Received: June 21, 2005; In Final Form: October 18, 2005

The ultrasonic velocities, densities, viscosities, and electrical conductivities of aqueous solutions of magnesium nitrate and magnesium acetate have been measured from dilute to saturation concentrations at $0 \le t/{}^{\circ}C \le 50$. The temperature derivative of the isentropic compressibility, κ_s , became zero at 2.28 and 2.90 mol kg⁻¹ for Mg(OAc)₂ and Mg(NO₃)₂ solutions, respectively, at 25 °C. The total hydration numbers of the dissolved ions were estimated to be, respectively, 24.3 and 19.2 at these concentrations. Differences in κ_s for various M²⁺ salts, using the present and literature data, correlated with reported $M^{2+}-OH_2$ bond lengths and to a lesser extent with cationic charge densities (ionic radii). The influence of anions on κ_s appears to follow the Hofmeister series and also correlates approximately with the anionic charge density. Substantial differences between $Mg(OAc)_2(aq)$ and $Mg(NO_3)_2(aq)$ occur with respect to their structural relaxation times (derived from compressibility and viscosity data) and their electrical conductivities. These differences were attributed to a much greater ion association in Mg(OAc)₂ solutions. Raman spectra recorded at 28 °C confirmed the presence of various types of contact ion pairs including mono- and bidentate complexes in Mg(OAc)₂(aq). In Mg- $(NO_3)_2(aq)$, only noncontact ion pairs appear to be formed even at high concentrations. The experimental results are supported by molecular dynamics simulations, which also reveal the much stronger tendency of OAc^{-} compared to NO_{3}^{-} to associate with Mg^{2+} in aqueous solutions. The simulations also allow an evaluation of the ion-ion and ion-water radial distribution functions and cumulative sums and provide a molecular picture of ion hydration in $Mg(OAc)_2(aq)$ and $Mg(NO_3)_2(aq)$ at varying concentrations.

1. Introduction

The presence, nature, and concentration of salts can dramatically alter the solubility and behavior of other molecules in solution.¹ Consequently, the solvation of ions in aqueous media is of prime importance in many areas including surface chemistry, environmental chemistry, and geochemistry. In particular, to understand the processes occurring in living cells^{2,3} (such as ion transport across cell membranes, the functioning of proteins, and ion channels), the nature of ion hydration is prerequisite information. The hydration of multivalent metal ions is especially interesting because of the presence of well-defined solvation shells and the formation of specific complexes.⁴ Magnesium ion is present at moderate concentrations in living cells⁵ and seawater⁶, and its salts are important industrially. The acetate ion occurs widely in nature, being produced by microorganisms and by the decomposition of humic acids,^{7,8} while nitrate is of special environmental importance in the atmosphere and in soils.⁹

It is well established¹⁰⁻¹⁶ that six water molecules are strongly bound in the primary hydration shell of Mg^{2+} in aqueous solutions. In fact, Mg^{2+} retains the hexahydrate structure, with an almost constant $Mg^{2+}-(OH_2)_6$ bond length irrespective of the nature of the counteranion.^{12,13} On the basis of X-ray diffraction studies of $Mg(NO_3)_2(aq)$, Caminiti et al.¹² suggested that nitrate ions do not produce any pronounced structuring effect in their neighborhood. As well as confirming that Mg^{2+} has an inner hydration shell of 6, they also proposed a second coordination shell of 12 water molecules, which was also suggested by Bol et al.¹⁰ Conductivity¹⁷ and vapor pressure¹⁸ measurements imply that complex formation between Mg^{2+} and NO_3^- in aqueous solutions (at concentrations $m \le 2.2 \text{ mol kg}^{-1}$) is unlikely.

Consistent with these measurements, several Raman spectral studies^{19–24} have concluded that contact ion pairs do not form in Mg(NO₃)₂(aq) up to saturation (3.85 mol dm⁻³) at 25 °C. Nevertheless, principal component analysis²⁵ of Raman spectra has revealed the presence of some associated species at M \geq 2.5 mol dm⁻³, which were earlier assigned to be solvent-shared ion pairs by Chang and Irish.²² James and Frost²⁶ reported the

Academy of Sciences of the Czech Republic.

existence of solvent-shared ion pairs in this system even at ≥ 0.5 mol dm⁻³ using a similar approach.

At higher temperatures (up to 120 °C), Peleg²¹ showed, again via Raman spectroscopy, that $Mg(OH_2)_6^{2+}$ remained intact, as suggested by Angell,²⁷ at concentrations $\leq 9.25 \text{ mol kg}^{-1}$ but, beyond that, NO_3^- entered the primary hydration shell of Mg^{2+} . Peleg also reported the existence of a perturbed quasi-lattice structure for Mg²⁺-NO₃⁻ contact ion pairs in Mg(NO₃)₂. 2.4H₂O and Mg(NO₃)₂•2H₂O melts. Irish et al.²⁸ proposed the presence of two bidentate contact ion pairs: $[Mg^{2+}(H_2O)_4(NO_3^{-})]$ and $[Mg^{2+}(H_2O)_2(NO_3^-)_2]$ in $Mg(NO_3)_2 \cdot 2.2H_2O$ melts. Chang and Irish²² later identified contact ion pairs in 9.25 mol kg⁻¹ Mg(NO₃)₂•6H₂O and inferred that a monodentate to bidentate conversion occurs as water is further removed. Very recently, Zhang et al.²³ studied aqueous Mg(NO₃)₂ droplets using an electrodynamic balance in conjunction with Raman spectroscopy and observed a large variety of contact ion pairs including monodentate and bidentate species.

Aqueous solutions of Mg(OAc)₂ appear particularly interesting with respect to the formation of different types of species at different concentrations. Caminiti et al.²⁹ reported the presence of a monoacetato complex in 0.25–1.5 mol dm⁻³ aqueous Mg-(OAc)₂ solutions, employing X-ray scattering and ¹³C NMR spectroscopy. Conductivity studies in very dilute solutions (≤ 0.002 mol dm⁻³) indicate ion association in Mg(OAc)₂(aq) with a modest association constant, K_A° , for 1:1 stoichiometry, of \approx 50 dm³ mol^{-1.30} An ultrasonic absorption study³¹ suggested that OAc⁻ did not penetrate into the primary hydration shell of Mg²⁺.

Investigating the symmetric and antisymmetric stretching modes of the carboxylate group by attenuated total reflection (ATR)-IR spectroscopy, Tackett³² observed only free ions in dilute (0.6 mol dm⁻³) Mg(OAc)₂(aq). Semmler et al.⁸ studied the C-C stretching modes in the Raman spectra of OAc⁻ at a pressure of 9 MPa and temperatures up to 150 °C in solutions containing MgCl₂, Mg(OAc)₂, NaOAc, and NaNO₃ having total mole ratios of OAc- to Mg2+ of 0.5 to 6 and suggested the existence of two monodentate complexes. Nickolov et al.33 reported the existence of mono- and bisacetato complexes in 0.65-3.24 mol dm⁻³ Mg(OAc)₂ solutions from Raman measurements. Using ATR-IR and Raman spectra of dilute (0.05-0.6 mol dm⁻³) Mg(OAc)₂, Quilès and Burneau³⁴ found no contact ion pairs, consistent with Tackett.³² Very recently, Wang et al.³⁵ studied supersaturated Mg(OAc)₂(aq) droplets ($m \ge 3.58$ mol kg⁻¹) using a droplet levitation technique with in-situ Raman spectroscopy. They detected bidentate complexes and also proposed the formation of bridged bidentate complexes. For a better overview, the various species reported in aqueous solutions of Mg(NO₃)₂ and Mg(OAc)₂ are summarized in Table 1.

Solutions of acetate and nitrate salts at moderate concentrations are also of interest in connection with the ubiquitous, but largely unexplained, Hofmeister series. This series of ions, established originally on the basis of their effects on protein solubilities,³⁶ has been observed in an impressive range of biological and biochemical phenomena.³⁷ However, despite some recent progress,³⁸ understanding of this series remains obscure and few papers deal with other than monovalent ions. Since OAc⁻ and NO₃⁻ lie toward the two extremes of the Hofmeister series (salting-out and salting-in, respectively), it is of interest to compare their physicochemical properties, which may shed light on this important topic.

It has long been postulated that, when an electrolyte is added in water, the constituent ions markedly modify the water

structure (hydrogen bonding), which affects the physicochemical properties of the solution.³⁹ Recent studies⁴⁰ contradict this century old understanding and showed that ions do not influence the water structure of the bulk water (second hydration sphere onward) but only the hydrogen bonding of the water in the immediate vicinity of ions, that is, water in the first hydration sphere, is broken or formed.

This paper presents a detailed study of the ultrasonic velocities, densities, viscosities, and electrical conductivities of aqueous solutions of $Mg(NO_3)_2$ and $Mg(OAc)_2$ from dilute to saturation concentrations and as a function of temperature. Fourier transform (FT)-Raman spectra of these solutions have also been recorded to clarify the role of ion association. The experimental data are complemented by molecular dynamics simulations of aqueous solutions of $Mg(NO_3)_2$ and $Mg(OAc)_2$ at 0.25 and 1 M concentrations. These calculations, which employ periodic boundary conditions to simulate the aqueous bulk, provide a picture with atomic resolution of solvation of individual ions and allow quantification of the degree of ion pairing in the magnesium nitrate vs acetate solutions in terms of ion—ion pair distribution functions.

2. Experimental Section

Mg(OAc)₂·4H₂O (>99%, SRL, India) and Mg(NO₃)₂·6H₂O (>99%, SD Fine Chemicals, India) were recrystallized twice from double-distilled water and then kept in a vacuum desiccator over P₂O₅. All solutions were prepared using double-distilled water and by the successive dilution of a stock solution. The concentrations were finally checked by complexometric titration against EDTA.⁴¹ The overall accuracy in the solution preparation was within \pm 0.3%.

The detailed measurement procedures for ultrasonic velocities at 3 MHz, densities, and viscosities are described elsewhere.^{42–44} The uncertainties in the measurements of ultrasonic velocity, density, and viscosity were within $\pm 0.01\%$, $\pm 0.01\%$, and $\pm 0.5\%$, respectively. Electrical conductivities were measured using platinized platinum electrodes and a Precision Component

Analyzer 6440A (Wayne Kerr, U.K.) at a field frequency of 1 kHz. The cell constant of 1.237 cm⁻¹ was determined by using a 0.1 mol kg⁻¹ aqueous KCl solution at different temperatures. The experimental uncertainty in the conductivity values was less than $\pm 0.4\%$.

Electrical conductivities, ultrasonic velocities, and viscosities of both systems were measured from 0 to 50 °C at 5 °C intervals as functions of salt concentration (0.0145 \leq *m*/mol kg⁻¹ \leq 6.545). Schott-Geräte CT 1450 or Julabo F32 HP thermostats were used to control solution temperatures to within ±0.02 °C.

FT-Raman spectra of aqueous solutions of $Mg(NO_3)_2$ and $Mg(OAc)_2$ were recorded at room temperature (28 °C) using a Bruker IFS 66 V optical bench with a FRA 106 Raman module attachment and a Nd:YAG laser operating at 1064 nm. The laser power was set at 200 mW, and 250 scans were accumulated and averaged with a resolution of 2 cm⁻¹. The spectra were recorded at the Sophisticated Analytical Instrumentation Facility, Indian Institute of Technology, Madras, India.

3. Computational Details

Classical molecular dynamics simulations of concentrated solutions of magnesium nitrate and magnesium acetate were performed. The unit cell contained 863 water molecules, 4 or 16 magnesium cations, and 8 or 32 nitrate or acetate anions, which corresponds to a 0.25 or 1 M salt concentration. The size of the cubic unit cell was approximately $30 \times 30 \times 30$ Å, and standard periodic boundary conditions were applied.⁴⁵ A 12 Å cutoff was used for intermolecular interactions. Longrange Coulombic interactions were accounted for using the particle mesh Ewald procedure.⁴⁶ Simulations were run in the NPT canonical ensemble at 300 K and 1 atm. A time step of 1 fs was employed, and all bonds involving hydrogen atoms were constrained using the SHAKE algorithm.⁴⁷ All systems were first equilibrated for 500 ps, after which a 1 ns production run followed.

A nonpolarizable force field was employed in all simulations. Technically, this is the simplest way to avoid the problem of a "polarization catastrophe",⁴⁸ which is particularly severe in the presence of multiply charged ions. Physically, this choice can be at least partially justified by the fact that in this study the interest is in the bulk properties of aqueous ions, which are less influenced by specific polarization effects than the interfacial ionic behavior.⁴⁹ For water, the SPCE model, which accounts for mean polarization effects by increasing the partial charges on oxygen and hydrogens,50 was employed. For ions, the general amber force field parameter set was used.⁵¹ For Mg²⁺, which is missing from this set, OPLS parameters were employed.52 Partial charges for acetate and nitrate were evaluated using the standard RESP procedure employing the Gaussian 03 program,⁵³ and all molecular dynamics (MD) simulations were performed using the Amber 8 program.⁵⁴ To directly check the effect of polarization interaction, several test calculations using a polarizable force field^{55,56} were also performed, with an imposed cutoff on induced dipoles in order to avoid the polarization catastrophe,⁵⁷ and compared with nonpolarizable simulations. The use of an empirical force field excludes studying the acid/base properties of the acetate ion, since this involves the breaking/ making of a chemical bond and, consequently, this is not considered in our simulations.

4. Results and Discussion

4.1. Densities and Isentropic Compressibilities. Within the limited temperature range investigated, the measured densities, ρ , of aqueous solutions of Mg(NO₃)₂ and Mg(OAc)₂ were found

to vary linearly with temperature at a fixed concentration. The least-squares fitted values of the parameters of the density equation ($\rho = a - bt$) are listed in Table 2. The present densities at 25 °C agree within ±0.2% with literature^{58–60} data for both Mg(OAc)₂ and Mg(NO₃)₂ solutions. The corresponding ultrasonic velocities, *u*, were comparable within ±0.2% for Mg-(OAc)₂(aq) and ±0.4% for Mg(NO₃)₂(aq) with literature^{58,61} data at 25 °C.

Isentropic compressibilities, κ_s , of Mg(OAc)₂(aq) and Mg-(NO₃)₂(aq) were calculated using

$$\kappa_{\rm s} = \left(u^2 \rho\right)^{-1} \tag{1}$$

and are plotted against concentration for the three temperatures in Figure 1. Because of the wide concentration range of interest here, an empirical equation^{42,43} was used to describe the κ_s values. The parameters so obtained are summarized in Table 3.

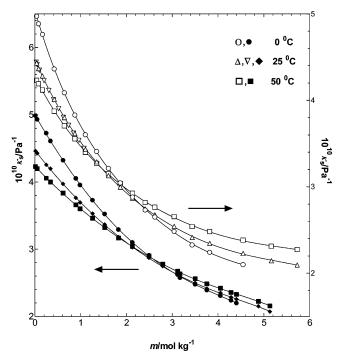

Figure 1. Isentropic compressibilities of aqueous solutions of Mg-(OAc)₂ (open symbols) and Mg(NO₃)₂ (solid symbols) as a function of concentration and temperature. Solid curves are calculated from the isentropic compressibility equation, $\kappa_s = a_1 + b_1m + c_1m^{1.5} + d_1m^2 + e_1m^{2.5} + f_1m^3$ (see ref 43), ∇ ref 58.

Figure 1 and Table 3 show that the equation can reproduce the data within the 95% confidence level.

It is apparent from Figure 1 that the κ_s isotherms for each electrolyte within the studied temperature range (0–50 °C) exhibit a crossover at an approximately constant concentration that appears to be characteristic. As the electrolyte concentration increases, κ_s decreases due to the simultaneous effects of ion hydration and the modification of water molecules located in the direct vicinity of the ions. The main contributor to these effects would be expected to be Mg²⁺ because of its higher charge density and hydration energy.⁶²

A long-standing assumption of solution chemistry is that the addition of electrolytes (ions) to water significantly alters the water structure, which is reflected in the changes in the physicochemical properties (viscosity, surface tension, etc.) of the solutions so formed. But recent reports suggest that ions only influence the hydrogen bonding of water molecules in their immediate vicinity, that is, the water molecules in the primary hydration shell.⁴⁰

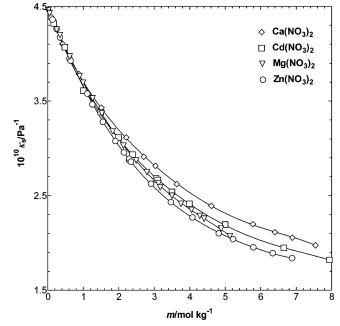

Figure 2. Isentropic compressibilities of various aqueous solutions of NO_3^- salts as a function of concentration at 25 °C: \bigcirc ref 42, \square and \diamondsuit ref 43.

The influence of cations on κ_s is illustrated in Figure 2, which plots κ_s for aqueous solutions of various metal nitrate salts at 25 °C. As would be expected from the greater electrostriction⁶³ associated with decreasing cationic radii (*r*),³⁹ the κ_s values at higher solute concentrations increase in the order of their M²⁺– OH₂ distances (*d*) (*d* = 2.04, 2.12, 2.31, and 2.44 Å for M = Mg, Zn, Cd, and Ca, respectively)⁶⁴ with Mg²⁺ as a partial exception.

On the other hand, comparison of the effects of anions on κ_s values is less straightforward. Figure 3 shows that Mg(OAc)₂ solutions are less compressible than Mg(NO₃)₂ solutions up to \approx 4.6 mol kg⁻¹ at 25 °C but this is reversed at higher concentrations. For comparison, κ_s data for MgCl₂ and MgSO₄ solutions⁶⁵ are also included in Figure 3. In contrast with the cations, the κ_s values do not correlate with the anion–water distances ($d(SO_4^{2-}-(H_2)O) = 3.70$ Å, $d(OAc^--(H_2)O) = 3.70$ Å, $d(CI^--(H_2)O) = 3.15$ Å, $d(NO_3^--(H_2)O) = 3.40$ Å) obtained from diffraction studies.^{12,13}

It is noteworthy that the κ_s data as presented appear to conform to the Hofmeister series.³⁶ OAc⁻ and SO₄²⁻ belong to the salting-out side, Cl⁻ is in the middle, and NO₃⁻ belongs to the salting-in side of the series. On this basis, Mg(OAc)₂ and Mg(NO₃)₂ would be expected to have qualitatively different

TABLE 3: Values of the Parameters of the Isentropic Compressibility Equation, $\kappa_s = a_1 + b_1m + c_1m^{1.5} + d_1m^2 + e_1m^{2.5} + f_1m^3$ (see ref 43), for Aqueous Solutions of Mg(OAc)₂ and Mg(NO₃)₂

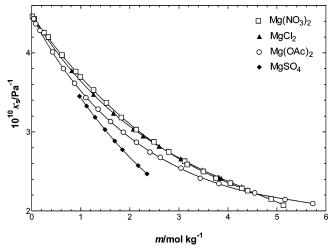

Figure 3. Isentropic compressibilities of aqueous solutions of various Mg^{2+} salts as a function of concentration at 25 °C: \blacktriangle and \blacklozenge ref 65.

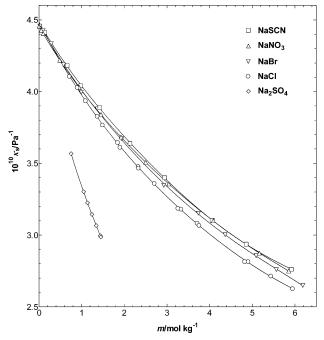

Figure 4. Isentropic compressibilities of aqueous solutions of various Na⁺ salts as a function of concentration at 25 °C: \Box ref 44, \bigcirc , \diamondsuit ref 65, \triangle ref 68, and \triangledown ref 69.

effects on the water molecules located in the first hydration shell in the immediate vicinity of ions. As discussed above (Figure 1), the crossover concentration for Mg(OAc)₂(aq) is lower than that for Mg(NO₃)₂(aq), which implies that OAc⁻ is more efficient in influencing the water molecules in its first hydration sphere than NO₃⁻. Further, the values of the estimated viscosity A- and B-coefficients, using the extended Jones–Dole equation^{66,67} for Mg(NO₃)₂(aq) and Mg(OAc)₂(aq), were estimated to be 0.0017 and 0.0074 dm^{3/2} mol^{-1/2} and 0.0022 and 0.217 dm³ mol⁻¹, respectively. The higher values of the viscosity Aand B-coefficients of Mg(OAc)₂(aq) suggest that OAc⁻ forms a more rigid structure with water molecules in the first hydration shell due to strong solvation of ions,⁶⁷ which is reflected in Figure 1.

To further investigate possible Hofmeister effects, Figure 4 plots κ_s values at 25 °C for various Na salts.^{44,65,68,69} The trend is again consistent with the Hofmeister series, taking the data at face value.³⁶

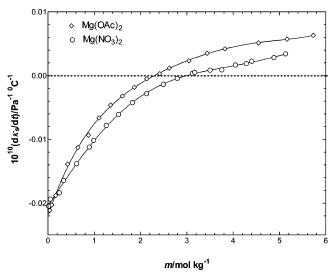

Figure 5. Temperature derivative of isentropic compressibility as a function of concentration for aqueous solutions of $Mg(OAc)_2$ and $Mg(NO_3)_2$ at 25 °C.

The crossover concentration for κ_s isotherms (Figure 1) can be considered^{42,43} as coinciding with the disappearance of the bulk water structure, with all the water molecules being incorporated into the first hydration shells of the ions, resulting in a more rigid structure for the solution. Beyond this concentration, the co-spheres of the cations and anions overlap leading to the formation of ion pairs.⁷⁰ Figure 1 shows that the κ_s isotherms for Mg(OAc)₂ and Mg(NO₃)₂ solutions do not cross at a fixed concentration but rather over narrow concentration ranges $(1.50-2.30 \text{ mol kg}^{-1} \text{ and } 2.00-3.00 \text{ mol kg}^{-1}, \text{ respectively})$ within the temperature range of study. To estimate the total hydration number of the ions at 25 °C, a plot of the temperature derivative of κ_s for both systems was made; see Figure 5. A two-degree polynomial equation was used to fit the data. Evidently, the $d\kappa_s/dt$ plots become zero at 2.28 mol kg⁻¹ and 2.90 mol kg⁻¹, respectively, for Mg(OAc)₂ and Mg(NO₃)₂ solutions.

The total hydration numbers, n_h , of Mg(OAc)₂(aq) and Mg-(NO₃)₂(aq) can be calculated using the empirical equation⁴²⁻⁴⁴

$$n_{\rm h} = (\kappa_{{\rm s},\phi} - \kappa_{{\rm s},{\rm h}} V_{\phi}) / [V_0(\kappa_{{\rm s},{\rm h}} - \kappa_{{\rm s},0})]$$
(2)

where $\kappa_{s,\phi}$ (= $(1/m\rho_0)(\kappa_s - \kappa_{s,0}) + \kappa_s V_{\phi}$, where *m* is the concentration in mol kg⁻¹ and ρ_0 and $\kappa_{s,0}$ are the density and the isentropic compressibility of the solvent, respectively) is the apparent molal isentropic compressibility of the solute, $\kappa_{s,h}$ is the isentropic compressibility of the hydration shell of the solute, $V_{\phi} (= M/\rho - (\rho - \rho_0)/\rho_0 m$, where *M* is the molar mass of the solute) is the apparent molal volume of the solute, and $V_0 (= M_0/\rho_0$, where M_0 is the molar mass of the solvent) is the molar volume of the solvent. Through the use of this expression, the total hydration numbers for Mg(OAc)₂ and Mg(NO₃)₂ solutions were estimated to be 24.3 and 19.2 at 2.28 and 2.90 mol kg⁻¹, respectively.

4.2. Structural Relaxation Times. The measured viscosities for $Mg(NO_3)_2(aq)$ are within $\pm 5\%$ of the literature values.^{59,60} No previous viscosity data appear to have been published for $Mg(OAc)_2(aq)$.

To help understand the nature of ionic interactions at different concentrations, the structural relaxation time, τ , was calculated using

$$\tau = 4\kappa_{\rm s}\eta/3\tag{3}$$

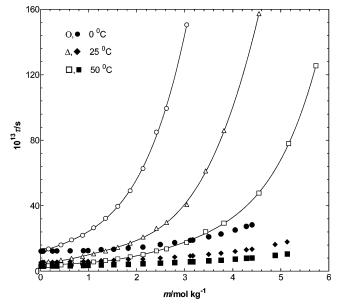

Figure 6. Variation of the structural relaxation time, τ , with concentration for aqueous solutions of Mg(OAc)₂ (open symbols) and Mg(NO₃)₂ (solid symbols).

The quantity τ can be considered as the time required to relieve the shear stress at constant strain through viscous flow. It is particularly sensitive to the formation of ion pairs because of coupling between ion-solvent and ion-ion interactions. Figure 6 shows the variation of τ with concentration at three temperatures for aqueous solutions of Mg(NO₃)₂ and Mg(OAc)₂.

The dramatic differences between the solutions of the two salts almost certainly reflect the differences in the extent and nature of their ion association. Although the existing information (Table 1) is somewhat contradictory, there is little doubt that $Mg(OAc)_2(aq)$ not only is more strongly associated than $Mg(NO_3)_2(aq)$ but also forms more contact (inner sphere) species. These issues will be discussed further below when considering the Raman spectra.

4.3. Electrical Conductivities. If ion pair formation in Mg- $(OAc)_2(aq)$ is significantly greater than in Mg $(NO_3)_2(aq)$, then measurable effects on ionic mobilities, that is, on their electrical conductivities, would be expected. Experimental specific electrical conductivities, κ , for aqueous solutions of Mg $(OAc)_2$ and Mg $(NO_3)_2$ are around $3-6\%^{71a}$ and $1-10\%^{71b}$ respectively, lower than the literature values at 25 °C.

Figure 7 plots κ vs *m* for solutions of the two salts at three temperatures. All the κ isotherms pass through a maximum (κ_{max}), which is located at 1.07 \pm 0.13 and 2.45 \pm 0.09 mol kg⁻¹ for the acetate and nitrate salts, respectively. At higher concentrations (>1 mol kg⁻¹), κ (Mg(OAc)₂(aq)) is substantially smaller than κ (Mg(NO₃)₂(aq)). Although a small part of these differences can be attributed to the greater mobility of NO₃⁻, λ° (NO₃⁻) = 71.5 cm² S mol⁻¹, than that of OAc⁻, λ° (OAc⁻) = 40.9 cm² S mol⁻¹,⁷² the greatest part is almost certainly due to the higher level of ion pair formation in Mg(OAc)₂(aq). Greater association of Mg²⁺ with OAc⁻ cf. NO₃⁻ is also consistent with the reported activity coefficients of Mg(OAc)₂-(aq)⁷³ and Mg(NO₃)₂(aq).⁷⁴

The reasons why OAc^- associates with Mg^{2+} more strongly than does NO_3^- are undoubtedly complicated. In addition to long-range electrostatic interactions, short-range covalent and polarization effects are probably important. The effects of solvation must also be considered. Because of their very different structures and chemical characteristics, the interactions

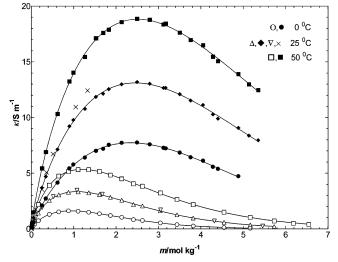

Figure 7. Variation of electrical conductivity with concentration for aqueous solutions of Mg(OAc)₂ (open symbols) and Mg(NO₃)₂ (solid symbols) at three temperatures: ∇ ref 71a, \times ref 71b.

of OAc⁻ and NO₃⁻ with water molecules differ considerably. In the Hofmeister series, OAc⁻ lies toward the salting-out end whereas NO₃⁻ is toward the salting-in end, which indicates a very different interaction of the two ions with solvent water. Acetate is hydrated by six water molecules²⁹ and is thought to modify the structure of water in a manner similar to that caused by alcohols,⁷⁵ probably due to the presence of its hydrophobic part. On the other hand, NO₃⁻ forms a H-bonded complex with two water molecules having two dominant structures.⁷⁶ It may be that the hydrophobic end of the CH₃COO⁻ ion promotes its entry into the primary hydration shell of Mg²⁺; however, it should be noted that the "absolute" Gibbs energy of hydration for OAc⁻ is about 60 kJ mol⁻¹ more negative (i.e., more favorable) than that of NO₃⁻.⁷⁷

The differences between Mg(OAc)₂(aq) and Mg(NO₃)₂(aq) for both τ (Figure 6) and κ (Figure 7) become more pronounced at lower temperatures, which suggests that ion pairing in the former increases with decreasing temperature. This is consistent with the measured negative enthalpy of complexation.⁷⁸ It is interesting to note that the concentration corresponding to κ_{max} for Mg(NO₃)₂ solutions coincides with the κ_s crossover. This is consistent with the presence of at least some types of ion pairs (probably noncontact) at higher concentrations.

4.4. FT-Raman Spectra. 4.4.1. Magnesium Acetate Solutions. The Raman spectra for Mg(OAc)₂(aq) are presented at various concentrations in Figure 8. The band positions associated with OAc⁻ are summarized in Table 4. Band assignments are based on those of previous investigations.^{8,32-35} The antisymmetric stretching mode (ν_8) is only very weakly observed in Raman spectra and so will not be considered further.

The broad COO⁻ symmetric stretching mode (ν_3) of OAc⁻, which appears in the 1400–1500 cm⁻¹ region (Figure 8), lies very close to, and contains contributions from, the CH₃ deformation modes ν_9 and ν_{13} .^{33,35,79} This band shows a blue shift, with increasing intensity on the high-frequency side at higher salt concentrations, which is reflected in an increase in the full-width at half (maximum) height (fwhh) of the band (Table 4). At 5.410 mol kg⁻¹, two wings on the high-frequency side of this band are apparent at ~1445 and ~1463 cm⁻¹. The ν_3 , ν_9 , and ν_{13} modes for solid Mg(OAc)₂·4H₂O also overlap. The resolved component bands were found to appear at 1436–1438, 1420–1421, and 1446–1455 cm⁻¹, respectively.^{33,79} In the solid phase, a bisacetato complex is the building unit for Mg(OAc)₂.^{79,80}

^a The values in parentheses represent the full width at half-maximum height (fwhh) for the given band.

As the CH₃ deformation modes (ν_9 and ν_{13}) are not sensitive to the metal-carboxyl group interactions, the observed frequency shift ($\Delta \nu_3 \approx 10 \text{ cm}^{-1}$) and the increasing asymmetry of the band on the high-frequency side can be attributed to changes in the COO⁻ stretching vibration due to complexation with Mg²⁺. Further, the appearance of the two high-frequency wings at 5.410 mol kg⁻¹ suggests the occurrence of both monoand bidentate complexes. Wang et al.³⁵ also observed two shoulders in the ν_3 Raman mode at ~1456 and 1443 cm⁻¹ at *m* \geq 3.58 mol kg⁻¹ for Mg(OAc)₂(aq) and attributed them to bidentate and bridged bidentate complexes, respectively. Nickolov et al.³³ employed band fitting techniques to the Raman spectra of Mg(OAc)₂(aq) and reported that bisacetato complexes were the dominant species in saturated solutions.

The C–C stretching band (ν_4) of OAc⁻ is probably the most useful with respect to establishing the existence of metal–acetato complexes.^{33–35,79} It has a high Raman scattering coefficient and does not overlap with other vibrations. In the present spectra

(Figure 8), it occurs as a reasonably sharp band, centered at ~938 cm⁻¹. As the solute concentration increases, this band shows a small blue shift (Table 4) and a simultaneous development of asymmetry on the high-frequency side with a weak shoulder at ~948 cm⁻¹. The ν_4 band is observed at 892 cm⁻¹ for HOAc and at 928 cm⁻¹ for free OAc⁻(aq).³⁴ For Mg(OAc)₂• 4H₂O(s), the band occurs at 947 cm⁻¹.³³ The variation in the position of the ν_4 mode with concentration suggests the

formation of mono- and bidentate contact ion pairs (inner-sphere complexes) at higher concentrations. Similar observations for Mg(OAc)₂(aq) have been made by Nickolov et al.³³ They resolved the v_4 band into three components at 930, 939, and 947 cm⁻¹ by curve fitting methods and ascribed them to free OAc⁻, monoacetato complexes, and bisacetato complexes, respectively. A blue shift of the v_4 band from 936 to 947 cm⁻¹ with increasing concentration of Mg(OAc)₂(aq) was ascribed to the transformation of free OAc⁻ to contact ion pairs between Mg²⁺ and OAc⁻.³⁵ Semmler et al.⁸ suggested the formation of monoacetato complexes in Mg(OAc)₂(aq) and were able to resolve a band at 939 cm⁻¹ above 100 °C.

Additional evidence in support of complex formation in Mg-(OAc)₂ solutions can be derived from the COO⁻ deformation or bending (ν_5) and in-plane rocking (ν_{11}) modes.⁷⁹ In the present spectra (Figure 8), ν_5 was observed at 654 cm⁻¹ for a 0.2745 mol kg⁻¹ solution, shifting to 666 cm⁻¹ at 5.410 mol kg⁻¹. Such a large blue shift can be attributed to the complexation of COO⁻ with Mg²⁺. However, at $m \ge 2.634$ mol kg⁻¹, a shoulder appears at ~621 cm⁻¹, ultimately producing a peak at 624 cm⁻¹ at m= 5.410 mol kg⁻¹. The appearance of two ν_5 bands is consistent with their observation (at 678 and 612 cm⁻¹) for solid Mg-(OAc)₂ at liquid nitrogen temperature.⁷⁹ This suggests that the 624 cm⁻¹ band may originate from bidentate complexes.³⁵

A broad envelope at 400–500 cm⁻¹, corresponding to the ν_{11} mode, is observed (Figure 8) in the present spectra of Mg-(OAc)₂(aq). This band probably overlaps with the water libration band, which occurs at ~450 cm⁻¹.⁸¹ At higher concentrations (≥ 2.634 mol kg⁻¹), the ν_{11} band becomes prominent at ~479 cm⁻¹. Its broadness suggests the presence of various environments for the COO⁻ moiety. At 5.410 mol kg⁻¹, an additional shoulder at ~496 cm⁻¹ is apparent. This is identical to that reported for solid Mg(OAc)₂·4H₂O,³³ which implies the presence of bisacetato complexes. A shift of the ν_{11} mode from 480 to 510 cm⁻¹ for aqueous Ni(OAc)₂ solutions has been ascribed to complex formation.⁸²

4.4.2. Magnesium Nitrate Solutions. Raman spectra of Mg- $(NO_3)_2(aq)$ are depicted in Figure 9. Unperturbed NO_3^- has D_{3h} symmetry and gives rise to symmetric stretching (ν_1), out-of-plane deformation (ν_2), asymmetric stretching (ν_3), and in-plane deformation or bending (ν_4) modes.^{21,22} The ν_3 and ν_4 modes are both Raman and IR active, whereas the ν_1 is Raman active only and ν_2 is IR active only. The band positions for NO_3^- in the present Mg(NO₃)₂ solutions are summarized in Table 5.

The inset in Figure 9 shows the variation of the ν_1 mode with increasing salt concentration. The intensity and the fwhh of this band increase as the concentration increases. The band position is constant at 1059 cm⁻¹ up to 2.493 mol kg⁻¹ but blue shifts by 4 cm⁻¹ at higher concentrations. There is also a slight increase in the fwhh (Table 5), which has been attributed²⁷ to the influence of hydrated cations on NO₃⁻. This implies the presence of noncontact ion pairs at high Mg(NO₃)₂ concentrations. A previous study²⁵ of the Raman spectra of Mg(NO₃)₂-(aq) using principal component analysis indicated the presence of some associated species, probably a solvent-shared ion pair at ≥ 2.5 mol dm⁻³.

Zhang et al.,²³ in their study of highly concentrated droplets of Mg(NO₃)₂(aq) using Raman microscopy, observed that ν_1 shifted from 1049 to 1055 cm⁻¹ when the concentration changed from 7.60 to 10.09 mol kg⁻¹ and suggested it was due to the formation of contact ion pairs. Peleg²¹ similarly reported ν_1 shifted from 1049 to 1053 cm⁻¹ when the Mg(NO₃)₂ concentration increased from 9.25 to 13.22 mol kg⁻¹ and also invoked contact ion pairs as the explanation. Above 9.25 mol kg⁻¹ (in

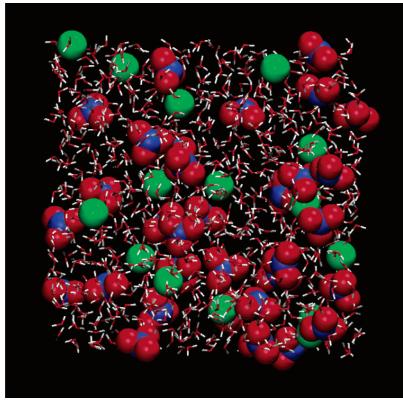

Figure 12. Snapshot from a simulation of 1 M Mg(NO₃)₂(aq). Color coding: Mg = green, N = blue, O = red, and H = white. For clarity, water molecules are displayed in stick representation.

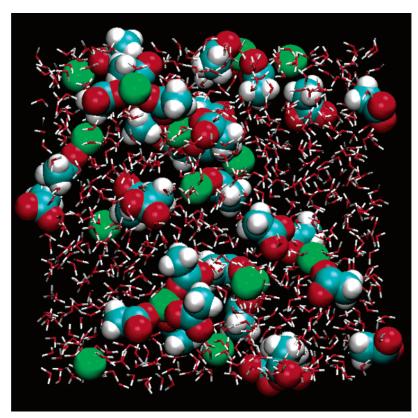

Figure 13. Snapshot from a simulation of 1 M Mg(OAc)₂(aq). Color coding: Mg = green, C = cyan, O = red, and H = white. For clarity, water molecules are displayed in stick representation.

hydrated melts), splitting of the ν_1 band has been reported and was thought to be evidence for the formation of different types of contact ion pairs.^{21–23}

Unperturbed NO_3^- gives a single ν_3 band at 1370 cm^{-1.76} Previously,^{42,43,76,83} it was concluded that water causes the

splitting of the ν_3 band due to hydration or solvent-shared ion pair formation. For example, bifurcated ν_3 bands appear at ~1341 and ~1402 cm⁻¹ in 3.43 mol kg⁻¹ Zn(NO₃)₂(aq).⁴² In the present study, no splitting of ν_3 was observed at lower concentrations and the band profiles matched well with those of Chang and Irish²² and Zhang et al.²³ At concentrations greater than 2.493 mol kg⁻¹, the band intensity increased asymmetrically on the high-frequency side and the band maximum occurred at ~1428 cm⁻¹ with a shoulder at ~1370 cm⁻¹. Peleg²¹ also reported a splitting of the ν_3 band in 2.78 mol kg⁻¹ Mg-(NO₃)₂ solutions. It seems reasonable to ascribe the ~1370 cm⁻¹ shoulder to unperturbed NO₃⁻⁷⁶ and the mode at ~1428 cm⁻¹ to NO₃⁻ perturbed by (or associated with) hydrated cations.²¹

The intensity of the broad band in the $1600-1700 \text{ cm}^{-1}$ region increases with concentration. However, as the $2\nu_2$ overtone for NO₃⁻ at ~1658 cm⁻¹ and the water deformation mode (at 1636 cm⁻¹) also occur in this region, no detailed analysis is possible.^{21,22}

The appearance of double in-plane deformation bands (ν_4), at ~750 and ~720 cm⁻¹, is considered diagnostic for contact ion pair formation.^{20–22} Our Mg(NO₃)₂ solutions produced a single Raman band at ~726 cm⁻¹ for 0.3404 mol kg⁻¹, which blue shifted by only ~2 cm⁻¹ up to 3.757 mol kg⁻¹. The intensity of the band was proportional to the concentration.²² At 4.883 mol kg⁻¹, the band shows a blue shift of ~8 cm⁻¹, suggesting perturbation of NO₃⁻ by hydrated Mg²⁺, as proposed by Angell.²⁷ The possible mode at ~760 cm⁻¹ (Figure 9) may be due to noise, because the 750 cm⁻¹ band for Mg(NO₃)₂(aq) appears only above 9.25 mol kg⁻¹.^{21,22}

The $\nu_{\rm O-H}$ envelope of pure water is thought to consist of four components, an ice-like component (C₁) at ~3230 cm⁻¹, an ice-like liquid component (C₂) at ~3420 cm⁻¹, a liquidlike amorphous phase (C₃) at ~3540 cm⁻¹, and monomeric H₂O (C₄) at ~3620 cm⁻¹.⁸⁴ In the present systems, the $\nu_{\rm O-H}$ mode exhibits one broad peak at ~3234 cm⁻¹ with a shoulder at ~3385 cm⁻¹. Upon addition of Mg(NO₃)₂, the shoulder grows relative to the ~3234 cm⁻¹ band. At 4.883 mol kg⁻¹, the shoulder becomes the main peak. The positive shift of the $\nu_{\rm O-H}$ band maximum has been ascribed to the disruption of the water structure and formation of bonds between water and ions.⁸⁵

In summary, the Raman bands observed at ~726, ~1059, and ~1390 cm⁻¹ along with ν_{O-H} suggest that NO₃⁻ does not bond directly to Mg²⁺ within the experimental concentration range. Nevertheless, there are changes in the spectra that suggest that noncontact ion pairs may be formed, particularly at high concentrations. Clearly, as noted above, there are major differences between the extent and the nature (type) of the complex-(es) formed in Mg(OAc)₂(aq) and Mg(NO₃)₂(aq). Although some interesting ideas have been proposed to account for such differences in general, see for example Collins⁸⁶ and Kiriukhin and Collins,⁸⁷ they are too speculative to warrant detailed discussion here.

4.5. Mean Distance Between Cation and Anion. To better ascertain the existence of different ionic species in different concentration regions, an attempt was made to determine the maximum possible mean cation—anion distance.⁸⁸ Assuming a random distribution of the ions in the solution without any attractive or repulsive interactions, the estimated mean cation—anion distance is depicted in Figure 10 as a function of concentration for both salt systems.

The mean cation—anion distance decreases sharply up to a solute concentration of ~1.0 mol kg⁻¹ according to this model but decreases gradually thereafter. A simple geometrical arrangement (Figure 11) illustrates the cation—anion separation, including water molecules: one nominally associated with the cation and another with the anion. For Mg(OAc)₂(aq), the Mg²⁺—OH₂ and OAc⁻—(H₂)O equilibrium distances obtained from X-ray diffraction^{12,64} should be taken into account along with the diameter of the water molecules. In Figure 11, the

separation is 8.62 Å, which corresponds to the mean distance between the ions at a concentration of 2.37 mol kg⁻¹, if a random distribution without ion-ion interactions is assumed. Similarly for $Mg(NO_3)_2(aq)$, the separation required by two water molecules between Mg^{2+} and NO_3^{-} is 8.32 Å, which corresponds to the mean distance at 2.86 mol kg^{-1} (Figure 10). These concentrations, 2.37 and 2.86 mol kg⁻¹ for Mg(OAc)₂ and $Mg(NO_3)_2$, respectively, are comparable with those at which $d\kappa_s/dt = 0$ (Figure 5), which lends support to the idea that they correspond to the situation in which the available water molecules are just sufficient to complete the first hydration shells of the dissolved ions. Above these concentrations solvent-shared or contact ion pair formation is inevitable, as the mean separation between the ions can no longer accommodate more than one water molecule. It is again emphasized that this conclusion is derived from purely (and "primitive") geometric considerations. No account has been taken of short-range attractive forces or even of geometric constraints, such as the presence of the CH₃ group in the acetate ion, which might allow its closer approach to Mg²⁺.35

4.6. Computational Results. Molecular dynamics simulations were used to study hydration and ion pairing in aqueous solutions of magnesium nitrate and acetate, yielding a statistically relevant picture with atomic resolution. Figures 12 and 13 present typical snapshots from simulations of 1 M Mg(NO₃)₂-(aq) and Mg(OAc)₂(aq), which show the qualitative differences between these two salt systems. In Mg(NO₃)₂(aq), most of the ions are separated from other ions and are fully hydrated. The opposite is true for Mg(OAc)₂(aq), where many of the Mg²⁺ ions are associated with OAc⁻ ions. Moreover, a significant

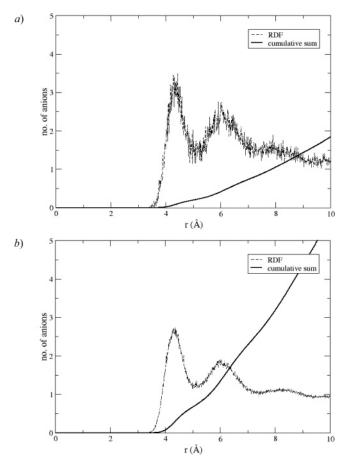

Figure 14. Magnesium—nitrate oxygen radial distribution function and cumulative sum for aqueous solutions at concentrations of (a) 0.25 M and (b) 1 M.

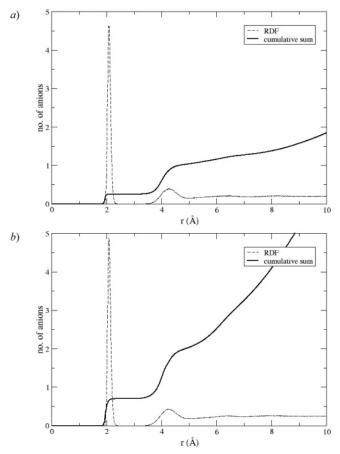

Figure 15. Magnesium–acetate oxygen radial distribution function and cumulative sum for aqueous solutions at a concentration of (a) 0.25 M and (b) 1 M.

degree of ion clustering is observed, particularly around Mg^{2+} , which is associated with more than one OAc^{-} .

The qualitative picture from the snapshots was quantified using statistically averaged (over nanosecond trajectories) data. In particular, the Mg^{2+} —anion and ion—water radial distribution functions (RDFs) were monitored, and cumulative sums were evaluated as integrals over these RDFs. The cumulative sums were normalized so as to provide the number of anions or water molecules within a particular distance from a given Mg^{2+} .

Figure 14 shows the magnesium–nitrate oxygen RDFs and cumulative sums for 0.25 and 1 M solutions. There are no contact ion pairs (which would correspond to a peak in the RDF at around 2.1 Å) present in either case. The RDF peak at 4.2 Å corresponds to ion pairs separated by one water molecule (i.e., a solvent-shared ion pair, SIP). There is also a broad feature at around 6 Å corresponding to ions separated by two water molecules (2 SIPs). It can be estimated from the cumulative sum that, on average, at 0.25 M, ~20% of NO₃⁻⁻ is transiently associated with Mg²⁺ as SIPs. This rises to about 60% at 1 M.

Analogous information for the magnesium acetate solutions is presented in Figure 15. The situation is very different from the nitrate solutions: even at 0.25 M there is significant contact ion pairing, reflected in the RDF peak at around 2.1 Å. From the cumulative sum, it can be deduced that ~25% of Mg²⁺ forms contact ion pairs with OAc⁻. Moreover, SIPs are also present (at around 4.2 Å). On average, there is one OAc⁻ per Mg²⁺ present either as contact ion pairs (CIPs) or as SIPs. At 1 M, this average rises to two, with ~0.7 OAc⁻ per Mg²⁺ present as CIPs.

The ion-water distribution functions provide information about the concentration-dependent hydration patterns of the

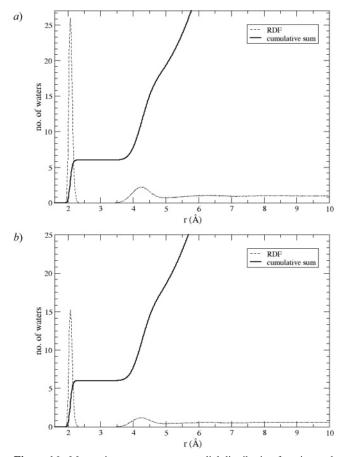

Figure 16. Magnesium—water oxygen radial distribution function and cumulative sum for aqueous solutions of magnesium nitrate at a concentration of (a) 0.25 M and (b) 1 M.

individual ions. Figure 16 shows the magnesium—water oxygen RDFs and the cumulative sum for 0.25 and 1 M solutions of $Mg(NO_3)_2$. For both concentrations, there is a rigid first hydration shell around Mg^{2+} containing six strongly bound water molecules, which is typical for alkaline-earth cations. The position of the first hydration shell peak at around 2.1 Å agrees very well with X-ray diffraction experiments.⁸⁹ A broader peak at around 4.2 Å marks a much "softer" second solvation shell containing roughly 12 water molecules. The existence of a second hydration sheath around Mg^{2+} containing 12 water molecules is consistent with both dielectric relaxation measurements⁹⁰ and vibrational spectra.⁹¹

The magnesium-water oxygen RDFs and the cumulative sums for Mg(OAc)₂(aq), depicted in Figure 17, are affected by strong ion pairing. Thus, the number of water molecules in the first hydration shell drops from 6 to approximately 5.6 at 0.25 M and to 4.8 at 1 M, consistent with them being partially replaced by acetate anions. On average, about one water molecule is displaced from the first hydration shell of Mg²⁺ in 1 M Mg(OAc)₂.

Test calculations employing polarizable potentials gave very similar results to the nonpolarizable simulations concerning the structure of the solutions and ion pairing. If anything, the tendency for ion pairing increased upon the inclusion of polarization. This is demonstrated, for example, in Figure 18, which shows the magnesium—acetate oxygen RDF and cumulative sum for the 0.25 M solution containing polarizable ions and water molecules. It can be seen that the results compare semiquantitatively to the results employing a nonpolarizable force field (see Figure 15a), except that the direct ion pairing is slightly enhanced.

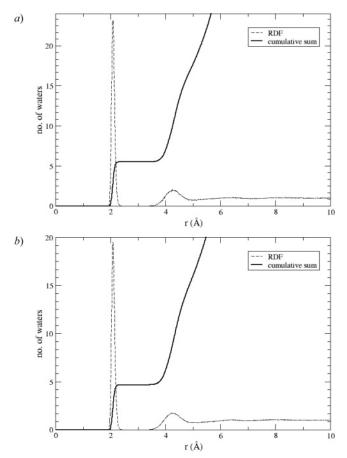

Figure 17. Magnesium—water oxygen radial distribution function and cumulative sum for aqueous solutions of magnesium acetate at a concentration of (a) 0.25 M and (b) 1 M.

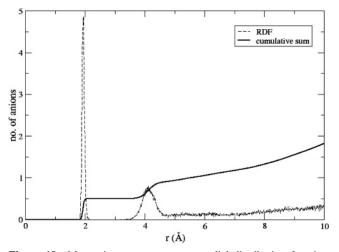

Figure 18. Magnesium–acetate oxygen radial distribution function and cumulative sum for an aqueous solution at a concentration of 0.25 M employing polarizable potentials.

5. Conclusions

Ionic charge density, especially of cations, appears to be a major factor influencing the isentropic compressibilities of aqueous electrolyte solutions. However, the present data for Mg- $(OAc)_2$ and Mg $(NO_3)_2$ solutions along with literature values for other salts indicate that anion effects follow the Hofmeister series. The significant differences, which exist between Mg- $(OAc)_2$ and Mg $(NO_3)_2$ solutions, with respect to their structural relaxation times, viscosities, and electrical conductivities, are consistent with a much greater degree of ion association in the former. This is confirmed by the Raman spectra of Mg $(OAc)_2$

(aq), which show substantial changes with concentration, consistent with the formation of mono- and bidentate complexes (contact ion pairs), whereas for $Mg(NO_3)_2(aq)$ only noncontact ion pairs are implied. The mean cation-anion separation estimated from a simple geometrical approach suggests that the electrolyte concentration at which $d\kappa_s/dt = 0$ (Figure 5) corresponds to the disappearance of bulk water from the solution. The experimental results are supported by MD simulations of 0.25 and 1 M solutions of magnesium nitrate and acetate. These simulations indicate, in accord with experiment, that contact ion pairs are absent in $Mg(NO_3)_2$ solutions, where only solvent-separated ion pairs (SIPs and 2 SIPs, the total number of which rises steeply with concentration) can be observed. In contrast, CIPs are prevalent in Mg(OAc)₂ solutions at both concentrations. The number of CIPs and SIPs increases strongly with concentration, and at 1 M, a significant ion clustering occurs. This is also reflected in the structure of the first hydration shell around Mg²⁺, from which on average about one water molecule is replaced by acetate.

Acknowledgment. A.W. and S.M. are grateful to the Director, Regional Research Laboratory, Jorhat, India for interest in this work, and A.W. is thankful to the Council of Scientific and Industrial Research, New Delhi, India for the award of senior research fellowship. Support (to P.J.) from the Czech Ministry of Education (Grant LC512) and from the U.S. NSF (Grants CHE 0431512 and 0209719) is gratefully acknowledged. The authors are also grateful to the Sophisticated Analytical Instrumentation Facility, Indian Institute of Technology-Madras, India for recording the Raman spectra.

(88) For example, a 1 M Mg(OAc)₂ solution is considered where the water molecules are taken as hard spheres of radius 1.4 Å. The ionic radii of Mg²⁺ and OAc⁻ are taken as 0.65 and 2.32 Å, and the corresponding volumes would be 1.15 and 52.31 Å³, respectively. At this concentration, ions would constitute a volume fraction of 6.37%. Now, a spherical box is taken to fill it randomly with the particles (ions) so that 6.37% is occupied. The maximum possible mean distance between a cation and an anion along the diameter of the sphere is calculated to be 11.72 Å.
