We study numerically formation of spatial optical solitons in nematic liquid crystals with competing nonlocal nonlinearities. We demonstrate that at the sufficiently high input power the interplay between focusing and thermally induced defocusing may lead to the formation of two-peak fundamental spatial solitons. These solitons have constant spatial phase and hence represent supermodes of the self-induced extended waveguide structure. We show that these two-peak solitons are stable in propagation and exhibit adiabatic transition to a single peak state under weak absorption.

INTRODUCTION

Spatial optical solitons represent optical beams propagating without spreading in nonlinear media due to the balance between diffraction, which tends to spread the beam and focusing from nonlinear response of the medium. They have been observed in variety of nonlinear optical materials exhibiting different types of nonlinearity including spatially local, nonlocal, Kerr-like or saturable [1, 2]. Typically the soliton formation has been discussed in the context of local nonlinearity, i.e. when the nonlinear response in a particular spatial location is determined by the light intensity in the very same location. The most prominent examples are the so called Kerr media where the light induced refractive index change is proportional to the light intensity. In recent decade there has been interest in the nonlocal nonlinear media, i.e. media with the nonlinear response (index change) in a specific point determined by the light intensity in the neighborhood of this point [3]. The spatial extent of this region relative to the soliton width determines the degree of nonlocality. The nonlocal nonlinearity has been identified in such diverse systems as thermal media [4], nematic liquid crystals (LC) [5, 6], Bose Einstein Condensate [7] and atomic clouds [8–10].

The typical fundamental bright optical solitons has form of finite beam, self-trapped by the nonlinear change of the polarization of the material. In this respect, in most situations, the soliton is nothing but a fundamental mode of the self-induced waveguide [11]. As such, the stationary intensity profile of fundamental soliton features single maximum. In principle it is possible to form stationary multi-peak solitons. However, these are not fundamental solitons. They can be realised, for instance, as vector solitons, i.e. objects formed by simultaneous propagation of few incoherently coupled optical beams (components), with each of them representing various (higher order) mode of the optical waveguide induced by the total intensity. These multi-hump solitons have been

demonstrated in number of systems including photorefractive and thermal media [12]. It is worth mentioning that in nonlinear media with spatially nonlocal nonlinearity multi-peak solitons can be formed as a bound state of two or more fundamental solitons with π phase shift between them. In local media out-of phase solitons tend to repel each other [1] but strong nonlocal nonlinearity introduces attractive potential, which causes formation of bound states of solitons [13, 14]. Such dipole and higher order, multiple solitons have been observed in nematic liquid crystals and media with thermal nonlinear response [15, 16]. However, no fundamental multi-peak solitons have been reported so far. While it has been shown that model of nonlinear media with periodic nonlocal response function supports multi-peak soliton, these solitons are unstable and break up in propagation [17].

In this paper we demonstrate theoretically that fundamental two-humped spatial solitons can exist in media with competing nonlocal nonlinearities [18]. Specifically, we discuss nonlinear model of nematic liquid crystals. We show numerically that competition between reorientational, focusing and thermal, defocusing nonlinearities leads, in our configuration, to the formation of two-peak fundamental solitons. These solitons which can be considered as super-modes of the self-induced waveguide structure appear to be stable and resistant to strong perturbations.

THEORY AND RESULTS

We consider propagation of optical beam in the nematic liquid crystal cell comprising LC located between closely placed (tens of micrometers) parallel glass plates located in the y - z plane. We assume that the internal surfaces of both plates are conditioned (for instance, by rubbing) to ensure that the molecules of LC are anchored and aligned at an angle $\theta = \theta_0$, with respect to the z -axis. Hence the LC in a cell behaves like an uniaxial optical

medium with constant refractive index. The electric field of the optical beam (wavelength λ_0 propagating in LC changes locally the orientation of molecules, leading to the intensity-dependent index change for extraordinary polarized light. If we consider beam propagation along the z -axis, the evolution of the amplitude of electric field $E(x, z)$ is described by [19]

$$2ik_0n(\theta_0)\frac{\partial E}{\partial z} = \frac{\partial^2 E}{\partial x^2} + k_0^2(n^2(\theta) - n^2(\theta_0))E, \quad (1)$$

where $k_0 = 2\pi/\lambda_0$, and

$$n(\theta) = \frac{n_o n_e}{\sqrt{n_o^2 \sin^2 \theta + n_e^2 \cos^2 \theta}} \quad (2)$$

is an effective index of refraction for the y -polarized (i.e., extraordinary polarized) light. Here n_o and n_e denote ordinary and extraordinary refractive indices, respectively. The index $n(\theta)$ depends on the local orientation of molecules, which follow the direction of electric field of the beam, here the molecular orientation angle θ is governed by the following relation:

$$\frac{\partial^2 \theta}{\partial x^2} - \frac{\Delta \epsilon \epsilon_o}{2K} \sin 2\theta |E|^2 = 0. \quad (3)$$

Here K is an effective elastic constant [19, 20] and $\Delta \epsilon = n_e^2 - n_o^2$. As the equations Eqs.(2-3) show, the light-induced reorientational index change is spatially nonlocal and it is always positive as the molecules tend to align along the direction of electric field. This leads to self-focusing of extraordinary polarized optical beam and formation of bright solitons, called nematons [19, 21]. In the following we will assume that the propagation of light in the liquid crystal is accompanied by weak absorption which causes its heating. This process is governed by the heat equation

$$\kappa \frac{\partial^2 T}{\partial x^2} + \frac{c \epsilon_0 \alpha}{2} |E|^2 = 0, \quad (4)$$

where T denotes temperature, κ - thermal conductivity, α - absorption coefficient and c is speed of light.

The light-induced heating modifies both, ordinary and extraordinary refractive indices of the liquid crystal [22], inducing effective self-defocusing of the extraordinary polarized beam. Therefore the nonlinear response of the nematic liquid crystal consist of two competing, spatially nonlocal processes: reorientation driven self-focusing and thermally-induced self-defocusing. It is worth mentioning that thermal nonlinearity alone can be also used to support bright solitons. This requires, however, the light beam to be ordinary polarized [23, 24]. Here we are concerned with the role of defocusing thermal effect on reorientational nonlinearity and consider standard nematons, formed by extraordinary polarized light.

FIG. 1. Soliton solutions in the nematic liquid crystal with competing focusing and defocusing nonlocal nonlinearities as a function of beam power. Spatial intensity (solid) and light-induced refractive index (dashed) profiles are shown (total power $P=1.4$ (a), 1.8 (b), 2.0 (c) and 2.2 (d)).

The temperature dependence of wide range of nematic liquid crystals is described by universal polynomial dependence [22]. In this paper, for sake of concreteness we will employ an empirical polynomial formula, which accurately represents thermal response of 6CHBT liquid crystal in its nematic phase, in the temperature range 18-42 degrees (Celsius) [25, 26]. Details of this dependence are presented in the Appendix.

In general, the elastic constant K in Eq.(3) is also temperature-dependent [20]. However, this dependence is weak and, as we checked, has no effect on our results. Hence it will be neglected in further discussions.

The stationary bright soliton solutions of the system of equations Eqs.(1-4) we found numerically with the help of the imaginary time method [27]. We assume the stationary solution of Eq.(1) in a form: $E(x, z) = E(x) \exp(i\beta z)$, where β is the propagation constant. Then, after taking z to be imaginary, $z \rightarrow iz$, the equations Eqs.(1-4) were solved iteratively until its solution converges to the stationary solution represent fundamental soliton of the system. In these simulations the temperature and molecular orientation, where kept constant at the boundaries: $T(x = \pm x_0) = T_0 = 20^\circ$ and $\theta(x = \pm x_0) = \theta_0 = 45^\circ$, with $2x_0$ being the width of computational window. We used finite difference to solve Eq.(3) and Eq.(4). Our simulations show that, as long as the focusing prevails, the system always supports existence of solitons. Typical intensity profiles of these solitons are depicted in Fig.1, for varying total power, $P = \int_{-\infty}^{\infty} |E(x)|^2 dx$. In particular, for low input power, when the nonlinearity is predominantly driven by molecular reorientation, the solitons have typical form of a single peak, bell-like, shape [see Fig.1(a)]. However, as the power increases, the thermal effect becomes relevant and the soliton broadens, acquiring first a flat top [Fig.1(b)] and eventually splits into two distinct peaks [Fig.1(c,d)].

It should be stressed that the two peak solution still represents a fundamental soliton with the constant phase across the soliton. Using a waveguide analogy for solitons, for low power, the soliton-formed waveguide is induced purely by reorientation of molecules and is smooth, function of spatial coordinates. When the thermal effects come to play, at higher power, the waveguide structure develops two internal peaks. This is clearly seen in refractive index profiles plotted with dashed line in Fig.1. It is worth mentioning that although degrees of nonlocality represented by equations Eq.(3) and Eq.(4) are comparable, they differently contribute to the resulting refractive index. The interplay between both, orientational and thermal effects, leads to formation of complex waveguide structure supporting multi-peak solitons.

FIG. 2. Illustrating the interplay between reorientational ($\Theta(\theta)$) and thermal ($\Gamma(T)$) contributions to the nonlinear response of liquid crystal induced by two different soliton intensity distributions (indicated by dashed line).

We can get clearer picture of the competition between thermal and reorientational mechanisms by utilizing the fact that the anisotropy, $n_e^2 - n_o^2$, is relatively small. Then by expanding formula Eq.(1) in series we arrive at the following approximate relation for the nonlinear response

$$n^2(T, \theta) - n^2(T, \theta_0) = (n_e^2(T) - n_o^2(T)) (\cos^2 \theta - \cos^2 \theta_0) = \Gamma(T)\Theta(\theta) \quad (5)$$

It appears that the nonlinearity is governed by product of two functions representing thermal ($\Gamma(T)$) and orientational ($\Theta(\theta)$) contributions, respectively. This interplay is different from typical nonlinear media with competing nonlinearities where different mechanisms contribute additively to the total nonlinear response. We illustrate the interplay between thermal and reorientational effects in Fig.2 for two examples of light intensity distributions representing single [Fig.2(a)] and two-peak [Fig.2(b)] solitons. It is evident that while $\Theta(\theta)$ is responsible for spatial focusing due to light induced reorientation of molecules of LC and reaches its maximum at the intensity maximum, the heat-induced contribution ($\Gamma(T)$) decreases with intensity causing spatial defocusing. As a result the full nonlinear response weakens and flattens in the center, and finally develops central dip for higher intensity. This is exactly the regime where the two peak soliton formation takes place.

FIG. 3. Dependence of soliton power on its amplitude for wavelength $\lambda_o = 532nm$ and initial orientation $\theta_o = 45^\circ$, background temperature $T_o = 20^\circ C$, elastic constant $K = 3.6pN$, thermal conductivity $\kappa = 0.135 \frac{W}{m^\circ C}$ and absorption coefficient $\alpha = 5.769 \frac{1}{m}$.

In Fig.3 we illustrate the relation between amplitude and the power of different soliton solutions. It is clear that two peak solitons emerge above certain critical power. The insets in Fig.3 show intensity profiles of various soliton solutions.

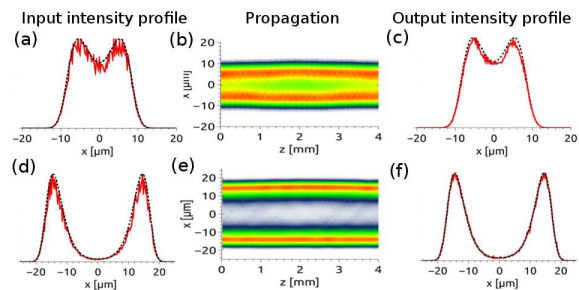

FIG. 4. Stability of two-peak solitons. (a, d) Input intensity profiles. red solid (black dashed) line indicate perturbed (exact) input soliton profiles; (b,e) soliton dynamics in propagation; (c,f) final beam profiles.

Since the bright soliton is a fundamental mode of the self-induced waveguide, one can think of these two-humped solitons as some kind of super-modes of the self-induced waveguide structure, which are well known in the context of waveguide couplers and waveguide arrays [28]. The nonlinear version of super-modes has been also demonstrated in nonlinear couplers and cold atoms trapped in double well potentials [29]. However, such symmetric nonlinear modes are subject to spontaneous symmetry breaking and results in spatially asymmetric intensity distribution [30, 31]. Therefore it is crucial to determine the stability of our two-peak soliton solutions. To this end we used the original system of equations Eqs.(1-4) to numerically propagate soliton solution. We added random perturbation to the amplitude of the exact solution and propagated it over many diffraction lengths.

We employed finite difference beam propagation method with Runge Kutta 4th order algorithm and with finite difference relaxation with multigrid algorithm technique. The results for two-humped solitons are shown in Fig.4. The left (right) panel in each row shows the initial (final) intensity distribution (solid red line), while the dynamics of propagation is shown by the contour plots. It is clear that the solitons are stable in propagation and they retain their two-peak structure. Moreover, it is evident that intensity perturbation is smoothed out in propagation [compare left and right panel plots in Fig.4]. This is due to the nonlocal character of nonlinearity which tends to average out any sharp intensity variations. Additional (not shown) simulations confirm that at large angles solitons survive acute collisions with another solitons, however in shallow angle collisions their identity is lost because the model is nonintegrable and collisions are inelastic.

FIG. 5. Absorption-induced adiabatic transformation of two-humped nematicon into a single peak soliton in propagation. (a) Evolution of the beam profile. (b) Variation of the power of the soliton and its amplitude as a function of propagation distance. Dashed black line follows stationary soliton solutions from Fig.3.

So far in our simulations we ignored linear loss. For typical experimental conditions with propagation distance of millimetres this assumption is justified. However it is interesting to see how the linear loss affects two-peak solitons in a long distance propagation. We illustrate this in Fig.5(a) where we plot the intensity evolution of, initially exact, two-peak soliton as it propagates in the presence of weak linear loss. As its power decreases the soliton itself undergoes adiabatic transformation from two-peak to a single-peak structure. At any point along its propagation the beam is, in fact, a soliton solution from the family represented in Fig.3, as indicated by a dashed line. This is evident in Fig.5(b) where we show evolution of power and amplitude of the beam during propagation.

Having in mind future experimental observations of the two-humped solitons we also address the issue of soliton excitation through the proper initial conditions. In Fig.6 we show numerically how the two-humped fundamental soliton can be created from the initial amplitude distribution given by two in-phase, weakly overlapping Gaussian beams. It is clear that the two-peak solitary beam

is formed in propagation. The visible oscillations and emission of radiation is caused by the mismatch between exact soliton profile and input beam. Notice that unlike solitons excitation in typical nonlinear media which is accompanied by outward emission of dispersive waves, here the radiation is confined to the center of the sample. This is because we deal here with so called infinitely nonlocal medium [32] where degree of nonlocality is as large as the transverse dimension of the medium. Consequently, the light induced waveguide is very broad extending to the sample boundaries imposing strong localization in the centre.

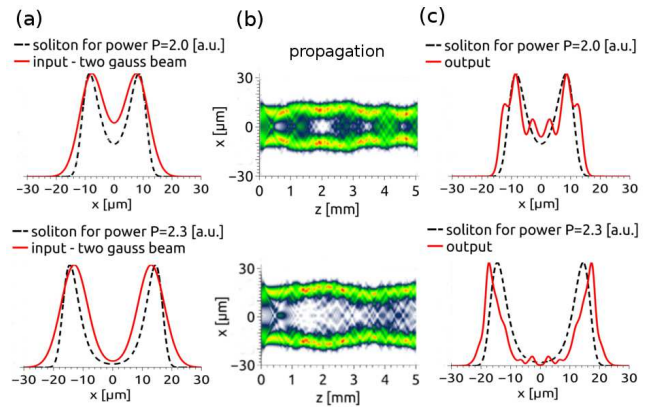

FIG. 6. Excitation of two-humped fundamental solitons. (a) initial amplitude distribution. (b) nonlinear evolution of the beam. (c) output intensity distribution of the soliton. The input power $P=2$ (top row), $P=2.3$ (bottom row)

CONCLUSIONS

In conclusions, we studied theoretically formation of fundamental bright solitons in nematic liquid crystals in the presence of competing nonlinearities: reorientational focusing and thermally-induced defocusing. We found that for sufficiently large input power the system supports formation of two-humped fundamental solitons with uniform phase. These solitons, which could be considered as super-mode solitons of the self-induced two-well index structure, appear to be stable in propagation. We also showed that these solitons could be excited by properly shaped amplitude of the input beam. While our calculations have been conducted using parameters of a specific type of liquid crystal, our results are applicable to a wide range of nematic liquid crystals since their birefringence exhibits similar thermal characteristic.

APPENDIX

The ordinary and extraordinary refractive indices of 6CHBT liquid crystal in the temperature range 18-42 degrees (Celsius) are modelled by the following empirical relation

$$n_o = \sum_{j=0}^3 a_j T^j, \quad n_e = \sum_{j=0}^3 b_j T^j, \quad (6)$$

where coefficients a_j and b_j are also function of the wavelength. For instance, for $\lambda=532$ nm, the coefficients a_j and b_j read:

$$a_0 = 1.659, \quad a_1 = 2.814 \times 10^{-3}, \quad a_2 = -0.103 \times 10^{-3}, \\ b_0 = 1.545, \quad b_1 = -1.861 \times 10^{-3}, \quad b_2 = 3.118 \times 10^{-5}.$$

where T is expressed in degrees (Celsius).

Figure Fig.7 illustrates the above temperature dependence. It clearly shows that while ordinary refractive index only weakly depends on temperature, the extraordinary index decrease fast with temperature. At roughly 42° the crystal undergoes phase transition from nematic to isotropic phase.

FIG. 7. Illustrating temperature dependence of ordinary (n_o) and extraordinary (n_e) refractive indices of 6CHBT liquid crystal, for $\lambda=532$ nm. n_{izo} denotes the refractive index in the isotropic phase.
