## SHELF OBSERVATIONS HYDROGRAPHY

Cruise of August 21-26, 1962

Hydrographic observations were made on the continental shelf off Chesapeake Bay, August 21-26, 1962. The observations were part of a continuing study to investigate physical and chemical characteristics of shelf water.

### METHODS

Stations were established at 10-mile intervals along traverses 20 miles apart (Fig. 1). On the outer shelf stations were made at 3 to 5 mile intervals to obtain greater detail. Station numbers (e.g. 720-20) are derived from the latitude with the first digit taken from the degrees north of 30°N (e.g. 37°) and subsequent two digits obtained from minutes of latitude (e.g. 37° 20', or 720). The second group of numerals, following a hyphen is derived from the distance in miles east of the 76° meridian of longitude through the mouth of Chesapeake Bay.

Observations consisted of: (1) Vertical profiles at fixed stations and (2) track measurements of surface water. Temperature and salinity were obtained in situ with an ICTI unit (induction conductivity temperature indicator) calibrated and adjusted to give readings with an accuracy of  $\pm 0.02^{\circ}\text{C}$  and  $\pm 0.05\text{‰}$ . ICTI profiles were supplemented with bathythermograph lowerings to 200 feet. Surface and bottom water samples were obtained with Nansen bottles. Chlorinity was determined by standard silver nitrate titrations and converted to salinity by the Knudsen equation. The chlorinity titrations provided a constant check on the electronic units and these data were used where necessary to correct values of the depth profiles. Oxygen concentrations were determined by the Winkler method. Drift bottles and Woodhead bottom drifters were released in groups of six on stations at 10 mile intervals. Time is reported in Eastern Standard Time.

## RESULTS

The distributions of measured parameters, temperature, salinity and dissolved oxygen concentration, are presented in Figures 2-10. Table 1 lists data of the vertical profiles; Table 2 gives drift bottle results.

Temperature.—Vertical distributions (Fig. 2) depict: (1) a warm relatively homogeneous surface layer, (2) a zone of pronounced temperature change between 40 and 70 feet and (3) a cool lower layer. Vertical gradients were greatest in section 710 at about the 50 foot depth. The thermocline shoals slightly in each section at about 50 miles offshore. A minimum temperature of  $9.60^{\circ}\text{C}$  occurred in moderately stratified water near the shelf edge in section 700. Cool water, defined by the  $12^{\circ}\text{C}$  isotherm, was closer to the surface in the north (section 720) than in the south (section 700) (Figs. 2, 3).

Salinity.—Freshened water of 28-29 ‰ extended about 25 miles off the Chesapeake entrance, traverse 700 (Fig. 4). Over most of the shelf salinity varied within narrow limits, from 31 to 33 ‰ both on the surface and at 80 foot depth (Figs. 4, 5). In section 700 near the shelf edge saltier water intrudes landward in a slightly stratified layer (Fig. 6).

Density.—Vertical variations of density ( $\sigma_{\text{sigmat}}$ ) conform to patterns of temperature over most of the shelf, but within 35 miles of the Chesapeake entrance, section 700, they reflect the influence of salinity gradients (Fig. 7). Vertical gradients of temperature and salinity in the lower layer near the shelf edge, section 700, combine to produce better vertical stability than corresponding water to the north.

Oxygen.—Surface water contained a relatively high concentration of oxygen, 6.93 mg/L, off the Chesapeake entrance (station 700-20) and reduced values, down to 3.00 mg/L, offshore to the north (Fig. 8). A minimal value, 2.96 mg/L, occurred in bottom water near the outer shelf, traverse 710 (Fig. 9). No close relation is apparent between patterns of oxygen and

temperature or salinity.

Circulation.--Sloping isocynals of the vertical density distribution (Fig. 7) suggest a weak southerly flow below the thermocline. Drift bottle recoveries, which reached 31 percent, suggest a southerly flow (Fig. 1) on the surface. Bottles released at offshore stations show greater dispersal than those of the inner shelf.

The cool water ( $12^{\circ}\text{C}$ ) near the shelf edge is apparently related to shelf water as evidenced by its relatively low salinity. Low temperature may have been inherited by cooling on the shelf during the previous winter season.
