ABSTRACT

A SOFTWARE SYSTEM FOR LARGE-SCALE STRUCTURAL OPTIMIZATION

**by
Keith MacBain**

This work is driven by recent developments in mathematical programming, the state-of-the-art of structural optimization, the spectacular performance of linear programming algorithms, and computer hardware developments which imply that applications of structural optimization might be used commonly in engineering design. Currently, there are few general purpose optimization routines available to the structural engineer and much of the work has addressed specific classes of problems. Further, there is little widespread use of the available routines, partly due to the large amount of familiarity one must have with the specific details of both the problem and the optimization method. In response, it is the intention here to prototype a software system that implements a general approach for structural optimization using the latest in mathematical programming techniques.

This work develops a general system that can be used for a variety of structural optimization problems in a manner analogous to the finite element method for structural analysis. The most commonly used structural elements, truss and beam, are included as well as techniques for plate optimization. Consideration is given to the software requirements of a general purpose structural optimization system and the demands of large structural systems typically encountered in design practice.

This general approach is aimed at using classical methods taken directly from the area of mathematical programming, specifically linear programming, which has seen considerable change in the last ten years. Here, sequential linear programming (SLP)

techniques are shown to handle a wide variety of structural constraints including stress constraints, displacement constraints, buckling, and frequency constraints. It is the purpose of this thesis to bring the latest developments in linear programming to the field of structural optimization in the form of a general purpose, state-of-the-art structural optimization system. The model was tested for sample structures and it was shown to effect a reduction in total structure volume of up to 80%.

BIOGRAPHICAL SKETCH

Author: Keith MacBain
Degree: Doctor of Philosophy in Civil Engineering
Date: May 2001

Undergraduate and Graduate Education:

- Doctor of Philosophy in Civil Engineering,
New Jersey Institute of Technology, Newark, NJ, 2001
- Master of Science in Structural Engineering
New Jersey Institute of Technology, Newark, NJ, 1997
- Bachelor of Engineering in Civil Engineering
New Jersey Institute of Technology, Newark, NJ, 1996

Major: Civil Engineering

Presentations and Publications:

Stop, look, listen.

ACKNOWLEDGMENT

I would like to express my deepest gratitude to Dr. William Spillers who served as more than my advisor over the years. His wisdom is great and I consider myself fortunate to have worked with him. Dr. M. A. Saadeghvaziri has also been a continual source of inspiration and direction and it has been a pleasure to know him. Special thanks are also given to committee members Dr. C. T. Thomas Hsu, Dr. John R. Schuring, and Dr. John Tavantzis for their valuable support and guidance. I also wish to thank Dr. David Perel for his unfailing assistance and immeasurable expertise, both of which were instrumental in making this work possible. He is truly a gem, not often found. The financial support received through a Presidential Fellowship cannot be overlooked and is greatly appreciated. Additionally, the help and support from graduate students Selahattin Ersoy and Alireza Yazdani–Motlagh was most encouraging.

CHAPTER 1 INTRODUCTION

This thesis is concerned with structural optimization, which is formulated as a mathematical programming problem as

$$\begin{aligned} & \text{Minimize } f(x) \\ & \text{subject to } g_i(x) \leq 0; \quad i=1, \dots, m \end{aligned} \tag{1}$$

Typically the objective function f represents the volume of material and the constraints g refer to the equations of structures and requirements concerning stresses and displacements although other objective functions and constraints are possible as the examples of this thesis indicate. It is a fact that no robust algorithm exists which will solve large-scale structural optimization problems. Were that not the case there would be no point to this thesis.

The overall goal of this thesis then is to design a software system which has the potential of mirroring the finite element packages now on the market. These packages are very robust (they solve a wide class of problems), they are inexpensive to use and therefore available to the general engineering profession for common applications, and they can handle large practical problems. The success of these finite element packages incidentally derives largely from our success with solving large systems of linear equations.

Optimization problems are generally more difficult than the problems typically dealt with using the finite element method. This is certainly clear of problems of linear stress analysis in which the solution of a single system of linear equations is involved. Generally linear mechanics problems have a unique solution which is of course not the case in problems of structural optimization. And in the past there have been difficulties

with finding optimization algorithms that work. That was certainly the case up to the 1990's when problem sizes numbered in the tens of equations.

During the 1990's there was a conjunction of activities that gave new hope to mathematical programming problems. The most obvious of these was the advances in computer hardware which decimated old concerns over problems of computer storage capacity. And of course computer speeds increased dramatically. The second development of the 1990's had to do with the so-called interior point methods which seem to have derived from the work of Karmarkar in 1984. Karmarkar showed that it could be more efficient to move through the interior of the feasible region when solving an optimization problem rather than staying on the boundary of it. His work had the added advantage of reducing linear programming problems to the solution of linear equations, where we have become very efficient.

Linear programming (LP) has always remained something of an enigma in the mathematical programming world. While general-purpose mathematical programming algorithms were dragging along having difficulties solving even small problems, linear programming algorithms were successively solving much larger problems. That remains the case today where LP problems with 12 million variables are cited [Bixby] and LP problems with thousands of variables have become routine. It is not surprising then that sequential linear programming (SLP) algorithms are proposed here for a general-purpose structural optimization system.

In the work that follows, a rather general description of structural optimization is first presented, then an SLP algorithm is proposed as a general purpose solver, next the outline of a general purpose software system for structural analysis is proposed, and

finally some typical applications are presented. In summary, this thesis presents a prototype of a general-purpose software system for structural optimization.

CHAPTER 2

STRUCTURAL OPTIMIZATION

The goal of structural optimization, as defined here, is to improve some initial structural system and ultimately identify a best design within a given set of constraints. It should be noted that although the equations of structures are often linear, the functional dependence of structural problems on design parameters is typically nonlinear, implying that most structural optimization problems are nonlinear programming problems. Developing a software system to solve structural optimization problems under a wide variety of constraints is the main focus of this thesis.

2.1 Previous Work and State-of-the-Art

Clearly, for structural optimization, an algorithm of some sort is required since the exhaustive search method is prohibitive for all but the most trivial problems. The total number of unique structures one can construct is an exponential function with the number of variables as the exponent and the number of possible values a variable can have as the base. Consider for example a simple structure with six variables (e.g., member sizes) and 10 possible values for each variable. In this case there are one million (10^6) distinct combinations, all of which must be evaluated for an exhaustive search to be carried out. Because this number increases exponentially with the number of variables, one can easily see that there should be a defined method to identify the optimum design.

In the most common formulation, the design variables are member sizes (i.e., cross sectional area) and the constraints are normally limits on member stresses or displacements. Often, weight or volume is minimized as this is a measure of the material used and thus the total cost. This basic problem is the focus of many optimization studies

due to its convenient formulation but there are many other factors that influence the total cost of a real structure. There has been work on more practical versions of structural optimization problems such as construction cost [Xu, 1995]. Other optimization problems commonly considered are shape [Pedersen, 1973] where the geometry of the structure is varied, and topology where the member connectivity is allowed to change. Additionally, specific dynamic properties of the structure such as frequency can be considered [Cassis, 1976; Xie, 1994].

In terms of existing software systems, some commercially available computer analysis programs such as ANSYS use sequential unconstrained minimization techniques (SUMT). These methods convert a constrained optimization problem into an unconstrained problem by introducing a penalty that adversely affects the objective function when constraints are violated. This allows for a very general formulation but is not however, entirely reliable and has been noted to be computationally expensive. This is because the approach overlooks the nature of the problem and computes the gradients numerically, a computationally expensive procedure. Furthermore, the number of independent variables is normally so limited that large-scale problems are not possible. Implementations such as ANSYS can strongly limit the number of variables one can use.

The most effective software now available uses what are called optimality criteria methods. These methods are typically heuristic and cannot be used in a general algorithm because they require the formulation to change as the objectives and constraints are varied. These methods are based on developing a condition that will be satisfied at the optimal point and then using this condition to construct an iterative scheme. Unfortunately, as the objective or constraints change, so does the optimality condition and thus a different optimality criteria is required. One detailed report [Rozvany, 1993]

expresses several formulations that can be used with different constraints but it is noted that each different set of constraints results in a different formulation. This does not lead to a single method applicable for a wide variety of problems.

The system MBB-LAGRANGE [Hornlein, 1993] uses a variety of methods including penalty, sequential linear programming, multiplier, optimality criteria, and reduced gradient methods. A numerical comparison of optimization methods was done [Schittkowski, 1994] with this package comparing the performance of several algorithms on 79 test problems including seven real-life problems ranging from one to 144 design variables and two to 2,136 degrees of freedom. In this work, no single algorithm was reported to solve all problems, further illustrating the need for a more robust approach. Recursive quadratic programming showed the best performance in this respect and was able to solve all but 13 problems within the specified accuracy and number of iterations. The authors did note, however, that there was no effort made to tune the control options and that an experienced user could obtain better results.

Another system, IDESIGN uses four state-of-the-art nonlinear optimization algorithms with efficient and reliable implementations [Arora, 1989]. This program allows the user to include subroutines that describe the specifics of a design problem and is structured to include a general-purpose interactive capability. This general-purpose optimization program has been under development since the late 1970's and has a wide range of options, including the ability to perform dynamic response optimization such as vibration isolation and designs for earthquake resistance among others.

Research with genetic algorithms (GA) has shown good results (e.g., Camp, 1998) and there are several advantages to using this approach. One of the strongest points is the ability to search the entire design space and thus possibly locate a global

minimum, even if it is a singular case (e.g., Sved, 1968). Another benefit is the ability to identify a number of good solutions rather than a single best solution. Furthermore, it is very easy to optimize with respect to a discontinuous set of design variables, a feature very useful for structural design where members are normally available in a finite number of sizes. Unfortunately, there is no guarantee that an optimal point will be obtained and it has been noted that GA can be computationally intensive. Additionally, there is no guarantee of feasibility or even progress at any given iteration and because of this, GA are not considered in this work.

It is not clear at this point what methods are most commonly used in practice although it is known that many real-life designs do not include any form of computer-based optimization effort. Often, the greatest effort in this regard is the engineering judgment of the designer. It has also been interpreted from the literature that most applications which do involve optimization use "in-house" programs that are written specifically for the needs of the user and are often neither freely available nor general purpose.

2.2 Structures as a Mathematical Programming Problem

Mathematically, the optimization problem can be expressed in the most general form as

$$\begin{aligned} & \text{Minimize } f(x) \\ & \text{subject to } g_i(x) \leq 0; \quad i=1, \dots, m \end{aligned} \quad (2)$$

where f is a scalar objective function of x , a vector of design variables and g_i represents one of the m constraints. In the above representation, both f and g are considered to be general nonlinear functions. In this work, the objective function f is taken as the total

structure weight. It is noted that although structural weight is an important part of the total cost of the structure, it clearly is not the only possible objective function to use. The set of constraints g is normally a vector but may be a scalar if there is only one constraint. In this context, a constraint is a upper or lower limit on a single structural response quantity and each additional constraint will add to the total number of constraints equations m . For example, one constraint might be an upper limit on the stress in a specific member. Given that there are normally several constraints on a structure, the dimension of g can be large.

In order to consider an optimization problem, there must exist more than one possible choice of designs, implying a statically indeterminate structure. Typically, there are a number of vectors, x that will satisfy the constraints, g . The collection of all such vectors is termed here the feasible space and the boundaries of this space will be referred to as the constraint surface. This space is not easily quantified in a general sense for all structures because it involves not only the constraints which are included but also the structure itself.

Some structural optimization problems have been shown to have isolated points, meaning here that the constraint surface is not connected. Specifically, in a case of two loading conditions [Spillers, 1975], as one approaches the optimal point with an arbitrarily small step, the objective is increased rather than decreased. In this case, it is because in the optimal solution, the cross sectional area of one member is zero which can be thought of as a discontinuity in the structure. Additionally, although there are specific cases of displacement related and frequency constraints that have been shown to be convex [Svanberg 1984], the solution space of a typical structural optimization problem is not convex.

2.3 Structural Equations

There are three different types of structures considered in this work, which also represent a majority of the commonly used structural analysis elements. These are the trusses, frames, and plates. Structural analysis is a well developed area and there are many texts [Wang, 1984] the reader can refer to for more information on the details and differences between them. For this work, the materials are assumed to be linear and elastic although non-linear geometry is also considered. For all of these structural elements, the following matrix equations apply.

$$\begin{aligned} N^T F &= P \\ F &= K \Delta \\ \Delta &= N \delta \end{aligned} \quad (3)$$

In the above, N is a transformation matrix that relates the local and global coordinate systems, F is a column vector of the member forces (internal forces), and P is a column vector of the nodal loads (applied loads). The matrix K is the primitive element stiffness matrix in the local element coordinate system, Δ is a column vector of the element displacements, and δ is a column vector of the nodal displacements. The first equation above represents force equilibrium at all joints (nodes), the second is a constitutive equation relating the element forces and the element displacements, and the third represents compatibility. These equations can be assembled to form the basic system of equations for linear elastic structures

$$\begin{aligned} N^T K N \delta &= P \\ K_E \delta &= P \\ K_E &\equiv N^T K N \end{aligned} \quad (4)$$

which defines the positive-definite elastic stiffness matrix, K_E .

Response quantities of the structure under some loading are termed here as state variables. These are variables that are dependent on the design variables. With these equations, one can now express the change in a state variable with respect to a change in a design variable. These are the terms that are needed to form a linear approximation of the constraints.

2.3.1 General Constraint Gradients

It will be seen later that it is necessary to express the constraints above in the Taylor series which requires the gradient of the constraints. This can be computed numerically through any number of numerical techniques but this procedure is normally computationally expensive and thus, best avoided. Fortunately, the gradients of structural equations can typically be expressed in a closed form and thus it is possible to obtain the gradients explicitly by simply differentiating equations (3).

Here, the general approach for explicitly obtaining the gradients is shown and specific equations are given in sections relating to each type of structure. Not all possible gradients are shown here, although the derivation is similar. When the member geometry is fixed, the three relations given in equations (3) above can be differentiated to obtain

$$\begin{aligned} N^T dF &= 0 \\ dF &= dK \Delta + K d\Delta \\ d\Delta &= N d\delta \end{aligned} \tag{5}$$

The above equations can be used to form any of the required gradients. For example, the change in joint displacement, $d\delta$ due to a change in member stiffness dK can be expressed using equations (3) and (5) as

$$\begin{aligned}
N^T dF &= 0 \\
N^T (dK \Delta + K d\Delta) &= 0 \\
N^T dK \Delta &= -N^T K N d\delta \\
d\delta &= -K_E^{-1} N^T dK \Delta
\end{aligned} \tag{6}$$

Similar expressions will be shown for other quantities relative to their specific structure types as discussed later. Additionally, the derivative of the stiffness matrix, dK mentioned in equation (5) will also be shown as it specifically is related to each structural element.

2.3.2 Geometric Nonlinearities

Geometric nonlinearities are considered in this work through the addition of a geometric stiffness matrix, K_G . Several references are available for the formulation of this matrix, sometimes termed the stress–stiffening matrix. This will be shown later for each element type that it is used but here, the change in the basic system shown in equation (4) is described. Essentially K_G is added to the elastic stiffness matrix to form

$$(K_E + \lambda K_G) \delta = P \tag{7}$$

If the displacements are small, an eigenvalue analysis can be performed where λ represents a critical load factor.

2.3.3 Truss Structures

The truss element is the simplest of the structural elements considered here. It is a line element with only axial stiffness. In two dimensions, each unsupported node of a truss structure has two displacement degrees of freedom and in three dimensions, each node will have three degrees of freedom. It is often modeled as an axial spring and the element

has one degree of freedom in its local coordinate system, displacement along the axis of the element. The primitive stiffness matrix, K for the structure is diagonal and each row contains a term K_i corresponding to element i shown here as

$$K_i = \left[\frac{A_i E_i}{L_i} \right] \quad (8)$$

Element i contributes to the transformation matrix N a sub-matrix corresponding to the positive and negative ends of that element. Each sub-matrix has two terms determined from the member geometry.

$$N_i^+ = \begin{bmatrix} \cos(\alpha_i) \\ \sin(\alpha_i) \end{bmatrix}^T \quad N_i^- = \begin{bmatrix} -\cos(\alpha_i) \\ -\sin(\alpha_i) \end{bmatrix}^T \quad (9)$$

If the member geometry is fixed and the objective function is the total structure volume or weight, the independent variables are the member areas. The objective function f of equation (1) is then linear in these variables and the constant multiplying each variable is normally taken as the member lengths. If different material densities exist, one can include a factor reflecting the respective densities and easily get the total structure weight. As required by equation (5) the differential dK is shown here

$$dK = \frac{\partial K}{\partial A} dA \quad (10)$$

Thus the terms in the derivative of the member stiffness matrix K with respect to the independent variable, the member area A are shown as

$$\frac{\partial K_i}{\partial A_j} = \begin{cases} \frac{E_i}{L_i} & \text{for } i=j \\ 0 & \text{for } i \neq j \end{cases} \quad (11)$$

The derivative of an $m \times m$ matrix (e.g., the stiffness matrix K) with respect to an $m \times 1$ vector (e.g., the member areas A) is a set of m matrices, each with dimension $m \times m$. This set of matrices cannot be written conveniently but as seen in equation (6), it is normally multiplied by the vector of member displacements Δ . Thus, the terms of this product can be neatly collected in a single matrix. The result is a matrix with the number columns is equal to the number of free variables (e.g., members) and the number of rows equal to the number of members multiplied by the number of displacements an element can have, in this case one. Column j of this single matrix is shown here as

$$\Phi_j = dK_j \Delta \quad (12)$$

where dK_j is obtained from equation (11). This results in a highly sparse matrix, in fact for the truss element discussed here it is diagonal, so the computer implementation of this (mentioned later) is done with a vector, although in the following equations it should be thought of as a matrix with the dimensions noted above.

Joint displacement constraints are examined first. Here the joint displacement δ is a vector with one term for each degree of freedom and it is desired to constrain some or all of them to be within some upper and lower limits. With equations (6) and (12), the change in joint displacement $d\delta$ due to some change in member area (i.e., stiffness) dA can be expressed through

$$\begin{aligned} d\delta &= \frac{\partial \delta}{\partial A} dA \\ &= -K_E^{-1} N^T \phi dA \end{aligned} \quad (13)$$

Similarly, the change in member displacements $d\Delta$ is shown as

$$\begin{aligned}
 d\Delta &= \frac{\partial \Delta}{\partial A} dA \\
 &= -N K_E^{-1} N^T \phi dA
 \end{aligned}
 \tag{14}$$

Equations (13) and (14) describe the change in the entire set of displacements due to a change in member stiffness. Each of these shows the inverse of the structural stiffness matrix in the equation. This is the formulation used in this work, largely for the simplicity of implementation. However, it is known that matrix inversion is a costly procedure and for greater efficiency, an implementation that does not require the inverse is possible.

Allowable stress constraints can be handled in two ways. One can first note that for member i , the stress in that member is defined as

$$\sigma_i = \frac{F_i}{A_i}
 \tag{15}$$

A simple substitution is made for convenience, such that S represents a diagonal matrix with the member areas along the diagonal and zeros elsewhere. With this, the change in member stress can be expressed by application of the chain rule as

$$\begin{aligned}
 S_i &= \frac{1}{A_i} \\
 d\sigma &= S dF + dS F
 \end{aligned}
 \tag{16}$$

Implementation of equation (16) has been shown to work in the examples discussed late but a second, more efficient method of dealing with stress constraints is to note that the stress in a member can be related to the displacement as shown

$$\begin{aligned}\Delta &= \frac{F L}{A E} \\ \sigma &= \Delta \frac{E}{L}\end{aligned}\tag{17}$$

In other words, one can simply express allowable stress constraints in terms of allowable displacements multiplied by the constant E/L and the change in Δ is shown above in equation (14). Such a substitution can either be done by the user explicitly or handled in the software.

At times it may be desired to limit the force in a member to a certain value. This case is different from those previously mentioned because here it is possible to specify constraints that cannot be satisfied. To illustrate this, consider the case of a determinant bar with an axial load. As the area is changed, so is the member stress but clearly the force in the member is constant. Thus, it is possible to impose constraints on the level of forces on individual members in a structure but one should note that it is easily possible to create a problem that cannot be solved. When these are included, the change in member forces is expressed by

$$dF = (I - KNK_E^{-1}N^T)\Phi\tag{18}$$

where I represents an identity matrix.

Local member buckling is defined here for a truss as when the compressive force in a member exceeds the Euler buckling load $\pi^2 EI/L^2$. This requires the section constant I which is often not included in truss analysis. However, one can assume that the second moment of inertia of the cross section I is related to the section area by

$$I = c_0 A^{c_1}\tag{19}$$

Given this, one can proceed with buckling constraints in the same manner as force constraints although in this case, only a lower limit would be provided indicating a compressive force.

2.3.4 Frame Structures

The frame element is a line element similar to the truss but with axial, shear, and flexural resistance. It is often referred to as a beam element and both two and three dimensional frame elements are considered here. The main difference between these two is that for the latter, torsional resistance is included. Additionally, the three dimensional frame element has flexural terms corresponding to bending about two different axis, both perpendicular to the axis of the element whereas the two dimensional element only has terms corresponding to bending about one axis. Axial stiffness is included in both cases.

The two dimensional beam element has three degrees of freedom at each node. These are displacement along the axis of the element, displacement perpendicular to the axis, and rotation of the node. Element i contributes to the total primitive stiffness matrix K the following 3x3 sub-matrix located on the diagonal.

$$K_i = \begin{bmatrix} \frac{AE}{L} & 0 & 0 \\ 0 & \frac{4EI}{L} & \frac{2EI}{L} \\ 0 & \frac{2EI}{L} & \frac{4EI}{L} \end{bmatrix} \quad (20)$$

Similarly, the transformation matrices relating the local and global systems for the positive and negative ends of member i are given below.

$$N_i^+ = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \frac{1}{L_i} & -1 \\ 0 & \frac{1}{L_i} & 0 \end{bmatrix} \quad N_i^- = \begin{bmatrix} -1 & 0 & 0 \\ 0 & \frac{-1}{L_i} & 0 \\ 0 & \frac{-1}{L_i} & -1 \end{bmatrix} \quad (21)$$

The member displacement matrix Δ shown in equation (3) contains a single sub-matrix for each element. The sub-matrix corresponding to member i is

$$\Delta_i = \begin{bmatrix} dx \\ \alpha^+ \\ \alpha^- \end{bmatrix} \quad (22)$$

where dx is the elongation of a member along its axis and α is the angle of rotation at the positive and negative ends. This angle is measured between a line tangent to the deformed member shape at that end and a line connecting the two nodes. For frames, the member stiffness matrix is no longer a linear function of the cross sectional area. This is because the second moment of inertia of the cross section I also appears in the matrix. In this work, the second moment of inertia, I is assumed to be related to the area by the equation

$$I = c_0 A^{c_1} \quad (23)$$

where c_0 and c_1 are constants that can be determined for a given family of beams or columns.

The geometric stiffness matrix K_G used for this element models large displacements and small strains. Note here that it depends only on the member force and length.

$$K_G = \frac{F}{30L} \begin{bmatrix} 0 & 0 & 0 \\ 0 & 36 & -3L \\ 0 & -3L & 4L^2 \end{bmatrix} \quad (24)$$

The first two terms of the change in member stiffness per a change in cross sectional for the 2D frame element can be expressed as

$$\frac{\partial K_i}{\partial A_i} = \frac{2E c_0 c_1}{L} \left\{ \begin{bmatrix} 1 & 0 & 0 \\ 0 & 2A^{(c_1-1)} & A^{(c_1-1)} \\ 0 & A^{(c_1-1)} & 2A^{(c_1-1)} \end{bmatrix} + (c_1-1) \begin{bmatrix} 0 & 0 & 0 \\ 0 & 2A^{(c_1-2)} & A^{(c_1-2)} \\ 0 & A^{(c_1-2)} & 2A^{(c_1-2)} \end{bmatrix} + \dots \right\} \quad (25)$$

Here, the second term is shown because it is possible to include the second order effects as will be discussed later. Furthermore, if $c_1 = 2$ as is commonly the case, using the first two terms is exact.

The three dimensional frame element is very similar to the 2D element just discussed. The 6 x 6 stiffness matrix for this element is essentially expanded to include the extra flexure, shear, and torsional stiffnesses.

$$K_i = \frac{1}{L} \begin{bmatrix} AE & 0 & 0 & 0 & 0 & 0 \\ 0 & I_x G & 0 & 0 & 0 & 0 \\ 0 & 0 & 4EI_y & 0 & 2EI_y & 0 \\ 0 & 0 & 0 & 4EI_z & 0 & 2EI_z \\ 0 & 0 & 2EI_y & 0 & 2EI_y & 0 \\ 0 & 0 & 0 & 2EI_z & 0 & 4EI_z \end{bmatrix} \quad (26)$$

Additionally, because there are more cross sectional properties, the number of equations that relate them to the cross sectional area should also be increased. The following equations are used

$$\begin{aligned}
 I_x &= c_0 A^{c_1} \\
 I_y &= c_2 A^{c_3} \\
 I_z &= c_4 A^{c_5}
 \end{aligned}
 \tag{27}$$

where I_x is the torsional constant and I_y and I_z are the flexural constants. This provides for a more generalized approach because each section property can be defined by different functions if desired.

2.3.5 Buckling and Second Order Terms

If an optimal design is sought with respect to the buckling load, it is necessary to express the change in this factor with respect to a change in the design variables. This is because as the material is redistributed, the buckling load will likely change. However, the statement of the problem is normally such that the applied load is constant and the final design should simply support a that load without buckling, although it is implied that the critical load is near. The Rayleigh quotient for the eigenvalue problem in equation (7) gives the load factor λ

$$\lambda = - \frac{\delta^T K_E \delta}{\delta^T K_G \delta}
 \tag{28}$$

where in this case, δ represents the nodal displacements associated with the first mode shape.

As noted earlier, the member stiffnesses are not seen in the matrix K_G , which is a function of only the axial force and the member length. This is worth noting because although the member force does change with the member stiffness, this is ignored to

arrive at an approximation of the change in the load factor $d\lambda$ with respect to a change in the member stiffness.

$$d\lambda \approx \frac{-\Delta^T dK \Delta}{\text{constant}} \quad (29)$$

In equation (29), Δ is the set of member displacements associated with the first buckled mode shape, computed through the eigenvectors of equation (7).

It is trivial to ensure that a loading on an initial structure is at or below the critical load by simply scaling the structure. This will give an initial load factor that is greater than or equal to one and the change in this load factor should be greater than or equal to zero, indicating that the critical load has increased. Note that equation (29) contains the set of independent variables (e.g., member areas) through dK which was shown in equation (10) and thus resistance to global buckling can be expressed in a single constraint: the change in the load factor $d\lambda$ should be greater than or equal to zero.

Even though linear approximations are being used, it is possible to include the effects of second order terms. This is considered because the stiffness matrix for the frame element contains terms which are a second order function of the member areas. The approach used here is to approximate the second order terms but still have a linear expression by modifying the Taylor series approximation

$$\begin{aligned} f &\approx f_o + \nabla f dx + \frac{1}{2} dx_o^T \nabla^2 f dx \\ &\approx f_o + \left[\nabla f + \frac{1}{2} dx_o^T \nabla^2 f \right] dx \end{aligned} \quad (30)$$

where in this case, dx_o is obtained iteratively to complete the linear expression in equation (30).

Clearly, the "exact" solution yields $dx_0 = dx$ so to approach this, one begins with the arbitrary assumption that $dx_0 = 0$, solves the optimization problem discussed later, and then sets $dx_0 = dx$. This forms a new expression from which a new dx is computed and completes one iteration. The function f being approximated here is the change in the member stiffness with respect to the member areas so Equation (25) gives expressions for ∇f and $\nabla^2 f$. It was initially thought that the extra iterations to compute dx_0 might be rewarded by the possibility of using a larger step size at each iteration. Unfortunately, this was not observed in the examples shown later and this procedure is not recommended.

2.3.6 Plate Structures

Plate elements are not explicitly considered in this work. Rather, an analogy [Timoshenko, 1940] was used to correlate a thin plate and a grid of beam elements. Interestingly, this analogy allows for the consideration of anisotropic plates. Summarized here, the familiar elasticity equations

$$\begin{aligned}\sigma_x &= \frac{E}{(1-\nu^2)}(\epsilon_x + \nu\epsilon_y) \\ \sigma_y &= \frac{E}{(1-\nu^2)}(\epsilon_y + \nu\epsilon_x) \\ \tau_{xy} &= G\gamma_{xy}\end{aligned}\tag{31}$$

can be expressed for an anisotropic plate as follows.

$$\begin{aligned}\sigma_x &= E'_x\epsilon_x + E''\epsilon_y \\ \sigma_y &= E'_y\epsilon_y + E''\epsilon_x \\ \tau_{xy} &= G\gamma_{xy}\end{aligned}\tag{32}$$

This shows four constants for the material properties which are chosen to coincide with the planes of symmetry with respect to the elastic properties. If one considers an isotropic plate, the four material properties can then all be expressed in terms of the modulus

$$\begin{aligned} E'_x &= E'_y = \frac{E}{(1-\nu^2)} \\ E'' &= \frac{\nu E}{(1-\nu^2)} \\ G &= \frac{E}{2(1-\nu)} \end{aligned} \quad (33)$$

Similarly, the familiar plate constant D which depends on the material property E now has four terms in this analogy.

$$\begin{aligned} D_x &= \frac{E'_x h^3}{12} \\ D_y &= \frac{E'_y h^3}{12} \\ D_1 &= \frac{E'' h^3}{12} \\ D_{xy} &= \frac{G h^3}{12} \end{aligned} \quad (34)$$

This leads to the beam element analogy and from this, Timoshenko shows that the differential equation of the deflection surface w is

$$\frac{B_1}{b_1} \frac{\partial^4 w}{\partial x^4} + \left(\frac{C_1}{b_1} + \frac{C_2}{a_1} \right) \frac{\partial^4 w}{\partial x^2 \partial y^2} + \frac{B_2}{a_1} \frac{\partial^4 w}{\partial y^4} = q \quad (35)$$

In the above, $B1$ and $B2$ are the flexural rigidities of elements oriented in the x and y directions while $C1$ and $C2$ are the torsional rigidities.

The direct conversion between the optimal grid and an equivalent plate is not done here but the steps above clearly outline the procedure. With the methods outlined

here, plate optimization can proceed in the same manner as outlined for three dimensional frames.

CHAPTER 3

A GENERAL PURPOSE SOLVER

The characteristics of a good algorithm for design optimization have been noted [Arora, 1989] to be generality, efficiency, and ease of use. It is thought here that such an approach would focus more on the formulation of the optimization problem than the specific method to solve it. A method that can handle a variety of problems well is often termed robust, and there has been much call for methods that are more robust [Thanedar, 1990]. A general-purpose optimization system must handle a variety of problems without the need to reformulate the problem or have intimate knowledge of the feasible space.

The objective function considered in this work is the amount of material used while the constraints can be displacements, stresses, and buckling. The most commonly encountered structural elements, specifically linear elastic truss and beam elements, will be used. A key point of this work is that it recognizes the interactive nature of the design process. With a general-purpose system, the engineer can specify particular design variables and objective function to obtain an initial design and then impose further constraints, change the design variables, or modify the objective to improve the design from that point. A general-purpose system would allow the designer to make these changes without additional consideration of the specific method. It is hoped that the work presented here will gain wider acceptance among structural engineers and provide a useful design tool which is easy to understand and implement without a tremendous degree of investment to the intimate details of a given problem.

3.1 Linear Programming

The branch of mathematics known as mathematical programming deals with optimization problems. There are several classes of problems, including dynamic, linear, quadratic, and geometric which are categorized based on how the objective and constraints are expressed. There are continual advances in mathematical programming including methods and algorithms that have brought a powerful collection of tools to the area of optimization and made it possible to solve large problems with greater reliability and speed. While it is sometimes possible to express specific structural optimization problems in one of these classes, (e.g., Arora, 1984) only linear programming will be considered in this work.

The selection of linear programming (LP) for this work is based on several factors. Primarily, there have been significant advances made in recent years in the field of linear programming. As a result, linear programming has much to offer as a component of a general purpose structural optimization solver. Linear programming has a rich history and has been used extensively in fields such as operations research for many years. There is a great deal of research that has been done in this area and new algorithms will continue to arise as this is a commonly used tool in many areas. Additionally, it is possible to express a wide range of problems in this format by making linear approximations of a general nonlinear function, as is done in this work. It is thought that the choice of linear programming is consistent with the goal of developing a single unified approach to general structural optimization.

3.1.1 Basic Linear Programming

For an optimization problem to be considered a linear program, both the constraints and the objective should be linear functions of the design variables. The reader is referred to any number of texts for a more complete description but some of the more important points will be outlined here. A standard LP is most commonly expressed in the form

$$\begin{aligned} &\text{minimize} && c^T x \\ &\text{subject to} && Ax=b, \quad x \geq 0 \end{aligned} \tag{36}$$

Here A is a matrix while b , c , and x are vectors. It should be noted that the minimum of a function is equivalent to the maximum of the negative of that same function. This means that the problem shown above can be stated equivalently as maximizing the negative of the objective and it is common to see an LP in either form. Further, one should note that inequality constraints can be written as equalities by introducing slack or surplus variables, thus the above is a reasonably general form. Equation (36) is often termed the primal problem and all linear programs have a related dual problem, which may be expressed as

$$\begin{aligned} &\text{maximize} && b^T y \\ &\text{subject to} && A^T y \leq c \end{aligned} \tag{37}$$

In the dual problem, there is no restriction on the sign of the dual variables, y and this will be returned to later. The primal – dual relationship gives that although the primal solution x and the dual solution y will normally be different, the value of the objective function for each is the same. In other words, the minimum of the primal problem in equation (36) and the maximum of the dual problem in equation (37) have the same value.

Linear programming problems were first solved by the simplex method which guarantees that if a solution exists, it will be found in a finite number of steps. This method locates the optimal point by moving along the perimeter of the feasible region until a point is found for which no movement along the perimeter will improve the objective function. There are many references available [Taha, 1992] regarding the specific details of how to solve linear programming problems with the simplex method.

It will be seen later that the non-negativity requirements of equation (36) must be released because in the formulation used here, the solution may be positive or negative. This is different than the standard LP which uses non-negative variables. There are different methods for working with unrestricted variables, and sometimes a procedure is implemented in the program. The most common method is to make a variable substitution for each free variable

$$x_f = x_p - x_n \quad (38)$$

Here x_f is the unrestricted variable and x_p and x_n are both positive, consistent with equation (36). A solution obtained in terms of these transformed variables can then be used to construct the unrestricted variables using equation (38).

Obviously this substitution doubles the number of variables if all are taken to be free, as is normally the case. A second approach, not often seen in the literature, is to recall that there is no such restriction on the dual variables mentioned before with equation (37). One can simply formulate the problem in terms of the dual variables and the solution will not need to be transformed back into the original problem variables. Additionally, there is no need to double the number of variables in the problem. This is the approach used here. It should be noted, however that the methods presented here are not dependent on this method and if one desired, the first method outlined above could

be used. There are already several LP solvers that include free variables explicitly so this is not a concern with that type of algorithm. As more sophisticated LP solvers become commonly available, it is thought that free variables will be routinely included in the solver.

3.1.2 Interior Point Methods

The majority of work in mathematical programming in the last ten years has been in the area of interior point algorithms. As the name implies, these methods search for an optimal point while always remaining interior to the feasible region. This is in notable contrast to the simplex method and its variations which improve a design by moving along the perimeter of the feasible region. Interior point methods have been used for both linear and nonlinear problems [Byrd, 1999; Boggs, 1996] including structural applications [Jarre, 1998].

Among the advances in the area of linear programming, interior point methods are at the forefront of recent developments, and have been noted for superior performance when dealing with large problems. There has been much focus on these methods since their introduction [Karmarkar, 1984] and it is not uncommon to see test problems with several thousand variables. Systems as large as 12 million variables [Bixby, 1991] have been solved with interior point methods. With this computing power, solving real structural problems is certainly possible.

3.1.3 Operation and Solvers

It is interesting to note that although the solution to an optimization problem lies on the boundary of the feasible region, interior point methods search for this point without

traversing the perimeter. This is perhaps the most notable difference from the simplex method and its variants. The search direction is normally obtained from the objective but to maximize progress, the feasible space is scaled. Karmarker's early work is termed a polynomial-time algorithm because it promises that the run time is, at worst, a polynomial function of the storage needed for the problem data.

Like the simplex method, there are a number of steps involved in approaching the optimal solution but interior point methods never exactly reach the optimal point. One can approach the solution within an arbitrarily closeness but not actually reach it exactly. Some researchers have proposed a combination of the two methods to overcome this but for most practical applications, the exact solution is not required. In fact, in this work it will be seen later that computation time can be decreased by forgoing the exact solution without any noticeable loss. This makes interior point methods even more attractive for this application.

There are several good LP solvers available at this time and based on the current level of interest and recent advancements, the future of LP is very promising. For this work, a single LP algorithm was used. This work does not use more advanced solvers (e.g., Vanderbei, 1989) because these are normally not free. The algorithm used here [Arbel, 1993] is freely available and solves the dual problem shown in equation (37). It is known as an affine-scaling dual algorithm and was chosen because it is an efficient interior point method as well as easy to follow and program. Simply outlined here, the dual algorithm is an iterative procedure which follows the steps outlined in Table 1.

Table 1 Affine – Scaling Dual Algorithm Steps

Step	Description	Equation
1	Select an initial feasible point, $z_0 > 0$ and y_0 . Set the iteration counter $k = 0$	$A^T y_0 + z_0 = c$
2	Define the diagonal scaling matrix D for iteration k	$D_k = \text{diag} \left[\frac{1}{z_1^k}, \frac{1}{z_2^k}, \dots, \frac{1}{z_n^k} \right]$
3	Find the step direction dy by solving	$[A D^2 A^T] dy = b$
4	Find the step direction dz by solving	$dz = -A^T dy$
5	Compute the step size α	$\alpha = \min \left\{ \frac{-z_i}{dz_i} : \forall dz_i < 0 \right\}$
6	Update the solution through	$y_{k+1} = y_k + \rho \alpha dy$ $z_{k+1} = z_k + \rho \alpha dz$
7	Increment k and return to step 2 or terminate if stopping criteria are satisfied	

The full derivation of the steps in Table 1 can be found in Arbel's book but some points will be mentioned here. Note that in step 1, the inequality of equation (37) is changed to an equality by the addition of the slack variables z . These are strictly positive and thus so is the diagonal scaling matrix D defined in step 2. At each iteration, the linear system in step 3 must be solved, which is the most computationally intensive part. In step 6, the variable ρ is a step size parameter, typically taken to be 0.95 and always between zero and one.

This method is simple to code and implement. It does not perform any pre-solve analysis or employ other more sophisticated tools which are commonly found in other LP

solvers. Other methods could easily be incorporated to the procedures used here, although this is beyond the intention of this work. It should be noted however that as the field of LP advances, the methods presented herein could easily take advantage of more sophisticated solving routines.

3.2 Sequential Linear Programming

Although structures are normally considered linear, this linear relation is between the forces and the displacements. However, the member and joint displacements are not a linear function of the member stiffnesses. A general structural optimization problem to minimize the volume of material used subject to a given set of constraints is nonlinear. Specifically, the objective is linear but the constraints are nonlinear. The approach used in this work is to make a linear approximation of the constraints in the vicinity of an initial design and cast this as an LP. Solving the LP will give a step size and direction that should be near the constraint surface if the step size and the constraint nonlinearity are not too large.

Sequential linear programming is the method of optimization chosen for this work because it is possible to express a wide range of problems in this format. The basis of all formulations herein will be sequential linear programming (SLP) which can incorporate the state-of-the-art in linear programming algorithms. This approach involves making an approximation of the problem (1) and solving this approximate sub-problem at each iteration to obtain a better estimate of the solution.

A nonlinear function can be approximated with the first few terms of the Taylor series as

$$f = f_o + \nabla f dx + \frac{1}{2} dx^T \nabla^2 f dx + \epsilon \quad (39)$$

where ϵ represents higher order terms. Given an initial point f_o one can search for a step dx that will improve the objective while not violating the constraints. If only the first two terms of (39) are considered, the problem is linear in the step dx and an associated LP can be formed and then solved in a finite number of steps by a number of optimization routines.

The solution to this linear sub-problem will give a step toward the optimal point and this sequence is repeated until some convergence criteria are satisfied or for a specified number of iterations. For each step, the following linear approximation is made which converts the general nonlinear optimization problem to a problem which is linear in the step, dx .

$$\begin{array}{ll} \text{minimize } f(x) & \Rightarrow \text{minimize } \nabla f_o dx \\ \text{subject to } g_i(x) \leq 0 & \text{subject to } g_o + \nabla g_o dx \leq 0 \end{array} \quad (40)$$

One can easily note that the linear approximation in equation (40) can be cast into the dual LP form shown in equation (37) with the following substitutions.

$$\begin{array}{ll} b^T & = \nabla f \\ A^T & = \nabla g \\ c & = -g_o \end{array} \quad (41)$$

Thus, at each iteration to complete the linear approximation and set up the dual LP, one must compute the gradient of the objective ∇f_o , the matrix of constraint derivatives ∇g_o , and the negative of the constraints g_o . All of these are evaluated at this some initial point x_o . When the dual LP formed with equation (41) is solved, the dual variable solution y is

actually the step dx in equation (40) for iteration i . The system is then updated according to the following equation before the next iteration.

$$x_{i+1} = x_i + dx \quad (42)$$

The SLP method has been chosen here due to its widespread use in other areas and recent advances in linear programming resulting in a large number of efficient algorithms available to solve such problems. There exists a good deal of software available for this problem (e.g., More, 1993). The development of an LP solver is not the intention of this work as there is a great deal that has already been done in this area. It should be noted that with this approach, it does not matter if there are one or several constraints of a particular type as in the optimality criteria methods noted earlier.

It has been noted that SLP is not globally convergent, which means that the method will not necessarily converge to a unique global minimum from an arbitrary starting point. This is not thought to be a problem however, for two reasons. First, one cannot undermine progress that has been made solely because the solution is not guaranteed to be the absolute best. Certainly it is foolish to discard an improved design that satisfies a given set of constraints simply because there is no guarantee associated with it. Second, analogous to the way steepest descent methods will normally converge to a local minimum depending on the starting point, it is thought that such a flexibility might give the designer the possibility to direct the solution by using an appropriate starting point.

Because this is to be performed iteratively, it is not necessary to obtain the exact solution at any given iteration. This is only one of the most noticeable advantages of the interior point methods. Currently, the LP solver begins with a zero vector as the starting point. This is somewhat arbitrary however and it is possible that a different starting point

would lead to an earlier solution. It was noted that for some problems, the direction of the LP solution didn't change much from one iteration to the next. With this in mind, it is thought that using the previous solution as a starting point in the LP may be worthwhile.

The number of LP and SLP iterations are both controlled manually in this work but investigation into the LP solver and stopping criteria could be useful. Specifically, it was found in this work that one does normally not need the exact solution at a given iteration, thus possibly reducing the time to solve the LP. If some convergence criteria were used, both of these parameters could be selected automatically by the program. Although a parametric study would give more insight as to the optimal number, it was noted that the optimal number may change depending on the problem and thus is best determined by the program at run-time.

3.2.1 Step Size

For structural applications, it is necessary to specify an allowable step size (i.e., change in member stiffness) that can be made at any iteration. The most obvious reason for this is that without restrictions, a step outlined in equation (42) could possibly cause the result to be negative, which of course is not possible for member areas. Clearly this means the step size should be limited such that

$$\begin{aligned} dx_i &\leq \alpha x_i \\ dx_i &\geq -\alpha x_i \\ 0 &< \alpha < 1 \end{aligned} \tag{43}$$

where α is referred to later as the step size parameter.

A second reason, however to limit the step size is for stability. This is because the constraint surface is nonlinear and a step that may remain within the linear

approximation of this surface, could actually fall well outside, particularly if the constraints are highly nonlinear. Thus the limitation on the step is normally governed by how well the linear approximation fits the problem. For practical use, it was found that values up to 0.5 could be used for more well behaved problems but if the problem is more nonlinear, values as small as 0.05 were used.

3.2.2 Scaling

At each iteration, one should begin with a point just within the feasible region. This should not be confused with the feasible starting point interior point methods normally require to begin. Note that both the structure and the LP each have a feasible region. In the context of the LP, the feasible point can simply be taken as zero, analogous to a null hypothesis. Additionally, more sophisticated LP solvers will generate such a feasible point if needed. The structure however should be treated differently.

It is desirable to begin with a point near the constraint surface because the linear approximation of the surface is centered about this point. Obviously if it is near a constraint, the approximation should be better than if it is far away. Also, it is possible that the linear approximation of the previous step was poor and the structure currently violates some constraints. To scale the current design to be nearer the constraint surface, a scale factor ρ is found and the entire structure is scaled by this amount.

For most constraints such as displacement or stress, it is a trivial matter to obtain this scale factor that will give a feasible point. One simply performs a line search over the set of constraints to identify the largest violation. If no constraint violations exist, the constraint closest to its allowable value is selected. The scale factor ρ is thus computed as

the maximum ratio of the current value of a state variable to the allowable value over the entire set of constraints.

$$\rho = \max \left\{ \frac{\text{value}_i}{\text{allowable}_i} \right\} \quad (44)$$

The entire set of member areas can then be multiplied by this ratio. Beam elements are slightly more complicated because such a linear scaling is not necessarily exact. This is because some terms in the stiffness matrices in equations (20) and (26) are not linear in the member areas. If a higher order quantity such as joint rotation or member end rotations represents an active constraint, scaling should proceed according to the computed value ρ raised to the power c_l used in equation (23). This of course, is only exact for trivial problems but gives a much more useful approximation.

In practice, even if the exact scale factor is available, it is normally not advisable scale the structure to exactly that point. One reason for this is that computer implementations can fail when dealing with the exact value of real numbers due to machine round-off. By providing a point slightly inside the feasible region, one is guaranteed that all constraints are satisfied and that a pre-solve analysis to obtain a feasible point will not be required in the LP solver. Throughout this work, a second factor, ξ was used to ensure that the scaled structure was within the feasible region rather than exactly at the boundary. With this and equation (44), the update of the solution shown in equation (42) actually becomes

$$x_{i+1} = \frac{\rho}{\xi} (x_i + dx) \quad (45)$$

where ξ is always greater than or equal to one. To ensure that this new iterate is feasible before the next iteration, a line search is performed which scans the constraints for either the greatest violation or the nearest to a boundary.

The factor ξ can be thought of as an exploration factor, allowing one to travel away from the current point in a direction away from the zero vector into the feasible region. As this factor is increased, the design becomes be further away from the constraint surface and conceivably a different direction for the optimal could be found in the coming iteration. This would be expected if one were near a local rather than global optimum, but this effect was not found in the examples used. One should note however, that if this factor is increased, the step size should also be increased appropriately if one wishes to reach the constraint surface.

3.3 Software Considerations

This work relies largely on the implementation of the methods outlined above. There are several computer programs that were written to implement the procedures outlined earlier. All work was done in the UNIX environment on an UltraSparc computer system. Although many shell scripts were written to create and process data, the two most important aspects are considered to be the computational details and the graphical user interface (GUI), and the details of each will be discussed shortly.

Three main components of the conceptual software layout are seen in Figure 1. Note that it is not necessary to use the same language for all components and in fact, it is wise to exploit the advantages of different languages. The analysis components perform the finite element analysis required for the evaluation of structural quantities such as

displacements, stresses, and such. These results are needed as outlined above for the optimization component of the system. Thus, these two components are where the majority of the computational work is done and as such, should be linked together as closely as possible because if communication between them is slow (e.g., if data is written to the disk), the performance will suffer. The third component, the GUI, does not need to be intimately tied to the other two because its function is normally generation and post-processing, even though analysis capabilities were provided. Separating the components in this way allows for greater flexibility because other components can easily be added.

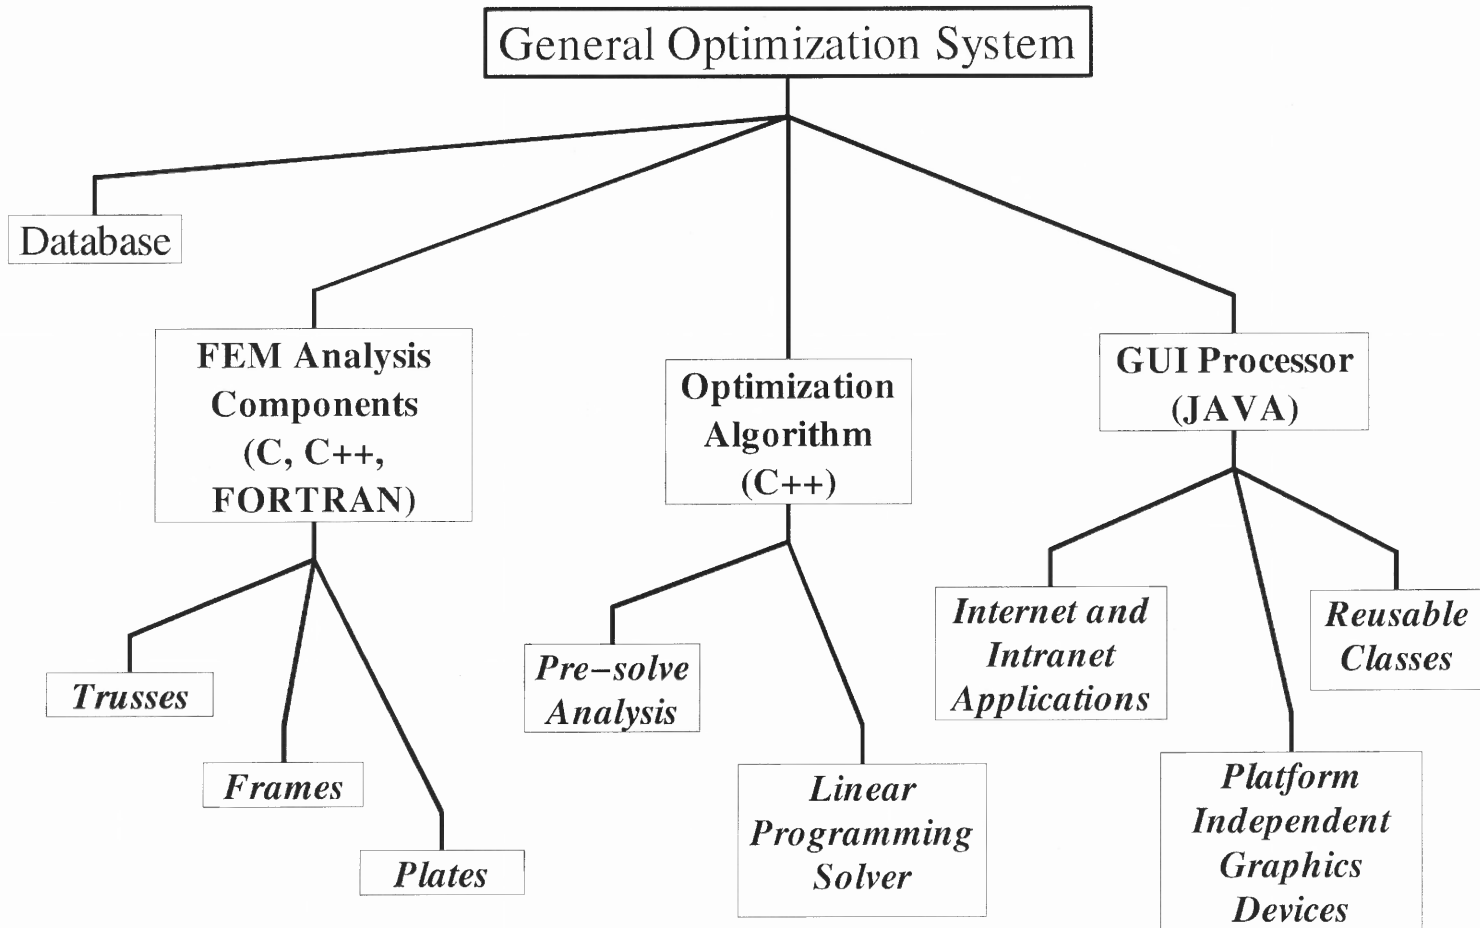

Figure 1 Conceptual Software Layout

Also shown in Figure 1 is a suggested point of entry for connection to a database, although this was not necessary here. It would be useful, however in real designs to obtain member sizes from a database because real member sizes belong to a discrete rather than continuous set. Even though the computed values may represent an optimal design, one needs to relate them to real values from a discrete set for any real structure. If these values were accessible through a database, the program could select among them. Such an implementation could possibly even favor less changes in member sizes, a real-world problem, by including that in the optimization problem.

3.3.1 Computational Details

The computer programming language C++ was used for all computational work and the code was compiled with the freely available GNU g++ compiler. C++ is a modern high-level object-oriented language. It supports inheritance, function and operator overloading, dynamic memory allocation, and several other features which are not used here. This is considered the best language for this application as it is common, well supported, easy to work with, and portable. Numerical precision can be greater than 96 bits, which is more than required here. Further, it is possible to incorporate routines written in other languages such as FORTRAN without loss of performance. The complete source code of the programs described here can be found in Appendix A.

One of the key features of the C++ programming language for this work is ability to allocate memory dynamically. As large systems are to be handled, large blocks of memory are often needed. However, it is desired not to request more memory than required for a given problem and there is no advantage in consuming large blocks of

memory for smaller problems. C++ provides a mechanism for exactly this task and all defined classes use it.

Similarly, overloaded functions can be written which have the same name but different parameter lists. This means that one can write the program once, overload the functions, and the appropriate one will be called based on the parameters. As an object-oriented language, user-defined classes can be constructed. A special class was created for each type structure investigated but as each can be derived from the same base class, object inheritance mentioned earlier means the main program doesn't need to be re-written based on the type of structure.

Although it is not strictly required for this work, a special class of object was created to simplify programming. This class was named 'matrix' and contains functions and overloaded operators to deal with the matrix equations. Overloading an operator allows the programmer to associate a symbol such as the plus sign with a function such as matrix addition. This simplifies code development because matrix equations can be written symbolically in the code rather than explicitly dealing with each individual element. Additionally, the strong type-checking system of C++ easily identifies erroneous statements. More importantly though, is the way memory can be handled when such a class is used.

The largest memory requirements of the program are in the matrices and it is important to deal with them efficiently. C++ supports two functions related to objects in general which are useful for this, specifically the constructor and destructor. In these, the programmer specifies what should be done when an object is created, destroyed, or its scope is lost. In this case, when a matrix is created, exactly the correct amount of space is requested for it. This means that memory is handled in an efficient manner because

specific requests for memory can be made at run-time when the exact requirements are known and memory can be released when it is no longer needed, even within a given function.

The details of the requests for memory are negotiated with the operating system and if a request is larger than the available RAM, space is allocated on the disk. Of course, disk access is much slower than RAM, but this is only done when no additional RAM is available. Fortunately the process is handled automatically and there is no need to write temporary files for large systems as was the norm several years ago. Thus, the size of a problem that the program can handle is not limited by the available RAM, which is normally considerable. For example, a structure with 1,000 degrees of freedom requires one million elements for the system matrix if it is stored densely. For double-precision variables which normally requires 8 bytes, the total storage is 8MB. This is a considerable amount but still well below the capacity of most modern PC's.

An important point to mention is that sparse matrix techniques were not used and only a few matrices noted earlier were not stored in dense fashion. This is admittedly a limitation but does not adversely affect the usefulness of this work. This was omitted for the sake of faster development of the algorithms used as well as smoother interaction between modules of the code. There are different methods for storing sparse matrices in memory and if any one is used, this must be accounted for in all functions that will access that block of memory.

The structural analysis follows traditional linear elastic analysis. The system matrix is assembled and Gaussian elimination is used to solve for the joint displacements. All routines were written by the author except the eigenvalue solver, which was adapted from the IBM Library subroutine, NROOT. Unfortunately, the eigenvalue solver not

only ignores sparsity, it proceeds to obtain all eigenvalues and vectors even though in this application, only the first is required.

The linear programming solver used in this work was mentioned earlier. It is very straight forward and there are few details to be mentioned. It is worth noting, however that this work began with different commercially available solvers illustrating the flexibility incorporated. By this it has been shown that a number of today's state of the art LP solvers can be used.

To begin an optimization run, a basic model and a set of constraints are required. The model is given to the program in the form of an input file which describes the initial geometry, loading, and member sizes. In this work, the input file was typically generated with scripts written for this purpose but this could easily be included in a GUI preprocessor as is commonly seen in FE programs. The program will look for a file named "basename.osi" where basename is a parameter that can be set by the user. At the end of the first successful iteration, a file named "basename.001.osi" is written and the three digit number is incremented for each successive iteration. This means that at the end of the optimization run, the working directory is populated with a collection of files, all similar to the input file but each containing data for that particular iteration. This was found to be very useful because it not only allows one to review the output of each iteration after the program has terminated, it also allows one to restart from any iteration, possibly with changes made to the design or the constraints.

It is important with any program to provide means to identify and handle possible problems that may occur. There are several reasons for abnormal program termination and in this work, error-handling techniques are accomplished through checking the return value of a function. This is more elegant than the FORTRAN method for

determining the success of a routine because it does not require extra variables in the parameter list and the return value can be ignored if desired. Each function is written to return a value, normally integer, and the value is checked before the program can proceed. For example, consider a function that returns the value zero after successful completion that would be called in the following statement

```
someFunction(parameter);
```

To ensure that the function is successful and terminate the program if a non-zero value is returned, the statement is written in the same line as

```
if(someFunction(parameters)) exit(0);
```

The program will terminate with a message if the constraints file has errors or unrecognized input. Linear scaling was mentioned earlier as a means to ensure that the current design is feasible but frame elements are not linear in the section areas. Because of this, after each scaling, a check is performed to ensure the structure is feasible. If it is not, two more attempts are made before the program exits with a message. In practice, it was found that no more than two attempts were required and only when the initial point was very far from feasible. If buckling is not among the constraints and a zero is found on the main diagonal while solving the system the program will exit and a message generated. All matrix operations that are dimensionally incorrect will cause immediate termination with a message.

Programs were written to accept a number of command line arguments to set the parameters at run-time rather than to recompile the source code when changes are made. These were found to be the most often changed parameters and it is thought that any optimization system should allow for these parameters to be user defined. Table 2 summarizes the case-sensitive command line arguments that can be set at run-time.

Table 2 Command Line Options

Flag	Description	Default Value
a	Step size	0.2
b	Basename	file
e	Output frequency	1
i	SLP iterations	1
I	LP iterations	10
r	restart	0
v	verbosity	0
V	LP solver verbosity	0
x	explore	1.01

3.3.2 Graphical User Interface

The iterative nature of this work naturally leads to the concept of a history, and it is often desirable to view the history of the optimization run. While it is possible to view this information numerically, it can be much more useful and efficient to review results qualitatively through a graphical representation of the entire structure. This is most easily understood by noting that although the objective function may decrease for a given iteration, it is often composed of positive and negative changes in the member sizes and it is difficult to determine the relative change without reviewing the entire set of members. The complete source code of the programs described here can be found in Appendix B.

The Java programming language was used for the post-processing programs. The freely available JDK 1.2 was used. This was selected primarily for its platform independence and ease of development when constructing a GUI. Although separate programs were developed and used for each type of structure, they differ only in the expected format of the input file and the specific details of the structural analysis. A

typical screenshot of one program is seen in Figure 2 which shows the menu items important for the GUI of an optimization system.

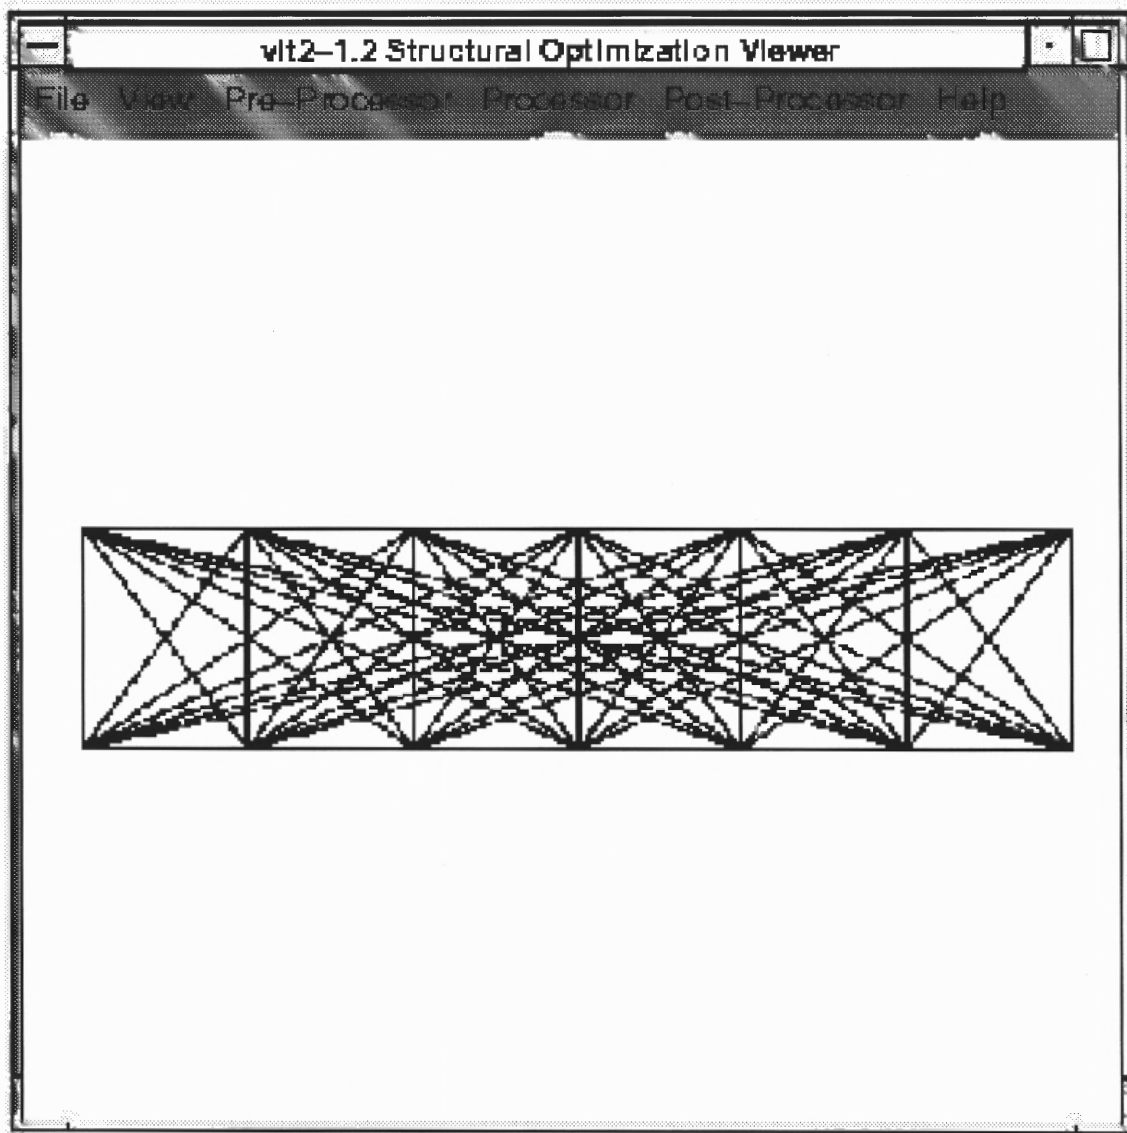

Figure 2 Screenshot of Graphical User Interface

As outlined, the GUI does not perform the optimization procedure mentioned above but rather reads and displays the data generated by the processor. It is possible however, to initiate the processor from the GUI giving the user the impression of seamless integration. Although the author prefers the non-graphical method because it is normally quicker and can be automated, this is thought to be an important part of a general optimization system. This is because nearly all modern applications are graphical in nature and many users are now unwilling to work with programs without a GUI. By separating the components as done here, the optimization system is flexible yet still accommodates the many users who prefer graphical interaction. Additionally, it is easier to add components or even connect each component to a central database.

Similar to C++, Java is an object-oriented language and supports classes but with Java, there is a rich library available allowing the programmer to derive custom classes based on existing classes. Because graphical components are often complicated, this makes Java a natural choice for a GUI. The most important parts of the program are derived from the JDK classes "Frame" and "Canvas". The first class provides the window and the second gives a drawing pane where all rendering of the structure is done. All Java programs use classes that were derived from these two.

An additional benefit of using Java in this application is that the language syntax is very similar to C, thus code written in C can often be inserted directly into a Java program. This was particularly true for the structural analysis aspect of the program. The post-processor has structural analysis capabilities, identical to those mentioned before. This feature along with the ability to identify maxima of structural response quantities is useful in the post-processor for determining which constraints are tight.

Graphically, an optimization system has all the requirements of a standard FE program as well as some additional requirements. The most important feature of a structural optimization GUI is the ability to interpret the member sizes graphically. In the programs developed here, it is possible to do this through setting the line color and thickness proportional to the member sizes. Each can be done independently so one can select color variations, thickness variations, both, or neither. The color scale was selected as a simple gradient from red, green and lastly blue in decreasing order. Thus, a member drawn in red would represent a large section and one drawn in blue would indicate a small size. This feature is not often seen in typical FE programs.

For simplicity, the GUI displays concentrated force loads as lines without arrows, and concentrated moments as well as supports are not shown at all. This is because these items are typically not editable in a post-processor and drawing them would require more programming effort than is warranted for a non-commercial program. Key-bindings are enabled so the user can advance through iterations quickly. An earlier version of the program also included a feature to automate the advancement after a short pause but this was rarely used and discarded in later versions. It is simple to include however, and thought that some users may find it useful thus recommended in a professional package.

Typically when viewing results for a given iteration, only a glance is sufficient and the numerical results are not needed. With this in mind, as each file is loaded, analysis is not performed unless the user requests it specifically through the menu. This allows the model to load much faster, particularly for large systems although details are available at any time.

Another special feature of the post-processor related specifically to structural optimization is the history plot. The program only stores the current model in memory but also keeps the volume of each model loaded. With this, a history plot can be seen instantly showing the volume versus the iteration. At any iteration, the display can be printed. This can be directed directly to the printer or saved as a postscript file.

Although there is a FE analysis tool included in the GUI, the pre-processor features are limited. Model generation was done outside of the system using other tools but ultimately this should be included in the main package. Currently, model generation is done by other programs written explicitly for that task but it is a trivial matter to include this in the main package. Additional features such as a display of the deformed shape might also be useful.

CHAPTER 4 EXAMPLES

In the following sections, several examples are presented. Results are shown graphically in the form of a volume versus iteration plot as well as a diagram of the final structure where lines are drawn with a thickness relative to the member size. The specific details such as the structural dimensions and final results are found in Appendix C in the form of an input file along with a description of the input file format. The name of the file is constructed by concatenating the basename, the iteration number, and the extension "osi" all delimited with a dot. Units are not discussed in any of the following because these represent illustrative examples and thus the units are not significant. For all examples, the numerical value for Young's Modulus (E) is 29,000 and the initial design begins with some arbitrary value for the member sizes, normally 1.0 for the area.

4.1 Truss Examples

One approach to structural optimization is to begin with an array of nodes and provide a member connecting every pair of nodes. The array is typically rectangular and in the case of collinear nodes, a single member connects only the nearest two nodes. It is clear that for any support conditions and loading, such a structure has a high degree of redundancy and in fact, some of the members may not be useful. However, the intention of starting with this array of nodes and arbitrary collection of members is to allow the optimization algorithm to determine which members are useful. Members which are not considered useful are identified by their very small cross sectional areas relative to the other members. This approach is a simple test of a structural optimization algorithm but also

interesting in that it yields the possibility of arriving at a design that is not only optimal, but which the designer may not have initially considered.

The decision to discard members due to their insignificant contribution to the structure could easily be incorporated into the optimization system but this was not done in this work. This approach is shown here as only an example, thus for the relatively small number of uses, it was not considered important to include. In this work, when it is thought that members could be removed, a script was run which identifies the smallest member and then removes all within a specified range of that size, typically 5%. If this step were to be included in the optimization system, one would also need to check for structural stability, which has already been investigated by other researchers.

An example of this many-bar truss is seen in Figure 3. For this case, the boundary conditions are pin-supports for the three nodes at the right, thus the structure resembles a simple cantilever. There is a single concentrated load at the free end of the cantilever, at mid-height and the structure has 74 members and 15 nodes. The objective here is to minimize the total weight of the structure and the constraints require that the displacement of all members is within the range

$$-0.001 \leq \Delta \leq 0.001 \quad (46)$$

Because equation (46) shows an upper and lower limit on the displacement of each member, there are 148 structural constraints. For this model, the step size limits in equation (43) give an additional 148 constraints resulting in a total of 296 constraints for this model.

Figure 3 Multi-bar Truss

After 30 iterations, a simple scan of the member sizes was performed and all bars that were found with an area within 5% of the minimum bar area were removed from the structure. The resulting structure was optimized with the same constraints for an additional 40 iterations to yield the structure seen in Figure 4. The entire history of the volume versus the iteration can be seen for the entire procedure in Figure 5 where a jump in volume is seen between iteration 30 of the initial structure and iteration 1 of the reduced structure because of the elements removed.

Figure 4 Optimal Solution t35s.040.osi

Figure 5 Iteration History for t35.osi

Another many-bar truss shown in Figure 6 is used to investigate the effect of changing the number of LP iterations. This example resembles a bridge in that it has two pin supports at the lower corners and a downward load mid-span. There are 61 bars and 14 nodes in this structure. The constraints are symmetric upper and lower limits on the set of member displacements. This is similar to equation (46) except the numerical value is changed to $0.488\text{E}-6$. Because the number of bars is different, there are now 122 structural constraints and 122 step size constraints for a total of 244 constraints on the

system. This was selected over the previous example for this step not because there are fewer constraints but because the optimized structure after 30 iterations, seen in Figure 7, more clearly suggests the final result and is arrived at without the procedure of removing small bars noted earlier. By not removing the small bars, a more meaningful comparison can be made because the only variable is the number of LP iterations.

Obviously, fewer LP iterations are desired because this would provide faster execution times but one might then be concerned with the accuracy of the solution at a given step and the stability of the overall method. A note here should be made that the number of SLP iterations is different than the number of LP iterations and it is the latter that is of concern here. Figure 8 shows that for this example, there is little gain in using more than five LP iterations. This shows more clearly that, as mentioned earlier, the exact solution of the LP is not required again emphasizing the usefulness of interior point methods where one can prematurely halt the LP solver.

Figure 6 Multi-bar Truss t16.osi

Figure 7 Optimal Solution t16.030.osi

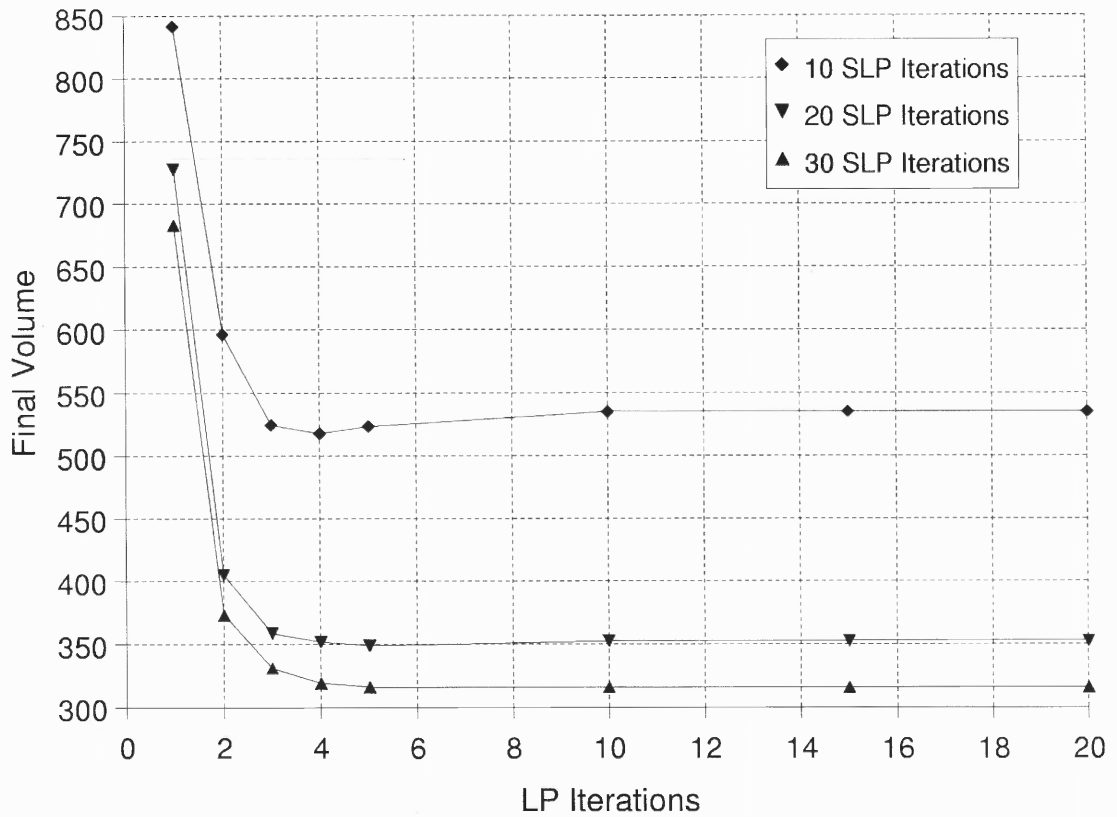

Figure 8 Comparison Using Different Number of LP Iterations

A different style of truss examined is an X-braced simply supported structure with 51 bars, 22 nodes, a pin support at each side, and a single concentrated load at mid-span. The optimal solution after 30 iterations using only the allowable member displacement constraints in equation (46), is seen in Figure 9 (xt210.030.osi). If the 102 allowable member displacement constraints are replaced by the same number of equivalent allowable member stress constraints, the same solution arises (xt213.030.osi). Equivalent replacement is done according to equation (16) and the optimal design is seen in Figure 10 which shows no apparent difference from the allowable displacement constraints. As noted earlier, the formulation for allowable member displacement is more compact. Because the solutions are equivalent, it is recommended to transform allowable stress constraints to allowable member displacement before the optimization begins.

It is interesting to note that if these 102 structural constraints are replaced by a single joint displacement constraint, a similar solution arises. The single joint displacement constraint requires that the vertical displacement at the point of loading is limited to the actual displacement of that same node in the previous allowable-displacement example (-0.0251 units). Numerically, there is little difference (xt211.030.osi) and the solution shown in Figure 11 appears very similar.

Figure 9 Optimal Solution xt210.030.osi

Figure 10 Optimal Solution xt213.030.osi

Figure 11 Optimal Solution xt211.030.osi

The structures in Figures 9 through 11 all show very similar results but a better comparison is seen in Figure 12, which shows the volume history for all three constraint conditions. The difference between the allowable displacement and allowable stress constraints is so small that the graph shows nearly a single line for the two and the data points are nearly coincident. The allowable displacement condition shows convergence to the same value although it starts at a different point because of the initial scaling mentioned in equation (45).

Figure 12 Comparison of Volume History Using Similar Constraints

The most interesting point of this problem however is as follows. One can note that in each panel, there is one diagonal member in tension and one in compression. It was initially thought that one could create a tension member preference by imposing more restrictive constraints on the compressive displacement (member shortening) or, conversely, applying less stringent constraints to the tension displacement (member elongation). For the latter, the symmetric constraints of equation (46) were changed to the unsymmetric case

$$-0.001 \leq \Delta \leq 0.1 \quad (47)$$

Interestingly, it was found that the structure cannot take advantage of the less stringent constraints on the tension members because the displacement of each tension member is related to that of a compression member in the same panel. In other words, if the displacement limit on a tension member were to be realized, the displacement limit on

the compression member in that same panel would be exceeded. This could have been determined before-hand through proper analysis but it is encouraging to note that the algorithm identifies such a behavior, possibly saving a designer much time.

The anticipated compression-only and tension-only solutions are seen in Figures 13 and 14 respectively. These structures were generated by manually removing all diagonals in compression or tension respectively, and then performing 30 iterations with the constraints in equation (46). All constraints are tight in the expected solution but it is interesting to note that both of these are less optimal than the initial solution (x1210.030.osi) in which all diagonals are present and some constraints are not tight. Figure 15 shows that the algorithm finds an optimal that is better with both tension and compression diagonal members, thus is performing correctly in not removing a diagonal member from each panel. This is a good example of how an optimization system can be used as a design tool because it can identify a design that is not only optimal but also may not be obvious.

Figure 13 Expected Diagonal-Compression-Only Solution

Figure 14 Expected Diagonal-Tension-Only Solution

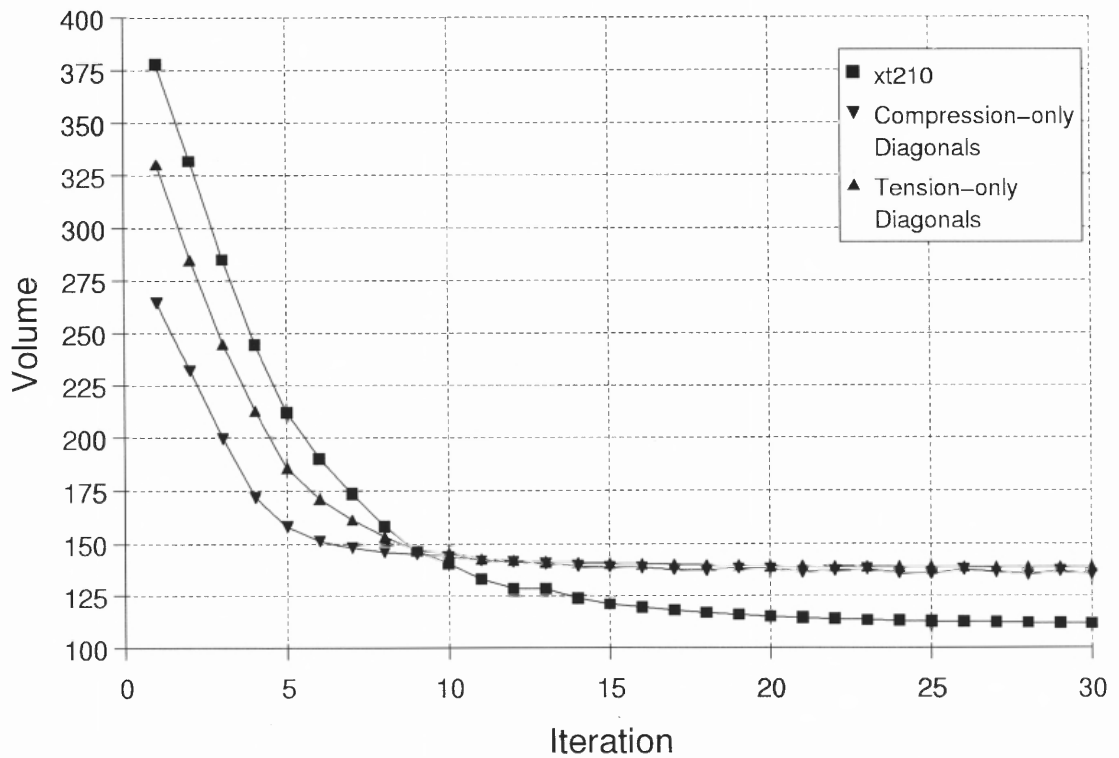

Figure 15 Optimal Solution with Compression and Tension Diagonals

4.2 Frame Examples

The simplest frame example discussed is a two-dimensional structure with two-elements of equal length, one beam and one column. There is one free node and a single force load applied in the horizontal direction. The only constraint is that the displacement of the free node in the direction of the load is limited to 0.1 units. This example is shown because it illustrates that the feasible design space can have local minima and, in this case, the algorithm successfully locates the global minimum. The optimal solution (f02.020.osi) and the volume history are seen in Figures 16 and 17 respectively. For this case, all material is being distributed to the beam element and the load is being carried axially by the beam.

Figure 16 Two-element Frame – Beam Solution f02.020.osi

Figure 17 Volume History for Beam Solution

One may have expected that the beam-solution would be the optimal design based on common sense but technically this is only correct for typical values the constants c_0 and c_1 from equation (22). Academically, there are values of these constants that will cause the column-solution (i.e., all material is distributed to the column element) to be preferred and the load will be supported by a single element acting in flexure. Assuming $c_1 = 2$ for both cases, the exact value of c_0 for which the column-solution becomes preferred over the beam-solution can be found by setting the displacements equal for the individual cases and using the A to I relation given in equation (22).

$$\begin{aligned}
 \frac{PL^3}{EI} &= \frac{PL}{AE} \\
 L^2 &= c_0 A \\
 c_0 &= \frac{L^2}{A}
 \end{aligned}
 \tag{48}$$

The previous example used $c_0 = 5$ but to satisfy equation (48), c_0 must be greater than 10,000. Although this is an unrealistic value for most cases, it is a good test of the algorithm. Figure 18 shows that the expected solution is found but the history seen in Figure 19 shows an interesting occurrence. Occasionally, as in this problem, the volume history shows an initial increase before a later convergence. This is interesting because what is happening is that the algorithm is beginning in the vicinity of a local minimum but to reach the global minimum (the column-solution), the volume must first increase to get away from the local minimum.

Figure 18 Two-element Frame – Column Solution f02a.030.osi

Figure 19 Volume History for Column Solution

This behavior is also seen more clearly in Figure 20 which shows the volume data from Figure 19 plotted on the ordinate versus the value of the beam element's area A_1 on the abscissa. Each point on this volume curve represents one iteration and because the change in area A_1 is monotonic, the points are in sequence. However, note that the first iteration is located with the largest A_1 and thus, the sequence moves to the left as the iteration number increases. Also seen on this graph is the feasible region for this problem which was generated by selecting a value for A_1 , solving for the value A_2 that would satisfy the single displacement constraint, and then computing the volume.

Figure 20 Location of Global Minimum

Note that in Figure 20, the volume curve has the same shape as in Figure 19 but is mirrored because the abscissa has changed. Also note that the volume curve is above the feasible region in accordance with equation (43). Even though this is a simple problem, it is worth noting because often the literature dismisses SLP because it doesn't guarantee that a global minimum will be found. Of course, this example still does not guarantee that a global minimum will be found in all cases but it does illustrate that it can occur. Further, it is well worth noting that even if a local rather than global minimum is found, it is still a form of optimal and likely better than the initial design. In short, an algorithm should not be dismissed solely because it doesn't guarantee a global minimum.

A more realistic frame example is a four-story, two-bay frame shown in Figure 21 which show the solution after 30 iterations. The applied loads are a concentrated

downward load at each node in addition to an applied moment at the exterior nodes representing fixed-end moments associated with a distributed load on a floor. The constraints are on the member displacement and rotation, all of which are found in the member displacement matrix described in equations (3) and (22). The values used are

$$\begin{bmatrix} -0.00001 \\ -0.0001 \\ -0.0001 \end{bmatrix} \leq \Delta_i \leq \begin{bmatrix} 0.00001 \\ 0.0001 \\ 0.0001 \end{bmatrix} \quad (49)$$

Similar to the truss example discussed earlier, the number of LP iterations was investigated for this example and again, it was found that fewer than expected LP iterations are required. This can be seen in Figure 22 which shows that for some cases, less iterations actually provide a slight improvement.

Figure 21 Optimal Solution of Two-bay Four-story Frame f242.030.osi

Figure 22 Comparison Using Different Number of LP Iterations

It was found that values of the step size parameter α in equation (43) greater than 0.3 caused variations from one iteration to the next and the resulting volume history is not monotonic. Figure 23 shows the volume history for this example using different values of α . From a practical point of view, there is little difference after 30 iterations but it is worth noting that the steps can vary greatly with large α and for frames, values less than 0.5 are recommended.

Figure 23 Comparison Using Different Step Size α

The nonlinear terms mentioned in equation (30) were included in this example but as seen in Figure 24 there is rarely an advantage and most times, the linear approximation is superior. Sometimes, improvement was noted for large step size parameter α , but was not seen consistently and this is not recommended. It is thought that this is because the degree of nonlinearity may be higher for the constraint functions, which were not approximated with this method, than for the stiffness matrix.

Figure 24 Comparison Using Nonlinear Terms

The first frame buckling problem to be discussed is the simple cantilever with a compressive axial load. In this case, 10 elements are used along the length of the cantilever and the problem is to find the optimal distribution of material that will support the load. The solution after 30 iterations is seen in Figure 25 and the area distribution is plotted in Figure 26. The volume history in Figure 27 shows an apparently good convergence but it does not show clearly that the relative distribution is still changing. This can be seen in Figure 28 which shows the area over the length at six different points in the iteration history. From this, one can see that the solution is very nearly approximated at iteration 20 but then continues to change, sometimes creating a shape with "pockets".

Figure 25 Optimal Solution for Cantilever with Axial Load col10.030.osi

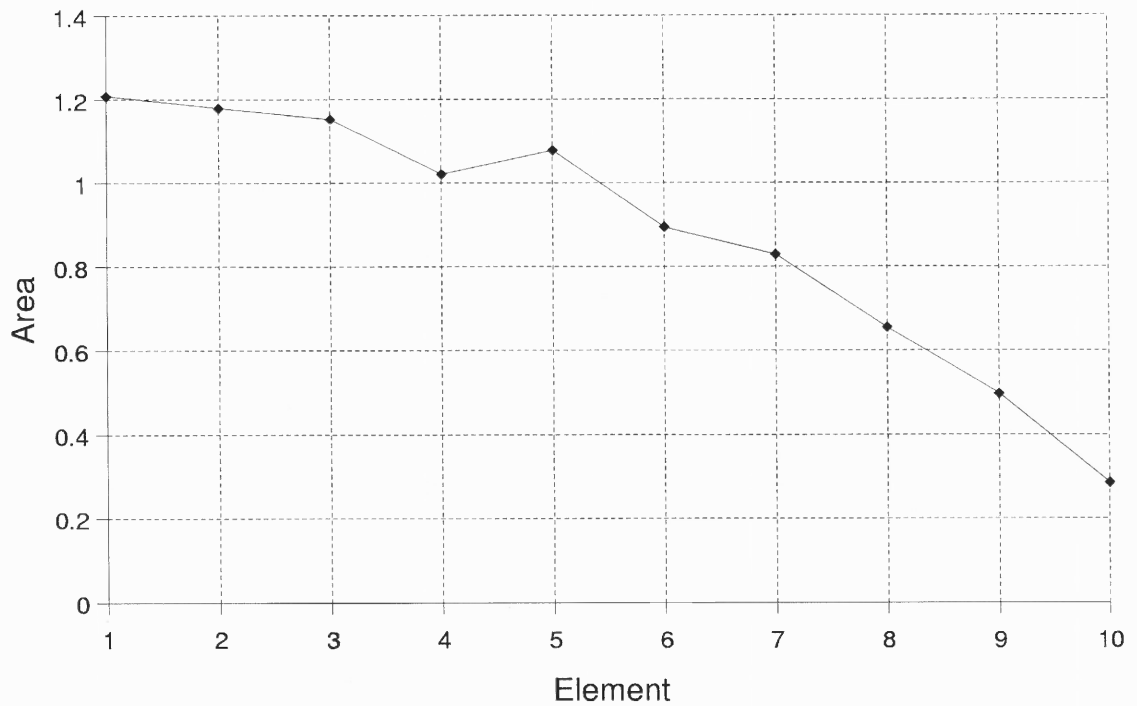

Figure 26 Area Distribution for col10.osi

Figure 27 Volume History for col10.osi

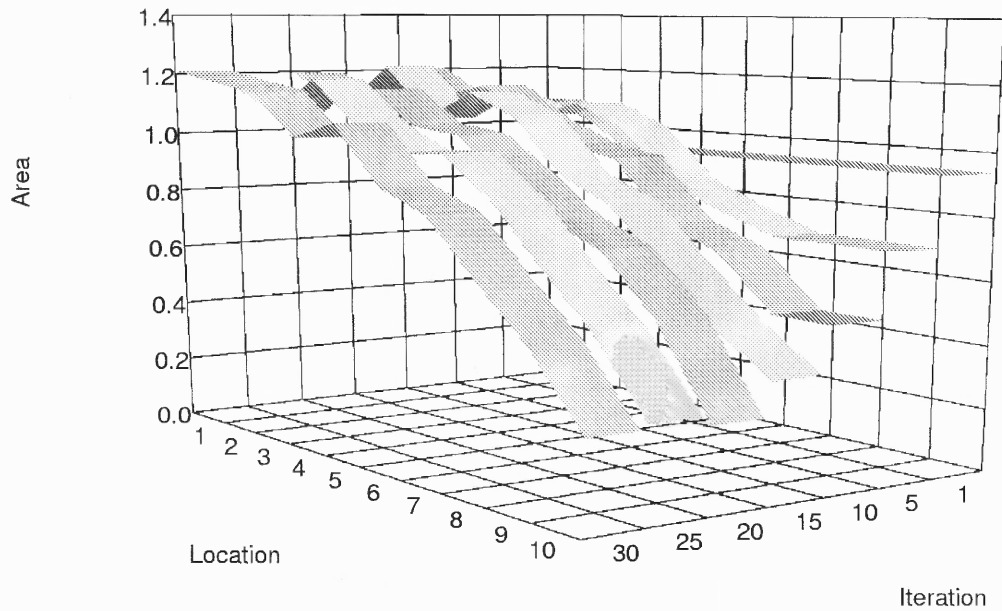

Figure 28 Area Distribution History for col10.osi

A one-story, one-bay frame was also used as a test problem for buckling. In this case, there is a downward axial load on each of the two free nodes and the columns are fixed at the base. It is interesting to note that the optimal solution in this case is dependent on the dimensions of the structure. A comparison is shown here for two structures, both with equal proportions and the same constants relating A to I in equation (23). The frame with the larger dimensions converges to the relatively equal member size solution seen in Figure 29 but the frame with the smaller dimensions converges to a column-solution seen in Figure 30 (col10s.030.osi). This transition from the distributed solution to the column solution was noted to be continuous by examining a range of structures, all with the same proportions, between these two examples.

Figure 29 Frame Buckling Problem – Distributed Solution f11b.050.osi

Figure 30 Frame Buckling Problem – Column Solution f11s.050.osi

It was commonly noticed in buckling problems such as this that there is not a monotonic approach to the optimal but rather a "zig-zag" as seen in the history Figure 31. This is due to the scaling mentioned in equation (45) and is accompanied by a change in the load factor seen in Figure 32. When dealing with buckling problems, scaling is done according to the load factor but this is not exact. This means that at different iterations, the load factor may be closer to one, although the program ensures that it is never less than one. For a given iteration, if the factor is closer to one, the volume will be less but it is not necessary to scale to exactly that point and this is the reason for the slight increase in volume seen at some iterations. Regardless, the general trend can clearly be seen in Figure 31 which shows an overall reduction in total structure volume.

Figure 31 Volume History for Frame Buckling Problem

Figure 32 Load Factor History for Frame Buckling Problem

4.3 Plate Examples

As mentioned earlier, in this work plate structures are modeled with a grid of three-dimensional beam elements. For a plate that acts primarily in flexure, it is not uncommon to use beam elements with a 3x3 stiffness matrix, slightly modified from the two-dimensional beam element stiffness matrix in equation (20) by replacing the axial stiffness term with a torsional stiffness term. However, in this work it is desired to find the optimal distribution of material such that the plate will support some critical Euler-buckling load and thus it is necessary to include the axial terms as well. With this in mind, the three-dimensional beam elements are used instead of forming a custom element expressly for this purpose. The 6x6 element stiffness matrix was described in equation (26).

One of the more challenging problems in plate optimization is to find the optimal distribution of material that will support some critical buckling load. This problem has been addressed by several researchers [Prasad, 1989; Spillers, 1990] with varying results. In fact, one study concluded that the optimal solution is not even a smooth, continuous distribution of material but rather approaches a number of thin stiffeners.

Similar to the frame buckling example shown above, the optimal grid with respect to buckling was seen to be a function of the section properties. If one selects section properties to represent very high shear stiffness, the optimal material distribution is different than that seen if axial and flexural stiffness are favored. This can be seen in the two grids shown in Figures 33 and 34 where the first suggests very high shear stiffness. The volume history for these examples is shown in Figures 35 and 36 respectively.

CHAPTER 5

SUMMARY AND CONCLUSIONS

This thesis has prototyped a computer system for structural optimization which uses the latest in linear programming techniques. It was shown that the developed system is able to handle various structure types as well as a wide variety of structural constraints. Further, sequential linear programming was shown to be a viable tool for a large-scale structural optimization system and the recent advances in linear programming are exploited for this purpose. The importance of a flexible, extensible approach was also shown through the development of a broad-based computer system.

The real test of the work done here involves its adoption by the engineering community to the extent that structural optimization can become as commonly used as the finite element method. In fact, the model for engineering design in the future has analysis augmented with optimization. Most of the analysis now done is concerned with designing something, analysis for its own sake is rare, and the underlying concern of engineering design is optimization. It is not difficult to predict this occurring in the near future. But a commercial version of a general engineering design (optimization) system will be both time-consuming and expensive.

5.1 Extensibility

There are many needed features not included in the software system discussed here: many element types, constraints, objective functions, etc. A practical approach to the development of a commercial software package would likely begin with a successful existing software system. The optimization would then sit on top of this system calling

the existing features as needed and supplying the new tools associated with optimization. In fact, some of this now exists in the finite element package ANSYS which has seriously limited optimization capabilities and is not written with structural engineering design in mind. ANSYS underscores the basic software need of shifting emphasis from analysis to design. The good part of this is the fact that hardware capabilities are improving by the minute.

5.2 Future Work

The most immediate work to be done has to do with a commercial working environment. We have contacted the engineering firm of Weidlinger Associates in the hope of working with them to develop a practical engineering tool but that has yet to develop. That practical tool will involve special features to help the engineering designer, probably in the form of a graphical user interface. Developing features like this is a labor-intensive process.

The most interesting technical issue to be resolved is the optimization routine. It is clear that the potential exists for a large-scale SLP solver to be used in optimization but there is as yet no experience with routines of this type in structural optimization. There is probably profit to be made in putting together structural designers and applied mathematicians to work on this task. The nice part of this is that in a properly designed software system, replacing the optimization routine should not be difficult.

In summary, extensions of this thesis will include:

- A focus on the features needed by the engineering designer in a practical working environment.

- Studies to determine the best optimization scheme to be used. (It is likely that problems of structural optimization have special properties that may be helpful in the optimization process. That is certainly the case in analysis where the system matrix is positive definite and sparse.) That is also the case of optimality criteria methods, which have unfortunately proven to have restricted generality.)
- Working with some finite element package like ANSYS or LARSA, which would provide a basis from which to develop a general-purpose software system.
- Human factor studies to assist in determining features appropriate to a general-purpose software system.

APPENDIX A C++ PROGRAMS

This appendix contains a complete listing of the source code for the programs written in C++ used in this work.

```

APPENDIX C INPUT FILE FORMAT

There are three very similar input file formats used in this work. All have the structural dimensions on the first line, followed by a number of blocks that describe the nodal and member details. Each block is a group of lines that all have the same number of terms and the lines in each block are ordered such that line i in a block corresponds to item i in the structure. The number of terms on each line varies according to the type of block and the terms are listed in the order described here.

The first line of the truss input file contains three integers which are the number of members, nodes and supports in the structure. Following this line are two blocks of data. The first block contains the nodal data and thus has one line for each node. Each data line in this block has four terms, which are the x coordinate, y coordinate, applied force in the x-direction, and the applied force the y-direction for a given node. The second block describes the member data and connectivity. Each line in this block also has four terms but these are the negative node number, positive node number, cross sectional area, and Young's Modulus for that member.

There are only two differences between the two-dimensional frame input file and the truss file just described. The first difference is that in the first block, there is one extra term required for the value of a concentrated moment at each node thus the total number of terms on each line in this block is five. The second difference is that there are more terms used to describe the member. Each line in the second block has, in order, the negative node number, positive node number, cross sectional area, second moment of the area (also known as the section constant I), and Young's Modulus for a given member.

The third type of input file is also very similar but there are three blocks of data after the first line. The first line has three integers that determine the number of nodes,

the number of nodes, and the total number of degrees of freedom. The first block describes the nodal data thus there is one line for each node. Each line in this block contains nine terms which are the x , y and z coordinates, the force loads in the x , y , and z directions, and the concentrated moments about the global x , y , and z axes.

The second block of data contains information about the members and there is one line for each member. Each line in this block contains 11 terms, and the first two are the negative node number and the positive node number. The following six terms describe the section and material constants for the member. These are the area, the torsional constant, the second moment of the area about the y and z axis, Young's modulus (E), and the shear modulus (G). The final three terms in each line of the second block describe the angles required to rotate the element into the global coordinate system. In order, these angles represent rotations about the x , y , and z axis.

The third block of data contains information about the degrees of freedom. There is one line for each node and each line has six integer values. The integers are used as flags and each can have a value of either zero or one. Each flag, in order, corresponds to one of the six possible degrees of freedom dx , dy , dz , θ_x , θ_y , and θ_z . A zero indicates the direction is free while a one indicates that direction is fixed.
