CERTIFICATE

This is to certify that this dissertation titled "M RI EVALUATION OF ANTERIOR CRUCIATE LIGAMENT TEARS WITH ARTHROSCOPIC CORRELATION" submitted by Dr.S.NAKKEERAN, appearing for PART-II MD BRANCH VIII – RADIODIAGNOSIS DEGREE EXAMINATION IN SEPTEMBER2006 is a bonafiderecord of work done by him undermy direct guidance and supervision in partial fulfillment of regulations of the TAMILNADU Dr.M.G.R.MEDICAL UNIVERSITY, Chennai. If orward this to the Tamilnadu Dr.M.G.R.Medical University, Chennai ai, Tamilnadu, India.

SignatureoftheGuide&HOD PROF.V.CHANDRASEHKAR, MD.,DMRD, HeadofDepartment, BarnardInstituteofRadiology, MMC,Chennai. SignatureoftheDire ctor PROF.T.S.SWAMINATHAN, MD.,DMRD.,FICR, Director, BarnardInstituteo fRadiology, MMC,Chennai.

SignatureofDean PROF.KALAVATHYPONNIRAIVAN,Bsc.,M.D., Dean,MadrasMedicalCollege, Chennai–600003.

DECLARATION

I declare that this dissertation titled "MRIEVALU **ATION OF ANTERIOR** LIGAMENT CRUCIATE TEARS WITH **ARTHROSCOPIC** CORRELATION " has been conducted by me under the gu idance and supervision of PROF. Dr. V. CHANDRASEKAR, M.D., D.M .R.D. It is submitted in part of fulfillment of the requirement for the award of the M.D., Radiodiagnosis, September 2006 examination to be he ld under Dr.M.G.R. MedicalUniversity, Chennai. This has not been subm ittedpreviouslybymefor theawardofanydegreeordiplomafromanyotherU niversity.

Dr.S.NAKKEERAN

ACKNOWLEDGEMENT

I would like to thank Prof. KALAVATHY PONNIRAIVAN, B.Sc., M.D., Dean, Madras Medical College and Research Ins titute, for giving me permissiontoconductthestudyinthisInstitution .

I express my sincere and heartfelt gratitude to my teacher and guide Prof. Dr. V. CHANDRASEKAR, M.D., D.M.R.D, H.O.D, Ba rnard Instituteof Radiology, Madras Medical College for having encour aged me to take up this study. Butforhisguidingspirit, perseverance and wisdom this study would not have been possible.

I am greatly indebted to my Director and other Professors, Prof. Dr. T.S.SWAMINATHAN, M.B., M.D., D.M.R.D., F.I.C.R., Director, Barnard InstituteOfRadiology,MMC,Prof.P.KUPPUSWAMY,M.D.,D.M.R.D.,Prof. N. KULASEKARAN, M.D., D.M.R.D., and Prof. A. P. ANN ADURAI., M.D., D.M.R.D.,fortheirsupport,valuablecriticismsan dencouragement.

I wish to thank all my Assistant Professors, Dr. P. UMAPATHY, D.M.R.D., Dr. SUNDARESWARAN, D.M.R.D., Dr. NESAMMA NIVANNAN, D.M.R.D., Dr. R. RAVI, M.D., and Dr. S. BABU PETER, M.D., for their valuablesuggestionsandsupport.

I wish to thank all my fellow postgraduates for the ir valuable criticism and untiring help.

Last but not least my sincere thanks to all the patients who co-operated for this study without whom this study could not have been possible.

INTRODUCTION

INTRODUCTION

Anterior cruciate ligament injury is the most commo nly injured of the major knee ligaments. Injuries occur frequently in both athletes and nonathletes. In United States the prevalence of ACL injury is about 1 in 3000, and approximately 2,50,000 injuries occur every yea r. Prompt assessment of fullextentof ligamentous damage is essential for appropriate management.

Because of its intraarticular location, the ACL has poor healing potential. The ruptured ACL does not form a bridgin g scar after complete disruption. The prognosis for a partially torn ACL may be favorable, if the synovialenveloperemains intact. Without treatment complete ACL injury can result in progressively increasing symptomatic knee instability and osteo arthritis.

Meniscusinjuryoccursinassociationwith50%ofac uteACLtears,and it increases to 90% in chronic ACL deficient knees. The incidence of articular cartilage lesions increases from 30% in acute ACL in juries to approximately 70% of knees with chronic ACL instability. The fund amental rationale for diagnosing and treating ACL injury is to prevent fu ture meniscal tears and associated joint damage.

For treating ACL injury the orthopaedician or arthr oscopist needs the answertofollowing questions:

- 1. Whether ACL is normal or abnormal? If ACL is normal invasive arthroscopy can be avoided in patients wit h suspected ACLinjury.
- 2. If abnormal, whether the tear is complete or partia 1? If partial conservative management or repair can be done. Howe ver in complete tears reconstruction needs to be done in ostof cases.
- 3. Whatisthestatusofassociatedstructuressuchas PCL, menisci, MCL, LCL, posterolateral, posteromedial plateau in ACL injured patients? Because an injury to above struct ures along withcompletetearofACLneedsearlyreconstructio nofACL.

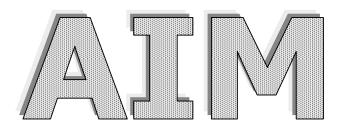

ACL injury can be diagnosed in majority of patients by history and clinical examination. The clinical diagnosis is fra ught with difficulty in acute cases and in large patients. Also partial tears are difficult to diagnose and the associated injuries could not be completely evaluat edby clinical examination.

Arthroscopy and arthrotomy are the criterion standa rds for definitive diagnosisbutareinvasiveandcostly.Itcangetu nnecessaryifACLturnsoutto benormal.

Spiral CT arthrography is more invasive than conven tional MR imaging.Itusesionizingradiationandissubject to the potential complications inherentinintraarticularinjection of iodinated contrastmaterial. Thecontinuingneedforabetternoninvasiveimagi ngmodalityforACL injury led to the use of MRI as a diagnostic and pr e- operative evaluation modality.

MRI is a recently devised modality for evaluation o f ACL and knee joint. Imaging is done in sagittal, axial and coron al planes using T1, T2 and STIRsequencesusingquadraturekneecoil.

The following study involves detailed evaluation AC L injury and its associated injuries using MRI and comparing with ar throscopic results. MR primary and secondary signs of ACL tear are also an alysed and their usefulnessassessedincomparisonwitharthroscopic findings.

ACLtear.

REVIEW OF LITERATURE

REVIEWOFLITERATURE

Theanteriorcruciateligament(ACL)isadensefib rousband composed of collagenfibrils. It is about 3.5 cm slong and 1 c mintransversediameter.ACL originates from the posteromedial aspect of the lat eral femoral condyle and courses through the lateral intercondylar notch in an anterior, inferior, and medial direction. It inserts on the tibia approxima tely 23-mm posterior to the altothemedialintercondylar anterior edge of the tibia, just anterior and later eminence (tibial spine). The ACL is not as strong a s the PCL and it is less strongatitsfemoraloriginthanatitstibialins ertion(Resnick, 1995).

ACL fascicles are organized into functional anterom edial and posterolateralbundlesorbands (Girgisetal) that are named for their location relative to each other at tibial insertion (*Resnick*, 1995). The stronger anteromedial bundle tightens with flexion of the kn ee and probably resists anterior translation of the tibia in flexion. The p osterolateral bundle tightens with knee extension and probably resists hyperexten sion. The physiologic property where part of the spiraled ACL is taut thr oughout the normal range of motion of the knee is termed isometry. Graft iso metry is one goal of reconstructivesurgery.

The ACL is an extrasynovial and intracapsular ligam ent. Bands of mesenterylikesynovium, arising from the posterior intercondylar region of the tibia, surround the cruciates (This accounts for fl uid of tenseen anterior to the normal ACL and posterior to the PCL) on MRI. The ex trasynovial location also helps to explain why hemarthrosis may be delay ed with acute ACL tear. Theprimaryblood supply to the ACL derives from ar teries to the surrounding synovial membrane. These in turn derive from branch es of the middle geniculate arterypier cing the posterior capsule. The central core of the ACL is relatively avascular. This may in part account for the generally ineffective healing of ACL tears. Tibial nervet erminal branch sinnervate the ACL.

MECHANISMOFINJURY

ACL tears occur with or without contact and with th e knee in any positionfromflexedtofullyextended. Themostco mmoncontactmechanismof injury is the valgus/abduction ''clip'' injury. These injuries are common in football players and occur with a lateral blow to t he partially flexed knee. Coexisting medial and lateral meniscal tears are common, as are medial collateralligamentinjury.

Hyperextension or varus-hyperextension from an ante rior blow (eg. injury from a motor vehicle accident or contact sports) is the second most common mechanism of ACL injury. The PCL or posterol ateral structures are also frequently injured. With more severe hyperextension, the knee may dislocate; the poplite alneurovas cular bundle or performance rone al nerve may be injured in this setting.

Adirectblowtotheflexedkneewiththeanklepla ntarflexed,asseenin turfinjuriesrepresentsthethirdmostcommonpatt ernofinjurytoACL. Increasingly, ACL tears are caused by noncontact me chanisms (*Stoller*, 1997). The pivot-shift mechanism is most commonly impli cated. This twisting injury typically occurs with rapid simultaneous dec eleration and directional maneuvers in skiers, football, basketball, or socce r players. The flexed knee incurs a valgus load, with internal rotation of the tibia or external rotation of the femur. Associated meniscal tears, collateral li gament injuries, and lateral patellar subluxation are common.

Noncontact hyperextension, such as that occurring in a gymnast or cheerleader who misses a landing, is another mechan ism of injury that may resultinACLinjury.

EVALUATIONOFACLINJURY

DiagnosisofACLinjurycanbedoneby

- i. Historyandphysicalexamination
- ii. MRI
- iii. CTarthrography
- iv. Arthroscopy
- v. Arthrotomy

The skilled clinician can diagnose up to 90% of ACL tears by history and physical examination (*Johnson and Warner; Lee et al, 1998*). Patients typicallyreportanaudible "pop" and giving wayat the time of injury. Aknee effusion usually develops over the next 24 hours. A tear is confirmed at physical examination using primarily the Lachmantest (*Swenson et al, 1995*). Anterior drawer and pivot shift tests are often helpful andarthrometric examinationmay be contributory. Diagnosis may be difficult inlarge patients, in patientswith strong secondary muscular restraints, and in the acute injury settingwhere there is soft tissue swelling and guarding. Partial ACL tears areespecially difficult to diagnose by physical examination (*Noyes et al, 1989*).MRImayprovidepivotal diagnostic information abouttheACL in all of thesesettings(*Otanietal, 2001;Munketal, 1998*).

Plain radiography of acute ACL injuries may show so ft tissue swelling and haemarthrosis. An avulsion of fanterior tibial eminence, lateral tibial rim fracture (segond fracture), posterior fracture of l ateral tibial plateau and an osteochondral fracture of lateral femoral condylem ay be associated with ACL injuries and can be identified in plain radiographs .

Bernard Stallenberg. Gevenois, A. Sintzoff, Matos, Andrianne and Sruyven et al studied 25 plain radiographs of ACL tear patients. They concluded that impaction of lateral femoral condyle on the lateral tibial condyle and avulsion of posterior tibial capsular junction represents the most frequent indirect radiographic sign of ACL tear.

Normal ACL was delineated as hyperechoic images on ultrasound in sagittal and transverse sections. On the other hand , no image of the ligament could be seen when the ligament was ruptured. Howev er it is highly operator dependent and complete evaluation of all knee joint structures could not be possible. Inmanyacute injured patients sonographi cwindow to visualize ACL ispoor. Richter J, David A, Pape HG, Ostermann PA and Muhr G et al evaluated ACL sonographically in 74 patients and th ey concluded that ultrasounddiagnosisrevealed88%ofallcompleteAC Lruptures.

SpiralCTarthrographyisanaccuratemethodfordi agnosingACLand meniscal tears. The direct signs of ACL tear are di scontinuity with intra ligamentous contrast material, discontinuity of ACL with fatty tissue in expectedACLcourse, abnormalcourse and abnormals hape. Indirect signs of ACL tears at spiral CT arthrography included anteri or translocation of the lateraltibialplateau, abnormal depression of the lateral femoral condylen otch and fracture of the posterior margin of the lateral tibial plateau.

Bruno C.Vanderberg et al studied 125 patients and compared dual detector CT arthrography findings with arthroscopy findings. The sensitivities re 90% and 96%, and specificities for the detection of ACL tears we respectively. Thesensitivity and specificity fort hedetectionofmeniscaltearsin knees with abnormal ACLs were 92% and 88%, respective ly. The sensitivity values for the detection of meniscal lesions in kne es with abnormal ACLs at spiral CT arthrography could be superior to those o btained at conventional en 69% and 88% but MR imaging, which have been reported to range betwe this observation remains to be assessed in a compar ative study. The location and configuration of meniscal lesions observed in k nees with abnormal ACLs could partially account for the decreased sensitivi ty of MR imaging. The meniscal separation and peripheral tears that are a ssociated with ACL tears

(can be missed at MR imaging) and could be better d etected at spiral CT arthrography.

Spiral CT arthrography is more invasive than conven tional MR imaging.Itusesionizingradiationandissubject tothepotential complications inherentinintraarticularinjectionofiodinatedc ontrastmaterial.

MRAPPEARANCEOFNORMALACL

Normal ACL shows low to intermediate signal intensi ty on all pulse sequencesslightlyhigherthanthatofPCL.

On sagittalimages ACL should be ruler straight alt hough mild sagging convexinferiorlymaybenoted with kneeflexion. Normal ACL is parallel to the intercondylar line of Blumensaat. The distal ACL de monstrates relatively increased signal presumably due in part to divergen ceoff ascicles distally. The proximal ACL at its origin is often less well seen on sagittal images than the remainder of the ACL, owing in part to proximity to adjacent intercondylar roof.

The ACL projects laterally in the intercondylar not ch in the coronal plane; the PCL projects medially. In the coronal plane, normal ACL fascicles areoftenfewinnumberandattenuatedinappearanc e.

In the axial plane, the proximal ACL appears as an elliptical low signal intensity band adjacent to the lateral wall of the upper intercondy lar notch. It gradually moves away from the wall and splits into a horseshoe (fan-shaped) array of fascicles as it approaches its tibial insertion (Roychowdhury et al,1996). The distal ACL is thus difficult to evaluate critically on axial imageswhereasproximalACLisbestevaluatedinaxialimages.

TheAMBformstheanteriorborderoftheACL.TheP LBrepresenting the bulk of ACL may display more intermediate signa l intensity on T1W images. The axial plane is helpful in spatially ide ntifying sites of tears correspondingtotheAMBandthePLB.

The individual low signal intensity fibers may be s eparated by linear stripes of intermediate to bright signal intensity on T1W images. These stripes are believed to represent fat and synovium and are usually identified at the tibial attachment of ACL.

MRIEVALUATIONOFACLINJURY

TheprotocolrequirementsofACLimagingaresequen cesinall3planes (sagittal, coronal, axial) that include both T1-wei ghted (or proton-weighted) and T2-weighted sequences in the sagittal plane. Whe n supine, patients are allowed to naturally externally rotate their legs. The sagittal plane usually approximatestheoptimalimagingplanealongthelo ngaxisoftheACL.

While the sagittal imaging plane is often most help ful in ACL evaluation, any of the 3 imaging planes may prove p ivotal in a given case. Coronalimagingisespeciallyusefulforevaluation of proximal tears (*Remeret al,1992*).Axial sequences are also very useful for evaluatin gthe proximal and middle aspect of the ACL. Axial images provide a un ique cross-sectional viewpointfreeofpartialvolumeartifactwiththe intercondylarroof(*Fitzgerald* etal,1993;Roychowdhuryetal,1997).

The ACL is usually seen to greatest advantage on T2 -weighted sequences,asopposedtoshort-TET1-weightedorgr adient-echoimages.Thisis due in part to increased signal seen in ligaments a nd tendons in short-TE sequences owing to magic-angle effect and other fac tors. Fast spin echo T2weighted sequences with fat saturation are obtained faster than conventional T2-weightedsequences.

Katahiraetal (2001) reported increased diagnostic accuracy prescribing images parallel to the long axis of the ACL off of an oblique-sagittal image (a "double-oblique" sequence). This extra sequence was T2-weighted with 3-mm slice thickness.

Joong K Lee, Lawrence Yao, T.Phelps, R.Wirth, John Czajka and Jeffery Lozman et al studied 79 patients and compared MR findings with t he findings of two common clinical tests anterior draw er and Lachman test in arthroscopically proven ACL tears. The sensitivity for MR imaging was 94% compared with 78% for anterior drawer test and 89% f or Lachman test with 100% specificity for all three.

MostACL tears occur (70-90%) in the midsubstance, 7-20% proximally near its origin. Only 3-10% occurs distally at the tibial attachment (*Remeret al, 1992; Resnick, 1995*). Studies report 92-100% sensitivity and 82-100% specificity of MRI for diagnosis of ACL tears (*Robertson et al, 1994; Mink et* al, 1988; Fitzgerald et al, 1993; Brandser et al, 1 996; Lee et al, 1988; Pope, 1993; Tungetal, 1993).

BNLakhar,KVRajagopalandP.Raietal studied173patientsofwhich 78 showed ACL tears. They reported 98.7% sensitivit y, 98.9% specificity, 98.1%positivepredictivevalueand98.8%negativep redictivevalueforMRIin diagnosisofACLtearincorrelationwitharthrosco py.

However, sensitivity is significantly decreased if other major ligamentousinjuries are present in the knee (*Rubin et al*, 1998). Less data are available on children. Decreased accuracy of MR has been reported in preadolescents (*McDermott et al*, 1998), but are cent study on patients aged 5-16 years demonstrated as ensitivity of 95% and aspectificity of 88% (*Lee et al*, 1999).

Definitionsofprimaryandsecondarysignsfortear sofAnteriorCruciate Ligament(ACL)

PRIMARYSIGNS

- 1) Abnormal signal intensity: Increased signal intensi ty on T2W images withinACL
- 2) Abnormal axis/angle>10 deg: when the fibers are not parallel to intercondylarlineofBlumensaatinthesagittalim ages.
- Discontinuity : when there is discontinuity of fibe rs of ACL focal or diffuseinsagittalorcoronalimages
- 4) CompletenonvisualisationofACLonallthreeimagi ngplanes

Primarysigns of a cute ACL tear (i.e., abnormalitie sinvolving the ACL proper) allow high accuracy in the diagnosis of ACL injury, even in the absence of secondary signs (*Brandser et al, 1996; Lee et al, 1998; Mink et al, 1988; Tungetal, 1993; Falchook et al, 1996*).

EricBrandser,Riley,Berbaum,ElKhouryandLeeBe nnetetal studied the independent value of primary and secondary sign s. They concluded that it is the primary signs that form the basis for determ in ing the status of the ACL.

BNLakhar,KVRajagopalandP.Raietal studied173patientsofwhich 78 showed ACL tears. They found that hyperintensity was the most common signseenin52(67%)patients.

Glenn Tung, Davis, Wiggins and Paul Fadale et al studied 103 MR examinations in 99 patients and they concluded that abnormal appearance of ACL on sagittal images is the single most sensitive and specific sign of ACL tear.

Lee, Siegel, Lau, Hildeboltand Matavaetal studied the accuracy of MR findings of ACL tear in paediatric population aged 5-16 years and they concluded that primary and secondary signs are high lyspecific and are useful for diagnosis.

SECONDARYSIGNS

1) Bone contusion: Medullary bright signal abnormalities seen on STIRimagesmaybeduetomicrofracture,edemaorhemorrhage.

- 2) Anterior tibial translation: At the level of midlat eral femoral condyle drawtangentiallinesalongposterior cortical marg in offemurand tibia and measure the distance.>5 mmis ab normal.
- Uncovered posterior hornof lateral meniscus: This signispresent, if on sagittalimages tangential lined rawnalong posteri or cortical margin of lateral tibial plateau intersects any part of poste rior horn of lateral meniscus.
- 4) PCL buckling: PCL is said to be hyperbuckled if any portion of its posteriosuperior border is concave. Conversely PCL is normal if this borderisstraightorconvexforitsentirelength.
- 5) Deep lateral femoral notch: Draw a tangent across t he sulcus on articular surface of lateral femoral condyle and me asure from this line todeepestpoint of sulcus. Depthgreater than 1.5 misabnormal.
- 6) Posterior PCL line: Draw a line tangent to posterio r margin of distal portion of PCL. If this tangent does not intersect posterior cortex of femurwithin5cmofitsdistalend, this signiss aidtobepresent.

MRI findings of an ACL tear apart from abnormalitie s of the ACL proper are termed secondary signs. The sensitivity of these signs is limited (*Brandser et al, 1996*), thus the absence of secondary signs in no way exc ludes ACL disruption. However, certain signs discussed be low have substantial (>80%) specificity.

Thomasvahey, JosephhuntandDonaldShellbourneetalevaluated theanterior tibial translocation in relation to femuras a predictor of ACL tear.

Translocation of 5mm or more had 58% sensitivity, 93% specificity and 69%accuracy for ACL tear. All knees with subluxation of7mm or more had toreACL. They also concluded that buckling of ACL is less sensitive and lessaccuratethananteriortranslocationasanindicatorofACLdisruption.

McCauley et al studied posterior displacement of lateral meniscus in relation to tibia on sagittal images as a predictor of ACL tear. A vertical line constructed through posterior cortical margin of ti bia intersecting lateral meniscushad97% specificity56% sensitivity for ACL tear.

Mark Cobby, Schweitzer and Resnick et alstudied 103 patients andconcludedthatlateralfemoralcondylopatellarsulcusdeeperthan1.5mmwasareliableindirectsignofACLtear.Nopatient withanormalACLhadasulcusgreaterthan1.2mmindepth.anormalACLhadasulcus

Brian J Murphy et al and his associates studied MRI bone signal abnormalities in the posterolateral tibial plateau and lateral femoral condyle and they concluded that bone impaction at the above areas suggest a diagnosis of complete ACL tear.

Glenn A. Tung, Lawrence M. Davis Michael E. Wiggins , Paul D. Fadale et al noted 73% prevalence of bone bruise in patients wit h ACL tear whounderwentimaging within 9 weeks of kneein jury and, in 91% of cases, the lateral compartment was involved. None of the patie nts with ACL tear had bone bruises when MR imaging was performed 9 weeks or longer after knee injury. In children, ligament laxity may allow abo nebruise to occur while the ACL is still intact.

Avulsion fracture of the proximal fibula (termed t he "arcuate sign") was associated with ACL tear in 13 of 18 patients i nonestudy (Juhng et al, 2002). This fracture is a marker for varus and hyperexte nsion injury to the posterolateralstructures. The "arcuate" signorfr actureisanavulsionfracture of the fibular head and styloid at the attachment o f the lateral collateral ligament and biceps femoris tendon. Although the av ulsion fracture may occasionally not be visualized on conventional radi ographs, the presence of edemaintheproximalfibulacanbeahelpfulsign ofthisinjury.

TheSegondfractureisanelliptical, verticallyor iented, 3x10mmbone fragment paralleling the lateral tibial cortex, abo ut 4-mm distal to the plateau. It has a 75-100% association with ACL tear (*Resnick, 1995*). In the acute setting, MRI often shows a bone bruise of the adjac ent edge of lateral tibial plateau secondary to meniscotibial ligament avulsio n. The adjacent Segond fragment may be difficult to visualize (*Weberetal, 1991*). If observed, the bone fragment demonstrates a marrow-edema pattern.

KarenceChanandResnicketal studiedtenpatientswithposteromedial tibial plateu injuries retrospectively. All ten pat ients had ACL tears at MR imaging. Five patients had posteromedial tibial pla teu fractures and five had posteromedial tibial plaeteu bruises. They conclude d that fracture of posteromedialtibialplateuispredictiveofanass ociatedACL tear. Bucklingor redundancy of the PCL (Boeree and Ackro yd, 1992) occurs frequently with ACL tear but also occurs with hyper extension of the normal knee (*Gentilietal1994*) and with quadriceps dysfunction.

The angle of PCL can also be used to evaluate ACLtears. McCauleyetal reported PCL angleless than 105 degree was 72% sensitive and 86% specificfor predicting ACL tears. The normal PCL angle is 113 to 114 degrees.

PARTIALACLTEAR

PartialtearsoftheACLarecommon,accountingfo r10-43%ofallACL tears (*Lee et al, 1998*). A tear involving less than 25% of the ACL has a favorable prognosis; a tear involving 50-75% of the ACL has a 50-86% probabilityofprogressingtoacompletetear(*Noyesetal,1989*).

Partial tears are typically underdiagnosed on physi cal examination. It has been shown in cadavers that laxity is absent by physical examination and arthrometric testing when the anteromedial band of the ACL is transected (*Lintneretal*,1995).

Several studies have documented suboptimal accuracy of MRI in the diagnosis of partial ACL tears (*Umans et al, 1995; Gentili et al, 1994; Lawrance et al, 1996*). Direct signs may include abnormal focal high sign al intensity, focal angulation and ligamenten largemen t. However, focal increased signal intensity in the ACL is nonspecific (*Umans et al, 1995*) and may be difficult to differentiate from partial-volume aver aging of adjacent intercondylar notch fluid. These limitations notwit hstanding, MRI does allow diagnosis of some partial tears missed on physical examination. Secondary signsofACLinjuryarenotusefulindistinguishin gpartialfromcompletetear (*McCauley,etal,1994*).

Roy chowdhury et al studied the usefulness of axial MR imaging for diagnosing and characterizing partial ACL tears as stable or unstable. Stable ACL include normalligaments and stable partial tea rs. Unstable ACL include unstable partial tear and complete tear. On axial M Rimages stable ACL swere elliptical, attenuated or increased intrasubstance signal intensity whereas unstable ACLs were isolated ACL bundle, nonvisualis ation and cloud like mass. They concluded that axial MR offers prognosti c potential to distinguish which patients will have unstable ligaments and req uire ACL reconstruction.

Thomas N. Vahey, Dale R. Broome, Kossmas J. Kayes, Donald Shelbourneetal studiedtheMRdifferentialfeaturesofacuteandc hronictears ofACL.AcuteACLtearscanbeaccuratelydistingui shedfromintactligaments as they are usually characterized by the presence o f edema. The findings of acute tear include discrete edematous mass or small er well defined edematous fociwithdisruptedligament.Allacutetearsover 4weeksofagehadedematous foci. Chronic tears can have potentially confusing appearance due to presence of bridging fibrouss cars that can mimic an intact ligamentso correlation with history and clinical examination should help in the sepatients. The findings of chronic tear include nonvisualisation of the ligame nt, continuous band with focalangulationandvisualizationofACLfragments butallwithoutedema.

An acute tear manifest by enlargement of the ACL an d increased internal signal but with visible intact fascicles h as been termed an interstitial tear". This should be differentiated from intralig amentous mucinous degeneration.

ARTHROSCOPY

The appearance of normal ACL varies from patient to patient, depending on its anatomy, the presence or absence o finjury and the synovial covering.

In a normal ACL the synovial covering is usually t hin with small capillaries coursing on the surface. If considerable e synovitis is present retractionofligamentummucosumandothersynovial tissuesmayberequired to observe the underlying ACL. With complete ruptur e of ACL considerable hemorrhage within synovial tissues is evident. Care ful probing and opening of its synovial sheath often demonstrate disrupted ACL bundles not evident during initial inspection.

A normal ACL feels taut or hard when hooked with a probing instrument. A torn ACL feels mushy without tension. A drawer or Lachman testcanbeperformedbytheassistantwhileACLis directlyviewed.

The tear is complete if there is marked pivotal shi ft, minimal resistance to probing and disruption of more than 90% of fasci cles. The tear is classified as partial if there is mild pivotal shift, substant ial resistance to probing and disruption less than 90% of fascicles. Before the use of MR all patients underwent diagnos tic arthroscopy. Diagnostic arthroscopy is invasive and considerably more expensive than MR and the accuracy is similar. The wide range of accu racy reports may be due to number of factors such as equipment, imaging techni que and expertise of radiologist and arthroscopic surgeon. Arthroscopy s hould be viewed as an imperfector relative golds tandard for the diagnos is of these disorders, because stretching or intrasubstance in juries to ACL may go undetected despite positive MR findings.

MR imaging affected patient management by enabling selection of patients with a surgical lesion and obviating an in vasive procedure in other patients. In addition to guiding treatment it helps in planning and timing of therapeuticarthroscopybeforesurgery.

MANAGEMENTOFACLTEAR

Patient activity level (and expectations for activity in the future) is the most important factor guiding treatment choice (*Swenson et al, 1995*). Associated meniscal and ligamentous injuries, degree of laxity, age, and willingness to pursue vigorous postoperative physical therapy are other major determinants.

Primaryrepairismostsuccessfulwhenavulsionocc ursateitherfemoral ortibialattachment.Patients with midsubstancete arsare not good candidates for ACL repair. Primary ACL repair and intraarticu lar augmentation producebetterresultsthanprimaryACL repairalon e. The surgical treatment that is strongly recommended in young athletes is either arthroscopic or open reconstruction of the ligament (followed by meniscal repair or partial meniscectomy of themeni scal tears). This should be performed right after the relief of the acute sympt oms (usually three weeks later). Acute repair might be considered only when the tibial insertion of the ligament has been avulsed with a fragment of bone.

Patients with injuries to the posterolateral struct ures and ACL have significantly greater instability and usually requisive relations of both areas. Unrepaired posterolateral knee injuries predispose to early ACL graft failure (*Hughston et al, 1985*). If both PCL and ACL tears are present, reconstructive surgery is usually necessary. Menisc alrepairs have a higher rate offailure in ACL-deficient knees than in ACL-recon structed knees

Evidence exists that "late" ACL reconstruction decr eases postproceduralstiffness.Surgeryisdelayeduntilmost of the swelling has subsided and range of motion is restored (*Swenson et al, 1995*).However, MRI enables the diagnosis of coexisting injuries that may precl ude a delayed approach. Bucket-handlemeniscal tears and posterolateral kne einjuries are examples of injuries that respond best to earlier intervention (*Veltrietal, 1994*).

MATERIALS AND METHODS

MATERIALSANDMETHODS

Aprospectivestudyof57patientswithhistoryof kneetraumaandpain referred from orthopaedic outpatient department was done in Barnard Institute of Radiology, Madras Medical College betw een March 2004 to Feb 2006. All 57 patients were subjected to MRI examina tion. MRI knee was performed using Siemens 1.5 Tesla superconducting M AGNETOM, using quadraturekneecoil.

METHOD

Patient was placed in supine position with kneepl aced in 5-10 degree of external rotation and extension.

MRTECHNIQUEUSED

Ascoutaxialviewwasobtainedtoplanforsagitt alandcoronalsections (perpendicular and parallel to posterior femoral condylar line). If needed obliquesagittalsectionsforACLwereperformedus ingcoronalslicethatshows theobliquecourseofACL.

INCLUSIONCRITERIA

All patients referred from orthopaedic department w ith history of knee traumaand kneepain with follow uparthroscopy wer eincluded in the study.

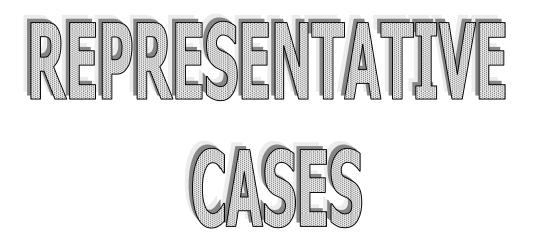

EXCLUSIONCRITERIA

- i. PriorH/Osurgery,arthroscopy
- ii. PatientswithMRincompatibledevicesorimplants
- iii. Patientswithclaustrophobia
- iv. Patientsonlifesupportsystems

The study confines to the ethics and was done with

the consent and full

cooperationofthepatients.

RESULTS AND ANALYSIS

RESULTSANDANALYSIS

TheabilityofMRIandclinicalexaminationtodiag noseACLinjurywas compared with arthroscopy and the results were anal yzed using various statistical tests. Primary and secondary signs for ACL tear in MRI were also studied indetail incorrelation with arthroscopy.

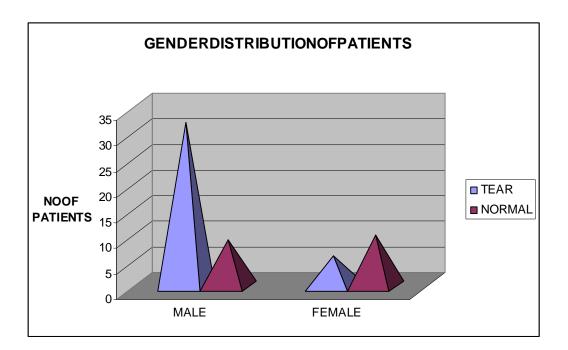

The final arthroscopic findings after evaluation w ith MR imaging were accepted as references tandard against which the MR findings were compared.

The sensitivity, specificity, positive predictive value, negative predictive valueand accuracy were calculated for clinical and MR imaging in diagnosing ACL tears in correlation with arthroscopy. The sens it ivity, specificity, positive predictive value, negative predictive value and accuracy were calculated for the primary and second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary signs of ACL tear in MR in a second ary second ary signs of ACL tear in MR in a second ary second ary signs of ACL tear in MR in a second ary second

Cohen's kappa is used to compare the correlation be tween the modalities. Values of kappa were classified as bad (less than 0.4), good (0.4– 0.75), excellent (greater than 0.75) following Land is and Koch's criteria.

DISCUSSION

DISCUSSION

MRI knee joint was performed on 57 patients who wer e referred from orthopaedic department with history of knee trauma and knee pain for the evaluation of ACL tear and its associated injuries.

Out of 57 patients, 41 (72%) were male patients and16(28%) werefemalepatients.32(78%)of41malepatientshadtearsand6(37%)of16femalepatients had tears. The sex of the patient was found to be significantlyassociated with ACL tears (p<0.01). Male preponder</td>ance may be related tomoreoutdooractivity, sports participation and more usage of vehicles. In thisstudypopulationa malepatient with kneein jury wastwo times more likely tohaveatornACL

Thesepatientswereintheagegrouprangingfrom14to64years.Outof57 patients, 34 (60%) were in the age group 20-40 years. Out of 57 kneeexamined,30(53%)wererightsideand27(47%)left.20patientshadACLtearonleftsideand18ontherightside.Inourstudy,patient withleftkneeinjurywas1.4timesmorelikelytohaveACLtear.

57 patients underwent clinical examination for ACL tear. Both anterior drawer and Lachmantest were done. By clinical exam ination 32 were classified as ACL tear and 25 as normal.

The positive predictive value for detecting complete tear was 93.5%.However out of 25 clinically reported normal ACLS 4turned out to becomplete tear. The sensitivity for detection of ACLtear was 78.9% and for

complete tear was 87.8%. 3 patients with clinicallymissed ACL complete tearhad bucket handle medial meniscal tears.Joong Lee et aland his associatesshowed sensitivities of 79% for anterior drawer and87% for Lachmantest fordiagnosis of ACL tear. Clinical examinational somissed 4 partial tears out of 5arthroscopically confirmed ACL partial tear.

Patients with knee trauma and knee pain were subjec ted to MR knee joint. ACL evaluation was done by scrutinizing sagi ttal, axial and coronal sections. Using sagittal images tibial and midsubst ance of ACL was evaluated and also the alignment to femoral intercondylar lin enoted. Axial and coronal imageswere used to visualize the femoral attachmen to fACL.

A diagnosis of complete tear of ACL was based on the following primary findings: a) abnormal high signal intensity within ACL b) abnormalaxis/angle(fibresnotparalleltointerc ondylarlineofBlumensaat)c) discontinuity of the fibres d) nonvisualistion of ACL.

For the diagnosis of partial tears the direct signs include focal increase in signal intensity, focal angulation, ligament enl argement and partial discontinuity.

Theprimarysigns were evaluated and ACL status cla ssified as normal, partial or complete tear. Of the 38 arthroscopicall y confirmed ACL tears, 33 were complete and 5 were partial tears. On evaluati on according to the site of tear, isolated midsubstance tear was noted in 25 (6 6%). Isolated femoral and tibial attachment tear were reported in 5% each. In 9 arthroscopically confirmed tears the exact location of tear could no the identified as it seems to involve both mid substance and femoral attachment. The results in our study are similar to the study by *Remeret* al *and Resnick* who reported 70% tears in mid substance, 5-20% near femoral attachment and 3-1 0% at tibial attachment. *Lakhar, Rajagopal and Rai et al* studied 78 ACL tears and concluded that mid substance was the most common tea rlocation seen in 66.7% of patients.

As shown in table 12, of the 33 arthroscopically pr oved complete ACL tears, 32 had complete tears proved by MR having 96 .9% sensitivity, 29 had positive clinical examination with 87.8% sensitivity y compared to sensitivity of 94% for MRI and 89% for clinical examination by Joo ngK. Lee et al.

Minketal reportedanaccuracyof95% for detection of comple teACL tear on MRI with 9.5% false positives and 4.5% fals e negatives. Our study showed an accuracy of 97.9%, positive predictive va lue of 96.9% and negative predictive value of 100% for complete tear.

A weighted Cohen's Kappa coefficient measure of com plete ACL tear diagnosiswasfoundtobe0.76forclinicalevaluat ionand0.95forMRI.

Of the 19 arthroscopically proved normal ACLs, 15 h ad negative MR findings and 3 patients had increased signal intens ity and reported as partial tear. As reported by *Umans et al*, 1995 this may be due to partial volume averagingofintercondylarnotchfluid. Primary findings were present in all the patients w ith ACL tears. Twentyeight(84%)of33 complete tear patients ha d more than one primary finding.15 patients had two findings and 13 patien tshad three findings.

Abnormal signal intensity of ACL was present in 27 of 33 arthroscopically confirmed complete ACL tears givin g a sensitivity of 81.8% and accuracy of 80.4% in our study. The results are similar to 79% sensitivity shown by *Leeetal* and his associates in the irstudy.

AbnormalBlumensaatangleoraxiswasseenin28of 33completetears givingasensitivityof84.8andpositivepredictiv evalueof96.5%.Theaccuracy fordiagnosingcompleteACLtearwas88.5% and Kapp avaluewas0.76.Of19 arthroscopically confirmed normal ACLs only one pat ient had abnormal axis givinga specificity of94.7%. This is similar to th eresults obtained by *Patricia Robertsonetal* sensitivity of 84% and accuracy of 84% and kvalue of 0.41 for the diagnosis of complete ACL tears.

Complete discontinuity was present in 17 patients o ut of 33 complete tears. It was not seen any of arthroscopically conf irmed normal ACLs giving 100% specificity. However these nsitivity was 51% a ndtheaccuracy was 40.4% for diagnosing complete ACL tear. *Kwanseop Leeet al* studied paedia trick nees and showed sensitivity of 21% and specificity of 10 0% for diagnosing complete tear.

Nonvisualisation of ACL was seen in 2 patients of 3 3 complete ACL tears. Even though specificity was 100%, the sensit ivity was 6%, Kappa value

0.04% which means poor correlation. Pvalue was 0.5 2 and not significant for diagnosing ACL tear.

In our study, abnormal axis was the single most use ful sign for diagnosing complete ACL tear with kappa value of 0. 76. Combination of abnormalaxis with abnormal signal intensity had 72 .7% sensitivity with 100% positive predictive value and specificity. They wer e the most useful signs in diagnosing complete ACL tear with combined kappa va lue 0.66 which means good agreement.

A medullary signal intensity pattern consistent wit h bone bruise was observed in 23 patients. It was present in 19 of 33 complete tear, 1 of 5 partial tear and 3 of 19 normal ACLs.

The sensitivity of bone bruise for predicting ACLtear was 52.6% andspecificity was 84.2% in our study in comparison tosensitivity of 44% andspecificity of 93% in the study byGlenn A. Tung et al.He also noted that thesensitivity increased to 73% when MRI was done within 9 weeks of injury.Gentilietalshowed sensitivity of 54% and specificity of 100%for bone bruiseinlateral compartment for predicting ACL tear.

As per table no 21 anterior tibial translation > 5m mshowed sensitivity of 60.5%, specificity of 84.2 and p value < 0.01 fo r diagnosing ACL tear. Comparativelyinastudyby *AmilcareGentilietal*, thesensitivitywas63% and the specificity80%. *Vaheyetal* reported 58% sensitivity,93% specificity, and 69% accuracy for ACL tears. Uncovered posterior horn of lateral meniscus in our study showed specificity of 89.5%, positive predictive value of 90.5% but sensitivity of only 50%. *Maccauleyetal* reported sensitivity of 56% and specificity of 97% in his study.

Buckled PCL was seen in 17 (44.7%) of 38 ACL tears and 3 of 19 normal ACLs with an accuracy of 57.9%. kappa value f or predicting ACL status was 0.23 which means poor agreement. *Robertson et al* showed an accuracy of 76% and kappa value of 0.41 in his retr ospective review of ACL tears.

Deeplateralcondylopatellarsulcus>1.5mmwasobs ervedin8(21.1%) of 38 ACL tears and 1(5.2%) of 19 normal ACLs in ou r study. This finding showed 94.7% specificity, 88.9% positive predictive value and only 21.1% sensitivity in our study. *Warren et al* found that only one(2%) of 47 patients with clinically intact ACLs had deep sulcus. In con trast, two (4%) of 52 patients with acute ACL tears and 13(13%) of 101 p atients with chronic ACL tears had a sulcus greater than or equal to 1.5mm indepth . *Cobby et al* in his study showed deep not chin5(12%) of 41 patients with ACL tears.

In our study only 6 arthroscopically confirmed part ial tears were present of which 4 were reported correctly on MRI. Out of 8 MR reported partialtearsthreeturnedouttobenormalonarth roscopy.Thismaybedueto inacute haemarthrosisof knee partial volume avera ging of fluid may result in increased signal. Bonecontusionandanteriortibialtranslationmore than5mmwerethe mostusefulsecondarysignsforpredictingACLstat usinourstudy.

Associated injuries included 19 meniscal tears, 16 involving medial menisci, 3 involving lateral menisci, 4 medial coll ateral ligament and 4 posterior cruciate ligament and one involving later al collateral ligament. Medialmeniscaltears were the most frequently asso ciated injury in our study. In 15 patients, MRI findings of associated meniscal and PCL injuries resulted inearly arthroscopic intervention.

SUMMARY

SUMMARY

MRIkneejointalong with clinical examination was done in 57 patients referred from orthopaedic department for evaluation of ACL tear and its associated injuries.

Of 57 patients, 72% were male patients. 32 (78%) of41 male patientshadtearsand6(37%) of 16 female patients had tears. In this study population,amale patient with kneein jury was two times morelikely to have torn ACL.

The patients were in the age group 14–64 years. 6 0% of them were in the age group 20–40. years. Inour study apatient with left kneein jury was 1.4 more times likely to have ACL tear.

MRI was extremely useful in diagnosing complete tea r with 96.9% sensitivity, 97.9% accuracy and 100% negative predi ctive value whereas clinical examination had 87.8% sensitivity, 88% acc uracy and 93.5% positive predictivevalue.

A weighted Cohen's kappa coefficient measure of MRI diagnosis of completetearwasfound to be 0.95, and 0.76 for clinical examination. Similarly for diagnosis of ACL tear, kappa value of MRI wasf for clinical examination. Values of kappa were clas good (0.4-0.75) or excellent (greater than 0.75), f ollowing Landis and Koch's criteria. Primary findings were present in all complete ACL t ear patients. Abnormal axis(p<0.001) was the single most useful s ign for diagnosing completeACLtearwith84.8% sensitivity,96.5% pos itivepredictive value and specificity of 94.7%. Combination of abnormal signa lintensity and abnormal axis increased the specificity and positive predict ive value to 100% with sensitivityof72.7%.

Of5arthroscopicallyproved partial tears, one tea rwasmissed by MRI and four by clinical examination. MRI showed poors pecificity for diagnosing partial tears as three reported in MRI as partial t earfound out be normalon arthroscopy.

Regardinglocationoftears,66% wereseeninmidsu bstance,5% eachin femoralandtibialattachmentand24% wereseento involvebothmidsubstance andfemoralattachment.

Onevaluation of secondary signs to predict ACL sta tus, bone contusion and anterior tibial translation were the most useful lwith specificities of 84.2%, 84.2% and sensitivities of 52.6% and 60.5% respective ly.

Because primary signs directly evaluate the ACL and are seen in all patients with complete tears, it is the primary sig ns that form the basis for diagnosingACLtear.

MRIalsohelpedindiagnosingassociatedinjuriesw ithACLtearswhich helped in planning management. MRI showed 16 medial meniscal tears, 3 lateral meniscal tears, 4 MCL, 4 PCL and 1 LCL tearassociated with ACLtears.Medialmeniscaltear was the most common associated injury with ACLtearinourstudy.

CONCLUSION

CONCLUSION

High spatial resolution MR imaging with quadrature knee coil is accurateforthedetectionofcompleteACLtears.

In this study population, a male patient with knee injury was two times more likely to have torn ACL. Similarly a patient w ith injury to left knee was 1.4 times more likely to have ACL tear.

Primaryfindingsform the essential basisfor diagn osis of ACL tears as they are visualized in almost all complete tears. A bnormal axis of the ACL is the single most useful sign in diagnosing complete ACL tear. Midsubstance of the ACL is the most common location of tear.

MRI showed associated meniscal and other ligament i njuries, which helped in early surgical reconstruction of ACL. Med ial meniscus tear was the most common associated injury in our study. So pre arthroscopic MRI helped in planning the timing of surgery in a considerable number of patients in our study.

Regarding partial tears, further studies are needed to evaluate the usefulness of MRI as the number of patients with partial tears is low in our study.

Finally we conclude that High spatial resolution MR imaging is highly accurate for the detection of complete ACL tears wi th excellent arthroscopic correlation and is therefore an ideal and more accu rate preoperative imaging

modalityfordiagnosingcompleteACLtearsandasso ciatedinjuries.
