES pipeline, and Doppler correction and continuum normalization were performed with IRAF. Figure 1 shows portions of the observed spectrum, compared with SDSS J1204+1201 ( $[\text{Fe}/\text{H}] =$

**Fig. 1.** Comparison of 2MASS J1808-5104 to other UMP stars (Placco et al. 2015; Frebel et al. 2015). Both SDSS stars were observed with Magellan/MIKE, at a resolution of  $R \sim 35,000$ . Our UMP star was observed at  $R = 50,000$  and has a higher S/N ratio than SDSS stars.

$-4.34$ ,  $T_{\text{eff}} = 5467$  K; Placco et al. 2015) and SDSS J1313–0019 ( $[\text{Fe}/\text{H}] = -5.00$ ,  $T_{\text{eff}} = 5200$  K; Frebel et al. 2015).

The measured radial velocities are 70.4, 66.5, and  $-29.1$  km/s ( $\sigma = 0.6$  km/s) in 19 October 2014, 21 October 2014 and 6 March 2015, respectively, showing that the star has a binary companion. No sign of the secondary is present in the spectra (whether on the blue or the red side), therefore we combined the individual spectra to achieve a S/N of about 150 per resolution element on the blue side and 300 on the red.

### 3. Analysis

The techniques applied to determine the stellar atmospheric parameters are described in detail in Placco et al. (2015b). Most of the work is based on equivalent widths (EW) measured by fitting Gaussian profiles to the observed atomic lines, using the Robospect package (Waters & Hollek 2013). The line lists used within Robospect were compiled from Roederer et al. (2012), the VALD database (Kupka et al. 1999), and the National Institute of Standards and Technology Atomic Spectra Database (NIST; Kramida et al. 2013). The model atmospheres are one-dimensional plane-parallel, no overshooting models computed in LTE from the grid of Castelli & Kurucz (2004).

For the stellar atmospheric parameter determination, as well as abundances from EW analysis and spectral synthesis, we used the latest version (2014) of the MOOG analysis package (Sneden 1973). The effective temperature was determined by imposing the excitation equilibrium of Fe I lines, and then we used the corrections described in Frebel et al. (2013) to bring the spectroscopic temperature into agreement with the photometric scale.

<sup>1</sup> <https://www.aavso.org/apass>

The surface gravity was obtained by ionization equilibrium of Fe I and Fe II, and the microturbulence was estimated by enforcing no trend of Fe I abundances with reduced equivalent width. Our stellar parameters are  $T_{\text{eff}} = 5440 \pm 100$  K,  $\log g = 3.0 \pm 0.2$  dex,  $v_t = 1.5 \pm 0.2$  km s<sup>-1</sup>, and  $[\text{Fe}/\text{H}] = -4.07 \pm 0.07$  dex.

Chemical abundances were derived from EW analysis for Na, Mg, Al, Si, Ca, Sc, Ti, Cr, Mn, Fe, Co, and Ni. From spectral synthesis, we were able to measure abundances for Li and Sr, and upper limits for C, N, and Ba. For Ba, the upper limit was determined from the 4934 Å feature, since the strong 4554 Å line fell in one of the gaps of the CCD. The elemental abundances and errors are shown in Table 1.

#### 4. Discussion

With  $V = 11.9$  and  $[\text{Fe}/\text{H}] = -4.1$ , 2MASS J1808–5104 is the brightest UMP star (see Figure 2). The star is slightly brighter than the giant UMP star CD–38 245 ( $V = 12.0$ ), which has stellar parameters  $T_{\text{eff}} = 4857$  K,  $\log g = 1.54$ , and  $[\text{Fe}/\text{H}] = -4.15$  dex (Yong et al. 2013).

The carbon abundance in a 1D analysis is  $[\text{C}/\text{Fe}] < +0.94$  or  $+0.87$ , depending on the adopted solar carbon abundance (Asplund et al. 2009; Caffau et al. 2010). However, the CH lines are affected by strong 3D effects at low metallicity (e.g., Bonifacio et al. 2009). Although there are no predictions regarding the 3D effects for a star like 2MASS J1808–5104, interpolating on calculations for stars in the range of  $T_{\text{eff}} = 4880 - 6550$  K,  $\log g = 2.0 - 4.5$ , and  $-5 < [\text{Fe}/\text{H}] < -3$  (Bonifacio et al. 2009; Caffau et al. 2012; Spite et al. 2013), the correction would be  $\Delta\text{C}(3\text{D} - 1\text{D}) \sim -0.4$  dex, meaning that in 3D the carbon abundance would be  $[\text{C}/\text{Fe}] \lesssim +0.5$ .

According to Aoki et al. (2007), a carbon-enhanced metal-poor star (CEMP) has  $[\text{C}/\text{Fe}] > +0.7$ . However, we notice that this suggestion was mostly based on stars with  $[\text{Fe}/\text{H}] > -3.5$ , and as the  $[\text{C}/\text{Fe}]$  ratio seems to increase at lower metallicities, perhaps this definition should be revised. Beers & Christlieb (2005) define CEMP stars as those with  $[\text{C}/\text{Fe}] > +1.0$ , a definition also adopted by Spite et al. (2013). If the normal (non-CEMP) stars indeed have higher  $[\text{C}/\text{Fe}]$  at lower metallicities (see, e.g., Fig. 13 in Placco et al. 2014b), perhaps a metallicity-dependent definition of CEMP should be considered. In any case, the 3D-corrected value of  $[\text{C}/\text{Fe}] \lesssim +0.5$ , surely puts 2MASS J1808–5104 in the category of non-CEMP star.

At the metallicity and  $\log g$  ( $= 3.0 \pm 0.2$ ) of our UMP star, it should be either leaving the subgiant branch or entering the bottom of the red giant branch (RGB), because it is less evolved than the giant ( $\log g = 1.5$ ) CD–38 245. This is important for the study of the light elements (C, N, O), since 2MASS J1808–5104 should be much less affected by mixing than CD–38 245. According to observations and calculations (including extra-mixing) for field and globular cluster giants (Gratton et al. 2000; Denissenkov & Vandenberg 2003; Denissenkov et al. 2015; Stancliffe et al. 2009; Shetrone et al. 2010; Angelou et al. 2011), during the first dredge-up (starting at  $M_V \sim 2.0$ ,  $\log g \sim 3.0$ ,  $\log L/L_\odot \sim 1.2$ ), there should only be a minor depletion of carbon ( $\Delta\text{C} < 0.1$  dex). Only when the star reaches the RGB bump ( $M_V \sim -0.2$ ,  $\log g \sim 2.0$ ,  $\log L/L_\odot \sim 2.1$ ) does a steep carbon depletion begin ( $\Delta\text{C} \gg 0.1$  dex).

Because CD–38 245 is above the RGB bump, it should have already experienced deep mixing. Indeed, only an upper limit is available for its carbon abundance (see, e.g., Spite et al. 2005). This upper limit in C and its N abundance place CD–38 245 among the mixed stars of the sample of metal-poor giants of

**Fig. 2.**  $V$  magnitudes for metal-poor stars with  $[\text{Fe}/\text{H}] \leq -3$ . 2MASS J1808–5104 is the brightest UMP ( $[\text{Fe}/\text{H}] < -4$ ). The literature data are from the compilation presented in Placco et al. (2014b).

Spite et al. (2005). With higher S/N data, we can try to measure the C and N abundances in 2MASS J1808–5104, so as to have a measurement of the abundances of those elements in the primeval Galaxy.

In Figure 3 the abundance pattern of 2MASS J1808–5104 is compared to the sample of Yong et al. (2013) and UMP stars from the literature, as compiled by Placco et al. (2015). The  $[\text{X}/\text{Fe}]$  ratios match other UMP stars, and also fits the extension of the Yong et al. (2013) pattern to the UMP regime.

The lithium abundance,  $A(\text{Li}) = 1.45$  dex, places 2MASS J1808–5104 in the group of “unmixed” (meaning without deep mixing) stars of Spite et al. (2005), thus confirming that 2MASS J1808–5104 is key to studying the light elements, since its abundances should reflect the “pristine” values of the time that the star was formed. For the neutron-capture elements, we were only able to determine an abundance for Sr,  $A(\text{Sr}) = -2.03$ , and an upper limit for Ba,  $A(\text{Ba}) < -2.20$ . These values are consistent with the “abundance floors” suggested by Hansen et al. (2015) for UMP stars.

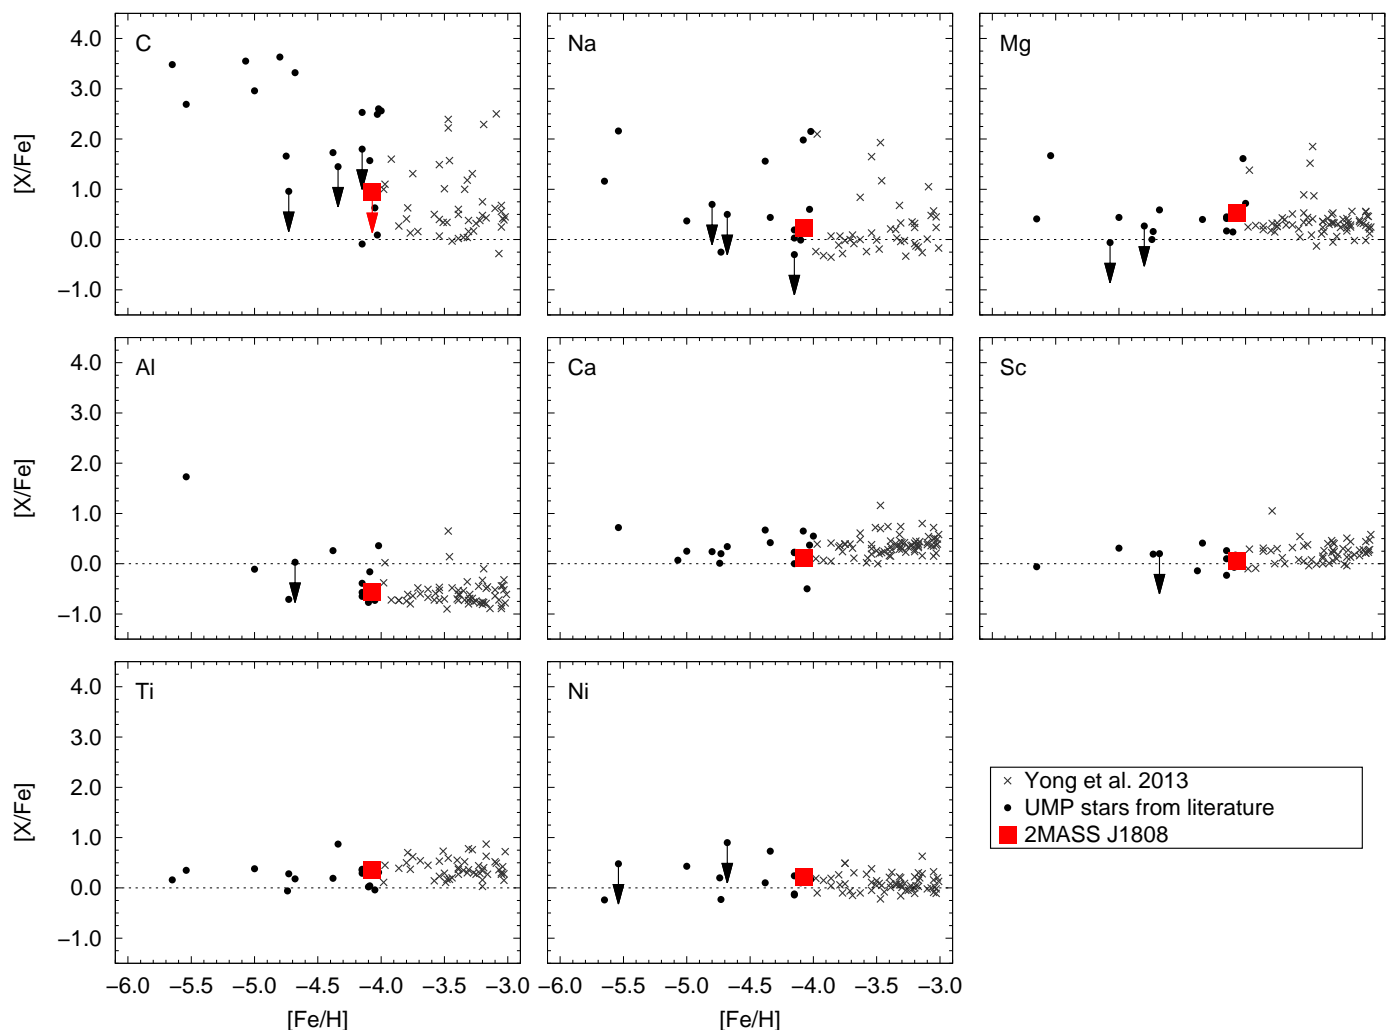

As a non-CEMP, very metal-deficient star ( $[\text{Fe}/\text{H}] = -4.1$ ), 2MASS J1808–5104 is important for understanding the percentage of CEMP stars at low metallicity (Placco et al. 2014b) and the channels that can form CEMP-no stars at such extreme metallicities (e.g., Cooke & Madau 2014). Perhaps this could be related to the binarity of 2MASS J1808–5104, because population III stars have a channel of low-mass binary formation (Stacy & Bromm 2014).

Although 2MASS J1808–5104 is a binary, the light elements are not enhanced. This star has an abundance pattern typical of other non-CEMP stars. This is consistent with mass transfer without significant enhancement of the light elements, according to binary population synthesis (Suda et al. 2013).

#### 5. Conclusions

Our new technique, which is based on the mismatch between the expected spectral type derived from the effective temperature of a star and its actual spectral classification, can successfully identify metal-poor stars. We have identified 2MASS J1808–5104 as the brightest ( $V = 11.9$ ) UMP star ( $[\text{Fe}/\text{H}] < -4$ ).

Variations in the radial velocities of this star, show that it belongs to a binary system, but the spectrum of the secondary

**Fig. 3.** Chemical abundances of 2MASS J1808–5104 compared to metal-poor stars with  $[\text{Fe}/\text{H}] \leq -3$  from Yong et al. (2013) and UMP from the compilation by Placco et al. (2015).

was not detected. The star has  $[\text{C}/\text{Fe}] \lesssim +0.9$  in a 1D analysis or  $[\text{C}/\text{Fe}] \lesssim +0.5$  if 3D effects are considered, making it a non-CEMP star. The abundance pattern is also typical of non-CEMP stars. The star seems to be leaving the subgiant branch or entering the bottom of the RGB, making it useful for studying the abundances of the light elements because the star should not have experienced any deep mixing yet.

We intend to perform higher S/N observations to detect C (from CH) and nitrogen (from NH). Also, we would like to increase our ultraviolet coverage, in order to reach other elements, such as oxygen (from OH) and heavy elements. Our new observations will also provide valuable information on radial velocities, so that we can characterize the binary system.
