Abstract

The hierarchy of fermion masses in the standard model may arise via the breaking of discrete gauge symmetries. The renormalizable interactions of the flavor-symmetry-breaking potential can have accidental global symmetries that are spontaneously broken, leading to pseudo-goldstone bosons that may drive inflation. We consider two-field, axion-monodromy inflation models in which the inflaton is identified with a linear combination of pseudo-goldstone bosons of the flavor sector. We show that the resulting models are nontrivially constrained by current cosmological data as well as the requirements of viable flavor model building.

I. INTRODUCTION

The prevailing approach to solving the horizon and flatness problems of conventional Big Bang cosmology is inflation, a period in which the universe underwent exponential expansion due to the effects of the nearly constant energy density provided by a scalar field [1]. Models of inflation are often studied in terms of the properties of the inflaton potential, with somewhat less focus on other roles the inflaton might play in extensions of the standard model. If the inflaton has no purpose other than to provide the source of the energy density that drives inflation, then model building becomes isomorphic to studying ways of generating different functional forms for the inflaton potential. These possibilities, now cataloged (see for example [2]), differ in their detailed predictions for the spectrum of fluctuations in the microwave background that are observed in experiments like Planck [3] and BICEP2 [4].

In this paper, we consider a scenario in which the inflaton is an integral component of an extension of the standard model that aims to address one of its substantial mysteries: the hierarchy of elementary fermion masses. Models of flavor based on horizontal discrete symmetries postulate that these symmetries are broken via a set of fields, called flavons, that couple to standard model fermions through higher-dimension operators. Discrete flavor symmetries can often lead to accidental continuous global symmetries among the renormalizable terms of the flavon potential. In the present work, we consider the possibility that the inflaton may be identified as a linear combination of the approximate goldstone bosons that arise when these accidental symmetries are spontaneously broken. We will ultimately be interested in two-field models of inflation, for reasons described below, which distinguishes the present work from the relatively sparse literature that explores the use of flavon fields for a similar purpose [5].

Consider the simplest possibility, a \mathbf{Z}_N flavor symmetry under which a single flavon field Φ transforms as $\Phi \rightarrow \omega\Phi$, where $\omega = \exp(2\pi i/N)$. If the fermions of the standard model are charged under the discrete group, then a tree-level Yukawa coupling that would otherwise be forbidden can arise via a higher-dimension operator. For example, for a down-type quark, one might have

$$\frac{1}{M_F^p} \bar{Q}_L H \phi^p D_R + \text{h.c.} \quad , \quad (1.1)$$

where H is the standard model Higgs doublet, M_F is the flavor scale, and p is an integer. The

Yukawa coupling is associated with the ratio $(\langle\phi\rangle/M_F)^p$ which can be much less than one; operators with different values of p can easily provide a hierarchical pattern of entries in the associated Yukawa matrix. If less than the Planck scale, the scale M_F is identified with that of new heavy states that account for the origin of the higher-dimension operators. However, a simpler assumption, that we adopt henceforth, is that the scale M_F is the reduced Planck scale M_* ; the desired operators appear as part of the most general set that are allowed by the local symmetries of the theory, as one expects based on our current understanding of quantum gravity [6]. An immediate implication of our assumptions is that the vacuum expectation value (vev) $\langle\Phi\rangle < M_*$, which will provide an important constraint in our attempt to identify the inflaton with a part of the field Φ .

To obtain an inflaton potential that is sufficiently flat, we require that the goldstone boson degree-of-freedom receives no contributions to its potential from renormalizable terms involving Φ . Let us therefore assume that $N \geq 5$. The renormalizable terms in the potential are simply

$$V(\Phi) = -m_\Phi^2 \Phi^\dagger \Phi + \frac{\lambda_\Phi}{2} (\Phi^\dagger \Phi)^2 . \quad (1.2)$$

Terms such as $(\Phi^4 + \text{h.c.})$ are forbidden by the \mathbf{Z}_N symmetry. Using the nonlinear decomposition

$$\Phi = \frac{\phi + f}{\sqrt{2}} \exp(i\theta/f) , \quad (1.3)$$

where $f/\sqrt{2} \equiv \langle\Phi\rangle$, one sees immediately that $V(\Phi)$ is independent of θ , *i.e.*, the potential $V(\theta)$ is exactly flat. The potential in Eq. (1.2) has an accidental global U(1) symmetry and the field θ is the goldstone boson that results from its spontaneous breaking. Global symmetries are not respected by quantum gravitational corrections, so it is no surprise that there are Planck suppressed corrections,

$$\mathcal{L} \supset \frac{c_0}{2} \frac{1}{M_*^{N-4}} \Phi^N + \text{h.c.} , \quad (1.4)$$

that generate a potential for θ , where c_0 is an unknown order-one coefficient. Planck-suppressed operators that directly break the discrete flavor symmetry are not present since we assume in this example (and will require in all our models henceforth) that we work with discrete gauge symmetries, which satisfy appropriate anomaly cancellation conditions and are immune to quantum gravitational corrections. For the reader who is unfamiliar with discrete gauge symmetries, we review the basic issues relevant to our model building in the appendix.

The operator in Eq. (1.4) leads to the θ potential

$$V(\theta) = c_0 M_*^4 \left(\frac{\langle \Phi \rangle}{M_*} \right)^N [1 - \cos(N\theta/f)] \quad , \quad (1.5)$$

where we have added a constant so that $V(0) = 0$. This is nothing more than the potential of “Natural Inflation” scenarios [7]. However, this potential is not adequate for our purposes. It is well known that if one requires that Natural Inflation provides $\sim 50 - 60$ e-folds of inflation and predicts a spectral index n_s within the range allowed by current Planck data, then f must be well above the Planck scale [8]. For our present application, this would imply that $\langle \phi \rangle / M_*$ is not a small flavor-symmetry-breaking parameter and we lose the ability to predict standard model Yukawa couplings in a controlled approximation.

We therefore must consider other ways of generating potentials for the pseudo-goldstone inflaton that allow a sub-Planckian decay content f . The options assuming a single field inflation model are limited. For example, models of “multi-natural” inflation [9], in which one arranges for additional sinusoidal terms in the potential, can accommodate a sub-Planckian flavon vev, but tend to predict $n_s = 0.95$ in this limit [9], at the very edge of the 95% exclusion region following from Planck data. A different class of models that can more easily provide cosmological predictions consistent with Planck data are two-field models of the axion monodromy type [10–17]. We will show that these can be adapted for the present purpose.

The two pseudo-goldstone fields can have their origin if there are two flavon fields, Φ and χ , that transform under the discrete group $\mathbf{Z}_p^\Phi \times \mathbf{Z}_r^\chi$. We assume that each field transforms only under one of the \mathbf{Z}_N factors,

$$\Phi \rightarrow \omega_\Phi \Phi \quad \text{and} \quad \chi \rightarrow \omega_\chi \chi \quad , \quad (1.6)$$

where $\omega_\Phi = \exp(2\pi i/p)$ and $\omega_\chi = \exp(2\pi i/r)$, where p and r are integers. For $p \geq 5$ and $r \geq 5$, the renormalizable terms in the potential are

$$V(\Phi, \chi) = -m_\Phi^2 \Phi^\dagger \Phi + \frac{\lambda_\Phi}{2} (\Phi^\dagger \Phi)^2 - m_\chi^2 \chi^\dagger \chi + \frac{\lambda_\chi}{2} (\chi^\dagger \chi)^2 + \lambda_p \Phi^\dagger \Phi \chi^\dagger \chi \quad , \quad (1.7)$$

where λ_p is a portal-type coupling. There is no difficulty in choosing parameters such that each field develops a vev. This potential has an accidental $U(1) \times U(1)$ global symmetry that is spontaneously broken. Extending our previous parameterization, we write

$$\Phi = \frac{\phi_0 + f_\theta}{\sqrt{2}} \exp(i\theta/f_\theta) \quad \text{and} \quad \chi = \frac{\chi_0 + f_\rho}{\sqrt{2}} \exp(i\rho/f_\rho) \quad . \quad (1.8)$$

Spontaneous symmetry breaking renders the fields ϕ_0 and χ_0 massive so that they are decoupled from the inflation dynamics. The potential for the goldstone bosons $V(\rho, \theta)$ that follows from Eq. (1.7) is exactly flat.

We will discuss later how to generate a potential for ρ and θ of the following axion-monodromy form

$$V(\rho, \theta) = \Lambda_1^4 \left[1 + \cos \left(\frac{\rho}{f_\rho} \right) \right] + \Lambda_2^4 \left[1 - \cos \left(\frac{n\rho}{f_\rho} - \frac{\theta}{f_\theta} \right) \right] , \quad (1.9)$$

where n is an integer. The first few terms in the expansion of the first cosine factor have the same form as $-m_r^2 r^2/2 + \lambda_r r^4/4!$, the shift-symmetry-breaking potential $W(r)$ assumed in the Dante’s Waterfall scenario discussed in Ref. [12]. In that work, $W(r)$ was assumed to be generated by non-perturbative effects associated with moduli stabilization in string theory, as for example in Ref. [11]. In this paper, we only consider field theoretic origins of the potential, where the emergence of the functional form given in Eq. (1.9) is readily obtained. For the purposes of graphical display, if one plots the potential as if ρ and θ were polar coordinates, one would find a “hill” generated by the first cosine factor, circumscribed by a descending spiral “trench” generated by the second. Inflationary trajectories track the minimum of the trench. As θ advances by $2\pi f_\theta$ along the trench, the ρ coordinate does not return to the same value; this monodromy allows for large numbers of e-folds to be achieved within a bounded, sub-Planckian region of field space. We assume that the decay constant f_θ satisfies

$$\frac{f_\theta}{\sqrt{2}} = \lambda M_* \approx 0.22 M_* , \quad (1.10)$$

where λ is a flavor-symmetry-breaking parameter of the same size as the Cabibbo angle. This will allow us to identify the field Φ (and perhaps in some models both Φ and χ) as flavons that can be used in flavor model building. We will see that the discrete symmetry $\mathbf{Z}_p^\Phi \times \mathbf{Z}_r^\chi$ serves four purposes: (i) it assures that there are goldstone bosons that have no potential generated by renormalizable couplings, (ii) it will serve as a flavor symmetry to create a hierarchy of standard model fermion Yukawa couplings, (iii) it will lead to the correct pattern of couplings in a new gauge sector that provides for the desired form of the inflaton potential, Eq. (1.9), and (iv) it will keep quantum gravitational corrections to the potential highly suppressed.

Our paper is organized as follows. In the next section, we discuss the inflationary dynamics that follows from the potential given in Eq. (1.9). We identify solutions in which

inflation ends when single-field slow-roll conditions are violated and other solutions where the termination of inflation is analogous to a hybrid model [18]. In Sec. III, we consider model building issues, in particular, how the discrete symmetries of the theory play an important role in assuring that we obtain the proper potential, and how the same symmetries can be used to produce a plausible model of standard model fermion masses. In the final section, we summarize our conclusions. A brief appendix is provided to review relevant facts about discrete gauge symmetries.

II. INFLATIONARY TRAJECTORIES

In this section, we consider inflationary trajectories in the two-field potential given by Eq. (1.9), that are compatible with flavor model-building requirement Eq. (1.10). We give two example solutions that differ qualitatively in how inflation ends. Note that a more general potential that subsumes Eq. (1.9) was studied in a different context in Ref. [19]; the types of trajectories described therein are consistent qualitatively with those presented here.

A. Termination without a waterfall.

For our first solution, we make the parameter choice $f_\rho = f_\theta \equiv f_1$ and also define $f_1/n \equiv f_2$. We assume $f_1 \gg f_2$, which is equivalent to $n \gg 1$. The potential Eq. (1.9) then takes the form

$$V(\rho, \theta) = \Lambda_1^4 \left[1 + \cos \left(\frac{\rho}{f_1} \right) \right] + \Lambda_2^4 \left[1 - \cos \left(\frac{\rho}{f_2} - \frac{\theta}{f_1} \right) \right]. \quad (2.1)$$

The second cosine term creates a series of trenches on the surface of the potential defined by the first cosine term. If the field θ is plotted as a polar coordinate, the trenches form spirals originating at $\rho = 0$. As in Ref. [12], it is convenient to work in the rotated field basis $\rho = c\tilde{\rho} + s\tilde{\theta}$ and $\theta = c\tilde{\theta} - s\tilde{\rho}$ with

$$c = \frac{f_1}{\sqrt{f_1^2 + f_2^2}} \quad \text{and} \quad s = \frac{f_2}{\sqrt{f_1^2 + f_2^2}}. \quad (2.2)$$

This allows us to rewrite the potential as

$$V(\tilde{\rho}, \tilde{\theta}) = \Lambda_1^4 \left[1 + \cos \left(\frac{c\tilde{\rho} + s\tilde{\theta}}{f_1} \right) \right] + \Lambda_2^4 \left[1 - \cos \left(\frac{\tilde{\rho}}{f} \right) \right], \quad (2.3)$$

where $f = f_1 f_2 / \sqrt{f_1^2 + f_2^2}$. The modulations in the potential due to the $\cos(\tilde{\rho}/f)$ term create the trench, whose location is given by $\partial V / \partial \tilde{\rho} = 0$, or

$$\sin\left(\frac{\tilde{\rho}}{f}\right) - s c \frac{\Lambda_1^4}{\Lambda_2^4} \sin\left(\frac{c\tilde{\rho} + s\tilde{\theta}}{f_1}\right) = 0 . \quad (2.4)$$

The inflaton is the linear combination of the fields that slowly rolls along the trench; inflation terminates when the slow-roll conditions are violated. With the assumptions made throughout this paper, the inflaton will be well approximated by the linear combination

$$\tilde{\theta} = s \rho + c \theta , \quad (2.5)$$

where c and s are given in Eq. (2.2). For the solutions considered in this subsection, the stability condition $\partial^2 V / \partial \tilde{\rho}^2 > 0$ will hold throughout this trajectory.

To study inflationary observables, we first consider a good approximation to the single-field inflaton potential, which holds for our choice of parameters and can be studied analytically, and then discuss an exact numerical approach that we use to confirm the validity of our results. Let us define $\kappa \equiv s c (\Lambda_1^4 / \Lambda_2^4)$ and consider parameter choices where $\kappa \ll 1$. It follows from Eq. (2.4) that to good approximation

$$\tilde{\rho}/f \approx 2\pi j , \quad (2.6)$$

where j is an integer. Given our assumption that $f_1 \gg f_2$, it follows from Eqs. (2.3)-(2.6) that $\partial^2 V(\tilde{\rho}, \tilde{\theta}) / \partial \tilde{\rho}^2 > 0$, confirming that the trench is stable. Substituting Eq. (2.6) into our original potential yields

$$V(\tilde{\theta}) = \Lambda_1^4 \left[1 + \cos\left(\delta + \tilde{\theta}/f_0\right) \right] , \quad (2.7)$$

where $\delta = 2\pi s c j$ and $f_0 = f_1/s$. Setting $j = 0$ is equivalent to redefining the origin of field space, so we will ignore δ henceforth. We note that the present approximation scheme differs from the one used in Ref. [12], in which one would expand the sinusoidal functions in Eq. (2.4) to linear order in their arguments, but is nonetheless accurate as we confirm numerically later. We note that $s \ll 1$ in the limit $n \gg 1$, so that the derived quantity f_0 can be super-Planckian even when the decay constants f_1 and f_2 are not.

We compare the predictions of the model to the latest results from the Planck Collaboration [3]. The slow roll parameters are defined by

$$\epsilon = \frac{1}{2} \left(\frac{V'}{V} \right)^2 , \quad \eta = \frac{V''}{V} \quad \text{and} \quad \gamma = \frac{V' V'''}{V^2} , \quad (2.8)$$

where the primes refer to derivatives with respect to the inflaton field and we work in units where the reduced Planck mass $M_* \equiv M_P/\sqrt{8\pi} = 1$. In the present case, these are given by

$$\epsilon = \frac{1}{2f_0^2} \tan^2[\tilde{\theta}/(2f_0)] \ , \quad (2.9)$$

$$\eta = -\frac{1}{f_0^2} \frac{\cos(\tilde{\theta}/f_0)}{1 + \cos(\tilde{\theta}/f_0)} \ , \quad (2.10)$$

$$\gamma = -\frac{1}{f_0^4} \tan^2[\tilde{\theta}/(2f_0)] \ . \quad (2.11)$$

Inflation ends when $\epsilon(\tilde{\theta}_f) = 1$. The initial value of the inflaton, $\tilde{\theta}_i$ is determined by the requirement that we achieve a desired number of e-folds of inflation, given in general by

$$N = \int_{\tilde{\theta}_i}^{\tilde{\theta}_f} \frac{1}{\sqrt{2\epsilon}} d\tilde{\theta} = 2f_0^2 \ln \left[\frac{\sin[\tilde{\theta}_f/(2f_0)]}{\sin[\tilde{\theta}_i/(2f_0)]} \right] \ . \quad (2.12)$$

We set $N = 60$ in the numerical results that follow. We evaluate the slow-roll parameters and the potential $V(\tilde{\theta})$ at $\tilde{\theta}_i$ in determining the spectral index $n_s = 1 - 6\epsilon + 2\eta$, the ratio of tensor-to-scalar amplitudes $r = 16\epsilon$, the running of the spectral index $n_r = 16\epsilon\eta - 24\epsilon^2 - 2\gamma$ and the scalar amplitude $\Delta_R^2 = V/(24\pi^2\epsilon)$. From Eqs. (2.9)-(2.11), it follows that

$$n_s = 1 + \frac{1}{f_0^2} \left(1 - 2 \sec^2[\tilde{\theta}_i/(2f_0)] \right) \ , \quad (2.13)$$

$$r = \frac{8}{f_0^2} \tan^2[\tilde{\theta}_i/(2f_0)] \ , \quad (2.14)$$

$$n_r = -\frac{2}{f_0^4} \tan^2[\tilde{\theta}_i/(2f_0)] \sec^2[\tilde{\theta}_i/(2f_0)] \ , \quad (2.15)$$

$$\Delta_R^2 = \frac{1}{12\pi^2} \Lambda_1^4 f_0^2 \left(1 + \cos[\tilde{\theta}_i/f_0] \right)^3 \csc^2[\tilde{\theta}_i/f_0] \ . \quad (2.16)$$

To illustrate a viable solution, consider the parameter choice (again, in units where $M_* = 1$)

$$f_1 = 0.22\sqrt{2} \ , \quad (2.17)$$

$$f_2 = f_1/21 \ , \quad (2.18)$$

$$\Lambda_1 = \Lambda_2 = 0.006 \ , \quad (2.19)$$

which corresponds to $n = 21$ and $\kappa \approx 1/21$. We find that the initial and final fields for the inflaton trajectory are given by

$$(\tilde{\rho}, \tilde{\theta})_i = (6.04 \times 10^{-4}, 6.74) \quad \text{and} \quad (\tilde{\rho}, \tilde{\theta})_f = (1.50 \times 10^{-4}, 19.14) \ , \quad (2.20)$$

FIG. 1: Path followed by the inflaton during 60 e-folds of inflation corresponding to the solution of Sec. II A, in units where $M_* = 1$. The background is a density plot where darker zones have lower values of the potential than lighter ones.

respectively. Using this value for $\tilde{\theta}_i$, we find the following set of cosmological parameters:

$$n_s = 0.96, \quad (2.21)$$

$$r = 0.060, \quad (2.22)$$

$$n_r = -0.00046, \quad (2.23)$$

$$\Delta_R^2 = 2.2 \times 10^{-9} . \quad (2.24)$$

Fig. 1 displays the path followed by the inflaton during the 60 e-folds of inflation for this particular solution. The predictions in Eq. (2.24) are consistent with the results from the Planck experiment [3]: $n_s = 0.968 \pm 0.006$, $r < 0.12$ (95% C.L.), $n_r = -0.003 \pm 0.007$ and $\Delta_R^2 = 2.19 \pm 0.08 \times 10^{-9}$. (The value of Δ_R^2 , also called A_s , was taken from the first column of Table 3 in Ref. [3].)

We may check the validity of the results in this section by numerically evaluating the slow-roll parameters in the two-field problem. Let a represent the linear combination of the fields that evolves along the minimum of the trench. Given that $da = \sqrt{d\tilde{\rho}^2 + d\tilde{\theta}^2}$ along the

trench, it follows that we can write the n^{th} derivative of the potential with respect to a as

$$\frac{d^n V}{da^n} = \left[\left(1 + \frac{d\tilde{\rho}}{d\tilde{\theta}} \right)_{tr}^{-1/2} \frac{d}{d\tilde{\theta}} \right]^n V \left(\tilde{\theta}, \tilde{\rho}(\tilde{\theta})_{tr} \right) , \quad (2.25)$$

where the subscript “tr” indicates quantities evaluated along $\tilde{\rho}(\tilde{\theta})_{tr}$, the solution to Eq. (2.4). Note that as the quantity da is defined above, the kinetic terms for a are canonically normalized. The slow roll parameters can be evaluated numerically according to Eq. (2.25). We find in this case that $n_s = 0.96$, $r = 0.060$, $n_r = -0.00046$ and $\Delta_R^2 = 2.2 \times 10^{-9}$, in agreement with the results in Eq. (2.24).

B. Termination with a waterfall.

For different choices of the model parameters, inflation will end before $\epsilon = 1$ is reached, at a point where there is no longer a solution to Eq. (2.4). At this point, the stability condition $\partial^2 V / \partial \tilde{\rho}^2 > 0$ is also not satisfied, and the fields evolve rapidly in a direction orthogonal to the original trajectory [12]. If one visualizes the motion by plotting the fields as polar coordinates, the evolution corresponds to a transition from spiraling to rapid motion in the radial direction, eventually ending at a global minimum. In Ref. [12] this was called the waterfall, in analogy to the behavior of hybrid inflation models [18], where stability in one field direction can be a function of the value of a second field.

Given an input of model parameters, we determine the final inflaton field value a_f by solving

$$\left. \frac{\partial^2 V}{\partial \tilde{\rho}^2} \right|_{tr} = 0 , \quad (2.26)$$

and then the initial value a_i from

$$N = \int_{a_i}^{a_f} \left| \frac{V}{V'} \right| da . \quad (2.27)$$

where the primes refer to derivatives evaluated numerically according to Eq. (2.25), and a ($\approx \tilde{\theta}$) is the canonically normalized inflaton field. Again, we set $N = 60$. To illustrate a

solution that ends with the waterfall behavior, consider the parameter choices

$$f_1 = 0.22\sqrt{2} \ , \quad (2.28)$$

$$f_2 = f_1/17 \ , \quad (2.29)$$

$$\Lambda_1 = 3.38 \times 10^{-3} \ , \quad (2.30)$$

$$\Lambda_2 = 1.61 \times 10^{-3} \ . \quad (2.31)$$

which corresponds to $n = 17$ and $\kappa = 1.13$. We find that the initial and final fields for the inflaton trajectory are given by

$$(\tilde{\rho}, \tilde{\theta})_i = (6.83 \times 10^{-3}, 1.63) \quad \text{and} \quad (\tilde{\rho}, \tilde{\theta})_f = (0.0281, 5.2970) \ , \quad (2.32)$$

respectively. Using this value for $\tilde{\theta}_i$, we find the following set of cosmological parameters:

$$n_s = 0.96, \quad (2.33)$$

$$r = 0.0078, \quad (2.34)$$

$$n_r = -7.2 \times 10^{-5}, \quad (2.35)$$

$$\Delta_R^2 = 2.2 \times 10^{-9} \ . \quad (2.36)$$

These are consistent with the ranges allowed by Planck, as quoted in the previous subsection. That Eq. (2.34) is much smaller than Eq. (2.22) is consistent with the observation of Ref. [19] that trajectories terminating at a saddle point of the potential can have significantly smaller r than those terminating near minima. Note that our solutions here and in the previous subsection do not involve fine-tuning; for example, we have checked in the present case that varying the initial value of $\tilde{\theta}$ at the 1% level only results in a change at the 2% level in the observables described above. The complete inflaton trajectory, extending beyond the point where Eq. (2.4) is no longer satisfied, can be found by solving the coupled equations of motion

$$\begin{aligned} \ddot{\rho} + 3H\dot{\rho} + \frac{\partial V}{\partial \rho} &= 0 \ , \\ \ddot{\theta} + 3H\dot{\theta} + \frac{\partial V}{\partial \theta} &= 0 \ , \end{aligned} \quad (2.37)$$

where H is the Hubble parameter. The result is shown in Fig. 2, assuming the initial field values $\rho(0) = 0.103$ and $\theta(0) = 1.63$ (equivalent to Eq. (2.32)) and $\dot{\rho}(0) = \dot{\theta}(0) = 0$. The qualitative form of the solution does not depend strongly on the choice of the initial

first time derivative, provided that the slow-roll conditions are satisfied. One can see from the plot that the bottom of the trench given by Eq. (2.4), denoted by the thick red line, approximates the actual trajectory, given by the thin green line, very well. The inflaton eventually oscillates about and then settles at the global minimum of the potential.

FIG. 2: Inflation trajectory, in ρ - θ space, overlaid on a contour plot of the potential, in units where $M_* = 1$. The bottom of the trench is indicated by the thick red line while the inflation trajectory is denoted by the thin green line.

III. MODELS

A. Origin of the potential

The successful inflation potentials presented in the previous section correspond to a potential of the form given in Eq. (1.9). Here we consider the possibility that this potential arises via the effects of anomalies associated with new gauge groups.

Hence, we extend the standard model gauge group by the additional factors $SU(N_1) \times SU(N_2)$, and introduce the fermions $A_L \sim A_R \sim (\mathbf{N}_1, \mathbf{1})$ and $B_L^{(i)} \sim B_R^{(i)} \sim C_L \sim C_R \sim (\mathbf{1}, \mathbf{N}_2)$. We would like the Lagrangian to contain the following interactions

$$\mathcal{L} \supset h_1 \bar{A}_R A_L \chi + \sum_{i=1}^n h_2^{(i)} \bar{B}_R^{(i)} B_L^{(i)} \chi + h_3 \bar{C}_R C_L \Phi^* + \text{h.c.} \quad (3.1)$$

Here, the h_j 's are Yukawa couplings and the terms shown generate heavy fermion masses when the Φ and χ fields develop vevs. The accidental global U(1) symmetries are each chiral when appropriate charges are assigned to the A , B and C fermions. However, these symmetries are anomalous with respect to the new gauge groups. Triangle diagrams lead to the interactions [13]

$$\frac{g_1^2}{32\pi^2} \left(\frac{\rho}{f_\rho} \right) F_1 \tilde{F}_1 + \frac{g_2^2}{32\pi^2} \left(\frac{n\rho}{f_\rho} - \frac{\theta}{f_\theta} \right) F_2 \tilde{F}_2 . \quad (3.2)$$

Note that the interactions in Eq. (3.1) are of exactly the same form as Eq. (2.1) of Ref. [13], so that the $F\tilde{F}$ interactions that are relevant in our case can be obtained by adjusting for the multiplicity of the given fermion field (either 1 or n), and taking into account that χ contains $\exp(i\rho/f_\rho)$ while Φ^* contains $\exp(-i\theta/f_\theta)$. With the $F\tilde{F}$ interactions included in the action, the potential is generated nonperturbatively by integrating over instanton gauge field configurations [20]. This leads to the form [13]

$$V(\rho, \theta) = \Lambda_1^4 \left[1 - \cos \left(\frac{\rho}{f_\rho} \right) \right] + \Lambda_2^4 \left[1 - \cos \left(\frac{n\rho}{f_\rho} - \frac{\theta}{f_\theta} \right) \right] , \quad (3.3)$$

with the scales Λ_1 and Λ_2 identified with the scale of strong dynamics for each SU(N) factor. (We assume N_1 and N_2 are chosen so that each group is asymptotically free, and that the gauge couplings in the ultraviolet are chosen so that any desired values of Λ_1 and Λ_2 can be achieved.) Redefining the origin of field space via

$$\rho \rightarrow \rho + \pi f_\rho \quad \text{and} \quad \theta \rightarrow \theta + n\pi f_\theta \quad (3.4)$$

puts the potential in the form that we previously assumed in Eq. (1.9). Note that the new gauge groups may be spontaneously broken at a scale well below Λ_1 and Λ_2 without affecting our conclusions.

The interactions given in Eq. (3.1) are clearly not generic. In the absence of our discrete charge assignments for Φ and χ , there would be no reason for the Φ field to avoid coupling to the A and B -type fermions directly, nor would there be any prohibition of explicit fermion mass terms. Hence, this sector is suggestive of additional symmetries even had we not put them forward immediately as a starting assumption in our model building. Given the transformation properties of Φ and χ fields under the $\mathbf{Z}_p^\Phi \times \mathbf{Z}_r^\chi$ symmetry, Eq. (1.6), we can account for the desired pattern on couplings in Eq. (3.1) by choosing

$$A_R \rightarrow \omega_\chi A_R , \quad B_R^{(i)} \rightarrow \omega_\chi B_R^{(i)} , \quad C_L \rightarrow \omega_\Phi C_L , \quad (3.5)$$

with the remaining heavy fermions taken as singlets under the discrete group. However, we must now enlarge the fermion content to assure that discrete gauge anomalies are cancelled (see the appendix), and do so in a way that assures that the additional fermions can become massive. To demonstrate that this can be accomplished, let us consider an example suggested by one of our previous cosmological solutions, discussed in Sec. II A, corresponding to the potential in Eq. (1.9) with $n = 21$. Let us choose $p = r = 21$. First, we note that there are 21 B -type fermions transforming each with \mathbf{Z}_{21}^X charge $+1$, where we specify the charge Q by defining the group element to be $\exp(2i\pi Q/21)$. This implies that the \mathbf{Z}_{21}^X - $\text{SU}(N_2)^2$ discrete anomaly cancellation condition would be satisfied by the B particle content alone. The A and C fermions, on the other hand, lead to anomalies, so we include additional fermions with matching gauge quantum numbers and the discrete transformation rules

$$\begin{aligned} A_R^{(i)} &\rightarrow \omega_\chi^{10} A_R^{(i)} & , & & A_L^{(i)} &\rightarrow A_L^{(i)} & \quad (i = 1 \dots 2) \\ C_L^{(i)} &\rightarrow \omega_\Phi^{10} C_L^{(i)} & , & & C_R^{(i)} &\rightarrow C_R^{(i)} & \quad (i = 1 \dots 2) \end{aligned} \quad (3.6)$$

which allow the anomaly cancellation conditions to be satisfied. Finally, we note that these fields will develop masses as a result of Planck-suppressed operators, for example, $\bar{A}_R^{(i)} \chi^{10} A_L^{(i)} / M_*^9 + \text{h.c.}$ and $\bar{C}_L^{(i)} \Phi^{10} C_R^{(i)} / M_*^9 + \text{h.c.}$, which lead to masses of order $\lambda^{10} M_* \sim 10^{11}$ GeV.

The discrete symmetry that we have assumed to assure the form of couplings in Eq. (3.1) also leads to a suppression of direct Planck suppressed corrections to the potential. Since quantum gravitational effects must respect the discrete gauge symmetry, the lowest order operators that will correct the potential have the form Φ^{21} / M_*^{17} or χ^{21} / M_*^{17} ; the scale of these corrections are of order $\lambda^{21} M_*^4 \sim 10^{-14} M_*^4$, negligible compared to the values of Λ_1 and Λ_2 that we found previously to be of order $10^{-3} M_*$.

B. Standard Model Flavor

The fields Φ and χ can now be utilized in constructing models of standard model fermion masses. These fields will appear in higher-dimension operators that generate the small entries of the standard model Yukawa matrices. Given our choice $\langle \Phi \rangle / M_* = \langle \chi \rangle / M_* = \lambda$, the size of these entries will be determined by powers of the Cabibbo angle λ . In this subsection, we present one example in which the desired set of higher-dimension operators is obtained via

Q_{1L}	Q_{2L}	Q_{3L}	u_R^c	e_R^c	t_R^c	d_R^c	s_R^c	b_R^c
6	5	3	2	-1	-3	-1	-2	-2
L_{1L}	L_{2L}	L_{3L}	e_R^c	μ_R^c	τ_R^c	ν_{1R}^c	ν_{2R}^c	ν_{3R}^c
0	0	0	5	3	1	-3	-3	-3

TABLE I: \mathbf{Z}_{21}^Φ charge assignments q , where the group transformation is defined by $\exp(2i\pi q/21)$. The Higgs doublet is a singlet under the flavor symmetry.

the same discrete symmetries that were used to obtain the inflaton potential. We focus on the $n = p = r = 21$ model just discussed, in which the Φ and χ fields each transform under a separate \mathbf{Z}_{21} symmetry. Of course, other choices of the symmetry group are possible, and the present choice does not suggest a unique set of fermion charge assignments (since there are many possible Yukawa textures that are viable). The example we give here will suffice by serving as a proof of principle¹.

The simplest incorporation of the $n = 21$ model in a flavor sector is via the identification of \mathbf{Z}_{21}^Φ as the flavor symmetry and Φ as the sole flavon field. The charge assignments of the standard model fermions and a set of right-handed neutrinos are given in Table I. Entries of the Yukawa matrices arise from \mathbf{Z}_{21}^Φ -invariant higher dimension operators. For example, the 1-1 entry in the up-sector Yukawa matrix involves the fields $\bar{Q}_{1L} H u_R$, which has flavor charge -8 . This arises at lowest order via

$$\frac{1}{M_*^8} \bar{Q}_{1L} H \Phi^8 u_R + \text{h.c.}, \quad (3.7)$$

and hence the corresponding Yukawa matrix entry is of order λ^8 . Since ω^8 and ω^{-13} are identical, there is another possible operator, $\bar{Q}_{1L} H \Phi^{*13} u_R / M_*^{13} + \text{h.c.}$, but it is of higher order and can be neglected. We may populate the remaining entries of the quark and charged

¹ It should also be clear that one could alternatively construct a model starting with the $n = 17$ potential that we discussed earlier, but there are no new qualitative insights gained by presenting two very similar examples.

lepton Yukawa matrices in a similar manner. We find

$$Y_u = \begin{pmatrix} \lambda^8 & \lambda^5 & \lambda^3 \\ \lambda^7 & \lambda^4 & \lambda^2 \\ \lambda^5 & \lambda^2 & 1 \end{pmatrix}, \quad Y_d = \begin{pmatrix} \lambda^5 & \lambda^4 & \lambda^4 \\ \lambda^4 & \lambda^3 & \lambda^3 \\ \lambda^2 & \lambda & \lambda \end{pmatrix}, \quad Y_e = \begin{pmatrix} \lambda^5 & \lambda^3 & \lambda \\ \lambda^5 & \lambda^3 & \lambda \\ \lambda^5 & \lambda^3 & \lambda \end{pmatrix}, \quad (3.8)$$

where order one coefficients in each entry have been suppressed. These achieve the desired ratios $m_u/m_t \sim \lambda^8$, $m_c/m_t \sim \lambda^4$, $m_d/m_b \sim \lambda^4$, and $m_s/m_b \sim \lambda^2$, with the charged lepton Yukawa mass eigenvalues comparable in size to those of the down quark sector. It is not hard to verify that the choice of right-handed neutrino charge assignments leads via the see-saw mechanism to a neutrino mass matrix of the form $[\langle H \rangle^2 / \Lambda_R] Y_\nu$, where Λ_R is the right-handed neutrino mass scale, $\langle H \rangle$ is the standard model Higgs vev, and Y_ν is a matrix in which each entry is of order λ^0 times a function of (typically many) undetermined order one coefficients. These can be chosen to obtain the desired phenomenology without unnaturally large or small values of the individual coefficients².

Finally, we must check that the standard model fermion charge assignments in this model satisfy the linear Ibáñez-Ross anomaly cancellation conditions for the non-Abelian gauge groups and gravity. Summing the \mathbf{Z}_{21}^Φ charges times the appropriate multiplicity factors for the color SU(3), weak SU(2), and gravitational anomalies gives 21, 42 and 63, respectively. These results mod 21 are zero, indicating that the discrete gauge anomaly cancellation conditions discussed in Appendix A remain satisfied.

IV. CONCLUSIONS

Models of standard model flavor that are based on discrete gauge symmetries can have accidental continuous global symmetries that are spontaneously broken. We have argued that a linear combination of the approximate goldstone bosons that may arise in these models can serve plausibly as the inflaton in two-field models of inflation based on the

² It is not necessarily the case that an alternative model that predicts the neutrino mass hierarchy via powers of λ is more desirable than this example. The reason is that the predictions for neutrino mass matrix entries in such a model also come multiplied by functions of products of a number of the order one operator coefficients. This can spoil the naive λ power counting without any individual operator coefficient being unnaturally small or large. This is a problem that is unique to the neutrino sector in such models when the mass matrix arises via the seesaw mechanism.

axion monodromy idea. These models can accommodate the current Planck data on the microwave background [3] while allowing the flavor-symmetry-breaking vacuum expectation values (vevs) to remain sub-Planckian. This is important in the present work since the ratios of the flavon vevs to the reduced Planck scale serve as small flavor-symmetry-breaking parameters in our models, which allows one to predict the standard model Yukawa coupling entries in a controlled approximation. In addition to making correct Yukawa coupling predictions possible, the discrete symmetries of the theory also maintain the correct pattern of the interactions in a new gauge sector, leading to the desired form of the inflaton potential; they also keep the quantum gravitational corrections to the potential well under control. The literature on models of standard model fermion masses is vast and it is imaginable that more economical and compelling examples of flavor-sector inflation models are yet to be found. The present work suggests that exploring the full landscape of such models may be a fertile direction for future investigation.

Appendix A: Discrete Gauge Symmetries, Briefly

It is well known that continuous gauge symmetries are not violated by quantum gravitational effects. Under what circumstances is the same true for discrete symmetries? It was noted long ago by Ibáñez and Ross (IR) [21] that a discrete group that arises as a subgroup of a continuous gauge symmetry inherits this protection. While the full theory must satisfy the anomaly cancellation conditions relevant for the continuous gauge groups, IR determined the conditions that are relevant in the low-energy theory, below the scale at which the continuous gauge symmetries are broken. Since some of the fermions in the complete theory may become massive and decoupled when symmetry breaking occurs, the low-energy theory includes only part of the fermion content that contributes to anomaly cancellation in the full theory. The low-energy constraints should refer only to the light fermion content, which in the present context corresponds to models defined below the reduced Planck scale M_* .

If the appropriate consistency conditions are satisfied, the discrete gauge symmetry can be treated as fundamental, without reference to specific high-energy embeddings.

The constraints that we apply in our model building are the linear IR conditions involving non-Abelian gauge group factors; these follow from triangle diagrams involving two non-Abelian gauge group factors and one factor of the continuous gauge group in which the discrete symmetry is embedded. For example, the \mathbf{Z}_N -SU(M)² anomaly cancellation condition is [21]

$$\sum_i C_i q_i = \frac{1}{2} r N . \quad (\text{A1})$$

Here r is an integer, q_i is the \mathbf{Z}_N charge of the i^{th} fermion (which transforms under \mathbf{Z}_N by $\exp[i2\pi q_i/N]$) and C_i is the Casimir invariant given by $\text{Tr}(T^a T^b) = C_i \delta^{ab}$, where the T^a are SU(M) generators in the representation of the i^{th} fermion. Since all the fermions in the model presented in Sec. III are in the fundamental representations of the relevant SU(M) gauge groups, $C_i = 1/2$; the linear IR conditions simply requires that the \mathbf{Z}_N charges of the fermions that transform under a specified SU(M) factor sum to an integer multiple of N . According to IR, when N is odd (relevant to the model of Sec. III) the gravitational anomalies linear in \mathbf{Z}_N are cancelled when the sum of all the \mathbf{Z}_N charges are also an integer multiple of N . It is straightforward to verify that these conditions are satisfied by the charge assignments displayed in Table I.

What about the other possible anomaly cancellation conditions? First, IR note that the linear conditions involving the Abelian gauge groups do not lead to any useful constraints on the low-energy theory [21]. Banks and Dine (BD) [22] later showed that the IR conditions non-linear in the discrete group make a tacit assumption about the high-energy embedding of the theory, through the requirement that both the light and the heavy fermions have integer U(1) charges. BD show that there are consistent, non-anomalous theories (ones in which the effective discrete symmetry at low energies is smaller than that of the full theory) in which the low-energy spectrum does not satisfy the non-linear IR constraints; their failure only implies the existence of heavy fermions with fractional charges. Thus, the non-linear IR conditions are not required for the consistency of the low-energy effective theory. BD note that the surviving discrete anomaly cancellation conditions are physically sensible: for example, the condition for the cancellation of the \mathbf{Z}_N -SU(M)² anomaly also guarantees that there are no t'Hooft interactions generated by SU(M) instantons that would explicitly break

the \mathbf{Z}_N symmetry. This physical constraint [23] is completely independent of the high-energy embedding.
