ABSTRACT

Systems and methods for implementing and using optoelectronic gates are disclosed. One such method includes superimposing an electrical data bit onto a first optical input to produce a pair of first-stage optical outputs. The first one of the pair of first-stage optical outputs carries the electrical data bit and the second carries the complement of the electrical data bit. The method further includes comparing an electrical target bit with the electrical data bit conveyed by the first first-stage optical outputs and with the complement of the electrical data bit conveyed by the second first-stage optical outputs, to determine whether the electrical target bit and the electrical data bit are same or different.

OPTOELECTRONIC LOGIC GATE**CROSS REFERENCE TO RELATED APPLICATIONS**

This application claims the benefit of U.S. provisional application 61/182,588, filed May 29, 2009, the entirety of which is incorporated herein.

FIELD OF THE DISCLOSURE

The present disclosure relates to optical processing and communication.

BACKGROUND

Boolean exclusive OR (XOR) and exclusive NOR (XNOR) logic gates are useful in applications such as label switching, parity checking, and pattern recognition. Existing implementations of all-optical logic gates are wavelength dependent and cannot process multiple signals at different wavelengths at the same time.

BRIEF DESCRIPTION OF THE DRAWINGS

Many aspects of the disclosure can be better understood with reference to the following drawings. The components in the drawings are not necessarily to scale, emphasis instead being placed upon clearly illustrating the principles of the present disclosure.

FIG. 1 is a block diagram of one embodiment of an optoelectronic logic gate as disclosed herein.

FIG. 2 illustrates a truth table showing outputs of the logic gate of FIG. 1, according to some embodiments disclosed herein.

FIG. 3 is a block diagram of another embodiment of an optoelectronic logic gate as disclosed herein.

FIG. 4 is a block diagram of a system for bit pattern detection using the logic gate of FIG. 3, according to some embodiments disclosed herein.

FIG. 5 illustrates an oscilloscope trace of the waveform channel from FIG. 4, according to some embodiments disclosed herein.

FIG. 6 is a block diagram of yet another embodiment of an optoelectronic logic gate, according to some embodiments disclosed herein.

FIG. 7 is a block diagram of another system for bit pattern detection using an optoelectronic logic gate, according to some embodiments disclosed herein.

FIG. 8 illustrates an example oscilloscope trace generated by the system of FIG. 7, according to some embodiments disclosed herein.

DETAILED DESCRIPTION

Disclosed herein is an optoelectronic logic gate that is wavelength independent. As a result, the techniques and systems disclosed herein can act on many input signals simultaneously, making use of the large bandwidth that the optical domain offers. Also disclosed herein are applications for target bit pattern extraction and data mining with prerecorded or real time streaming input data. The techniques disclosed herein allow target bit pattern extraction and data mining without prior knowledge about the data bit stream other than the data rate. The systems disclosed herein can be scaled, for example, by incorporating multiple interferometric switches and supplying multiple optical frequencies from a mod-

ulated laser. In this manner, longer target patterns can be detected in streaming data, and faster data rates can be supported.

5 An example method disclosed herein includes superimposing an electrical data bit onto a first optical input to produce a pair of first-stage optical outputs. The first of the pair of first-stage optical inputs carries the electrical data bit and the second carries the complement of the electrical data bit. The method also includes comparing an electrical target bit with the electrical data bit conveyed by the first first-stage optical outputs and with the complement of the electrical data bit conveyed by the second first-stage optical outputs, to determine whether the electrical target bit and the electrical data bit are same or different.

10 An example apparatus disclosed herein includes a first stage interferometric switch and a second stage comprising a pair of interferometric switches. The first stage interferometric switch is configured to: receive an electrical data bit and a first optical input; and output a pair of first-stage optical outputs. The first one of the pair of first-stage optical inputs carries the electrical data bit and the second one carries the complement of the electrical data bit. Each of the pair of interferometric switches in the second stage receives one of the first-stage optical outputs. The pair of interferometric switches in the second stage is configured to produce another optical output indicating whether the electrical target bit and the electrical data bit are same or different.

15 Another example apparatus disclosed herein includes a first stage interferometric switch and a second stage comprising a pair of optical modulators. The first stage interferometric switch is configured to: receive an electrical data bit and a first optical input; and output a pair of first-stage optical outputs. The first one of the pair of first-stage optical inputs carries the electrical data bit and the second one carries the complement of the electrical data bit. Each of the pair of optical modulators in the second stage receives one of the first-stage optical outputs. The pair of optical modulators is configured to produce another optical output indicating whether the electrical target bit and the electrical data bit are same or different.

20 Yet another example apparatus disclosed herein includes a first stage interferometric switch and a means for comparing. The first stage interferometric switch is configured to receive an electrical data bit and a first optical input; and output a pair of first-stage optical outputs. The first one of the pair of first-stage optical inputs carries the electrical data bit and the second one carries the complement of the electrical data bit. The means for comparing compares an electrical target bit with the electrical data bit conveyed by the first first-stage optical outputs and with the complement of the electrical data bit conveyed by the second first-stage optical outputs, to determine whether the electrical target and the electrical data are same or different.

25 Another method is disclosed herein for detecting a target pattern in a data stream. The method includes receiving an electrical target bitstream having N bits; receiving an electrical data bitstream; and generating N delayed electrical data bitstreams from the received electrical data bitstream. Each of the N delayed electrical data bitstreams is delayed by an additional bit time as compared to the previous one of the N delayed electrical data bitstreams. The method also includes superimposing the data bits from one of the N delayed electrical data bitstreams onto a first optical input bitstream to produce a pair of first-stage optical output bitstreams. The first one of the pair of first-stage optical output bitstreams carries the data bits from the one of the N delayed electrical data bitstreams and the second one carries complement of the

data bits from the one of the N delayed electrical data bitstreams. The method also includes comparing the target bits from the electrical target bitstream with the data bits conveyed by the first one of the first-stage optical output bitstreams and with the complement of the electrical data bit
5 conveyed by the second one of the first-stage optical output bitstreams to determine whether each of the target bits is same as each of the respective data bits. The method also includes repeating the superimposing and the comparing with successive ones of the N delayed electrical bitstreams; and indicating a match when N of the target bits are determined to be same.

An example apparatus is disclosed for detecting a target pattern in a data stream. The apparatus includes an electrical domain delay generator; a first stage interferometric switch; a second stage; and a match stage. The electrical domain delay generator is configured to: receive an electrical data bitstream; and generate N delayed electrical data bitstreams from the received electrical data bitstream. Each of the N delayed electrical data bitstreams is delayed by an additional bit time as compared to the previous one of the N delayed electrical data bitstreams. The electrical domain delay generator is also configured to receive an electrical target bitstream having N bits. The first stage interferometric switch is configured to: receive the data bits from one of the N delayed electrical data bitstreams; receive a first optical input bitstream; and output a pair of first-stage optical output bitstreams. The first one of the pair of first-stage optical output bitstreams carries the data bits from the one of the N delayed electrical data bitstreams and the second one carries the complement of the data bits from the one of the N delayed electrical data bitstreams. The second stage includes a pair of optical amplitude modulators. The first optical amplitude modulator receives one of the first-stage optical output bitstreams and the electrical target bit stream. The second optical amplitude modulator receives the other the first-stage optical output bitstreams and the complement of the electrical target bit stream. The pair is configured to produce another optical output bitstream indicating whether the target bits and the data bits are same. The match stage is configured to: monitor the another optical output bitstream for an indication that one of the target bits and a respective one the data bits is same; and indicate a match when N of the target bits are determined to be same.

Another example apparatus is disclosed for detecting a target pattern in a data stream. The apparatus includes: an electrical domain delay generator; an array of interferometric switches; a pair of optical wavelength combiners; a second stage including a pair of optical amplitude modulators; an optical wavelength splitter; and a match stage. The electrical domain delay generator is configured to: receive an electrical data bitstream; and generate N delayed electrical data bitstreams from the received electrical data bitstream. Each of the N delayed electrical data bitstreams is delayed by an additional bit time as compared to the previous one of the N delayed electrical data bitstreams. In the array of interferometric switches, each switch is configured to: receive a respective one of the N delayed electrical data bitstreams; receive a first optical input timing bitstream at one of a plurality of different wavelengths; and output a pair of first-stage optical output bitstreams at a respective one the different wavelengths. The first one of the pair of first-stage optical output bitstreams carries the data bits from the one of the N delayed electrical data bitstreams and the second one carries the complement of the data bits from the one of the N delayed electrical data bitstreams. The pair of optical wavelength combiners is configured to: receive one of first-stage optical

output bitstreams from each of the interferometric switches; combine the received first-stage optical output bitstreams to produce a combined first-stage optical output bitstream. The first optical wavelength combiner carries the data bits from the one of the N delayed electrical data bitstreams. The second optical wavelength combiner carries the complement of the data bits from the one of the N delayed electrical data bitstreams. The first optical amplitude modulator in the second stage receives one of the first-stage optical output bitstreams and the electrical target bit stream, the second optical amplitude modulator in the second stage receives the other the first-stage optical output bitstreams and the complement of the electrical target bit stream. The pair of optical amplitude modulators in the second stage is configured to produce another optical output bitstream indicating whether the target bits and the data bits are same. The optical wavelength splitter is configured to produce a plurality of optical output bitstreams together indicating whether the target bits and the data bits are same. The match stage is configured to: monitor the plurality of optical output bitstreams for an indication that one of the target bits and a respective one the data bits is same; and indicate a match when N of the target bits are determined to be same.

FIG. 1 is a block diagram of one embodiment of an optoelectronic logic gate as disclosed herein. Logic gate 100 receives an input optical signal 105. Logic gate 100 also receives as input an electrical data signal x 110, and an electrical target signal y 115, both of which are treated as binary or bit values. Logic gate 100 performs a Boolean logic XNOR and XOR function on the two binary values (data signal x 110 and target signal y 115), to produce as output an optical XNOR signal 120 and an optical XOR signal 125. Logic gate 100 is thus an optoelectronic gate, since an optical input is transformed into an optical output, based on two control signals in the electrical domain.

Logic gate 100 utilizes three 1x2 (one input, two output) interferometric switches (IS) 130-A, 130-B, 130-C. Logic gate 100 includes two parts or stages. A first stage 135 comprises the single interferometric switch 130-A for single bit operation. The first stage 135 is also referred to herein as the “data imprint stage”, since data signal x 110 is imprinted, or superimposed, onto input optical signal 105. A second stage 140 comprises the two interferometric switches 130-B, 130-C, configured in parallel. The second stage 140 is also referred to herein as the “comparator stage”, since in this stage the input data superimposed on the optical signal is compared with target signal y 115. This comparison is performed in the electrical domain. Interferometric switches 130-A, 130-B, 130-C work as follows. When a control voltage V_{π} is applied, the entire input optical signal is directed to one of the output ports; similarly, when the applied control voltage is $V_{2\pi}$, then the entire input optical signal is directed to the other output port. Thus, in FIG. 1, when V_{π} is applied to interferometric switch 130-A, the entire input optical signal 105 received at input port 145-A is directed to a first output port 150-A; when $V_{2\pi}$ is applied to interferometric switch 130-A then all of input optical signal 105 is directed to a second output port 155-A. Similarly, interferometric switch 130-B includes an input port 145-B and two output ports 150-B, 155-B, and interferometric switch 130-C includes an input port 145-C and two output ports 150-C, 155-C.

Because a voltage of $V_{2\pi}$ results in an optical 0 bit (i.e., minimum optical power) being produced at the first output port, voltage $V_{2\pi}$ represents an electrical 0 bit (i.e., logic FALSE) Similarly, V_{π} represents an electrical 1 bit (i.e., logic TRUE), since it results in an optical 1 bit (i.e., maximum optical power) being produced at the first output port. When a

5

non-zero optical input is presented to an interferometric switch **130-A**, **130-B**, **130-C**, then the outputs at the two ports of that interferometric switch **130-A**, **130-B**, **130-C** are complementary to each other, and are independent of the applied electrical bit.

In this manner, the first stage interferometric switch **130-A** is configured to receive an electrical data bit and a first optical input, and outputs a pair of first-stage optical outputs. The first one of the pair of first-stage optical inputs carries the electrical data bit and the second one carries the complement of the electrical data bit. Each of the pair of interferometric switches in the second stage is configured to receive one of the first-stage optical outputs. The pair of interferometric switches in the second stage produces another optical output indicating whether the electrical target bit and the electrical data bit are same or different. The pair of interferometric switches in the second stage is thus a means for comparing an electrical target bit with the electrical data bit conveyed by the first first-stage optical outputs and with the complement of the electrical data bit conveyed by the second first-stage optical outputs, to determine whether the electrical target and the electrical data are same or different.

Having discussed the structure of logic gate **100**, the resulting operation of logic gate **100** will now be discussed with continued reference to FIG. **1**. When electrical data bit x **110** is applied to the interferometric switch **130-A** of the first stage **140** and input optical signal **105** is an optical **1**, the output at the port **150-A** of interferometric switch **130-A** is $1 \cdot x$ and the output at port **155-A** of interferometric switch **130-A** is $1 \cdot \bar{x}$. In this manner, an electrical data bit x **110** is superimposed onto an optical input **105** to produce a pair of first-stage optical outputs **150-A**, **150-B**, where first of the pair **150-A** carries the electrical data bit and the second of the pair **150-B** carries the complement of the electrical data bit.

In the second stage **140**, the optical output at port **150-A** of interferometric switch **130-A** is supplied to the optical input of interferometric switch **130-B**. Target signal y **115** is applied as the electrical input of interferometric switch **130-B**. Similarly, the optical output at port **155-A** of interferometric switch **130-A** is supplied to the optical input of interferometric switch **130-C** and the interferometric switch **130-C** is driven electrically by a signal **160** that is the negation of target signal y **115** (i.e., \bar{y}). Though FIG. **1** shows separate target bit inputs to interferometric switches **130-B**, **130-C**, in other embodiments these target bit inputs are both driven by the same electrical waveform but biased at different DC levels, resulting in inverse modulations.

Combiner **165** combines output port **150-B** of interferometric switch **130-B** with output port **150-C** of interferometric switch **130-C**, producing a result which output from logic gate **100** as optical XNOR signal **120**. Correspondingly, combiner **170** combines output port **155-B** of interferometric switch **130-B** with output port **155-C** of interferometric switch **130-C**, producing a result which is output from logic gate **100** as optical XOR signal **125**. Thus, when the input data bit is x and the target bit is y , then optical XNOR signal **120** is $x \cdot y + \bar{x} \cdot \bar{y}$, and at the same time optical XOR signal **125** is $x \cdot \bar{y} + \bar{x} \cdot y$. In this manner, the electrical target bit y **115** is compared with the electrical data bit x **110** (conveyed by the first output **150-B** of the first-stage optical outputs), and the electrical target bit x **110** is also compared with the complement of the electrical data bit (conveyed by the second output **150-C** of the first-stage optical outputs), to determine whether the electrical target bit y **115** and the electrical data bit x **110** are same or different.

FIG. **2** illustrates a truth table showing outputs of logic gate **100**. As can be seen in truth table **200**, if $x=y$, then the value of

6

binary signal **120** is 1, but if $x \neq y$, then the value is 0, which is identical to an XNOR gate. Correspondingly, if $x \neq y$, then the value of binary signal **125** is 1, but if $x=y$, then the value is 0, which is identical to an XOR gate.

As described above, logic gate **100** produces two outputs, optical XOR signal **125** and optical XNOR signal **120**. FIG. **3** is a block diagram of another embodiment of an optoelectronic logic gate disclosed herein which produces a single XNOR output. Logic gate **300** is similar to that of FIG. **1** but amplitude modulators **305**, **310** are used in place of interferometric switches **130-B** and **130-C**. In other words, a first stage **320** includes an interferometric switch **325** and a second stage **330** includes amplitude modulators **305**, **310**. No loss of generality is caused by use of amplitude modulators, since the output at port **150** of any interferometric switch is identical to the output of an amplitude modulator under the same conditions. A combiner **335** combines outputs from amplitude modulators **305**, **310** to produce an optical XNOR signal **340**.

The components of logic gate **300** are arranged similarly to logic gate **100**. One output **345** of interferometric switch **325** provides optical input to amplitude modulator **305**, while target electrical signal y **350** controls amplitude modulator **305**. Another output **355** of interferometric switch **325** provides optical input to amplitude modulator **310**, while negated target electrical signal \bar{y} **360** controls amplitude modulator **310**.

The behavior here is similar to that of the switches described above in connection with FIG. **1**: when optical input to interferometric switch **325** is an optical **1** and electrical data bit x is applied to interferometric switch **325**, the output at port **345** is $1 \cdot x$ and the output at port **355** is $1 \cdot \bar{x}$. Therefore, the output of amplitude modulator **305** is $x \cdot y$ and the output of amplitude modulator **310** is $\bar{x} \cdot \bar{y}$, such that the combined output **340** is $x \cdot y + \bar{x} \cdot \bar{y}$. In this manner, the first stage interferometric switch **325** is configured to receive an electrical data bit and a first optical input; and output a pair of first-stage optical outputs. The first one of the pair of first-stage optical inputs carries the electrical data bit and the second one carries the complement of the electrical data bit. Each of the pair of optical modulators **305**, **310** in the second stage **330** receives one of the first-stage optical outputs. The pair of optical modulators **305**, **310** is configured to produce another optical output indicating whether the electrical target bit and the electrical data bit are same or different. The second stage **330** is thus a means for comparing an electrical target bit with the electrical data bit conveyed by the first of the first-stage optical outputs and with the complement of the electrical data bit conveyed by the second of the first-stage optical outputs, to determine whether the electrical target and the electrical data are same or different. Each of the pair of optical modulators is also configured to produce a pair of second-stage optical outputs. The second stage is configured to produce the another optical output by combining one of the second-stage optical outputs from one of the pair of optical modulators with one of the second-stage optical outputs from the other one of the pair of optical modulators.

FIG. **4** is a block diagram of a system for bit pattern detection which uses a stored data stream and single XNOR logic gate **300**. As described herein, a match between target signal bits in the range $y_1 \dots y_N$ and the input data bits in the range $x_{m+1} \dots x_{m+N}$ represent a match on a target pattern of length N -bits inside the streaming input data. System **400** detects this match by looking for N consecutive "1" bits that are synchronized with the target signal at output **340** of logic gate **300**. Having found these consecutive bits, system **400** counts

this electronically (counter not shown), confirming both the existence and the location of the target pattern in the input data stream.

In other words, stage **330** of logic gate **300** (the comparator stage) is driven periodically by the target pattern **410** which includes of bits $y_1 \dots y_N$, and if the target pattern matches the input data stream then the output of system **400** indicates N consecutive “1” bits were detected. This approach relies on relative timing between the input data signal and the target pattern. That is, the target pattern will not be detected if y_1 does not overlap with x_{m+1} in time. For this reason, although target pattern **410** is a single series of bits, system **400** provides input to stage **330** as multiple series of bits, each with a different delay. In this manner, the target pattern includes all possible relative timings.

In FIG. 4, the example input data stream **420** has the value “CRE” and the 8-bit target pattern **410** has the value “R”. (“CREOL” is “010000110101001001000101” in binary. “R” is “01010010” in binary). In this example the target pattern **410** is 8 bits long, so comparator stage **330** checks all 8 possible relative timings between the input data and the target pattern consecutively.

System **400** operates on a stored input signal **420**. This stored input signal **420** is provided to first stage **320**, which produces eight delayed versions **430-1** . . . **430-N** of the input signal and eight delayed versions **440-1** . . . **440-N** of the negated input signal. Delayed samples **430-1** . . . **430-N** are provided, consecutively, to amplitude modulator **305** in stage **330**. Delayed samples **440-1** . . . **440-N** are provided, consecutively, to amplitude modulator **310** in stage **330**. The outputs of amplitude modulators **305**, **310** are combined by combiner **450**. After combination, optical output **340** includes waveforms **460-1** . . . **460-N**, each one corresponding to a respective delay. As can be seen in FIG. 4, only one of the delayed channels (bottom channel **460-N**) results in 8 consecutive “1” bits that synchronized with the target pattern at the output, which confirms the existence and the location of the letter “R” in the input data stream.

FIG. 5 illustrates an oscilloscope trace of waveform channel **460-N**. As can be seen in trace **500**, all 8 bits of the target pattern match one by one to the corresponding bits in the input data stream. A person of ordinary skill in the art should recognize that an electronic counter can be substituted for the oscilloscope.

While system **400** uses single XNOR logic gate **300**, another embodiment of a bit pattern extraction system uses the dual output logic gate **100** but monitors only optical XNOR signal **120**. Yet another embodiment of a bit pattern extraction system uses the dual output gate of FIG. 1 but monitors only optical XOR signal **125**. Still another embodiment monitors optical XNOR signal **120** and optical XOR signal **125** at substantially the same time, which results in an improved signal-to-noise ratio of the system and reduced probability of false positives.

Unlike conventional electrical or all-optical logic gates, the optoelectronic logic gates disclosed herein are independent of the input wavelength. This independence allows all the relative timing signals to be provided to the comparator stage simultaneously, using a different wavelength for each channel. This speed-up allows N -bit pattern matching for real time streaming data.

FIG. 6 is a block diagram of another embodiment of an optoelectronic logic gate which uses N optical data channels to detect an N -bit target pattern. Each data channel is on a different wavelength and is time-delayed by one bit with respect to its neighboring channels. Logic gate **600** is optimized for 8 bit long target pattern extraction, but the prin-

ciples are applicable to N bits. For example, multiple interferometric switches can be used together with the spectrum of a mode-locked laser with multiple stable comb lines.

Like other embodiments described herein, logic gate **600** includes a first stage **603** which superimposes or imprints an electrical data bit onto an optical signal, and a second stage **605** which compares the input data superimposed on the optical signal with an electrical target data bit. Logic gate **600** also includes a match stage **607** which produces an output indicating whether the target bits and the data bits are the same. In the embodiment of FIG. 6, the first stage **603** is implemented with an array of interferometric switches, the second stage **605** is implemented with optical amplitude modulators, and the match stage **607** is implemented with an optical splitter.

Rather than a single electrical bitstream, the first stage receives as input a set of N delayed electrical data bitstreams **660-1** . . . **660-N**, each delayed by an additional bit time as compared to the previous one. Each interferometric switch **620-1** . . . **620-N** in the first stage also receives as input an optical signal **610-1** . . . **610-N** at a different wavelength. Each interferometric switch **620-1** . . . **620-N** superimposes a respective delayed version of data bit **660-1** . . . **660-N** onto the optical signal **610-1** . . . **610-N** at a respective wavelength, producing as output a pair of first-stage optical output bitstreams **640-1** . . . **640-N**, **650-1** . . . **650-N** at a respective one of a plurality of different wavelengths. The first one **640-1** . . . **640-N** of the pair of optical outputs carries the data bits from the respective delayed electrical data bitstreams. The second one **650-1** . . . **650-N** of the pair of optical outputs carries the complement of the data bits from the respective one of the N delayed electrical data bitstreams.

The second stage **605** is configured to receive an electrical target bit stream **680-1** . . . **680-N**, a complement of the electrical target bit stream **690-1** . . . **690-N**, and the pair of first stage optical output bitstreams **640-1** . . . **640-N**, **650-1** . . . **650-N**. The second stage **605** is further configured to produce another optical output bitstream indicating whether the target bits and the data bits are same.

Match stage **607** is configured to monitor the plurality of optical output bitstreams for an indication that one of the target bits and a respective one the data bits is the same. and to produce an output **697** representing whether the target bits and data bits match. In some embodiments, output **697** indicates a match when N of the target bits are determined to be same.

Having discussed the structure of logic gate **600**, the resulting operation of logic gate **600** will now be discussed with continued reference to FIG. 6. N optical inputs **610-1** . . . **610-N** on separate wavelength channels $\lambda_1 \dots \lambda_N$ are each modulated by a corresponding first-stage interferometric switch **620-1** . . . **620-N**. The wavelengths are combined by two virtually imaged phased arrays (VIPA) **630**, **635**. Input to VIPA **630** is provided by one of the optical outputs **640-1** . . . **640-N** of a corresponding interferometric switch **620-1** . . . **620-N**. Input to VIPA **635** is provided by the one of the other optical outputs **650-1** . . . **650-N** of a corresponding interferometric switch **620-1** . . . **620-N**. Each wavelength carries the same input data, but with an additional 1-bit time delay with respect to its neighboring channels. The example logic gate **600** embodiment shown in FIG. 6 realizes the time delay in the electrical domain by driving the interferometric switches **620-1** . . . **620-N** with delayed electrical waveforms. Other embodiments realize the time delay between the channels in the optical domain by delaying the modulated optical signals

Multiple input data streams, together covering all the possible relative timings with respect to the target waveform,

enter stage **330** (comparator stage) of logic gate **600**. Specifically, data stream **660-1 . . . 660-N**, representing x , enters amplitude modulator **305** and data stream **670-1 . . . 670-N**, representing \bar{x} , enters amplitude modulator **310**. Amplitude modulator **305** then compares x (**660-1 . . . 660-N**) to the target pattern **680-1 . . . 680-N**. Amplitude modulator **310** then compares \bar{x} (**680-1 . . . 680-N**) to the negated target pattern **690-1 . . . 680-N**. In this manner, logic gate **600** simultaneously checks all data streams for the target pattern. Another VIPA **695** at the output of stage **330** separates the channels of combined optical output signal **697** into an output signal **697** which indicates whether the target bits and the data bits are the same. When used in a target detector, the channels may be provided to N corresponding electronic counters, which will check for 8 consecutive “1”s synchronized with the target signal.

FIG. 7 is a block diagram of a system for bit pattern detection in streaming data. System **700** uses an optoelectronic gate **710** which is similar to logic gate **600**, but fiberized couplers **720** are used to combine the modulated channels instead of virtually imaged phased arrays. Although system **700** uses fiberized components, other embodiments implement the same layout on the chip scale for improved channel number and stability.

A multiple wavelength optical input is provided to virtually imaged phased array **730**, which performs spatial separation of the single input into two inputs at two wavelengths, λ_1 and λ_2 . The separated optical signals are provided to interferometric switches **750**, **755**, respectively. Interferometric switches **750**, **755** form a first stage **760**, imprinting input data onto optical signal λ_2 and its 1-bit delayed version is imprinted onto λ_1 .

After data imprinting by first stage **760**, the wavelengths are combined with a fiberized coupler (not shown). The comparator stage **770** then processes both wavelengths (i.e., both input signals) simultaneously. After comparator stage **770**, the wavelengths are separated with another VIPA **780**. In the example system of FIG. 7, data carried on these wavelengths is depicted as an oscilloscope trace **790**. When used in a target detector, the separate wavelengths are provided to N corresponding electronic counters, which will check for N consecutive “1”s synchronized with the target signal.

FIG. 8 illustrates the oscilloscope trace from FIG. 7 in further detail. As can be seen in trace **800**, the channel λ_2 has two consecutive “1” bits, while the other channel does not. Thus, the system has successfully detected and located the 2-bit long target pattern inside the real time streaming input data, in the time slot between 40 ns and 80 ns.

As noted earlier, an electronic counter can be substituted for the oscilloscope. In some embodiments of the streaming data detector, the counter takes into account a periodic target stream, where the presence of N consecutive “1” bits does not necessarily imply the existence of the N -bit long target pattern. Since the target waveform is periodic, an input data stream that includes any cyclic permutation of the target waveform will also result in N consecutive “1” bits in one of the channels. Therefore the necessary and sufficient condition for confirming the existence of the target pattern inside the input data is having N consecutive “1” bits where the first “1” bit overlaps in time with the first bit of the target waveform y_1 . In other words, the electronic counter should always start counting at the beginning of the target waveform.

Using the approaches herein, data mining at tens of GHz rates should be possible using commercially available components and incorporating the techniques disclosed herein together with stabilized high speed modelocked lasers as the source of optical combs. The actual data processing speed of

the optoelectronic logic gates disclosed herein linearly increases with the number of channels used in the system, since the logic gate operates on N bits from different channels simultaneously.

The foregoing disclosure as been presented for purposes of illustration and description. The disclosure is not intended to be exhaustive or to limit the disclosure to the precise forms disclosed. Various modifications or variations are possible in light of the above teachings. The implementations discussed, however, were chosen and described to illustrate the principles of the disclosure and their practical application to thereby enable one of ordinary skill in the art to utilize the disclosure in various implementations and with various modifications as are suited to the particular use contemplated. All such modifications and variations are within the scope of the disclosure as determined by the appended claims when interpreted in accordance with the breadth to which they are fairly and legally entitled.

What is claimed is:

1. A method for detecting a target pattern in a data stream, the method comprising:
 - generating N delayed electrical data bitstreams from an electrical data bitstream having N bits, each of the N delayed electrical data bitstreams being delayed by an additional bit time as compared to the previous one of the N delayed electrical data bitstreams;
 - superimposing the data bits from one of the N delayed electrical data bitstreams onto a first optical input bitstream to produce a pair of first-stage optical output bitstreams, the first one carrying the data bits from the one of the N delayed electrical data bitstreams and the second one carrying a complement of the data bits from the one of the N delayed electrical data bitstreams;
 - comparing target bits from an electrical target bitstream having N bits with the data bits carried by the first one of the first-stage optical output bitstreams, and with a complement of the electrical data bit carried by the second one of the first-stage optical output bitstreams, to determine whether each of the target bits is same as each of the respective data bits;
 - repeating the superimposing and the comparing with successive ones of the N delayed electrical bitstreams; and
 - indicating a match when N of the target bits are determined by the comparing to be same.
2. The method of claim 1, further comprising: receiving the electrical target bitstream.
3. The method of claim 1, further comprising: receiving the electrical data bitstream.
4. An apparatus for detecting a target pattern in a data stream, the method comprising:
 - a first stage comprising an array of interferometric switches, each of the interferometric switches configured to output a pair of first-stage optical output bitstreams at a respective one of a plurality of different wavelengths, the first one of the pair carrying data bits from a respective one of a plurality of N delayed electrical data bitstreams and the second one of the pair carrying a complement of the data bits from the respective one of the N delayed electrical data bitstreams;
 - a second stage configured to receive an electrical target bit stream, a complement of the electrical target bit stream, and the pair of first stage optical output bitstreams, and further configured to produce another optical output bitstream indicating whether target bits from the electrical target bitstream are the same as data bits from the N delayed electrical data bitstreams; and a

11

match stage configured to monitor the plurality of optical output bitstreams for an indication that one of the target bits and a respective one of the data bits is same, and to indicate a match when N of the target bits are determined to be same.

5. The apparatus of claim 4, wherein the second stage comprises a pair of optical amplitude modulators.

6. The apparatus of claim 4, wherein the second stage comprises a pair of optical amplitude modulators, the first one of the pair of optical amplitude modulators configured to receive one of the first-stage optical output bitstreams and the electrical target bit stream, the second one of the pair of optical amplitude modulators configured to receive the other of the first-stage optical output bitstreams and the complement of the electrical target bit stream.

7. The apparatus of claim 4, each of the array of interferometric switches configured to receive an optical input timing bitstream at one of a plurality of different wavelengths.

12

8. The apparatus of claim 4, further comprising a pair of optical wavelength combiners configured to:

receive one of the first-stage optical output bitstreams from each of the interferometric switches; and

combine the received first-stage optical output bitstreams to produce a combined first-stage optical output bitstream,

the first optical wavelength combiner in the pair carrying the data bits from the one of the N delayed electrical data bitstreams, the second optical wavelength combiner in the pair carrying the complement of the data bits from the one of the N delayed electrical data bitstreams.

9. The apparatus of claim 4, further comprising: an optical wavelength splitter configured to produce a plurality of optical output bitstreams together indicating whether the target bits and the data bits are same.
