Abstract— A coupled Bloch-wave approach is employed to analyze active photonic-crystal (PhC) waveguides and cavities. Gain couples the otherwise independent counter-propagating Bloch modes. This coupling is shown to limit the maximum attainable slow-light enhancement of gain itself and to strongly affect the mode selection in PhC lasers.

Keywords—PhC lasers, Coupled-mode theory, Bloch waves, Slow-light.

INTRODUCTION

The slow-light (SL) enhancement of gain in photonic-crystal waveguides allows for the fabrication of shorter devices when realizing active structures. In particular, PhC lasers based on line-defect waveguides are ideal candidates for energy efficient light sources in high density PhC integrated circuits [1,2]. Solving Maxwell equations by a finite-difference-timedomain (FDTD) technique is a rigorous, but extremely timeand memory-consuming approach to analyze PhC devices [3]. Furthermore, FDTD simulations are not always useful to shed light on the physics of the investigated structures. Conversely, coupled-mode theory has been widely used to investigate the impact of SL effects in both passive [4,5] and active [6] PhC waveguides. In particular, the complex optical susceptibility arising by the interaction of the field with the active medium is treated in [6] as a weak perturbation of the passive structure, which induces a coupling between the otherwise independent counter-propagating Bloch modes. The fundamental limitations to the SL gain-enhancement imposed by the gain itself have been investigated in [7] by a rigorous, non-perturbative approach. In this work we use the perturbative approach of [6] to study an active PhC waveguide; we analyze the implications of the gain perturbation on the group index and then we study a PhC laser modelled as a cavity consisting of an active PhC waveguide and two mirrors. Interestingly, it is shown that our model predicts, consistently with [7], a reduction of the maximal group index caused by increasing the gain and it can be used to understand the impact of the gain-induced coupling on the selection of PhC laser lasing mode.

I. NUMERICAL MODEL

The forward- (+) and backward-propagating (-) guided electric field of the passive waveguide in the frequency-domain are denoted by $E_{0,\pm}(r,\omega)=\mathbf{e}_{0,\pm}(r,\omega)e^{\pm ik_z(\omega)z}$, where z is the propagation direction and $\mathbf{e}_{0,\pm}(x,y,z)=\mathbf{e}_{0,\pm}(x,y,z+a)$ are the Bloch waves, with k_z propagation constant and a the PhC lattice constant. The electric field of the active waveguide is expanded as $E=\psi_+(z,\omega)E_{0,+}+\psi_-(z,\omega)E_{0,-}$, where $\psi_\pm(z,\omega)$ are slowly-varying amplitudes. By neglecting nonlinear effects, two coupled differential equations for $\psi_\pm(z,\omega)$ are derived [6]:

$$\begin{cases} \frac{\partial \psi_{+}(z,\omega)}{\partial z} = i\kappa_{11}(z,\omega)\psi_{+}(z,\omega) + i\kappa_{12}(z,\omega)e^{-i2k_{z}(\omega)z}\psi_{-}(z,\omega) \\ -\frac{\partial \psi_{+}(z,\omega)}{\partial z} = i\kappa_{21}(z,\omega)e^{i2k_{z}(\omega)z}\psi_{+}(z,\omega) + i\kappa_{11}(z,\omega)\psi_{-}(z,\omega) \end{cases}$$
(1)

The self- and cross-coupling coefficients induced by the active material gain $g_0(\omega)$ are indicated as $\kappa_{11;12;21}(z,\omega) \simeq -\frac{i}{2}g_0(\omega)\left[n_g(\omega)/n_s\right]\Gamma_{xy,11;12;21}(z,\omega)$, where n_s and n_g are the slab material refractive index and the passive waveguide group index. Confinement factors $\Gamma_{xy,11;12;21}(z,\omega)$ are given by

$$\Gamma_{xy,11}(z,\omega) = \frac{a \int_{S} \epsilon_{0} n_{s}^{2} |\mathbf{e}_{0}(\mathbf{r},\omega)|^{2} F(\mathbf{r}) dS}{\int_{V} \epsilon_{0} n_{b}^{2}(r) |\mathbf{e}_{0}(\mathbf{r},\omega)|^{2} dV}$$

$$\Gamma_{xy,12}(z,\omega) = \frac{a \int_{S} \epsilon_{0} n_{s}^{2} [\mathbf{e}_{0,-}(\mathbf{r},\omega) \cdot \mathbf{e}_{0,+}^{*}(\mathbf{r},\omega)] F(\mathbf{r}) dS}{\int_{V} \epsilon_{0} n_{b}^{2}(r) |\mathbf{e}_{0}(\mathbf{r},\omega)|^{2} dV}$$

with $\Gamma_{xy,21} = \Gamma^*_{xy,12}$; V is the volume of a PhC supercell, S the transverse plane at position z and $n_b(r)$ the background refractive index, whereas F(r) = 1 (= 0) in the slab (holes). Due to the z-periodicity of $\mathbf{e}_{0,\pm}$ and F(r), the coupling coefficients are periodic with z. If the single unit cell is discretized with a sufficiently small space step Δ_z , the coupling coefficients can be assumed constant within it. By defining $c_{\pm} = \psi_{\pm} e^{\pm i k_z z}$, Eq. (1) is turned, in each Δ_z , into an initial-value problem, whose solution in matrix form is

$$\begin{bmatrix} c_{+}(z_{0}+\Delta_{z}) \\ c_{-}(z_{0}+\Delta_{z}) \end{bmatrix} = \begin{bmatrix} T_{\Delta_{z},11} & T_{\Delta_{z},12} \\ T_{\Delta_{z},21} & T_{\Delta_{z},22} \end{bmatrix} \begin{bmatrix} c_{+}(z_{0}) \\ c_{-}(z_{0}) \end{bmatrix}$$
 (2)

with

$$T_{\Delta_{z},11;22} = \cosh[\gamma(z_{0})\Delta_{z}] \pm i \frac{\kappa_{11}(z_{0}) + k_{z}}{\gamma(z_{0})} \sinh[\gamma(z_{0})\Delta_{z}],$$

$$T_{\Delta_{z},12;21} = \pm i \frac{\kappa_{12;21}(z_{0})}{\gamma(z_{0})} \sinh[\gamma(z_{0})\Delta_{z}], \text{ and}$$

$$\gamma(z_{0}) = \sqrt{\kappa_{12}(z_{0})\kappa_{21}(z_{0}) - [\kappa_{11}(z_{0}) + k_{z}]^{2}}.$$

By successive application of Eq. (2), the single unit cell transmission matrix \mathbf{T}_a is obtained and the transmission matrix of N cascaded cells is given by \mathbf{T}_a^N . From Frobenius theorem, \mathbf{T}_a^N can be written as $\mathbf{T}_a^N = \mathbf{M} \lambda^N \mathbf{M}^{-1}$, where \mathbf{M} contains the eigenvectors of \mathbf{T}_a arranged by columns and λ is a diagonal matrix with the eigenvalues of \mathbf{T}_a on the main diagonal. Multiplying by \mathbf{M}^{-1} both sides of

$$\begin{bmatrix} c_{+}(Na) \\ c_{-}(Na) \end{bmatrix} = \mathbf{M} \boldsymbol{\lambda}^{N} \mathbf{M}^{-1} \begin{bmatrix} c_{+}(0) \\ c_{-}(0) \end{bmatrix}$$
 (3)

the Bloch waves of the active waveguide at input and output are obtained, i.e. $\mathbf{c}_B(Na) = \boldsymbol{\lambda}^N \mathbf{c}_B(0)$. From here, it is apparent that $\boldsymbol{\lambda}^N$ is the evolution matrix in the basis of the Bloch waves of the active waveguide. If the eigenvalues of \mathbf{T}_a are denoted by $\lambda_{1,2} = e^{\pm i\phi}$, $\phi = \cos^{-1}[Tr(\mathbf{T}_a)/2]$ is the dispersion relation of the active waveguide and $n_{g,Pert}(\omega,g_0) = c\,Re\{\partial\phi(\omega,g_0)/\partial\omega\}$ the associated group index, with c vacuum light speed. Within this approach, a PhC laser consists in the cascade of an active PhC waveguide and two mirrors, which, for simplicity, are modelled as standard reflectors. The complex round-trip-gain (RTG) of the cavity is computed as the product, at a given reference plane, of the left and right field reflectivity. Longitudinal resonant modes are those for which \angle RTG is an integer multiple of 2π . For each longitudinal mode, threshold gain is found as the smallest g_0 value which ensures |RTG| = 1 [8].

II. SIMULATION RESULTS

The reference structure is the line-defect waveguide on which the PhC lasers realized in [2] are based. Dispersion relation and Bloch modes of the passive waveguide are computed by the free software package MIT Photonic-Bands (MPB) [9]. Fig. 1a and 1b display magnitude and phase of $\Gamma_{xy,12}(z,\omega)$ at different frequencies. Since the z-variation of $\angle\Gamma_{xy,12}(z,\omega)$ on a unit cell is approximately linear with a slope equal to $2\pi/a$, the first-order Fourier component of $\kappa_{12}(z,\omega)$, which synchronously couples $E_{0,+}$ and $E_{0,-}$, is proportional to $g_0(\omega) \left[n_g(\omega)/n_s \right] < |\Gamma_{xy,12}(z,\omega)| >$. Since < $\Gamma_{xy,11}(z,\omega) > \text{and} < |\Gamma_{xy,12}(z,\omega)| > \text{ have comparable val-}$ ues, the magnitude of the cross-coupling coefficients is comparable with the self-coupling coefficient. This peculiar characteristic of the active PhC waveguides arises from the 2π phase shift of the non-negligible z-component of $\mathbf{e}_{0,\pm}$ along the propagation direction. Fig. 1c reports the group index $n_{g,Pert}$ of the active waveguide as a function of frequency at different g_0 values. At small gain values, the dispersion relation of the active waveguide is not significantly perturbed, and the group index diverges as the frequency approaches the band-edge of the passive waveguide, i.e. $k_z \alpha/2\pi = 0.5$ with a frequency $f \approx 189.387$ THz. On the contrary, at larger gain values the group index is reduced and it even starts to decrease in the close proximity of the band-edge. Remarkably, this behaviour is consistent with that reported in [7] and obtained with a non-perturbative treatment. Furthermore, if the gaininduced coupling is neglected (i.e., $\kappa_{12;21} = 0$), the group index monotonically diverges with the frequency approaching the band-edge (Fig.1d). This proves the key role played by cross-coupling in limiting the maximum attainable SL enhancement of gain. With this coupled Bloch-wave approach we have then modelled the PhC lasers presented in [2]. The mirrors reflectivity is set to $r^2 = 0.98$ [10] and g_0 is assumed to be frequency-independent. The inset of Fig. 2b displays a scheme of principle of the cavity, with the field reflectivity from the left facet towards the cavity denoted by $r_{ea,R}$. Fig. 2a and 2b focus on a cavity with length L = 5a, showing magni-

Fig. 2. Magnitude of $r_{eq,R}$, at different g_0 , for L = 5a; black line is level 1/r. (b) Phase of $r_{eq,R}$; inset: scheme of principle of the cavity (c) Mode frequencies versus cavity length. M_0 is the mode at the band-edge. (d) Threshold gain for the onset of lasing of the various modes.

tude and phase of $r_{eq,R}$ versus frequency at increasing g_0 values. The threshold condition corresponds to the level 1/r, corresponding to the horizontal line in Fig. 2a. The red spots track the longitudinal resonant mode M_1 , with frequency f =191 THz, as it approaches the lasing onset at $g_0 = 16.2 \text{ cm}^{-1}$. The mode located exactly at the band-edge (M_0 , shown in Fig. 2b) requires higher gain for achieving threshold, because the maximum attainable $|r_{eq,R}|$ around the band-edge is limited by the gain induced cross-coupling. This is a consequence of the fact that the field backscattered by the waveguide and the field backscattered by the right mirror facet are out of phase at the band-edge. Fig. 2c,d report, at each cavity length, all the longitudinal modes and corresponding threshold gain. The frequency shift of mode M_1 towards the SL region observed by increasing cavity length (Fig. 2c) well reproduces the experimental [2] and numerical [3] trends. Conversely, without the gain-induced distributed feedback, the group index and the effective gain resulting from SL enhancement would monotonically increase towards the band-edge; consequently, the cavity would behave as a SL enhanced FP laser and, independently of the cavity length, the mode M₀ would be the sole lasing one.

III. CONCLUSIONS

In conclusion, the gain-induced coupling between counterpropagating Bloch modes has been found to be responsible for the degradation of the SL enhancement of gain discussed in [7]. Moreover, this coupling strongly affects the lasing mode threshold gain properties of PhC lasers.
