ABSTRACT

The formation of a diurnal thermocline in the ocean mixed layer under a stabilizing buoyancy flux was simulated successfully by large-eddy simulation, reproducing various features consistent with observation. The analysis of the simulation result revealed that the formation of a diurnal thermocline passes through two different phases: the formation of a thermocline (formation stage) and increasing thickness of the thermocline thereafter (growth stage). Turbulent kinetic energy (TKE) flux dominates TKE production within the mixed layer, but turbulence maintained by shear production at the thermocline causes stratification below the mixed layer. In addition, once the thermocline is formed, both the gradient and flux Richardson numbers maintain constant values at the thermocline. It was also found that a diurnal thermocline cannot be formed in the absence of both wave breaking and Langmuir circulation. Furthermore, the effects of stratification on turbulence were investigated based on the time series of various physical variables of turbulence at the diurnal thermocline and within the mixed layer, and the mechanism for diurnal thermocline formation is discussed.

1. Introduction

Strong turbulence usually exists near the surface in the ocean mixed layer as a result of wave breaking (WB; e.g., Agrawal et al. 1992; Drennan et al. 1996), leading to the response to a surface stabilizing buoyancy flux that is fundamentally different from the atmospheric boundary layer. A diurnal thermocline (or “thermocline” hereafter) is formed at a certain depth during the day in the ocean mixed layer while a temperature gradient remains small near the surface. A strong temperature gradient, however, appears near the surface during the night in the atmospheric boundary layer.

Understanding of the dynamical process of diurnal thermocline formation is essential for predicting the sea surface temperature and the vertical transport of heat, momentum, and dissolved gases in the upper ocean. Only a few studies, however, have been made so far to understand the diurnal thermocline, based on

field observation (Stommel et al. 1969; Delnore 1972; Kudryavtsev and Soloviev 1990; Brainerd and Gregg 1993; Caldwell et al. 1997), mixed layer models (Woods and Barkmann 1986; Kraus 1988; Noh and Fernando 1991; Noh 1996), or laboratory experiments (Kantha and Long 1980; Hopfinger and Linden 1982; Noh and Long 1990), and the mechanism for its formation is not yet clearly understood.

Noh (1996) suggested that turbulent kinetic energy (TKE) production is dominated by the TKE flux divergence F in the upper mixed layer as a result of WB, and that a diurnal thermocline is formed by the positive feedback between F and buoyancy decay P_b . He also suggested that once the thermocline is formed, local balance is observed among P_b , shear production P_s , and dissipation ϵ (i.e., $P_s - P_b - \epsilon = 0$), and the flux Richardson number Rf ($= P_b/P_s$) remains constant at the thermocline. Turbulence maintained by shear production at the thermocline causes stratification below the mixed layer by allowing heat transport across the thermocline, which is also found in observation data (Brainerd and Gregg 1993; Caldwell et al. 1997). These suggestions were based on the mixed layer model results, however.

Meanwhile, recent progress in the reproduction of realistic turbulent flows in the ocean mixed layer by using large-eddy simulation (LES: Skillingstad and Denbo 1995; McWilliams et al. 1997; Skillingstad et al. 1999; Noh et al. 2004, 2006; Min and Noh 2004; Li et al. 2005; Sullivan et al. 2007; Polton and Belcher 2007) provides us with the possibility of investigating the dynamical process of the ocean mixed layer at a fundamental level. Although there are a few examples of LES for the ocean mixed layer under a stabilizing buoyancy flux (Min and Noh 2004; Li et al. 2005), the formation of a diurnal thermocline has not been considered yet.

Therefore, in this paper an attempt has been made to reproduce the formation of a diurnal thermocline in the ocean mixed layer under a stabilizing buoyancy flux by using LES and to clarify its dynamical process by analysis of LES data. In particular, investigation was focused on how turbulence at the thermocline is modified during the formation of a diurnal thermocline. It was also investigated how the result is affected by Langmuir circulation (LC), WB, radiation penetration, and the diurnal variation of the surface buoyancy flux.

2. Simulation

For the simulation, we used the LES model for the ocean mixed layer developed by Noh et al. (2004), in which both LC and WB are realized. The modified filtered equation is given by

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -\frac{\partial \pi}{\partial x_i} - \varepsilon_{ijk} f_j (u_k + u_{sk}) + b \delta_{i3} - \frac{\partial \tau_{ij}}{\partial x_j} + \varepsilon_{ijk} u_{sj} \omega_k + X_i, \quad (1)$$

where π is the generalized pressure [$= p/\rho_0 + (\mathbf{u} + \mathbf{u}_s)^2 - |\mathbf{u}|^2/2$], τ_{ij} is the subgrid scale Reynolds stress, and b is buoyancy [$= -g(\rho - \rho_0)/\rho_0$]. Here LC is generated by the vortex force $\varepsilon_{ijk} u_{sj} \omega_k$ with the Stokes drift velocity u_{si} (Craik and Leibovich 1976), and WB is realized by a stochastic forcing X_i .

The random forcing X_i is designed to reproduce the turbulence with the length l_0 and time scale \mathfrak{S}_0 corresponding to those of near-surface small-scale turbulence generated by WB (Noh et al. 2004). It is expressed as

$$X_i = \frac{A u_*}{\mathfrak{S}_0} G(0;1) (1 - \delta_{i3}) \delta(z), \quad (2)$$

where $G(0;1)$ is the Gaussian random function with a mean of 0 and variance of 1, δ is the delta function, and u_* is the frictional velocity. The length and time scales of random forcing at the surface are given by $l_0 = 1.25$ m

and $\mathfrak{S}_0 = 0.1 l_0 / A u_*$, based on observational evidence (Agrawal et al. 1992; Craig and Banner 1994; Drennan et al. 1996; Gemmrich and Farmer 1999). The value of an empirical constant $A = 3$ is determined so that the profile of the resultant dissipation rate is consistent with observation. Here the random forcing is designed to reproduce the realistic turbulence structure near the sea surface generated by WB rather than to simulate a realistic WB process.

For simplicity, we assumed that both the wind stress and wave fields are in the x direction and further assumed that the wave field is steady and monochromatic. The associated Stokes velocity is then given by $u_s = U_s \exp(-4\pi z/\lambda)$, with $U_s = (2\pi a/\lambda)^2 (g\lambda/2\pi)^{1/2}$, where a is the wave height, λ is the wavelength, and g is the gravitational acceleration. For wave height and wavelength, typical values were used such as $a = 1.0$ m and $\lambda = 40$ m, which makes $U_s = 0.196$ m s⁻¹. Simulations were also performed in the absence of WB ($A = 0$) and/or LC ($U_s = 0$) to investigate their effects.

The LES model used in this study was developed based on the Parallelized LES Model (PALM), which has been applied to simulate various geophysical turbulence phenomena. Details of the LES code can be found in Raasch and Schröter (2001). The model domain was 300 m in the horizontal direction (x and y) and 80 m in the vertical direction (z). The number of grid points was $240 \times 240 \times 64$, and the corresponding grid sizes were 1.25 m in all directions. Simulation was also performed with $240 \times 240 \times 128$ grid points ($\Delta z = 0.625$ m) to examine the sensitivity to the vertical resolution. A free-slip boundary condition was applied at the bottom. The wind stress was given by $u_* = 0.01$ m s⁻¹, which corresponds to the wind velocity 5–10 m s⁻¹ at 10 m above the sea level (Fairall et al. 2003). The Coriolis force was given by $f = 0.5 \times 10^{-4}$ s⁻¹, corresponding to latitude 20°, so the Ekman length scale u_*/f is much larger than the Monin–Obukhov length scale u_*^3/Q_0 .

Initially, integration started with a mixed layer of uniform density without surface buoyancy flux. Once a quasi-equilibrium state was reached after an 8-h integration, the constant surface buoyancy flux $Q_0 = 5 \times 10^{-7}$ m² s⁻³ was imposed. Turbulence reaches quasi-equilibrium over a period of $O(f^{-1})$ in the LES of the ocean mixed layer (McWilliams et al. 1997). This moment was defined as the initial time (i.e., $t = 0$ h). If the surface freshwater flux and salinity variation are neglected, Q_0 corresponds to the surface heat flux H_0 by $Q_0 = (g\alpha/\rho c_p) H_0$, where $\alpha = -\rho^{-1} d\rho/dT$ and c_p is the specific heat at constant pressure, and a pycnocline corresponds to a thermocline. The condition in the present simulation corresponds to $La_t [\equiv (u_*/U_s)^{1/2}] = 0.23$ and $Ho [\equiv -2Q_0\lambda/(2\pi U_s u_*^2)] = -0.33$.

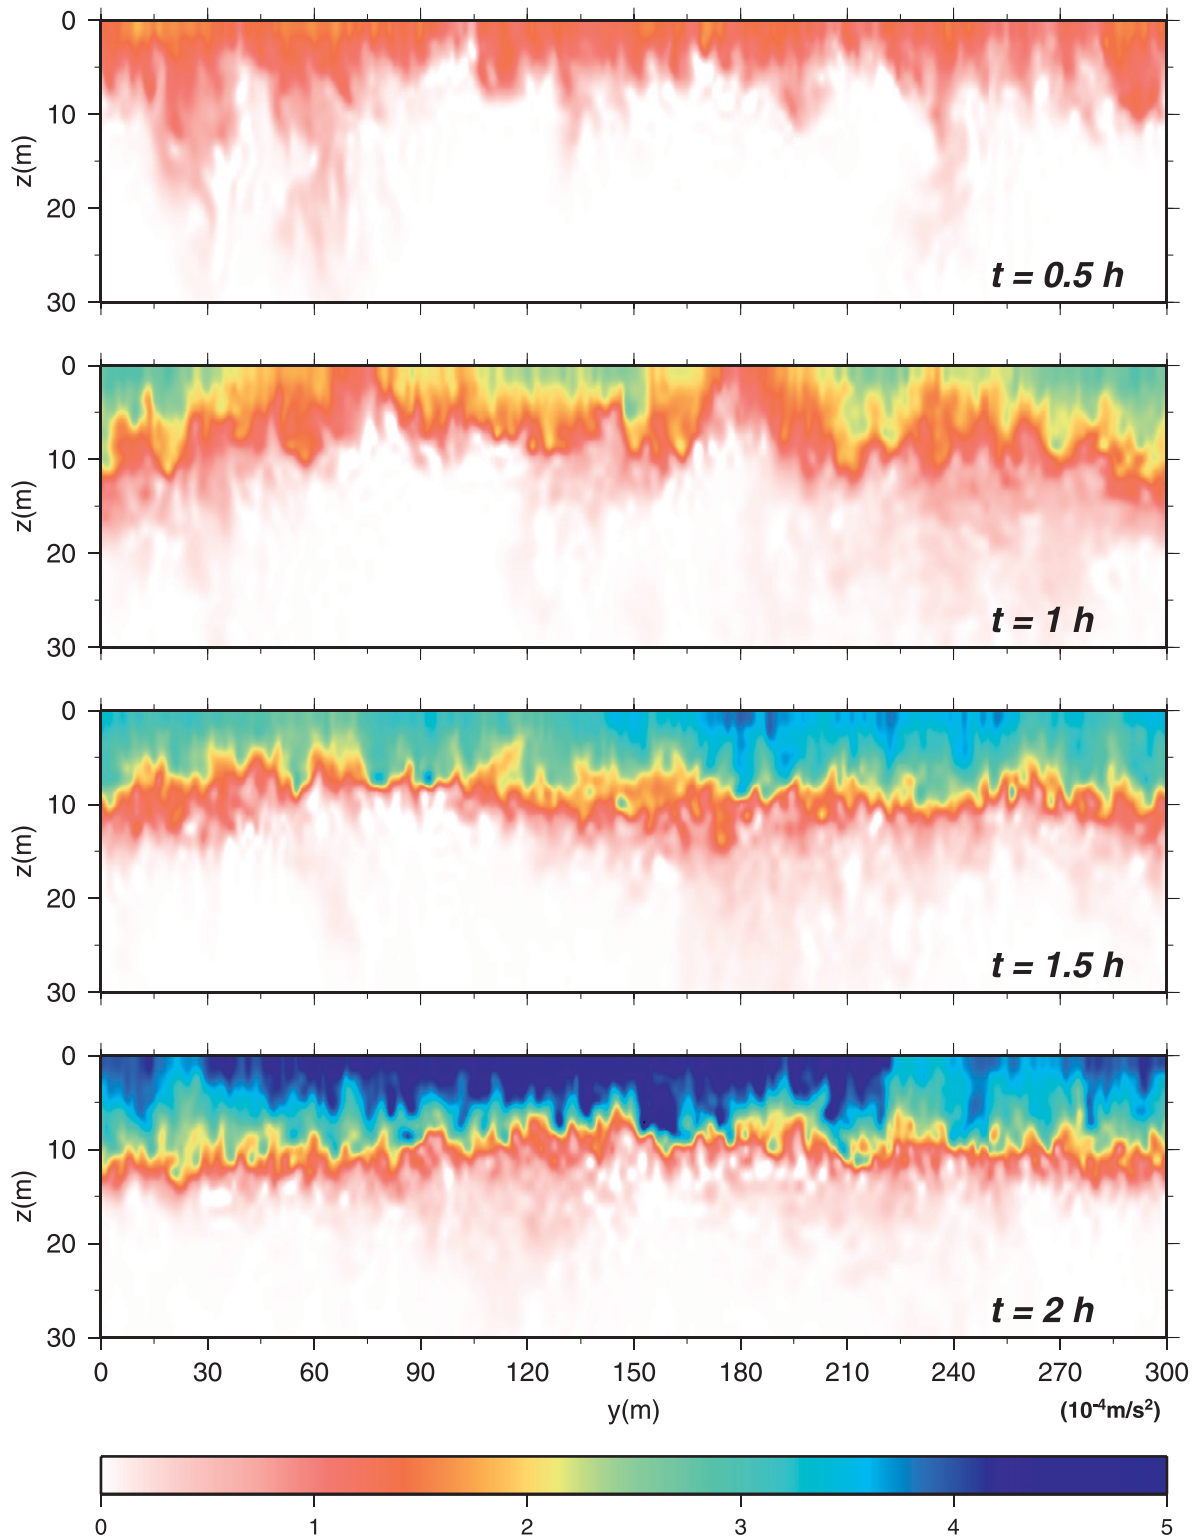

FIG. 1. Variation of buoyancy distribution at the vertical cross section with time ($\Delta t = 0.5 h$).

Because the primary concern in this paper is to understand the fluid dynamical process of diurnal thermocline formation, a constant buoyancy flux was used and solar radiation penetration was neglected. The effects of radiation penetration and diurnal variation of the surface heat flux were investigated, however, using the simulations considering these effects.

3. Results

a. Formation of a diurnal thermocline

Figure 1 shows how buoyancy distribution in the vertical cross section evolves in the initial stage of thermocline formation. At $t = 0.5$ h, a well-defined thermocline (or pycnocline), has not formed yet, and buoyancy is transported downward (similar to the case of a passive scalar). Buoyancy penetrates deeper at some locations, following downward jets of LC. The front of buoyancy discontinuity appears at $t = 1$ h at a certain depth, where fluctuation continues to decrease with increasing stratification.

Corresponding evolutions of the horizontal mean values of buoyancy B , vertical shear of the horizontal mean velocity $S^2 [= (\partial U/\partial z)^2 + (\partial V/\partial z)^2]$, and dissipation rate ε are shown in Fig. 2, but for a longer period ($t < 8$ h). Hereafter all variables appearing in the present paper are horizontally averaged ones, and dissipation and flux terms include both resolved and subgrid-scale parts.

An exponentially decreasing B appears at early times ($t = 0.5$ h), similar to the case of constant eddy diffusivity. After some time ($t = 1$ h), a weak thermocline appears near $z = 8$ m and stratification $N^2 (= \partial B/\partial z)$ at this depth continues to increase until $t = 2$ h. This depth will be called the mixed layer depth h in the present paper. After $t = 2$ h, however, the thermocline increases its thickness with time, causing stratification below the mixed layer, whereas the increasing rate of N^2 becomes much weaker (see also Fig. 4a).

From the balance of the TKE budget, Niiler and Kraus (1977) predicted that h is proportional to the Monin–Obukhov length scale L ($\equiv u_*^3/Q_0$) or $h = mL$ with the proportional constant m in the range 2.5–16, although they did not predict the growth of thermocline thickness. It gives $h \sim 5$ –32 m in the present simulation, which is consistent with Fig. 2a.

Formation of a diurnal thermocline suppresses the momentum flux as well as the buoyancy flux across it, and it induces velocity shear at the thermocline. The vertical shear S^2 appears at $t = 1$ h and increases with time. After $t = 2$ h, however, the vertical range of S^2 , which is equivalent to the thickness of the thermocline,

FIG. 2. Evolution of vertical profiles with time ($\Delta t = 1$ h, and the dotted lines represent $t = 0$ and 0.5 h): (a) B , (b) S^2 , and (c) ε .

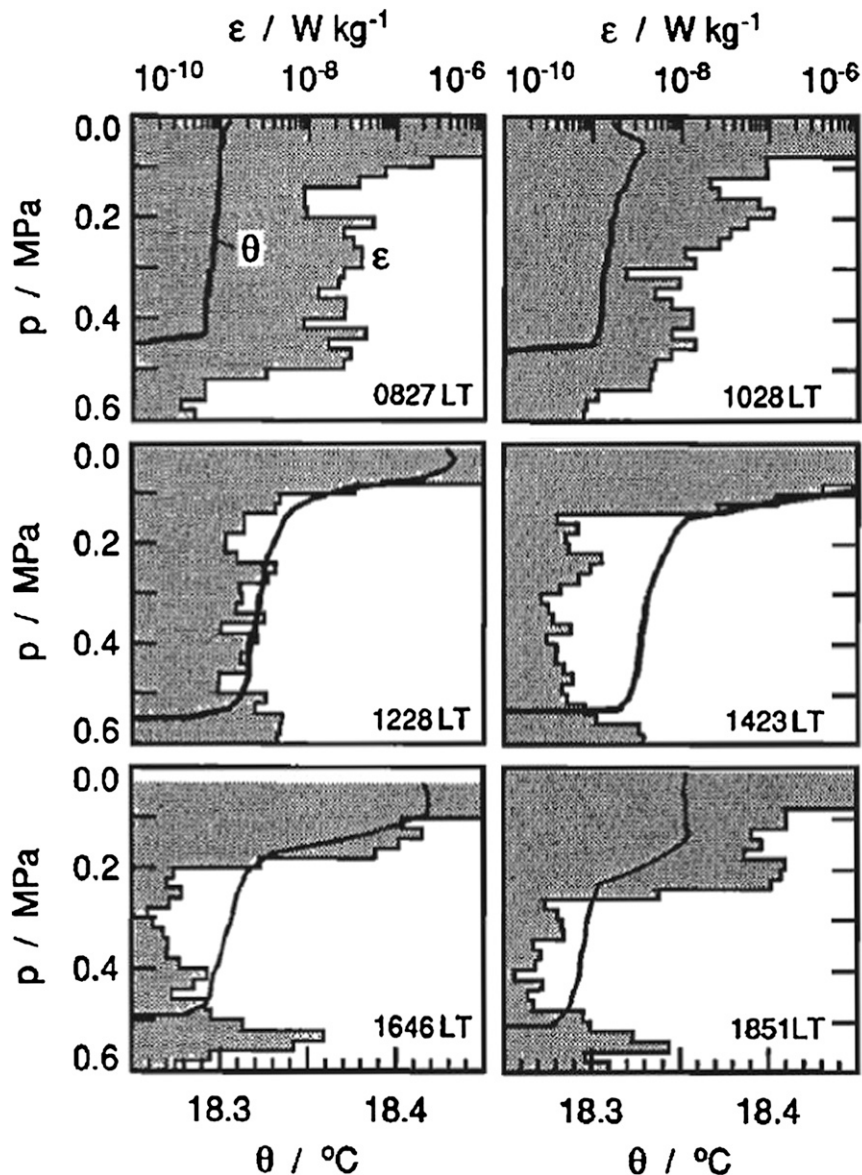

FIG. 3. Profiles of hourly averages of dissipation ε (shaded) and potential temperature θ on 17 Oct during Patches Experiment (PATCHEX) (Brainerd and Gregg 1993, their Fig. 12). The surface stabilizing buoyancy flux was applied during 0900 and 1623 LT. (1 MPa = 100 m in water.)

increases with time, whereas the increasing rate of S^2 for a given depth becomes much weaker (see also Fig. 4b). It is also observed that increasingly larger values of the maximum S^2 appear at deeper depth with time (see also Fig. 4b).

The dissipation rate ε decreases below the thermocline initially, as the TKE flux from the sea surface is shut off by the formation of a thermocline, and then increases later at the thermocline ($10 \text{ m} < z < 20 \text{ m}$) after $t > 2 \text{ h}$ along with increasing shear production.

The evolution of profiles of B , S , and ε (shown above) suggests that the formation of a diurnal thermocline passes through two different phases: the formation of a thermocline until $t \sim 2 \text{ h}$ (“formation stage”) and increasing thickness of the thermocline thereafter (“growth stage”).

Most features shown in Fig. 2 are clearly evidenced from observational data (Brainerd and Gregg 1993; Caldwell et al. 1997). For example, Fig. 3 shows the formation of a diurnal thermocline at $z \sim 10 \text{ m}$ and the

FIG. 4. Time series of physical variables (dotted line: $z = 3.75$ m; solid line: $z = 7.5$ m; dashed line: $z = 12.5$ m): (a) N^2 , (b) S^2 , (c) Rf, (d) Ri, (e) $w'^2/2$, (f) $(u'^2 + v'^2)/2$, (g) $w'^2/(u'^2 + v'^2)$, (h) K_h , (i) K_m , (j) l_m , (k) l_b , (l) l_d , and (m) l_s .

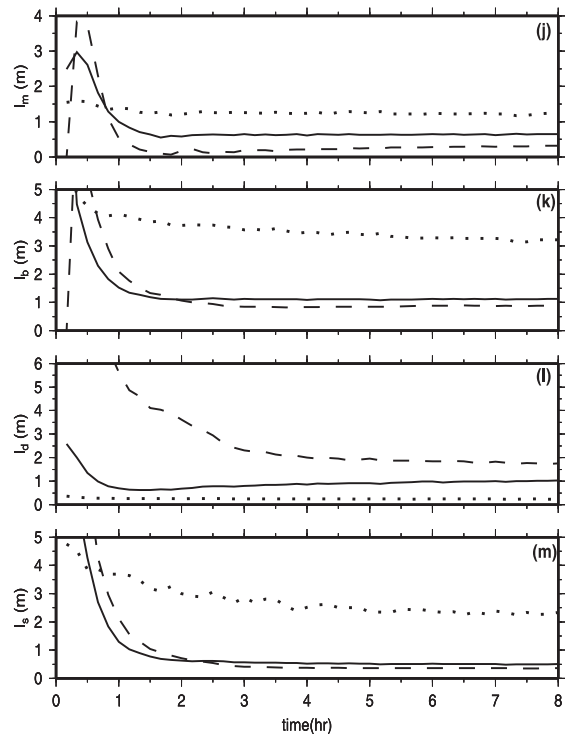

FIG. 4. (Continued)

decrease of ε below the mixed layer with $\varepsilon/(d\varepsilon/dt) \sim 1\text{--}2$ h during the formation stage (1228 LT), followed by the growth of thermocline thickness up to 10 m and the slow increase of ε at the thermocline during the growth stage (1423 LT, 1646 LT). Note that the formation of the thermocline is slower in Fig. 3 because of the diurnal variation of Q_0 starting with a very small value (see section 3f). The profiles equivalent to Fig. 2 could also be obtained from the mixed layer model by Noh and Kim (1999, their Fig. 2).

b. Evolution of turbulence at the diurnal thermocline

To investigate how turbulence is modified during the formation of the diurnal thermocline, the time series of various physical variables were calculated at $z = 3.75$, 7.5, and 12.5 m (Fig. 4). Here $z = 3.75$ m represents the depth within the mixed layer. The thermocline starts to form near $z = 7.5$ m and reaches $z = 12.5$ m at a later time as its thickness increases. Time series analysis confirms the transition from the formation stage to the growth stage at $t \sim 2$ h.

At $z = 7.5$ m, N^2 increases rapidly initially, but the increasing rate becomes much smaller after $t \sim 2$ h. The development of N^2 is delayed at deeper depth ($z = 12.5$ m). It is also found that N^2 approaches a larger value at deeper depth, in the same way as S^2 (Fig. 2b), which is due to weaker TKE and vertical mixing there

(see Figs. 4e,h). The development of S^2 follows a similar pattern but lags behind N^2 by 0.5–1 h. Note that S^2 ($z = 7.5$ m) is still negligible at $t = 0.5$ h. Both N^2 and S^2 remain very small within the mixed layer ($z = 3.75$ m), as expected from Fig. 2, although they also increase slowly with time. The values of N^2 and S^2 are comparable to observational data both within the mixed layer and at the thermocline (Brainerd and Gregg 1993; Caldwell et al. 1997).

Both Rf ($= P_b/P_s$) and Ri [$= (N/S)^2$] at the thermocline increase initially to very large values ($Rf \cong 2$ and $Ri \cong 4$ near $t = 0.5$ h) and then fall to constant values of $Rf \cong 0.4$ and $Ri \cong 0.35$. The initial peaks of Rf and Ri can be understood by the time lag in the growth of S^2 compared to N^2 , as shown in Figs. 4a,b. Caldwell et al. (1997) observed $Ri \sim 0.2$ – 0.5 at the diurnal thermocline. Both Ri and Rf are always larger than 1 within the mixed layer in which P_s is negligible (see also section 3e).

Both horizontal and vertical TKE, $w'^2/2$ and $(u'^2 + v'^2)/2$, at the thermocline decrease rapidly during the formation stage but increase slowly thereafter. The vertical TKE is more strongly affected by stratification than the horizontal TKE so that the ratio r [$= w'^2/(u'^2 + v'^2)$] drops rapidly to about 0.15 during the initial stage, but it remains invariant thereafter. It is consistent with observation data $r \sim 0.15$ – 0.25 (Schumann and Gerz 1995; Caughey et al. 1979). Within the mixed layer, both vertical and horizontal TKE show a weak decreasing tendency, and r remains at a much larger value of $r \cong 0.32$.

Vertical eddy viscosity K_m and diffusivity K_h are calculated by $(\overline{u'w'^2} + \overline{v'w'^2})^{1/2} = K_m S$ and $-\overline{b'w'} = K_h N$. Their values at the thermocline become very large initially because momentum and buoyancy are effectively transferred downward by large-scale eddies such as LC in this stage, even though N^2 and S^2 are negligible. After the formation of a thermocline, K_m and K_h fall by a factor of 10–100. Much stronger vertical mixing is always maintained within the mixed layer.

Finally, we examined the mixing length scale l_m , defined by $K_h = ql_m$, and the dissipation length scale l_d , defined by $\varepsilon = q^3/l_d$, using $q = (w'^2)^{1/2}$, in comparison with l_b ($= q/N$) and l_s ($= q/S$), which are often used for the scaling of length scales (Figs. 4j–m; Britter et al. 1983; Hunt et al. 1988). Although l_m shows a similar temporal variation to l_b for a given depth, l_m/l_b is different depending on depth. It suggests that l_m cannot be estimated by q and N only but may also be influenced by other factors, such as z .

On the other hand, l_d reveals a temporal variation that is apparently unrelated to l_b . The initial decrease of l_d at $z > 7.5$ m can be understood from the fact that large eddies from the surface, including LC, are broken down

FIG. 5. Profiles of the terms of TKE budget (F , thick solid; P_s , dashed; P_b , dotted; ε , thin solid; P_L , dash-dot-dash).

by the formation of a thermocline rather than scaled by l_b or l_s .

c. TKE budget

The TKE budget in the presence of LC and WB can be derived from (1) as

$$\frac{\partial E}{\partial t} = F + P_s - P_b - \varepsilon + P_L + W\delta(z) \quad (3)$$

under the horizontally homogeneous condition, where E ($= \overline{u'_i u'_i}/2$) is TKE, F [$= -\partial\Pi/\partial z = -\partial(\overline{\pi'w'} + u'_i \overline{w'}/2 - 2\overline{u'_i s'_{i3}})/\partial z$] is the divergence of TKE flux Π , P_s ($= -\overline{u'w'}\partial U/\partial z - \overline{v'w'}\partial V/\partial z$) is shear production, P_b ($= -\overline{b'w'}$) is decay by buoyancy, ε is dissipation, P_L [$= u_s \partial(\overline{u'w'})/\partial z$] is the contribution from the vortex force (see, e.g., Kantha and Clayson 2000), and W is the TKE influx at the surface from wave breaking. Here u'_i , π' , and b' are fluctuating components of velocity, generalized pressure, and buoyancy, and $s'_{ij} = (\partial u'_i/\partial x_j + \partial u'_j/\partial x_i)/2$. Noh et al. (2004) showed that W from a random forcing X_i in (1) is evaluated as αu_*^3 with $\alpha \cong 40$. Because W dominates TKE production near the surface, the integration of (3) over an arbitrarily small depth δ from the surface leads to $\Pi(\delta) \cong W$ from $\Pi(0) = 0$. Therefore, W can be regarded as the surface boundary condition of Π rather than a separate term in the TKE budget, if we only consider the TKE budget below $z = \delta$.

Profiles of the terms in the TKE budget in the ocean mixed layer at $t = 8$ h, shown in Fig. 5, reveal that TKE production is dominated by F within the mixed layer ($z < h$), whereas the local balance $P_s - P_b - \varepsilon = 0$ is observed at the thermocline, as suggested by Noh

FIG. 6. Evolution of vertical profiles of B with time ($\Delta t = 1$ h, and the dotted line represents $t = 0.5$ h): (a) EXP O, (b) EXP W, and (c) EXP L.

FIG. 7. Profiles of the terms of TKE budget: (a) EXP O, (b) EXP W, and (c) EXP L (F , thick solid; P_s , dashed; P_b , dotted; ϵ , thin solid; P_L overlaps with F in EXP L).

FIG. 8. Time series of physical variables at $z = 12.5$ m (EXP LW, thick solid; EXP L, dashed; EXP W, thin solid; EXP O, dotted): (a) R_f , (b) R_i , and (c) $w^2/(\overline{u^2} + \overline{v^2})$.

(1996). It is also found that P_L is much smaller than F within the mixed layer and becomes negligible at the thermocline.

d. Effects of wave breaking and Langmuir circulation

Simulations were also performed in the absence of WB and/or LC to investigate their effects. Figure 6 shows the evolution of B profiles from experiments without both LC and WB (EXP O), with WB only (EXP W), and with LC only (EXP L).

Strong stratification appears near the surface without forming a diurnal thermocline in EXP O, similar to the atmospheric boundary layer (Fig. 6a). In this case, the maximum values of both S^2 and N^2 appear near the surface. It is important, however, to mention that the case corresponding to EXP O actually occurs in the ocean under the very weak wind stress in which WB and LC cannot occur. For example, Soloviev and Lukas (1997) observed that strong stratification near the sea surface appears during calm weather in the western equatorial Pacific warm pool. A diurnal thermocline is generated in EXP L and EXP W (Figs. 6b,c), although the depth of

the thermocline from EXP W and EXP L is slightly shallower than in the case where both WB and LC are present (EXP LW; Fig. 2a). It should be mentioned, however, that, if Ho becomes very small ($Ho < -0.5$ at $La_t = 0.23$), LC breaks down and strong stratification appears near the surface in the case of LC only, similar to the case of EXP O (Min and Noh 2004).

The corresponding profiles of the terms of the TKE budget are shown in Fig. 7. In EXP O, shear production dominates TKE production, as expected, as in the atmospheric boundary layer, and $P_s - P_b - \epsilon = 0$ is observed from the surface. The case from EXP W is similar to that from EXP LW, although shear production is somewhat larger at the thermocline. On the other hand, EXP L suggests that the vertical transport of buoyancy and TKE by LC may play a similar role to the TKE flux. The existence of a small amount of F near the surface in EXP L reflects the strong TKE production near the surface by P_L , which can be inferred from the substantial increase of vertical TKE near the surface in the presence of LC (McWilliams et al. 1997; Noh et al. 2004; Li et al. 2005) and its downward transport by LC.

TABLE 1. Feedback mechanisms between P_b vs F and P_b vs P_s .

P_b vs F
Increase stratification by P_b ($N \uparrow$)
→ decrease TKE and eddy diffusivity ($K_h \downarrow$)
→ suppress TKE flux ($F \downarrow$)
→ decrease TKE and eddy diffusivity ($K_h \downarrow$)
→ increase stratification ($N \uparrow$)
•••
⇒ Positive feedback leads to the continuous decrease of TKE and K_h and increase of N at a certain depth
⇒ formation of a diurnal thermocline
P_b vs P_s
Increase stratification by P_b ($N \uparrow$)
→ decrease TKE and eddy diffusivity ($K_h \downarrow$)
→ increase velocity shear and shear production ($S \uparrow$, $P_s \uparrow$)
→ increase TKE and eddy diffusivity ($K_h \uparrow$)
→ decrease stratification ($N \downarrow$)
•••
⇒ Negative feedback leads to the local balance ($P_b - P_s - \varepsilon = 0$), which maintains N , TKE, and K_h at a certain level
⇒ growth of the thermocline thickness

The comparison of the time series of R_f , R_i , and r at the thermocline ($z = 12.5$ m) shows that the large values of these parameters at the initial stage appear only in EXPL and EXPLW (Fig. 8). It explains that these large values are due to LC, which causes the strong vertical component of TKE and strong vertical mixing without shear. On the other hand, the equilibrium values remain invariant, suggesting that they are determined by the interaction between turbulence and stratification and insensitive to the details of WB and LC.

e. Mechanism for the formation of a diurnal thermocline

Important questions arising from the diurnal thermocline formation shown in previous sections are why a thermocline appears at a certain depth (formation stage) and why the thermocline thickness grows with time thereafter (growth stage).

The fact that F disappears at $z = h$ (Fig. 5) suggests the role of F in the formation of a diurnal thermocline, whereas the growth of the thermocline thickness occurs under the condition $P_b - P_s - \varepsilon = 0$. Based on these features, each stage can be explained in terms of a different feedback mechanism, as summarized in Table 1 (Noh 1996).

According to the feedback mechanism presented in Table 1, under the interaction between P_b and F , TKE and K_h decrease and N increases continuously with time at a certain depth, leading to the formation of a diurnal thermocline across which fluxes of both buoyancy and

FIG. 9. Evolution of vertical profiles of B with time ($\Delta t = 1$ h, and the dotted line represents $t = 0.5$ h) (a) in the presence of radiation penetration and (b) under the diurnally varying surface buoyancy flux.

TKE are prohibited. On the other hand, under the interaction between P_b and P_s , the values of TKE, K_h and N are maintained at certain levels, and it allows the downward transport of buoyancy below the mixed layer.

These two different feedback mechanisms are also reflected in the evolution of ε shown in Fig. 2c. During the formation stage ($t < 2$ h), the positive feedback between F and P_b causes the decrease of ε with time, but during the growth stage ($t > 2$ h) it increases while approaching $P_s - P_b - \varepsilon = 0$ along with the increase of P_s . Noh (1996) also showed using the mixed layer model that the thermocline cannot increase its thickness in the absence of P_s .

FIG. 10. Time series of physical variables at $z = 12.5$ m (EXP LW, solid; EXP LW_R, dashed): (a) Rf, (b) Ri, and (c) $w^2/(u^2 + v^2)$.

The relation $Rf = 1 - \varepsilon/P_s$ can be obtained from $P_s - P_b - \varepsilon = 0$ at the thermocline. When P_s is the only TKE source, $\varepsilon = m_s P_s$ with $m_s \sim 0.5$ was suggested by Niiler and Kraus (1977) and Davis et al. (1981), which is also supported from Fig. 5. It implies $Rf \sim 0.5$ at the thermocline. On the other hand, within the mixed layer, the relation $Rf = 1 - \varepsilon/P_s + F/P_s$ is obtained, and a much larger value of Rf is expected because $F \gg P_s$ there. Figure 4c shows that $Rf(z = 3.25 \text{ m}) \cong 1.2$, $Rf(z = 7.5 \text{ m}) \cong 0.5$, and $Rf(z = 7.5 \text{ m}) \cong 0.4$. Because $Pr (\equiv K_m/K_h)$ remains invariant with time (Figs. 4h,i), $Ri [= Rf(Pr)]$ also remains constant (Fig. 4d).

f. Effects of radiation penetration and diurnal variation of heat flux

In the present work, the effects of radiation penetration have been neglected because it is not directly involved in the mechanism for the formation of diurnal thermocline by the interaction between turbulence and stratification. Nonetheless, the diurnal thermocline is usually formed at a shallow depth, so the effects of radiation penetration must be included for a realistic

prediction of the ocean mixed layer. For this purpose, Paulson and Simpson's (1977) formula type I was used, such as $R_{SW} = -I_0[0.58 \exp(-z/\zeta_1) + 0.42 \exp(-z/\zeta_2)]$, where I_0 is the surface irradiance, $\zeta_1 = 0.35$ m, and $\zeta_2 = 23$ m.

Figure 9a shows the evolution of buoyancy profiles obtained from the simulation corresponding to EXP LW, where radiation penetration is included (EXP LW_R). As expected, a large amount of buoyancy is transferred downward below the mixed layer, which makes $B(z = 0)$, corresponding to sea surface temperature (SST), substantially smaller than in Fig. 2. The thermocline also becomes slightly deeper because turbulence is less strongly suppressed by stratification. The general pattern of buoyancy profile evolution remains invariant, however. The time series of Rf, Ri, and r at $z = 12.5$ m follow a similar pattern, but their equilibrium values are slightly smaller (Fig. 10). It suggests that both N^2 and S^2 decrease at the thermocline in EXP LW_R, but $Ri [= (N/S)^2]$ tends to be smaller because radiation penetration allows the downward transport of buoyancy but not of momentum.

FIG. 11. Time series of physical variables at $z = 12.5$ m (EXP LW, solid; EXP LW_H, dashed): (a) Rf, (b) Ri, and (c) $w'^2/(\langle u'^2 \rangle + \langle v'^2 \rangle)$.

Also investigated was how the diurnal thermocline formation process is modified under the diurnal variation of the surface buoyancy flux. For this purpose the surface buoyancy flux was imposed in the form $Q_0[1 - \cos(2\pi t/T)]$ with $T = 8$ h, for the simulation corresponding to EXP LW. As expected, the initial thermocline formation is slower ($t \sim 2$ h) because Q_0 is smaller, but the stronger thermocline and higher $B(z = 0)$ appear when Q_0 is larger ($t \sim 4$ h; Fig. 9b). It is interesting to observe that $B(z = 0)$ decreases when Q_0 decreases after $t = 4$ h in spite of the continuous supply of buoyancy into the mixed layer, because the depth of the thermocline increases. The corresponding decrease of SST is also observed from observation data shown in Fig. 3 (1646 LT).

g. Sensitivity to the vertical resolution

Unlike the previous LES dealing with the homogeneous mixed layer (Noh et al. 2004), stratification is generated in the present LES. The vertical motion of eddies is suppressed under stratification, and the results

are more likely to be affected by the vertical resolution. Therefore, EXP LW was repeated with half the vertical grid size ($\Delta z = 0.625$ m; EXP LW_H).

The overall results shown in previous sections (Figs. 1, 2, 4, and 5) remain essentially invariant under EXP LW_H. Meanwhile, the vertical TKE at the thermocline is slightly larger in EXP LW_H, causing the slight decrease of Rf and Ri and the slight increase of r at the thermocline ($Ri \cong 0.25$, $Rf \cong 0.3$, and $r \cong 0.2$; Fig. 11). It is also found that the transport of heat and momentum to below the mixed layer is slightly delayed, as can be inferred from the large fluctuation of Rf at $z = 12.5$ m during the initial stage in Fig. 11.

4. Conclusions

Large-eddy simulation of the ocean mixed layer under a stabilizing buoyancy flux was performed. The formation of a diurnal thermocline was reproduced successfully, in agreement with observation and mixed layer model results. The analysis of the simulation result revealed that the formation of a diurnal thermocline

passes through two different phases: the formation of a thermocline (formation stage) and increasing thickness of the thermocline thereafter (growth stage). It was also found that the TKE flux divergence dominates TKE production within the mixed layer, but the local equilibrium $P_s - P_b - \varepsilon = 0$ is achieved at the thermocline. The turbulence maintained by the local equilibrium at the thermocline causes stratification below the mixed layer. Based on these features, two different feedback mechanisms that control the formation and growth stages were suggested (Table 1).

Various physical variables at the thermocline—such as S^2 , N^2 , Rf, Ri, K_m , K_h , vertical and horizontal TKE, and length scales—vary significantly during the formation stage, but they approach constant values in the growth stage thereafter. The development of S^2 lags behind N^2 by 0.5–1 h, causing the initial appearance of abnormally large values of Rf and Ri. The mixing length scale may be related to the buoyancy length scale $l_b (= q/N)$, but the dissipation length scale is not.

It was found that a diurnal thermocline cannot be formed in the absence of both WB and LC. In this case, TKE production is dominated by shear production near the sea surface, and strong stratification and shear appear near the surface, similar to the atmospheric boundary layer. Meanwhile, a diurnal thermocline is formed in the presence of either WB or LC only, although the depth of the thermocline tends to be shallower. Radiation penetration makes the depth of the thermocline slightly deeper and the values of Rf, Ri, and r at the thermocline slightly smaller.

The present work was focused on understanding the dynamical process of diurnal thermocline formation. For a realistic prediction of the response of the ocean mixed layer to the surface heating, however, it may be necessary to consider various other aspects, such as the appearance of strong stratification near the sea surface under calm weather and the generation, propagation, and breaking of surface gravity waves. It is expected that a similar mechanism underlies seasonal thermocline formation, but a separate study may be required for its understanding because of the much longer time scale and the diurnal cycle of heat flux. Meanwhile, further analysis of the LES data can be applied to elaborate the ocean mixed layer model, especially in the presence of WB and LC (e.g., Li and Garrett 1997; D'Alessio et al. 1998; Noh 2004; Kantha and Clayson 2004).
