## 1 ABSTRACT

Epithelial folding is an important morphogenetic process that is essential in transforming simple sheets of cells into complex three-dimensional tissues and organs during animal development (Davidson, 2012). Epithelial folding has been shown to rely on constriction forces generated by the apical actomyosin network (Martin et al., 2009; Roh-Johnson et al., 2012; Sawyer et al., 2010). However, the contributions of mechanical forces acting along lateral and basal cell surfaces to epithelial folding remain poorly understood. Here we combine live imaging with force measurements of epithelial mechanics to analyze the formation of two epithelial folds in the *Drosophila* larval wing imaginal disc. We show that these two neighboring folds form via two distinct mechanisms. These two folds are driven either by decrease of basal tension or increase of lateral tension, none of them depends on apical constriction. In the first fold, a local decrease in extracellular matrix (ECM) density in prefold cells results in a reduction of mechanical tension on the basal cell surface, leading to basal expansion and fold formation. Consistent with that, a local reduction of ECM by overexpression of Matrix metalloproteinase II is sufficient to induce ectopic folding. In the second fold a different mechanism is at place. Here basal tension is not different with neighboring cells, but pulsed dynamic F-actin accumulations along the lateral interface of prefold cells lead to increased lateral tension, which drives cell shortening along the apical-basal axis and fold formation. In this thesis I described two distinct mechanisms driving epithelial folding, both basal decrease and lateral increase in tension can generate similar morphological changes and promote epithelial folding in the *Drosophila* wing discs.

## 2 ZUSAMMENFASSUNG

Die Faltung von Epithelien ist ein wichtiger morphogenetischer Prozess, der die Entstehung komplexer, dreidimensionaler Gewebe und Organe aus einfachen Zellschichten ermöglicht (Davidson, 2012). Es ist bekannt, dass Kräfte erzeugt durch das apikale Aktomyosin-Netzwerk wichtig sind für die erfolgreiche Faltung von Epithelien (Martin et al., 2009; Roh-Johnson et al., 2012; Sawyer et al., 2010). Die Rolle von mechanischen Kräften, die entlang der lateralen und basalen Seite wirken, ist jedoch kaum verstanden.

Wir verbinden Lebendmikroskopie mit der Messung von mechanischen Eigenschaften, um die Entstehung von 2 Epithelfalten in den Imaginalscheiben von *Drosophila* zu verstehen. Wir können dadurch zeigen, dass die beiden Falten durch unterschiedliche Mechanismen entstehen. Sie entstehen entweder durch eine Verringerung der Spannung auf der basalen Seite oder durch eine Erhöhung der Spannung auf der lateralen Seite, aber keine von beiden entsteht durch zusammenziehende Kräfte auf der apikalen Seite. Die erste Falte entsteht durch eine lokale Verringerung der extrazellulären Matrix in den Vorläuferzellen, was zu einer Reduktion der Spannung auf der basalen Seite und zur Ausbildung der Falte führt. Die zweite Falte wird durch einen anderen Mechanismus ausgebildet. Hier ist nicht die Spannung auf der basalen Seite reduziert sondern dynamische Anreicherungen von F-Aktin auf der lateralen Seite resultieren in einer erhöhten lateralen Spannung, die zu einer Verkürzung der Zellen und damit zur Ausbildung einer Falte führt. In meiner Arbeit zeige ich 2 neue Mechanismen zur Entstehung von Epithelfalten auf, durch Absenken der Spannung auf der basalen oder Erhöhen auf der lateralen Seite.

## 5 INTRODUCTION

### 5.1 Tissue morphogenesis is required for the basic organization of embryos and organs

Tissue morphogenesis is a major outstanding biological process that causes an organism to develop its shape. It is one of three fundamental questions of developmental biology along with the control of cell growth and cellular differentiation. To form a complex and functional organ, simple tissues must be folded, stretched, bended, and otherwise sculpted into a precise organism. Tissue morphogenesis requires that cytoskeletal machines generate forces that change cell shape and deform the tissue. To understand how the tissue gets its shape, we should explore the molecular mechanism by which the cytoskeleton generates force to drive cell shape change and how biochemical and mechanical signals direct force generation in hundreds or thousands of cells to control coordinated cell behavior.

#### 5.1.1 The cellular structure of the epithelial cell

Epithelial tissues are widespread throughout the body. They are sheets of cells that cover body surfaces, line body cavities and hollow organs, and are the major tissue in glands. They perform a variety of functions that include protection, secretion, absorption, excretion, filtration, diffusion, and sensory reception. Epithelial cells have three principal shapes: squamous, columnar, and cuboidal. These can be arranged in a single layer of cells as simple epithelium, or in layers of two or more cells deep as stratified (layered). Epithelial cells are characterized by a remarkable apical-basal polarity. The epithelial cells in the tissue are tightly connected by adherens junctions through the adhesion molecules to form a continuous sheet. Actin cytoskeleton forms networks at the cell cortex and is connected through cell-cell adhesion and cell matrix adhesion (integrin and ECM) (Fig. 1). Here, we introduce each important epithelium cell structure from apical to the basal, respectively.

**Figure 1. The cellular structure of epithelia cells**

actin cytoskeleton forms networks at the cell cortex and is connected through cell-cell adhesion and cell matrix adhesion. Modified after (Kim and Nelson, 2012)

### Adherens junctions

Adherens junctions are protein complexes that occur at cell–cell junctions in epithelial tissues, which link the cells into a continuous sheet and separate the apical and basolateral membranes of each highly polarized epithelium cell. Adherens junctions are required for maintaining the tissue integrity, as disruption of them causes disorganization of the epithelial architecture and increases the invasive capacities of cells (Behrens et al., 1989; Chen and Obrink, 1991; Martin and Jiang, 2009). The core components of adherens junction are cadherin adhesion molecules which are  $\text{Ca}^{2+}$ -dependent transmembrane adhesion proteins forming homophilic and heterophilic bonds between adjacent cells. It plays an important role in the segregation of cell groups (Takeichi, 1995). Adherens junctions can function as clusters during zonula adherens assembly and dynamic cell–cell interactions allowing the rearrangement of cells within cell sheets (Nelson et al., 2005). Adherens junctions also play important roles in morphogenetic movements because they link the cytoskeletal activities of neighboring cells which can propagate forces to adjacent cells, and integrate them to shape tissues, organs, and entire early embryos (Brieher and Yap, 2013). It has long been recognized that cadherins function in close cooperation with the cytoskeleton, particularly with actin filaments (F-actin). The cadherin can bind to the F-actin of the cell by an alpha-beta catenin complex. The  $\beta$ -catenin binds to the cytoplasmic

## INTRODUCTION

domain of the cadherin and to  $\alpha$ -catenin, which links the complex to the F-actin via actin-associated proteins, including vinculin,  $\alpha$ -actinin, formin, zonula occludens protein 1 (ZO1) and afadin (Kobielak and Fuchs, 2004; Pokutta et al., 2002). Cadherin-based adherens junctions are coupled to myosin II-dependent actin contractility. Adherens junctions are enriched in cortical actomyosin and are physically linked to the actomyosin networks in the apical epithelial cell cortex (Miyake et al., 2006; Shewan et al., 2005). Adherens junctions are also localized by circumferential actin belts. These circumferential actin belts, or actomyosin networks that display pulsed contractile behavior can deform cell-cell junctions. Additionally, cadherin adhesions promote actin assembly at the junctional cortex by recruiting actin regulators, such as Arp2/3, formins, CD2AP and cortactin in epithelial cells (Carramusa et al., 2007; Helwani et al., 2004; Kovacs et al., 2002).

Adherens junctions are also enriched in and associate with microtubules (MTs) as well as F-actin (Stehbens et al., 2009). Cadherin–cadherin interactions are sufficient for recruiting microtubules (Stehbens et al., 2006). Microtubule inhibition disrupts adherens junction organization (Meng et al., 2008; Stehbens et al., 2006). MTs that interact with cadherin adhesions have been thought to be responsible for regulating junctional integrity. A number of mechanisms can couple microtubules to adherens junctions. First, perijunctional MTs that run along the apico-lateral axis, adherens junctions link to microtubule minus ends by two novel proteins PleKHA7 and Nezha that were linked to p120 catenin (Meng et al., 2008). Second, cortical MT-binding proteins may capture MTs and potentially anchor them at junctions. These include the MT-based motor dynein, which is found at cadherin contacts and interacts directly with  $\beta$ -catenin (Ligon et al., 2001). Third, cadherin junctions are also enriched in cortical proteins that can bind to the dynamic plus-ends of MTs (Kumar and Wittmann, 2012).

### **Cell cytoskeleton**

The cell's cytoskeleton is made of filamentous proteins, and it provides mechanical support to the cell and its cytoplasmic constituents. The cytoskeleton is a major determinant of cell-shape changes that drive the formation of complex tissues during development. The epithelium cells

## INTRODUCTION

contain three main kinds of cytoskeletal polymers: actin filaments (F-actin), microtubule (MT), and Intermediate filaments. These polymers work together to form the cytoskeleton to control the shape and mechanics of the epithelium cells.

Actin filaments (F-actin) are the thinnest fibers of the cytoskeleton and are polymers of actin subunits (G-actin) (Moore et al., 1970). Individual filaments polymerize and depolymerize, are crosslinked with each other to form branched networks or bundles of straight filaments, and filament networks. Dynamic actin filament networks are widely distributed throughout the cell, forming a range of cytoskeletal structures and contributing to cell shape changes, cell motility, contraction, adhesion and protrusion (Blanchoin et al., 2014). F-actin is polarized and has a fast growing barbed-end (the minus (-) end) and a slow growing pointed-end (the plus (+) end). F-actin is highly dynamic and their polymerization is usually correlated to their disassembly. Actin polymerization proceeds through three steps: nucleation, elongation and steady state. Addition of ATP-actin occurs at the barbed end, leading to filament elongation. Elongation will continue whilst the rate of elongation is greater than the loss of ADP-actin from the pointed end. When the dissociation rate of ADP-actin exceeds the rate of ATP-actin association, the filament shrinks. Actin treadmilling occurs when the rate of association of ATP-actin and the rate of loss of ADP-actin are balanced. Polymerization and depolymerization of F-actin are tightly controlled by additional proteins. For example, Arp2/3 complex simultaneously controls nucleation of actin polymerization and branching of filaments (Pollard, 2007; Svitkina and Borisy, 1999); Profilin catalyzes ADP to ATP exchange and promote F-actin assembly (Wolven et al., 2000). Cofilin mediates filament disassembly (Bamburg, 1999). The cooperation between each component is extensive and each protein has an optimal concentration. F-actin in a cell is constantly shrinking or growing in length, and bundles and meshworks of microfilaments are continuously forming and dissolving. These dynamic changes in the organization of actin filaments cause dynamic cell shape change.

Myosins are motor proteins that hydrolyze ATP to move along F-actin (Tyska and Warshaw, 2002). The myosin superfamily is a diverse family of proteins, each containing a conserved head domain and a divergent tail domain.

## INTRODUCTION

Myosins have the actin-binding sites and the ATP-hydrolysis sites in the head domain. The head domain of Myosin binds the F-actin and moves along the filament towards the barbed (+) end by using ATP-hydrolysis to generate force. Myosin II is firstly found in muscle cells to promote muscle contraction, myosin II is also found in non-muscle cells, and recent studies have shown that non-muscle myosin-II (myosin II) generate cortical tension to mediate cytokinesis and cell shape changes during development. Unlike muscle myosin II, non-muscle myosin II (myosin II) can undergo dynamic assembly and disassembly, allowing its spatial and temporal regulation (Tan et al., 1992). The myosin II is a hexamer of three pairs of subunits which contains two heavy chains, two essential light chains (ELCs) and two regulatory light chains (RLCs) (Hartman and Spudich, 2012). In *Drosophila*, the myosin II heavy chain is encoded by zipper (zip), the regulatory light chain by spaghetti squash (sqh) and the essential light chain by Mlc-c (Karess et al., 1991; Young et al., 1993). The assembly and activity of myosin II filaments is regulated by dynamic phosphorylation and dephosphorylation of myosin II RLC (Bresnick, 1999; Vibert et al., 1986) (Heissler and Manstein, 2013). Myosin II activity is modulated by a large number of kinases, such as myosin light chain kinase (MLCK), Rho-associated, coiled coil-containing kinase (ROCK), leucine zipper interacting kinase (ZIPK) and myotonic dystrophy kinase-related CDC42-binding kinase (MRCK) (Matsumura, 2005; Munjal and Lecuit, 2014). Motor proteins myosin together with F-actin form an actomyosin network that generate the contractile force to drive various cell shape changes during the tissue morphogenesis (Pilot and Lecuit, 2005).

Microtubules (MTs) are also an important part of the cytoskeleton within the cell cytoplasm, which consists of polymerised  $\alpha$ - and  $\beta$ -tubulin dimers. MTs are self-assembled from  $\alpha$ - and  $\beta$ -tubulin dimers when supplied with a pool of GTP. MTs are stiffer than F-actin and have the most complex assembly and disassembly dynamics. During mitosis, the microtubule cytoskeleton rearranges itself into a high-fidelity DNA-segregating machine called the mitotic spindle. The assembly and disassembly of MTs can generate pushing and pulling forces that, together with motor proteins, separate chromosomes into two identical sets and contribute to the correct positioning of nuclei in cells (Dogterom et al., 2005). For MTs, the motors are members of the dynein

## INTRODUCTION

or kinesin families, they have essential roles in organizing the microtubule cytoskeleton. The ability of the mitotic spindle to find and align chromosomes partly depends on the complex assembly dynamics of individual MTs (Jordan and Wilson, 2004). Besides the role of MTs in the cell mitosis, microtubule cytoskeleton also provides mechanical support for the cells and is important in cell shape changes, organization of the cytoplasm, transport, and motility (Glotzer, 2009; Waterman-Storer et al., 1999). For example, MT can control changes in epithelial cell height. MTs aligned along the apical-basal axis rotate to align with the planar axis, promote the cell shortening during the columnar-to-squamous conversion of amnioserosa cells in fly embryos (Pope and Harris, 2008). Moreover, microtubule polymerization along the apical-basal axis promotes cell elongation in Neural tube formation in *Xenopus* (Burnside, 1973).

Intermediate filaments are less dynamic than actin filaments (F-actin) or microtubules (MTs) and resist tensile forces much more effectively than compressive forces. They can be crosslinked to each other, as well as to actin filaments and microtubules by plectins (Wiche, 1998). Unlike MTs and F-actin, intermediate filaments are not polarized and cannot support directional movement of molecular motors. Intermediate filaments commonly work in tandem with MTs, providing mechanical strength and resistance to shear stress.

### Extracellular matrix (ECM)

The extracellular matrix (ECM) is the non-cellular component widely present on the basal side of epithelial sheet. A dense, sheet-like form of ECM that underlies epithelia forms basement membranes that separate tissues and protect them from mechanical stress. The ECM is composed of two main classes of macromolecules: proteoglycans (PGs) and fibrous proteins (Jarvelainen et al., 2009; Schaefer and Schaefer, 2010). The main fibrous ECM proteins are collagens, elastins, fibronectins and laminins. Collagen IV is the most abundant, comprising 50% of the proteins of the basement membranes (Kalluri, 2003). The network of collagen IV is thought to define the scaffold integrating other components such as, laminins, nidogens or perlecan, into highly organized supramolecular architectures. Collagens IV are divided into two subfamilies,  $\alpha 1$ -like and  $\alpha 2$ -like, split already in Cnidaria (Aouacheria

## INTRODUCTION

et al., 2006). *Drosophila* has two genes encoding a chain of Collagen IV, named *viking* (*vkg*) and *Collagen at 25C* (*Cg25C*) belonging to the  $\alpha 2$ -like and  $\alpha 1$ -like subfamilies respectively (Leparco et al., 1986; Monson et al., 1982; Yasothornsrikul et al., 1997).

ECM proteins are very important during development. They provide not only essential physical scaffolding for the cellular constituents that is essential for migration and anchorage of the cell, but also are required for tissue morphogenesis, differentiation and homeostasis (Frantz et al., 2010). Loss-of-function mutation of many ECM molecules such as fibronectin, laminin, or collagen are embryonic lethal (Rozario and DeSimone, 2010). The ECM is a highly dynamic structure, constantly undergoing a remodeling process where ECM components are deposited, degraded, or otherwise modified. The most significant enzymes in ECM remodeling are matrix metalloproteinase (MMP) which is specialized in degrading the ECM (Cawston and Young, 2010). For example, migration of endothelial and immune cells, depends on expression of MMPs to locally degrade ECM at the leading edge such that cells can freely migrate (Friedl and Gilmour, 2009). MMPs are expressed at branching tips of the epithelial network, mediating dynamic ECM remodeling and facilitating collective epithelial migration during branching morphogenesis of the mammary gland (Lu et al., 2008; Wang et al., 2010). Similarly, *Drosophila* MMP-2 is specifically expressed in early fly embryos to facilitate tracheal branching morphogenesis (Guha et al., 2009). On the other hand, overexpression of MMPs promotes tumor cell invasion because of deregulated ECM. Many MMPs are frequently overexpressed in various cancers (Ilan et al., 2006; Kessenbrock et al., 2010; Page-McCaw et al., 2007).

The primary intercellular structures that mediate the regulatory effects of ECM adhesion on cell behavior are the focal adhesions. These macromolecular complexes mediate cell anchorage to ECM by physically coupling integrins to the actin cytoskeleton. Integrins are transmembrane protein and adhesion molecules composed of an  $\alpha$ - and  $\beta$ -subunit. The coupling Integrins to the ECM not only provides a substrate for tissue migration, but also can transmit the force during many morphogenetic processes (Haigo and Bilder, 2011; He et al., 2010). Actomyosin contractions can thus generate forces on the

underlying ECM substratum by pulling on integrins, and these forces can be transmitted to neighboring cells via deformation of the elastic ECM meshwork (Ulrich et al., 2009). Moreover, the forces generated by actomyosin network cannot result in any cellular behaviors, such as migration or cell deformation, unless they are coupled to the plasma membrane or the ECM via adhesion complexes.

### **5.1.2 Mechanical force drives cell shape change during tissue morphogenesis**

During tissue development, mechanical forces cause any morphogenetic process, for example changes in size, shape, and position. Forces are typically generated by actin-myosin networks and transmitted via cytoskeletal elements and adhesion molecules within and between cells. How mechanical forces exerted by cells shape the tissue have been described in the second half of the 19th and first half of the 20th century and continued by seminal contributions from Holtfreter, Steinberg, and others, who analyzed how specific cell affinities and cell behaviors coordinately drive morphogenesis (Keller, 2012). One major challenge in analyzing the role of forces in morphogenesis is to monitor mechanical forces in vivo during the cellular process. Recent advancements have led to the development of various biophysical techniques that can measure mechanical forces in living organisms, such as laser cutting devices and micropipettes to analyze mechanical and adhesive properties of cells and tissues (Chu et al., 2004; Kiehart et al., 2000; Maitre et al., 2012; Rauzi et al., 2008). Relative values of cortical tension can be estimated by monitoring how much cortex opens following laser ablation, assuming that cortex retraction velocity is proportional to its tension (Mayer et al., 2010; Salbreux et al., 2012). Similarly, junction tension of a cell is monitored by tissue recoil in response to laser ablation of single cell junctions (Landsberg et al., 2009). 3D vertex models have been used to study the tissue morphogenesis by doing simulations based on the force measured from cells by laser ablation (Farhadifar et al., 2007). This model has allowed analyzing the contribution of global and local forces on cell shapes in epithelial tissues. Based on those techniques, the roles of mechanical force

## INTRODUCTION

have already been clear during various tissue morphogenesis processes. For example, in the *Drosophila* wing disc, it has been shown that anisotropic accumulation of myosin II at cell-cell junctions facing the compartment boundary generate mechanical tension, that prevent cell mixing and straighten the shape of the boundary (Aliee et al., 2012; Landsberg et al., 2009; Monier et al., 2010; Rudolf et al., 2015). Furthermore, planar polarized actomyosin at specific cell junctions generate force to drive shortening these junctions, which give rise to the cellular rearrangements underlying *Drosophila* germ-band extension and vertebrate neural tube folding (Nishimura et al., 2012; Rauzi et al., 2008). Yu and Fernandez-Gonzalez show that local mechanical forces direct the assembly of new cell contacts during the axis elongation in *Drosophila* embryos (Yu and Fernandez-Gonzalez, 2016). In *Drosophila* dorsal closure, the lateral epidermis moves dorsally over the amnioserosa (AS) cells to close the dorsal hole of the embryo epidermis (Harden et al., 2002). Contraction of the supracellular actin-myosin ring within the leading edge of the epidermis and apical constriction of AS cells are thought to drive dorsal closure (Almeida et al., 2011; Gorfinkiel et al., 2009; Hutson et al., 2003; Solon et al., 2009). Moreover, it has been proposed that contraction of the supracellular actin-myosin ring within the leading edge of the epidermis transform the initially transient pulsatile apical constrictions of AS cells into a stable apical constriction of the AS that is required for effective dorsal closure (Solon et al., 2009). In ascidian gastrulation, increased cortical tension at the cell apex and along the lateral junctions promotes apical cell constriction and apical-basal cell shortening (Gorfinkiel et al., 2009). Furthermore, Pulsatile actomyosin flow generating contraction force at the mesoderm cell apex drives apical constriction of mesodermal cells, that trigger gastrulation in *C. elegans* (Roh-Johnson et al., 2012) and *Drosophila* (Martin et al., 2009; Rohrschneider and Nance, 2009), in *Xenopus* (Kim and Davidson, 2011). Likewise, during *Drosophila* oogenesis, pulsatile MyoII contraction at the basal side of follicular cells generates an anisotropic circumferential contraction, which compresses and thus elongates the oocyte along its AP axis (He et al., 2010).

### 5.1.3 Coordinated cell behavior induces globe tissue deformation

The analysis of actin-myosin dynamics in individual cells provides insights into how mechanical forces are locally generated and deform the cell. However, only collective cell behavior is controlled and coordinated at larger tissue scale can result in changes of the tissue shape (Heisenberg and Bellaiche, 2013). It has been found that the planar cell polarity (PCP) signaling pathway provides insight in the molecular and cellular mechanisms by which individual cell dynamics are coordinated to generate large tissue-scale deformation. Besides apical–basal polarity, epithelial cells display another key polarity, planar cell polarity (PCP). PCP is established through the localization of mutually exclusive subsets of core PCP proteins to opposing domains along the cell cortex, forming a pattern that propagates throughout the tissue. PCP could direct polarity accumulation of actomyosin at the specific junctions, which leads to preferential constriction of these junctions, driving cell intercalation along the elongation axis during Convergent extension (Walck-Shannon and Hardin, 2014). Convergent extension movements narrow tissues along one axis while elongating them along the perpendicular axis, contributing to many developmental processes including axial elongation, organogenesis, and neural tube closure. There are two main pathways determining PCP in tissues: the Wnt/Frizzled (Fz) and the Fat–Dachsous–Four-jointed (Fat–Ds–Fj) pathways (Goodrich and Strutt, 2011; Gray et al., 2011). In vertebrates, Wnt/Fz-PCP signaling plays a major role for cell intercalations driving germ-layer morphogenesis during gastrulation and neurulation (Roszko et al., 2009). Particularly, polarized localization of the Wnt/Fz-PCP component *Celsr1*, a vertebrate homolog of *Drosophila* Flamingo, at apical junctions along the DV axis of the neural plate direct myosin accumulation at the DV junctions to generate the contraction force, driving AP-oriented cell intercalation and neural plate bending (Nishimura et al., 2012). The *Drosophila* Fat–Ds–Fj pathway plays fundamental roles for the regulation of *Drosophila* epithelial tissue morphogenesis (Baena-Lopez et al., 2005; Mao et al., 2011). Fat and Ds encode protocadherins, whose heterophilic binding is modulated by the four-jointed (Fj) Golgi resident kinase (Ishikawa et al., 2008; Simon et al., 2010). In many *Drosophila* epithelial tissues, Ds and Fj are expressed in tissue-wide opposing gradients (Yang et

al., 2002). Fat and Ds are found planar polarized in specific domains of the Fj and Ds tissue-wide expression gradients and are necessary to polarize the distribution of the myosin Dachs (Ambegaonkar et al., 2012; Bosveld et al., 2012; Brittle et al., 2012). Once polarized, Dachs locally increases cortical tension along the lines of its polarized localization, leading to oriented cell rearrangements that shape the *Drosophila* dorsal thorax epithelium (Bosveld et al., 2012).

Tissue deformation is driven not only by PCP signaling pathway, in cell aggregates, many signaling molecules can be transported within and/or among cells to direct the cell behavior, such as contraction, adhesion, migration, proliferation and apoptosis (Okuda et al., 2015). These cell activities generate mechanical forces, which induce tissue deformations. Signaling pathways not only coordinate individual cell dynamics to generate large tissue-scale deformations, but tissue-scale deformations also feed back on the organization of signaling centers, thereby modulating tissue patterning (Heisenberg and Bellaiche, 2013).

### **5.2 The epithelial folding is one of the most studied morphogenetic events**

Epithelial folding is critical for transforming of flattened epithelial sheets into three-dimensional structures. Epithelial fold formation involves a series of cell shape changes that is driven by mechanical forces. This process plays an important role in the embryogenesis of both vertebrates and invertebrates (Zartman and Shvartsman, 2010). Besides this, the epithelial folding is also important for the organ formation and helping organs work properly. Various epithelial folding, such as folds and villi, are found in the lumens of animal tubular organs. Multiple folds along the longitudinal direction of the tubes are a common structure observed in the airways, esophagus, oviducts, etc (Wiggs et al., 1997). On the other hand, folds along the circumferential direction (circular folds) are observed in the small intestines. These folds help intestines to absorb more nutrients and more materials because they expand the surface area of the intestine (Burgess, 1975). In several mammals, including humans, the cortex folds during development to produce the fissures, sulci,

and gyri of the mature brain (Molnar and Clowry, 2012). Cortical folding is essential for brain function, as defects are associated with severe mental disorders including autism and schizophrenia (Harris et al., 2004; Wisco et al., 2007). These folding processes always proceed through a similar sequence of rapid cell shape changes, which include apical constriction, cell elongation and subsequent shortening. In this thesis, I mainly introduce three classic folding processes.

### **5.2.1 Ventral furrow formation in the *Drosophila* embryo**

Ventral furrow formation is a classic folding process in the embryonic development of *Drosophila*. It has been most studied as the model of folding. Ventral furrow formation is a comparatively simple but important mechanical process as it is the first large scale morphogenetic movement in the *Drosophila* embryo. During gastrulation, the ventral furrow and posterior midgut invaginations bring mesodermal and endodermal precursor cells into the interior of the embryo, so that the single-layered blastula is reorganized into three germ layers that are known as the ectoderm, mesoderm, and endoderm (Sweeton et al., 1991). The first observable event in this process is the flattening of the apical surfaces of cells within the most ventral region of the cellular blastoderm (Figure 2A). The cells progressively constrict their apical sides to get the wedge shape (Figure 2B) and finally shorten along their apical–basal axis. The blastoderm epithelium invaginated towards inside of embryo (Figure 2C), and then the ventral furrow is completely internalized (Figure 2D). Once inside the embryo, the mesoderm precursor cells lose their epithelial structure and disperse into single cells that divide, attach to the ectoderm and migrate out on the ectoderm to form a single cell layer (Leptin and Grunewald, 1990).

Apical constriction of mesoderm precursor cells has been widely thought to drive the ventral furrow formation (Kam et al., 1991; Lecuit and Lenne, 2007; Leptin, 2005). Apical constriction is conventionally thought to be driven by the continuous purse-string-like contraction of a circumferential actomyosin belt underlying adherens junctions (Hildebrand, 2005). Recently, it has been found that pulsed actin–myosin network contractions that occur at the medial apical

## INTRODUCTION

cortex generate contraction force, driving apical constriction to promote ventral furrow formation (Martin et al., 2009). However, 2D and 3D finite elements methods (FEM) model of ventral furrow formation in *Drosophila* have shown that apical constriction within the ventral domain alone is not sufficient to drive internalization of the furrow, and it revealed the potential importance of apical–basal shortening outside of the ventral domain in furrow formation (Conte et al., 2008; Munoz et al., 2007). Some authors also suggested that ectodermal cells could help to drive ventral furrow invagination by pushing lateral sides of the precursor mesoderm; facilitating inward buckling and reinforcing internalization of the ventral furrow (Conte et al., 2009; Conte et al., 2012; Leptin and Grunewald, 1990).

### 5.2.2 Neural tube formation in Vertebrate

The neural tube forms also by the processes of folding (Gilbert, 2006). Neural tube formation is an important and necessary process during the development of the central nervous system. The proper development of the neural tube is paramount to animal survival. Improper neural tube closure is one of the most

## INTRODUCTION

common human birth defects (Sadler, 2005). The process of neurulation appears to be similar in amphibians, reptiles, birds, and mammals (Gallera, 1971). The neural plate originates from a flat neuroepithelium, grows rapidly and becomes thickened, resulting in invagination and formation of the neural groove. Following continued cell division the groove becomes deeper, and the folds thicken so that they eventually meet and fuse, converting the neural groove into the neural tube which subsequently differentiates into the brain, the spinal cord, and other neural tissue of the central nervous system (Suzuki et al., 2012)(Figure 3A-C). In the *Xenopus* embryos the cell shape changes and cellular mechanisms during neural tube formation have been analyzed. Prior to neurulation, the shape of the neuroepithelial cell is cuboidal. The neuroepithelial cells first elongate along apicobasal axis to become columnar. During this phase, parallel microtubules assembling along the apical-basal axis have been suggested to promote the cell elongation (Burnside, 1973). Apical constriction is followed after cell elongation. In contrast to the situation observed during *Drosophila* gastrulation, apical constriction during vertebrate neural tube formation is associated with the contraction of the actin-myosin networks that underlie junctions (Baker and Schroeder, 1967; Burnside, 1973). During apical constriction, superficial neural cells in the neural plate accumulate F-actin on their apical side to form a thick F-actin band. The cells undergo apical constriction by the constriction of the actomyosin-based F-actin ring, leading to a change from a columnar shape into an apically narrow wedge-like shape (Haigo et al., 2003; Lee et al., 2007; Schroeder, 1970). These cell shape changes are thought to occur near the midline, thereby generating forces that bend the neural plate and bring the two lateral neural folds together for closure (Suzuki et al., 2012).

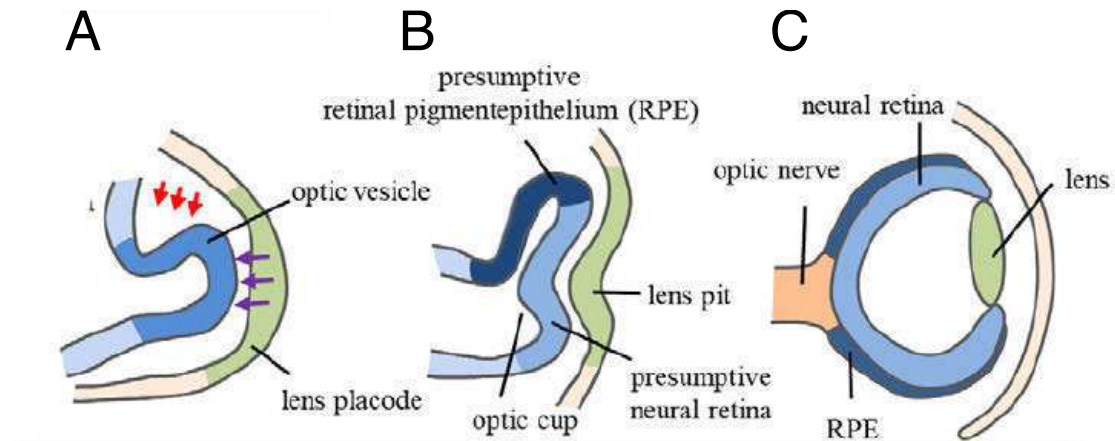

**Figure 3. The process of neural tube closure**

Dorsal views (Top) and transverse sections (Bottom) of generalized amphibian embryos in early (A), middle (B), and late (C) neurulae. (A) Neural plate (blue) is flat at the beginning. (B) The lateral borders of the neural plate elevate to form the neural folds, further form the neural groove. (C) The edges of the neural folds eventually meet at the dorsal midline, where they fuse to form the neural tube. Modified after (Suzuki et al., 2012)

### 5.2.3 Vertebrate eye development

The vertebrate eye is also an excellent model to study the mechanisms required for epithelial invagination. Organogenesis of the eye is a multistep process that starts with the formation of optic vesicles followed by invagination of the distal domain of the vesicles and the lens placode resulting in morphogenesis of the optic cup. Invagination of the lens pit occurs in precise coordination with invagination of the optic vesicles so that their shapes are completely matched (Figure4 A-C). It has been hypothesized that optic cup invagination is driven by the apical constriction of the neuroepithelial cells located at the rim between the presumptive retina and retinal pigment epithelium (RPE) domains (Eiraku et al., 2011). In contrast to apical constriction, recently, basal constriction of the neuroblasts has been proposed as the driving force that contributes to optic cup folding (Nicolas-Perez et al., 2016; Olmedo et al., 2009). It has also been shown that Integrin-mediated adhesion to the ECM plays a fundamental role during optic cup folding in medaka fish (Bueno-Sanchez et al., 2009). In the mouse eye, it has been shown that Cdc42/IRSp53-dependent contractile filopodia tether presumptive

lens and retina and thereby coordinate invagination of presumptive lens and retina (Chauhan et al., 2009). Recently, tracking of individual cells in zebrafish has shown that epithelial flow through this rim contributes to neural retina expansion and optic cup folding (Heermann et al., 2015; Picker et al., 2009).

**Figure 4. Vertebrate eye development**

(A-C) Transverse section of a chick embryo. Orange indicates the mesoderm and endoderm. Light blue indicates the neural plate. Dark blue indicates the presumptive retina. The presumptive lens ectoderm is shown in light green. (A) The presumptive lens ectoderm becomes thickened to form the lens placode. (B) Lens placode subsequently invaginates from the ectoderm to form the lens pit and optic vesicle invaginates to form optic cup. (C) Neural retina and lens are formed. Modified after (Zhang et al., 2016)

### 5.3 The mechanical mechanism of the epithelial folding

#### 5.3.1 Apical constriction promotes the fold formation

Apical constriction is a major mechanism that promotes the epithelial folding, such as gastrulation in many organisms and neural tube formation in vertebrates. As early as 1902, Rhumbler has proposed that apical constriction may drive the bending of cell sheets in a variety of developmental systems (Rhumbler, 1902). Apical constriction causes the apical surface area to shrink relative to that of the basal surface and typically transforms cells from a cuboidal or rectangular geometry to a wedged shape. After apical constriction and cell elongation, the cells undergo shortening and basal surface expansion to form a fold. Apical actomyosin networks have long been implicated in generating the contraction force that drives apical constriction (Martin et al., 2009). Apical actin-myosin networks exhibit a wide variety of behaviors,

## INTRODUCTION

including actin-myosin flows, contractile pulsing, and the formation of actin-myosin fibers, to generate force (Martin, 2010). Rho-kinase (Rock) and Shroom are notable regulators of the actomyosin cytoskeleton during the apical constriction (Borges et al., 2011; Haigo et al., 2003; Sai et al., 2014). Rho GTP exchange factor (Rho GTPase) are required to localize myosin II apically in the cell in several vertebrate and invertebrate systems (Barrett et al., 1997; Hacker and Perrimon, 1998; Nishimura and Takeichi, 2008). For example, in the ventral furrow formation of *Drosophila* embryo, it is initiated by the transcription factors Snail and Twist, which cooperatively activate G protein-coupled receptor signaling and recruit the guanine nucleotide exchange factor (PDZ-RhoGEF2) to the apical surface (Costa et al., 1994; Kolsch et al., 2007; Manning et al., 2013). RhoGEF2 is anchored at the plasma membrane in the apical junctional area through the apically targeted transmembrane protein T48 to activate RhoA (Kolsch et al., 2007). RhoA activation is spatially and temporally coordinated to control actin-myosin contractility during apical constriction. Actomyosin contraction to induce the reduction of apical area must be stabilized to prevent relaxation back to the original shape. Especially, pulsatile contractions happen in the medial apical surface of cell. During the *Drosophila* gastrulation, it has been found that mesoderm cell shape is maintained in a ratchet manner between contractile pulses such that cells apically constrict (Martin et al., 2009). It has been found that the high levels of the transcription factor Twist are required to stabilize apical cell shape by stabilizing myosin and F-actin at the medial apical area during apical constriction (Martin, 2010; Mason et al., 2013). Apical constriction does not act alone, however, as recent work in *ascidian* shows that the dynamic balance of cortical tension in apical versus basolateral cell domains plays a large role in regulating the specific aspects of cell shape, such as apical-basal elongation, that determine how the sheet is bent (Sherrard et al., 2010). It was recently reported that apical constriction generates cytoplasmic flow to transmit the tension apicalbasally that leads to apical-basal cell elongation (He et al., 2014). Simultaneously, the attachment of actin networks to cell-cell junctions allows forces to be transmitted between cells. Maintaining cell-cell adhesion is necessary for apical constriction of populations of cells folding epithelial tissues (Alvarez and Navascues, 1990;

Keller, 1988; Sweeton et al., 1991).

### 5.3.2 The role of Cell proliferation in the fold formation

During ventral furrow formation in embryo, mesodermal precursor cells did not undergo cell division. However, during other types epithelial folding process, cells undergo a series of cell shape changes, always accompanied with the cell dividing. Upon mitotic entry, columnar epithelial cells become short and change to spherical shapes, which involves remodeling of the actomyosin cortex (Kunda et al., 2008). The mitotic rounding force is generated by an increase in hydrostatic pressure, which is balanced by the contractile force of the actomyosin cortex (Stewart et al., 2011), allowing mitotic cells to expand and undergo cell division under confined conditions (Lancaster et al., 2013). After chromosome condensation, microtubules are reorganized into the spindle, and the actomyosin network is further organized to form the contractile ring for cytokinesis. During the mitosis, these dramatic cell shape changes and cytoskeleton remodeling in epithelium cells, could also affect the tissue morphogenesis. It has been found mitosis plays an active role in the epithelial invagination of the *Drosophila melanogaster* tracheal placode (Kondo and Hayashi, 2013). Besides this, differences in the rate of cell proliferation in the tissue may generate compression force resulting in folding. Miller, S. A. and colleagues have hinted at the role of differential cell proliferation in formation of large-scale epithelial folds in early chick embryos (Miller et al., 1994a). Based on mathematical models, Richman has proposed that cerebral cortical folding occurs as a result of differential growth between upper and lower cortical layers, which generates stress that is sufficient to induce cortical surface buckling (Richman et al., 1975). Recently, Taber and colleagues have reported that the mechanical stresses between the two layers feed back to induce patterns of growth within the brain, and these patterns of differential growth in the subcortical regions are sufficient to induce folding of the cortex (Bayly et al., 2013). After that, Fernandez and colleagues proposed that basal progenitors increase significantly neurogenesis at later stages, precisely when upper layers form, and that this enables the differential growth between layers and ultimately drives cerebral cortical folding

(Fernandez et al., 2016; Kriegstein et al., 2006). Regardless of the underlying biological mechanism, differential growth induced tissue buckling appears to be a common mechanism to fold sheets of cells. Moreover, patterned cell proliferation can drive new branch formation by forming budding and clefting in various branched organs. Budding in mammalian epithelial organs appears to be powered by a noninvasive form of collective cell migration along with cell proliferation (Ewald et al., 2008). In contrast, clefting at the branch tip in lung and kidney requires proliferation to enlarge the tip, which deforms and splits (Schnatwinkel and Niswander, 2013).

### **5.3.3 The role of extracellular matrix (ECM) in the fold formation**

The ECM and its receptors play diverse regulatory roles throughout development. Mechanical linkage between cell–cell and cell–extracellular matrix (ECM) adhesions regulates cell shape changes during tissue morphogenesis. It has been proposed that integrin-mediated adhesion to the ECM plays a fundamental role during optic cup folding in medaka (Bueno-Sanchez et al., 2009). Increased cell-ECM adhesion at the basal surface is predicted to promote basal expansion and drive epithelial invagination (Kondo and Hayashi, 2015). Laminin is a major component of the ECM, that interacts with integrins to mediate adhesion to the cytoskeleton of overlying cells (Miner and Yurchenco, 2004). It has been shown that laminin-dependent basal constriction is required for midbrain-hindbrain boundary constriction (MHBC) in zebrafish (Gutzman et al., 2008). The role of laminin has also been demonstrated during mouse salivary gland branching (Hosokawa et al., 1999). Recent work has delineated that ECM architecture play an important role in branching (Kim and Nelson, 2012). In the mammary gland, ECM is thick accumulations of basal membrane around bud flanks, ductal structures, and in cleft regions. ECM is thinner at end bud tips at which epithelial expansion occurs (Fata et al., 2004; Moore et al., 2005). ECM components are dynamically expressed in distinct regions of the mammary gland and are thought to have important roles in regulating the branching process. Accumulating evidence shows increased activity of matrix-degrading proteases –matrix metalloproteinases (MMPs) near the invading bud that will

loosen the fibrous ECM, and thus can promote branching morphogenesis (Alcaraz et al., 2011).

The epithelial folding is achieved through a variety of mechanisms involving systems of cells. The different mechanisms discussed here are not necessarily mutually exclusive. Some of different mechanisms can work in combination to drive folding. For example, basal relaxation normally precedes apical constriction. While it is still not understood how the different mechanical forces are integrated to regulate the cell shape changes during epithelial folding. Moreover, most of studies on the epithelial folding are focused on the apical side. However, how mechanical forces act along lateral and basal side of fold cells and how these mechanical forces coordinately change cell shape in 3D level have not been understood. *Drosophila* wing imaginal disc is a very simple epithelial tissue and easy to be imaged in 3D level. It can be cultured ex vivo so that we can observe the developmental process by live imaging. So It is a good model to study how mechanical forces changed cell shape in 3D during epithelial folding.

### **5.4 The model of the *Drosophila* imaginal wing disc**

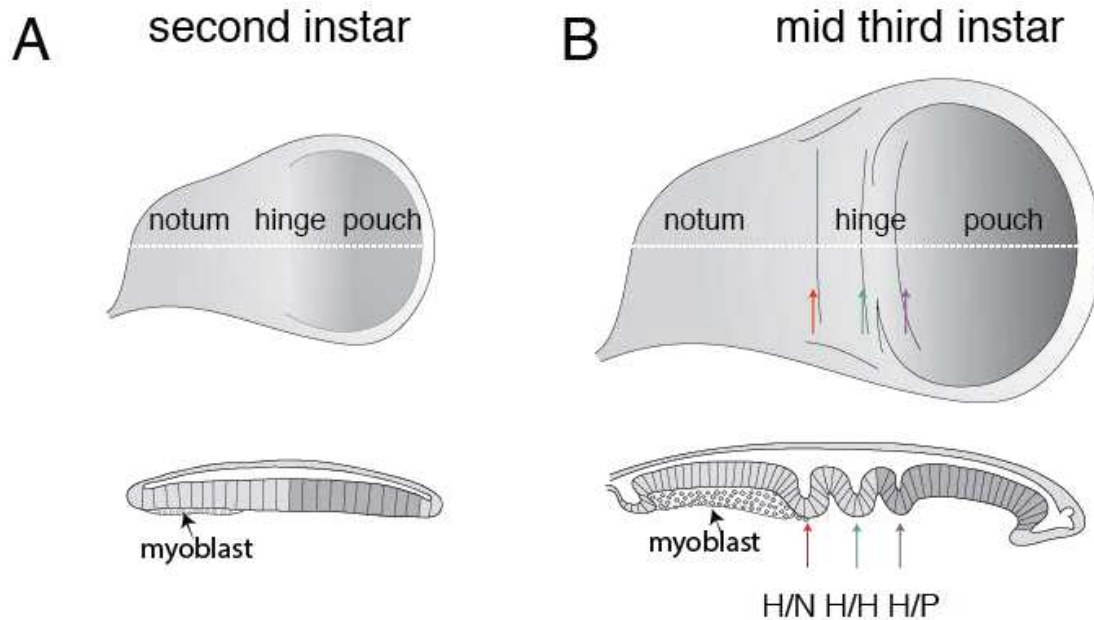

During the *Drosophila* larva stage, the future appendages have already existed inside of the larva as imaginal discs. There are pairs of imaginal discs that will form, for instance, the wings or legs or antennae or other structures in the adult. The developing *Drosophila* wing imaginal disc is a very simple organ and provides an excellent system to study tissue morphogenesis during organogenesis. The wing imaginal disc comprises ~20 cells when it is formed during embryonic development. These cells proliferate during the three larval stages to generate a disc of ~50,000 cells in the late third instar. The wing disc is a simple single-layered and sac-like epithelial sheet. During early larval development, wing disc cells display a uniform morphology. Cells are cuboidal shape with an apico-basal length of approximately 8  $\mu\text{m}$ . During mid-to-late larval stages cells on one side of the epithelial sac flatten and become squamous. Cells on the other side of the wing disc elongate along their apical-basal axis and become highly columnar, approximately 30 – 50  $\mu\text{m}$  tall cells. The columnar epithelium is very flat and tall, and contributes to the main parts

## INTRODUCTION

of the adult wing, while the squamous epithelium is thin and will degrade during wing disc bending in the pupa stage (Diazbenjumea and Cohen, 1993). The wing disc is subdivided into the notum, hinge and blade territories at the early third instar. These territories give rise to three corresponding adult structures. The fundamental structure of the wing epithelium is similar to all other epithelia, cells are tightly connected through cellular junctions and display an apical-basal polarity, and their basal surface adheres to an organized extracellular matrix (ECM). The epithelial cells have surprisingly dynamic cytoskeleton architecture to allow them to change shape and to adopt various forms to enable proper tissue function. The *Drosophila* wing disc as a good model system has big advantage. Firstly, progress in *Drosophila* genetics allows studying many developmental processes that are difficult to study in other systems (Belacortu and Paricio, 2011; Bischof et al., 2007; Southall et al., 2008), and the use of wing imaginal discs as experimental systems overcomes the limitations of lethal embryonic mutations, because patches of mutant tissue can be generated and analyzed at later developmental stages. Secondly, due to the benefits of modern imaging techniques, genetic tools, laser ablation or biophysical modelling approaches in the *Drosophila* wing discs, tissue mechanics has been widely studied in this tissue (Landsberg et al., 2009; Pasakarnis et al., 2016). Recent advancements have led to the ability to culture the wing disc for more than 12h ex vivo that can help us to observe many dynamic cell behaviors and cytoskeleton changes in developing wing discs (Zartman et al., 2013). Live imaging of cultured wing discs has enabled to describe the process of wing disc eversion during the early pupa stage, as well as some other processes, such as the formation of sensory organs, pupa cell divisions at the dorsal/ventral boundary, patterned apoptosis, and wound healing (Aldaz et al., 2010). Based on these advantages of wing disc modeling, it is possible to study the process and mechanical mechanism of hinge fold formation, which have not been understood so far. During wing disc development, three stereotypic folds appear in the prospective hinge region and morphologically separate notum and wing blade region in the columnar epithelium of wing imaginal disc (**Figure 5**). According to the position of folds, we named them hinge-notum (H/N) fold, hinge-hinge (H/H) fold and hinge-pouch (H/P) fold,

respectively. How is the position of the folds determined? To answer this question, we need to understand how wing disc is developed and how wing disc subdivided into different territories.

**Figure 5. The development of the *Drosophila* wing disc**

Schemes of x-y and cross-section y-z views of wing discs before (A) and after (B) folding. The wing disc pouch is shaded in dark grey. The dotted lines in the x-y views of wing disc indicate the position of cross-section y-z views. The three types of folds are indicated. Red arrow shows hinge-notum fold (H/N), green arrow shows hinge-hinge fold (H/H), purple arrow shows hinge-pouch fold (H/P).

#### 5.4.1 The development and patterning of *Drosophila* wing imaginal disc

The signaling pathways that govern growth and patterning in the wing disc have been well studied. Two of the main signalling pathways involved are the Wingless (wg) /Wnt and Decapentaplegic (Dpp) pathways (Affolter and Basler, 2007; Gonsalves and DasGupta, 2008). The wing disc has axis specification, which is mediated by the Anterior-Posterior (AP) and Dorsal-Ventral (DV) compartment boundaries. Wing disc patterning centers are established at these two compartment boundaries. Dpp is a member of the conserved Bone morphogenetic protein (BMP) family of secreted signaling molecules, which is produced in ten cells width strip along AP compartment boundaries (Williams et al., 1993). The Wingless signaling molecule is expressed in a ring of cells corresponding to the hinge folds and a strip of cells along the DV compartment boundaries (Baker, 1988). The two signalling molecules Dpp and Wingless are secreted from their producing cells and form

## INTRODUCTION

long-range gradients, to specify growth and patterning of the wing disc by activating downstream genes (Lecuit et al., 1996; Zecca et al., 1996). For example, Dpp induces the expression of the *omb* and *spalt* genes, Wingless controls expression of the *sense-less* and *distalless* genes. These two signaling pathway cooperate to induce and maintain graded expression of *vestigial* and *scalloped* that encode a transcription factor that promotes cell survival and proliferation (Aegerter-Wilmsen et al., 2007). These two signaling pathway also cooperated to control cell height of wing disc. Cells in the center of the pouch are tallest and display high Wingless and Dpp signalling activities, whereas cells in more lateral regions, which are shorter, transduce only low Wingless and Dpp signalling activities (Widmann and Dahmann, 2009a; Widmann and Dahmann, 2009b).

Moreover, these two signaling pathway also specify cell identities by activating downstream transcription factors during wing disc development. The *Drosophila* wing imaginal disc is subdivided along the proximal-distal axis into the notum, hinge and pouch territories (Casares and Mann, 2000; Diaz-Benjumea and Cohen, 1993). During early development, the developmental decision between wing and notum is defined by the antagonistic activities of Wg and the EGF-receptor ligand Vein that are expressed at the most ventral and dorsal sides of the wing disc, respectively (Baonza et al., 2000). Wg induces wing-fate specification and restricts the expression of Vein to the most dorsal side of the early wing disc by activating a pouch-determining gene *vg*. EGF-R Pathway that is activated by *iroquois* gene complex (*iro-C*), is required for the proper formation of notum (Diez del Corral et al., 1999; Wang et al., 2000). The wing is subdivided into wing pouch and hinge. In the absence of Wg function, neither wing pouch nor hinge is specified, leading to a duplication of the notum (Morata and Lawrence, 1977; Sharma and Chopra, 1976). Wg signaling induces different responses in wing hinge and pouch. *Hth* gene is one of the targets of Wg signaling within the hinge during the third instar. *Hth* collaborates with its coeffector *tsh* to specify hinge fate and to repress wing pouch fate by repressing *vg* (Azpiazu and Morata, 2000; Casares and Mann, 2000; Wu and Cohen, 2002). JAK/STAT signaling is localized to the wing hinge. Recently it has been found that *Stat92E* is downstream of *vg* and *Homothorax* (*Hth*) and is required for hinge fate

specification by cell-autonomously regulating hinge-specific factors, for example Zfh2, dachsous (ds) and Msh (Ayala-Camargo et al., 2013).

### **5.4.2 The mechanical force regulates cellular dynamics in *Drosophila* wing imaginal disc**

In addition to the important role of signaling pathway in the wing disc development, the mechanical forces also control the morphogenesis and growth in the wing disc by regulating various cell behaviors. Due to the development of mechanical measurement methods in vivo, such as laser ablation of individual cell junctions, more and more mechanically controlled processes have been identified in the *Drosophila* wing disc. The most studied mechanical process is compartment boundary formation. It has been shown that actomyosin accumulated at cell junction along compartment boundaries increase the mechanical tension, that could prevent cell mixing and maintain straight boundaries (Landsberg et al., 2009; Major and Irvine, 2006; Monier et al., 2010). A recent paper continued to dig at this question and found that a local increase in mechanical tension induces biasing cell intercalations to shape the compartment boundary in the *Drosophila* wing disc and histoblast nests (Umetsu et al., 2014). In addition, mechanical models of tissue growth have predicted that the buildup of compressive stress at the center of the wing disc that results from inhomogeneous growth in the tissue could provide an inhibitory growth signal that stabilizes uniform cell division patterns (Hufnagel et al., 2007). Moreover, the distribution of mechanical stress has been measured in the wing disc using photoelasticity, showing that cells are compressed in the center and stretched in the periphery (Nienhaus and Wiedenmann, 2009; Schluck et al., 2013). Mechanical stress could modulate cytoskeletal assembly to regulate cell shape change and cell behavior during wing disc development. In the wing discs, cell divisions are preferentially aligned radially in the center of the wing disc, In contrast, cells at the periphery of the disc become stretched in the direction tangential to the boundary of the tissue, and cell divisions are preferentially aligned along the stretched direction (Aegerter-Wilmsen et al., 2012; Legoff et al., 2013). This kind of oriented cell divisions in the wing disc has shown that it is directed by circumferential mechanical forces which influence cell shapes and thus orient

the mitotic spindle in the wing disc (Mao et al., 2013). In general, the signaling pathway and mechanical cue work together to direct the morphogenesis and growth of wing disc.

### **5.4.3 The epithelium folding in the hinge of *Drosophila* wing imaginal disc**

During late third instar, three prominent transverse folds spanning the presumptive dorsal hinge region of wing imaginal disc run parallel to one another and separate morphologically into notum, hinge and pouch territories. These three folds are thought to be important for the development and function of the adult hinge structure. Wild type adult *Drosophila* wings are held normally parallel to the main body axis. Downregulating of JAK/STAT activity disrupt the hinge-notum (H/N) fold in the wing disc and causes loss of the auxiliary sclerites 1(AS1) in the adult hinge, so that the adult wings are held out at 30–80° from the principal body axis (Johnstone et al., 2013). Fate mapping experiments have previously identified the AS1 as being derived from the region of H/N fold (Bryant, 1975). These suggested that the normal fold morphology might contribute to the subsequent development of auxiliary sclerites. Moreover, At the onset of metamorphosis, the wing disc undergo eversion along the wing margin that bring dorsal and ventral wing and hinge surfaces into apposition at the basal surface. During this process, the H/H fold disappeared, while N/H fold became deeper. Three hinge folds are thought to accommodate the bending of the wing disc (Aldaz et al., 2013).

However, the mechanism of these hinge fold formation has not been studied very well. Only a few studies about hinge fold formation have been done as follows. H/N fold is formed along the border of notum and separates it from remaining regions of wing disc. Previous studies have suggested that H/N fold is achieved at the border of Iro expression region due to the interaction between Iro-C expressing and non-Iro-C expressing cells (Villa-Cuesta et al., 2007). Iro-C are expressed in the prospective notum and are required to specify body wall identity. Cells lacking these proteins convert to the hinge fate (Diez del Corral et al., 1999). H/P fold localizes in the border of wing pouch and hinge, which is covered by *Dorsocross* (Doc) expression domain.

## INTRODUCTION

Doc is transcription factor downstream of wg and antagonizes vg expression in the pouch, which has been shown to contribute to hinge fold formation in the wing disc (Sui et al., 2012). However, the mechanical process involved in the hinge fold formation is not clear so far, and the mechanical mechanism of these hinge fold formations have not been studied.

## 6 Aim

In this study, my first aim was to show the process of hinge fold formation in real time. My second aim was to explore the mechanical mechanism of hinge fold formation at the 3D level. To do this, firstly, I improved the methods of wing disc culture so that we can observe the process of hinge fold formation *ex vivo*, then I quantified the cell shape changes during hinge fold formation. Secondly, I tested whether hinge fold formation relies on the mechanical mechanism that has been found in the folding of other epithelia, such as apical constriction and cell proliferation. After that, I observed the dynamic distribution of F-actin and ECM and measured the tension not only from the apical side, but also from the basal and lateral side in the wing disc cells at the different time points of hinge fold formation. Next, I continued to explore the reason for differential tension generation in pre-fold cells and neighboring cells by drug treatment or genetic manipulation.

## 7 MATERIALS AND METHODS

### 7.1 Fly husbandry

Flies were fed by standard fly food and the stocks were maintained at 18 °C. Those flies, which were used for experiments, were cultured at 25 °C except the special indication.

### 7.2 Fly stocks and genetics

Fly stocks for all experiments were taken from the stock collection of Prof. Dr. Christian Dahmann or were requested from the denoted authors.

**Table 1. List of the used fly stocks for experiments**

<b>Fly Stock</b>	<b>Reference</b>
1) <i>yw, hs-flp; Sp/CyO; MKRS/TM6B</i>	D145
2) <i>Indy-GFP</i> (Quinones-Coello et al., 2007)	M. Osterfield/S.Shvartsman
3) ; <i>E-cad-tomato</i> (Huang et al., 2009),	Katja Röper
4) ; <i>E-Cad-KI(GFP)</i> (Huang et al., 2009)	Huang et al., 2009
5) <i>yw sqhAX3;sqh-UtrophinABD::GFP /cyo</i>	Rauzi et al., 2010
6) ; <i>collagenIV-GFP/cyo</i>	Tian Xu
7) <i>y,w,hs::flp; E-Cad-KI(GFP),act5C&gt;CD2&gt;Gal4;UAS-CD8-cherry</i>	U515
8) ; <i>E-Cad-KI(GFP),cdc2E1-24/cyo-RFP</i> (Stern et al., 1993)	Suzanne Eaton
9) <i>sqh[AX3]/FM7;ap-Gal4,sqh::sqhGFP</i>	D808
10) ;; <i>UAS-sqhRNAi /TM6B</i>	D832
11) ; <i>UAS-CD8-cherry ; dpp&gt;Gal4,tub-GAL80ts/TM6b</i>	Elisabeth knust
12) ; <i>UAS-CD8-cherry; dpp&gt;Gal4/TM6b</i>	Elisabeth knust
13) ; <i>UAS-Mmp2</i>	BL #58705
14) <i>Indy-GFP; 30A-Gal4&gt;UAS-CD8-cherry/cyo</i>	derived from BL #37534
15) <i>Indy-GFP;; doc-Gal4&gt;UAS-CD8-</i>	derived from BL #46529

<i>cherry/TM6B</i>	
16) <i>y w ;Sp / CyO; hh-GAL4, UAS-DsRed / TM6B</i>	D 365
17) <i>;;UAS-wg-RNAi</i>	VDRC # 13351
18) <i>;; UAS-TcfDN</i>	BL #4784
19) <i>UAS- armS10</i>	D816
20) <i>Zfh-GAL4</i>	BL #46702
21) <i>w;;UAS-wg/TM6B</i>	D837

### 7.3 Phenotypic markers

Table 1. Phenotypic markers, which were used for labeling the flies genotype

Gene	Explanation
<i>y</i>	yellow mutation, yellow body color
<i>w</i>	white mutation, white eyes
<i>FM7</i>	Heterozygous <i>FM7</i> females ( <i>FM7/X</i> , above) have heart shaped, red eyes. <i>FM7/FM7</i> females and <i>FM7/Y</i> males have bar shaped red eyes, balancer for X chromosome
<i>Sp</i>	numerous stenopleural bristles, balancer for 2nd chromosome
<i>CyO</i>	curled wings, balancer for 2nd chromosome
<i>MKRS</i>	shortened body-covering bristles, balancer for 3rd chromosome
<i>TM6B</i>	numerous humeral bristles and short and thick larvae, balancer for 3rd chromosome

### 7.4 Experimental setup

#### 7.4.1 Generation of wild type clones

Stocks for wild type clone induction are: *y,w,HS::flp;; E-Cad-KI(GFP),act5C>CD2>Gal4;UAS-CD8-cherry*. The second instar larvae were heat shocked for 15–20 min at 37 °C and transferred to 25 °C for 48 h before dissection.

#### 7.4.2 Inhibition of wing disc cell proliferation

Stocks for inhibition of cell proliferation are *E-Cad-KI(GFP),cdc2E1-24 /cyo-RFP*. Homozgote *E-Cad-KI(GFP),cdc2E1-24* mutant and *E-Cad-KI(GFP)* larvae were staged and incubated in 25 °C, then we dissected them at 72hAEL instar, then cultured and imaged them at the same chamber in 30 °C incubation situation for 15 h, the imaging interval time is 5 min.

#### 7.4.3 Knockdown of sqh

Female *sqh[AX3]/FM7;;ap-Gal4,sqh::sqhGFP[4]* crossed with male *UAS-sqhRNAi*, F1 progeny were incubated in 29 °C and dissected at 72hAEL, 76hAEL, 84hAEL and 108h AEL instar.

#### 7.4.4 Ectopic expression of mmp2

Male *w; UAS-CD8-cherry; dpp>Gal4,tub-GAL80ts/TM6b*; crossed with female *UAS-Mmp2*. F1 progeny were incubated in 18 °C until second instar and transferred to 29 °C for 12h and 24h before dissection.

#### 7.4.5 Downregualting wg

Stocks for downregualting wg in posterior compartment: male *w; UAS-CD8-cherry; hh>Gal4,tub-GAL80ts/TM6b* crossed with female *UAS-wg-RNAi*. F1 progeny were incubated in 18 °C until second instar and transferred to 29 °C for 48h before dissection.

Stocks for downregualting wg in *dpp* experection strip: male *w; UAS-CD8-cherry; dpp>Gal4/TM6b* crossed with female *UAS-TcfDN*. F1 progeny were incubated in 25 °C and dissected at 3<sup>rd</sup> larva instar.

#### 7.4.6 Upregulating wg

Stocks for upregulation wg in *dpp* or *zfh* expression strip: male *w; UAS-CD8-cherry; dpp>Gal4/TM6b* crossed with female *UAS-armS10. Zhf-GAL4/y; UAS-CD8-cherry*; crossed with female *UAS-wg*. F1 progeny were incubated in 25 °C and dissected at 3<sup>rd</sup> larva instar.

### 7.5 Antibody staining of wing imaginal discs

Larvae were washed and dissected in PBS (phosphate buffered saline) and transferred to a 0.5 ml reaction tube on ice containing PBT (1xPBS containing 0.1% Triton-X-100, 0.1% Bovine serum albumin and 0.02% sodium azide), 4% Formaldehyde and 0.4% Triton-X-100, then rotate this reaction tube for 30 - 40 min at room temperature for fixation.

After fixation the larvae were washed 3 times in PBT. Primary antibodies were diluted in 200 µl PBT, fixed larvae was transferred to it for incubation over night at 4°C. The larvae were washed again 3 times in PBT. The secondary antibodies were diluted in 200µl PBT and added to the larvae, following incubation for 2hrs at room temperature. After that, the larvae were washed again 3 times in PBT. Then larval carcasses were transferred to an objective slide, PBT residues were removed by a piece of tissue, then added a drop of PPDA (p-Phenylenediamine), the wing imaginal discs were separated from larvae and mounted using double-sided tape (Tesa 05338, Beiersdorf, Hamburg, Germany) as spacer between the microscope slide and the cover slip to avoid flattening of the tissue.

### 7.6 Used antibodies

Antibody staining was done with fixed wing discs by using the following antibodies:

**Tab 3. Used antibodies for staining of fixed ovarioles.**

Primary antibodies	Dilution	Reference
rat anti-DE-cadherin	1:50	DCAD2, Developmental Studies Hybridoma Bank (DSHB)
mouse anti-PSβ-integrin DSHB	1:200	(DSHB)
secondary antibodies	Dilution	Reference
Goat anti-mouse IgG Alexa Fluor 633	1:200	Molecular Probes, Life Technologies (A-21126)
Donkey anti-rat Cy5 IgG (H+L)	1:200	Jackson ImmunoResearch Laboratories, Inc. (712-175-153)

Fluorophore coupled dye	Dilution	Reference
Rhodamine phalloidin	1:200	Molecular Probes, Life Technologies (R-415)
Alexa Fluor 488 phalloidin	1:200	Molecular Probes, Life Technologies (R-415)

### 7.7 Imaging of fixed samples

Images were acquired on the inverse Leica SP5 MP, a multiphoton laser scanning microscope provided by the Light Microscope Facility at the CRTD Dresden. Objectives that were used are the following: Leica HC PL APO 40x 1.25-0.75 Oil. The following laser lines were used for the respective dyes: Argon Laser 488 nm for Alexa Fluor 488 (Ex: 496 nm, Em: 519 nm), Laser DPSS 561 nm for Rhodamine-Phalloidin (Ex: 540 nm, Em: 565 nm), HeNe Laser 633 nm for Alexa Fluor 633 (Ex: 632, Em: 647). Images had always a resolution of 1024x1024 pixels, Z-Stacks images were taken with sections 1µm apart. see also ( [https://www.biodip.de/wiki/SP5\\_MP,\\_inverse,\\_CRTD](https://www.biodip.de/wiki/SP5_MP,_inverse,_CRTD))

### 7.8 Wing disc culture

#### 7.8.1 Stage larvae

1. Put 30 to 50 fluorescence flies which are 3-4 days old after hatched into cages with apple juice plates. Put some dry yeast solutions into the middle of apple juice plates for the food of these flies.
2. The second day, change the fresh apple juice plates with yeast food every two hours (at least five times). Collect and label these apple juice plates which have the eggs and incubate them in 25 °C incubator.
3. Hatched larvae from the apple juice plates were fed on standard food until the proper stages.

**7.8.2 Material for sterile dissections and wing disc culture**

- Sterile disposable plastic petri dish (60 mm)
- Sterile 2 pairs of dissection forceps
- Sterile dissection probe
- 100 µl Micropipette with disposable tips
- Mattek glass bottom dishes No.P35G-1.5-20C
- Millicell standing inserts, EMD Millipore PICM01250
- Whatmann filter paper
- Parafilm M Pre-cut Rolls, Laboratory Sealing Film

**7.8.3 Culture medium**

**Table 1: Composition of Wing Disc Medium (donated by Natalie)**

Components	Concentration	Source
Grace's medium	10mL	Sigma #G9771
BIS-TRIS	5mM	Sigma #B4429 1% from stock 500mM (1g in 10ml H <sub>2</sub> O)
FBS	5%	Gibco 16000-036
Penicillin streptomycin (P/S)	1%	Sigma #P4333 or Gibco 15140-122
Ecdysone (20HE)	20nM	Sigma #H5142 0.1% from working stock 0.02mM. original stock 1 mg/ml =2mM(5mg in 5ml ethanol)

Grace's medium (Sigma Aldrich, G9771) was prepared according to the manufacturer's instruction, the pH was adjusted to ~6.7 at room temperature (using 1M NaOH) and the medium was then filter sterilized.

#### **7.8.4 Sterile dissection of 68h-76h AEL wing discs**

Our protocol was optimized to prevent the larva and wing disc expose into contaminants, which require dissection by using sterile or disposable instrument under clean environment.

1. Collect the proper stage larvae.
2. Washed larvae 3 times by 1X PBS in the sterile petri dish.
3. Put several drops of culture medium (30 $\mu$ l) in a new sterile petri dish. (The medium drops are stable because of hydrophobic interactions, the surface tension of the drop is strong enough to keep the larva trapped.), then wash a larva in the medium drop.
4. Move the larva into a new medium drop and do dissection.
5. Seize larva by cuticle at mid-body and cut it into two pieces with 2 pairs of forceps.
6. Move the head part of larva into other new medium drop, turn over the cuticle to expose the wing disc outside by forceps. Carefully remove the gut.
7. Move the cuticle with two wing discs into other new medium drop. Carefully cut the wing discs from the trachea by dissection probe.
8. Wash the discs by transferring them sequentially through three drops by 100  $\mu$ l Micropipette.

#### **7.8.5 Mounting of 68h-76h AEL wing discs**

1. Prepare a strip of filter paper, place it along the imaging dish wall and humidify with PBS using a micropipette (100 $\mu$ l).
2. Prepare the insert chamber by cutting off the legs of the Millicell insert with a sharp Scissors.
3. Transfer the wing discs with 20 $\mu$ l medium into the center of the cover slip of Mattek chamber by 100  $\mu$ l Micropipette.
4. Remove a little of medium by 100 $\mu$ l Micropipette to make the medium drop flat, then gently pull the trachea of wing disc to move it to the edge of medium drop by dissection probe. Make sure the wing disc lays down flat in the medium and apical side of the wing disc faces downwards to the coverslip.

5. Place the insert chamber on top of the medium drop.
6. Rapidly add 200  $\mu$ l medium into the insert chamber.
7. put the lid of the chamber on it and seal by parafilm.

## 7.9 Drug treatment

The Rho kinase inhibitor Y-27632 (Sigma) was resuspended in PBS at 25 mM concentration and was used in culture medium at a final concentration of 1 mM.

Latrunculin A (Abcam) resuspended in DMSO at 1mM concentration was used in culture medium at a final concentration of 4 $\mu$ M.

Collagenase Type I (Sigma-Aldrich, 1% in PBS) was diluted in culture medium to a final concentration of 0.02%.

## 7.10 Time-lapse imaging

### 7.10.1 X-Y Time-lapse imaging

We used the following markers for wild type folding live imaging: *Indy-GFP*; *E-cad-tomato*). To observe F-actin dynamics, the following stocks for live imaging: *yw sqhAX3;sqh-UtrophinABD::GFP/Cyo;sqh-sqh::mCherry*. Imaging was performed using a Leica SP5 MP confocal microscope with a 40x/1.25 numerical aperture oil immersion objective. For long-term imaging of fold formation, laser output power is 20%. The resolution is 1024\*700 pixels, 4.5024 pixels per micron. Images stacks of 30- 40  $\mu$ m were taken every 3 min or 5 min with optimal sectioning (1.3  $\mu$ m). To observe F-actin dynamics, images stacks of 30- 40  $\mu$ m were taken every 17 to 22 sec with optimal sectioning (1.3  $\mu$ m). The resolution is 1024\*250 pixels, 4.5024 pixels per micron.

### 7.10.2 Lateral-side Time-lapse imaging

The following stocks for lateral-side live imaging: *yw sqhAX3;sqh-UtrophinABD::GFP/Cyo;sqh-sqh::mCherry*. The proper stage wing discs were mounted with the lateral side facing to the objective. The position of the wing disc was fixed by attaching the lateral edge of the notum part of the disc to the imaging chamber using double-sided tape.

Light microscopy imaging and laser ablation experiments were performed on the Zeiss LSM 780 NLO system (Carl Zeiss Microscopy, GmbH, Jena, Germany) with Zen Black software 2011 SP4, equipped with Ti:Sa laser Chameleon Vision from Coherent (Santa Clara, USA). For all imaging experiments we used 40x/1.2 C Apochromat objective (Carl Zeiss Microscopy, GmbH, Jena, Germany). GFP labelled tissue was imaged with 488 nm laser line with detection band from 489 to 659 nm on internal GaAsP detector of LSM 780. Pinhole size was always set to 1 A.U. Image acquisition was always set so that pixel dwell time was 0.64  $\mu$ s. Using region of interest (ROI) tool, we chose the rectangular ROI which allow for acquisition frame rate of 1 frame per second. Images were taken by X-Y scanning of the cell lateral surfaces every 10 sec.

## 7.11 Laser ablation

### 7.11.1 Apical and basal laser ablation

Laser ablation experiments were performed as described previously (Landsberg et al., 2009). Cell edges were visualized by *indy-GFP*. *30A-Gal4>UAS-CD8-mcherry* and *Doc-Gal4>UAS-CD8-mcherry* were used to label the H/H fold and H/P fold, respectively. Wing discs were mounted in culture medium with their apical side facing the objective for cutting apical cell edges. For cutting basal cell edges, the basal side was facing the objective. An inverted microscope with a 63x/1.2 NA water immersion objective equipped with a pulsed, third harmonic solid state UV-laser (355 nm, 400 ps, 20 mJ/pulse) was used. Wing discs were recorded with a time delay of 0.25 sec. The vertex displacement after laser ablation was analyzed with Fiji (Schindelin et al., 2012). The two vertices of the ablated cell junctions were manually tracked in the recorded images and the vertex distance increase over time measured. The initial recoil velocity  $v_0$  was based on the vertex distance increase between the average vertex distance before ablation and the vertex distance measured in the first image acquired 0.25 sec after ablation.

### 7.11. 2 Laser ablation of lateral cell edges

To ablate lateral cell edges, wing discs were mounted in culture medium with their lateral sides facing to the objective as described above. Laser ablations were performed on a Multiphoton Laser Scanning Microscope Zeiss LSM 780 NLO using a C-Apochromat 40x/1.2 W objective. Utr::GFP was used to label the lateral cell edges. Using region of interest (ROI) tool, we chose the rectangular ROI which allow for acquisition frame rate of 1 frame per second. We collected all together 50 frames. A lateral cell edge was identified and ablated using a laser beam of length 2  $\mu\text{m}$  and width 0.3  $\mu\text{m}$ . Laser ablation of selected regions was always done after fifth frame. The ablation was performed with approximately 60-70 mW of average power (50%) at 800 nm. The two cutting edges of opening F-actin fibers were manually tracked in the recorded images by Fiji and the distance increase were measured over time.

## 7.12 Image processing and analysis

Acquired images were processed and analyzed with Fiji and the custom made software Packing Analyzer (Aigouy et al., 2010). Seven to eleven stacks were projected by the maximum intensity projection method. Cells were segmented, tracked and their descendants were traced to establish cell lineages using Packing Analyzer.

### 7.12.1 Quantifications of cell shape changes

Several Y-Z cross-sections perpendicular to the folds were generated from acquired movies by Fiji. Apical and basal vertices of each cell were manually tracked over time. The apical and basal indentations ( $d_a$  and  $d_b$ ), the average apical and basal cross-section lengths ( $l_a$  and  $l_b$ ) of cells inside the folds, and the height of cells outside the folds ( $h$ ) were then extracted from the tracking using Matlab.

### 7.12.2 Quantifications of apparent apical cell area and basal cell area

The apical cell mesh was obtained by first projecting 5-8 slices of z-stacks showing DE-Cad::mTomato using the maximum intensity projection tool in Fiji. The basal cell mesh was obtained by first projecting 2-3 basal slices of z-

stacks showing Indy-GFP. Cells in the apical and basal cell meshes were then segmented and tracked over time using Packing Analyzer (Aigouy et al., 2010). Pre-fold cells were identified by tracking cells inside folds back in time.

After segmentation, the following processing steps were done stepwise:

Post process → finish all

Recenter → fake recentering

Tracking → track cells V2

Virtual cloning → Clone No.1 was defined, → fold cells were marked by a left mouse click, then choosing “track clone” a new \*.png file was created for each movie frame that represents the cell as a selection.

Virtual cloning → Clone No.2 was defined → neighboring cells were marked by a left mouse click, then choosing “track clone” to finish the neighboring cells selection.

Plots → Plots clone info → get the excel files “plot\_clone\_cells\_” from the folder.

Transfer cell area unit from pixel to  $\mu\text{m}^2$  according to the resolution rate of corresponding movies.

Align the folding frame for each movie, calculate and plot the average fold cell area and average neighboring cell area per frame overtime by matlab.

### **7.12.3 Quantifications of apical elongation of fold cells**

E-cad-tomato labeled the apical cell mesh. 3-5 apical slices of a z-stack were projected by the maximum intensity projection method for each time point of the movie. We selected one cell edge of each pre-fold cell that was best aligned with the longitudinal direction of the fold and tracked the vertices at the ends of these cell edges over time by Fiji. The total length of these edges was then defined as the in-plane length of the fold  $L$ , tracked as a function of time and normalized with respect to the length of the fold at the initiation of apical indentation  $L_0$ .

### **7.12.4 Quantifications of clone size**

We projected 5-8 apical Z-stacks by maximum intensity projection to obtain the apical cell mesh. The cell number of clones located in the notum or pouch region of the wing disc was then manually counted.

### **7.12.5 Quantification of wing disc cell number**

The apical cell mesh of cells was obtained by first projecting 5-8 slices of z-stacks showing DE-Cad::mTomato using the maximum intensity projection tool in Fiji. The first projected movie frame was then segmented using Packing Analyzer. The initial number of cells in the wing disc was obtained from this software. The number of dividing cells in subsequent movie frames was manually counted. Wing disc cell number was calculated by initial number of cells plus with the dividing cell number for each frame.

### **7.12.6 Measurements of Vkg-GFP levels**

To quantify Vkg-GFP intensities per cell at the basal surface, we segmented the basal side of the wing disc based on Indy-GFP fluorescence using Packing Analyzer. We then projected 3-5 basal z-slices of the image stacks by maximum intensity projection to obtain the basal Vkg-GFP intensity images. The Vkg-GFP intensity images were then overlaid with the cell segmentation. Vkg-GFP pixel intensities were then measured in each segmented fold cell and each segmented neighboring cell by Fiji.

### **7.12.7 Measurements of F-actin levels**

To quantify F-actin levels at the lateral edge of single cell, F-actin dynamics was visualized by sqh-UtrophinABD::GFP, and wing discs were mounted with apical face to the objective. Image Z-stacks were taken from apical to basal every 17-22 sec. Y-z cross-sections that were generated by Fiji were analyzed. For Figure 21B, wing discs were mounted with the lateral side facing to the objective. F-actin intensity was measured over time using Fiji by drawing a rectangular region of size 7.3  $\mu\text{m}$  times 14.6  $\mu\text{m}$  that covered the lateral surface of the cell of interest. Cell height was measured over time using Fiji by tracking apical and basal vertices of the cell of interest. The cross correlation between lateral F-actin intensity and changes of cell height was quantified by Matlab.

To quantify F-actin levels in medial apical surface of single cells (Figure S8e-g), wing discs were mounted with their apical side facing the objective. Image

z-stacks were taken from apical to basal. Projected 3-5 apical z-slices of the image stacks by maximum intensity projection to obtain the apical F-actin intensity images, cell outline was visible by sqh-UtrophinABD::GFP marker.

To quantify F-actin levels in medial basal surface of single cells, wing discs were mounted with their basal side facing the objective. Images Z-stacks were taken from basal to apical. 3-5 apical or basal z-stacks were projected by the maximum intensity projection method. Medial F-actin intensity and cell area were measured over time using Fiji by manually identifying the contour of the cell and extracting the areas and average F-actin intensities. The cross correlation between F-actin intensity and changes of cell area was quantified by Matlab.

### **Statistical analysis**

A two-sample, unpaired Student's t-test was used for statistical analysis. Significance levels:  $p < 0.05$  (\*),  $p < 0.01$  (\*\*),  $p < 0.001$  (\*\*\*).  $P \geq 0.05$  = not significant (n.s.) Average values and SEM (Standard error of the mean =  $STDEV/SQRT(n)$ ) were calculated with Excel.

## 8 RESULTS

### 8.1 Hinge fold formation in the *Drosophila* wing disc

During the third instar larval stage of *Drosophila* development, the initially flat wing imaginal disc epithelium gradually forms three stereotypic folds in the hinge region (**Figure 5**). These three folds morphologically separate the blade region from the notum region. However, how these folds form in the hinge region has not been known.

#### 8.1.1 Hinge fold formation in the fixed *Drosophila* wing disc

To understand the formation of these three folds, we first observed the fold formation in fixed wing discs at different developmental times. At 76h after egg lay (AEL), the H/H fold forms as the first fold. At 84h AEL, H/P and H/N folds start to form at the same time. All three folds are positioned parallel to each other and invaginate further during wing disc development. Some H/N fold cells are covered basally by myoblast cells. So, in my thesis, I mainly focused on studying the mechanisms of H/H fold and H/P fold.

**Figure 6. Three hinge folds form during the development of *Drosophila* wing disc, as observed in the fixed tissue**

(A-F) Top view (A-F) and cross-sectional images (A'-F') of fixed wing discs of larvae of the indicated times after egg lay stained for E-cadherin-GFP and F-actin. Top view images were shown by E-cadherin-GFP. Cross-sectional images were shown by F-actin staining. H/N fold (red arrow), H/H fold (green arrow) and H/P fold (purple arrow) are indicated. In this and the following figures, top views are shown with dorsal to the left and posterior up; in cross-sections the apical surface of columnar cells is to the top, unless otherwise indicated. Dotted lines in top views indicate the position of the corresponding cross-sections. Scale bars are 10  $\mu\text{m}$ .

### 8.1.2 *Ex vivo* live-imaging of hinge fold formation in the *Drosophila* wing disc

I developed a protocol for live imaging of wing imaginal discs in culture to better understand the process of hinge fold formation. To make sure the wing disc are growing healthy and normal in cultured condition as in vivo, I first checked whether cells are healthy and morphogenesis proceeds normally under these culturing conditions. Indeed, cell proliferation proceeds up to 10 hours in culture, confirming that wing disc cells are healthy and dividing under these culturing conditions. (**Figure 7A**). Furthermore, morphogenesis of wing discs cultured *ex vivo* proceeds normal, as H/H and H/P folds in cultured wing

discs were indistinguishable in shape from the hinge folds of fixed wing discs at same age (**Figure 7B,C**). These findings indicated that cultured wing discs develop normally.

I used a cell membrane marker, Indy-GFP, to label the cell outlines and obtained more than 5 movies that properly recorded the process of hinge fold formation. In order to compare the movies and to compensate for different starting times of the movies, I defined the first detectable apical invagination of the H/H fold as the reference time point  $t_{AAI}=0h$  (AAI, after initial apical invagination) for each movie. Then, I aligned the time for these 5 movies according to this. Before apical invagination, precursor fold cells are called by pre-fold cells. The folding processes were shown from apical section and cross-section of several movie frames (**Figure 8A-B**). I confirmed that the H/H fold forms first, while the H/P fold forms subsequently after 3 to 5 hours. That is consistent with the observation in fixed wing disc.

**Figure 7. Cell proliferations and fold formation in cultured wing discs**

(A) Number of cells in a wing disc over the time of culturing is shown.

(B) Top view and cross-sectional images of a fixed wing disc of 84h AEL larva stained as indicated.

(C) Top view and cross-sectional images of a live wing disc of 72h AEL cultured for 10 hours stained as indicated. Scale bars are 10  $\mu\text{m}$ . H/H fold (green arrow) and H/P fold (purple arrow) are indicated.

### 8.1.3 Quantitative analysis of cell shape changes during H/H and H/P folds formation

I characterized the cell shape changes during the formation of the H/H and the H/P fold. Cell shape was quantified in 12 cross-sections (taken from 5 wing discs) perpendicular to the fold direction. The quantification was

performed by manually tracking the apical and basal vertex of cells at each time point (**Figure 8C**). The apical and basal indentations ( $d_a$  and  $d_b$ ), the average apical and basal cross-section length of cells inside the folds ( $l_a$  and  $l_b$ ), and the average apico-basal height ( $h$ ) of the tissue surrounding the folds are quantified (**Figure 8D**). After 5 hours of folding, I found the average apical indentation ( $d_a$ ) in both folds reached about 40% of the height of the neighboring cells for both folds (**Figure 8E**). The apical length of folding cells ( $l_a$ ) in cross-sections was increased in both folds (**Figure 8E**). The deformations of the basal tissue surfaces however varied between the two folds: the basal deformations ( $d_b$ ) in H/H fold reached 10% of the tissue height, however, the basal deformation ( $d_b$ ) in H/P fold did not change (**Figure 8E**). The average basal cross-sectional length ( $l_b$ ) was increased in both folds, but was more pronounced in the H/H fold, indicating that in particular the H/H fold cells widen their basal cross-sectional surface area. The differences of cell shape changes during H/H and H/P fold formation imply that these two folds form via different mechanisms.

**Figure 8. Quantification of cell shape changes during H/H and H/P fold formation from cross-sectional images**

(A) Top view and cross-sectional images of a time-lapse movie of a cultured wing disc expressing Indy-GFP, showing the formation of H/H and H/P folds. Time relative to initiation of apical invagination of H/H fold is shown. Dotted lines in top views indicate the position of the corresponding cross-sections. Scale bars are 10  $\mu\text{m}$ .

(B) Top view and cross-section images of the boxed region of the time-lapse movie shown in (A) at indicated time points. Scale bars are 10  $\mu\text{m}$ .

(C) Overlay of cross sectional segmentation with original image. Imaged wing discs have been segmented by connecting the tracking of the apical and basal vertex of cells at each time point.

(D) Scheme showing the geometrical quantities obtained from the segmented epithelium.  $d_a$  and  $d_b$  denote the apical and basal indentations,  $l_a$  and  $l_b$  denote the average apical and basal cross sectional lengths of cells in the fold, and  $h$  denotes the apico-basal height of cells surrounding the fold.

(E-I') Individual (dotted lines) and averaged dynamics of shape changes during H/H and H/P fold formation for  $n=12$  cross-sections of 5 wing discs. All geometrical quantities are normalized by the cell height  $h$  of the neighboring cells. The curves are a function of normalized time, where individual trajectories were normalized with a time scale  $T_{fold}$ . Error bars represent s.d. 0h AAI corresponds to the first appearance of a visible apical indentation. (E-E') Cell height  $h$  of the neighboring cells of H/H fold cells or H/P fold cells. (F/F') Apical indentations of H/H fold cells or H/P fold cells. (G-G') Basal indentations of H/H fold cells or H/P fold cells. (H-H') average apical cross sectional lengths of cells in the H/H fold or H/P fold. (I-I') average basal cross sectional lengths of cells in the H/H fold or H/P fold. (Matlab performed by Silvanus Alt)

## 8.2 The potential mechanism of fold formation in the wing disc

There is major interest in morphogenetic folding processes which have been widely studied during e.g. ventral furrow formation in embryos. Here, I want to study morphogenesis by looking at fold formation in the *Drosophila* wing disc to unravel unknown mechanisms involved in morphogenesis.

### 8.2.1 Reduction of myosin II activity prevents H/P, but not H/H fold formation

The motor protein myosin II is required for the folding of several epithelia by promoting apical constriction. To test whether myosin II is required for hinge fold formation of wing imaginal discs, I inhibited myosin II activity by expressing double-stranded RNA targeting the gene spaghetti squash (*sqh*) encoding the myosin II regulatory light chain. Expression of *sqh*<sup>dsRNA</sup> in the dorsal compartment greatly reduced the levels of Sqh-GFP compared with controls (Figure 9 A, B), proving that we are successfully reducing Sqh and thereby myosin II activity in the wing disc. At 76h AEL the H/H fold forms in the control wing discs (Figure 9A). In wing discs expressing *sqh*<sup>dsRNA</sup>, the H/H fold does form with some delay and is present at 96h AEL (Figure 9B, D). The H/N and H/P folds are formed in control wing discs at 96h AEL (Figure 9C), while they are not present in the wing discs expressing *sqh*<sup>dsRNA</sup> (Figure 9D). That suggested H/H folds still can form, albeit delayed in comparison to

control wing discs, but H/P and H/N folds cannot form when myosin II activity is inhibited. I conclude that myosin II activity is essential for the formation of the H/P and H/N folds, but is largely dispensable for the H/H fold.

**Figure 9. The role of myosin II during fold formation**

(A, B) Top view and cross-sectional views of control wing discs (A, *ap-Gal4*, *sqh-GFP*) or wing discs expressing *sqh<sup>dsRNA</sup>* in the dorsal compartment of 76 h AEL larvae. (A, B) *Sqh-GFP* channel is shown. (A', B') stained for *Sqh-GFP*, *E-cadherin* and *F-actin*. (A'', A''', B'' and B''') *E-cadherin* channel is shown.

(C, D) Top view and cross-sectional views of control wing discs (C, *ap-Gal4*, *sqh-GFP*) or wing discs expressing *sqh<sup>dsRNA</sup>* in the dorsal compartment of 96 h AEL larvae. Only the *E-cadherin* channel is shown. The dotted lines in the x-y views of wing disc indicate the position of cross-section y-z views. H/H fold (green arrow) and H/P fold (purple arrow) are indicated. Scale bars are 10  $\mu\text{m}$ .

### 8.2.2 Apical constriction does not appear during H/H fold and H/P fold formation

Previous studies showed that apical constriction is a classic mechanism driving fold formation (Martin et al., 2009). So I was wondering whether apical constriction plays an important role in the hinge fold formation of wing disc. I analyzed apical projected cell area and cell elongation along the fold direction in the apical plane. I found apical area of H/H fold cells decrease gradually

after apical invagination (**Figure 10A-E**), however, H/H and H/P fold cells do not elongate and move significantly along the direction of the fold during the first 10 hours of folding (**Figure 10F-G**). However, considering the geometrical bias of projection in the folded region after apical invagination, I also did the cross-section analyses and found the apical length of folding cells ( $l_a$ ) in cross-sections was increasing in both folds after apical invagination (**Figure 8E**). Based on the fold cells do not elongate significantly along the direction of the fold (**Figure 10F-G**), therefore, apical area of fold cells is not decreased but it is due to the geometrical bias of projection after folding. Oppositely, apical areas of fold cells were increased after folding. The basal length of folding cells ( $l_b$ ) in cross-sections was increasing in both folds, consistent with basal area of folding cells increasing in the basal plane over time (**Figure 8E and Figure 10C,H**). Taken together, these data indicated that formation of the H/H and the H/P folds in the *Drosophila* wing imaginal disc does not occur through apical constriction. It may rather occur through basal cell expansion.

**Figure 10. Quantification of cell shape changes during H/H and H/P fold formation from maximal projection of apical and basal surface**

(A-A') Top view and cross-sectional images of a time-lapse movie of a cultured wing disc expressing E-cad-tomato and Indy-GFP. Time relative to initiation of apical invagination of H/H fold is shown. Dotted lines in top views indicate the position of the corresponding cross-sections. Scale bars are 10  $\mu\text{m}$ .

(B-D) Top view, basal view and cross-sectional images of the boxed areas of the time-lapse movie shown in (A) at indicated time points. H/H fold (green arrow) and H/P fold (purple arrow) are indicated. Scale bars are 10  $\mu\text{m}$ .

(E) Apparent cell apical area for H/H fold cells (green) and neighboring cells (grey) as a function of time relative to initiation of apical invagination of H/H fold. Mean and s.e.m. are shown. (n=3 wing discs).

(F) The segmentation of the maximal projection of apical cell mesh in the fold region. H/H fold cells are labeled by dark grey. The tracked vertexes are labeled by red dots.

(G) Relative length change of H/H and H/P folding regions in 3 representative wing discs compared to the length of the folds at the beginning of apical indentation (0min AAI), as a function of time.

(H) Apparent cell basal area for H/H fold cells (green) and neighboring cells (grey) as a function of time relative to initiation of apical invagination of H/H fold. Mean and s.e.m. are shown. (n=3 wing discs).

### 8.2.3 Cell proliferation is not required for hinge fold formation

Differences in the rate of cell proliferation within one tissue can lead to compression and thereby promote epithelial folding (Miller et al., 1994a). To test whether the cell proliferation rates between the pouch and notum region are different during hinge fold formation, I generated the CD8-mCherry marked clones in 48h AEL wing discs by heat-shock induced stochastic recombination and allowed the clones grow two days in vivo, then dissected the wing discs to count the increased cell numbers per clone at the pouch and notum region, respectively. I found that the average cell numbers of clones generated in the pouch and notum region was not significantly different (**Figure 11 A-B**), showing that the cell proliferation rates of notum cells and pouch cells are similar and different rates are not essential for hinge fold formation.

Still proliferation *per se* could induce cell shape changes and cytoskeleton remodeling in epithelium cells that could also affect the tissue morphogenesis. For example, mitotic cells rounding can facilitate the epithelial invagination in the *Drosophila melanogaster* tracheal placode (Kondo and Hayashi, 2013). To test if cell proliferation *per se* is required for H/H or H/P fold formation, we checked whether the folds still form in the absence of cell divisions. To do this, I temporarily blocked cell division by using a temperature-sensitive allele of the Cyclin-dependent-kinase *cdc2* (*cdc2<sup>ts</sup>*), which is essential for cell cycle progression in wing imaginal discs. Increasing the temperature of cultured *cdc2<sup>ts</sup>* wing discs from 25°C to the restrictive temperature of 30°C resulted in an immediate block of cell division. Interestingly, the three hinge folds formed normally in *cdc2<sup>ts</sup>* wing discs despite the absence of cell divisions (**Figure 12A-D**), showing that cell proliferation is not required for this process.

**Figure 11. The cell proliferation rate is similar between pouch and notum region**

(A) A wing disc (96 h AEL) carrying 48h old clones of cells marked by the expression of CD8-mcherry (*Act5C>Gal4, UAS-CD8-mCherry*). Adherens junctions are labeled by E-cad-GFP (green). Scale bar is 10  $\mu$ m.

(A-D) Top view and cross-sectional images of time-lapse movies of control (A, B) and *Cdc2<sup>ts</sup>* (C, D) cultured wing discs expressing E-cad-GFP are shown for the indicated time points after shifting the temperature from 25°C to 30°C. Dotted lines in top views indicate the position of the corresponding cross-sections. Scale bars are 10 μm. H/H fold (green arrow) and H/P fold (purple arrow) are indicated.

### 8.3 Reduction of ECM mediated decreased basal tension in the fold cells promotes H/H fold formation

In contrast to other well established systems of fold formation, wing disc hinge fold formation seems not to be due to apical constriction or differences in cell proliferation rates. It also does not depend on the compression arising from cell division. Furthermore, H/H and H/P fold formation differ in the occurring cell shape changes and after myosin II depletion, arguing that the mechanisms for H/H and H/P fold formation might be different. We therefore

want to elucidate the novel mechanical mechanism driving H/H and H/P fold formation, respectively. First I investigated the mechanism driving H/H fold formation.

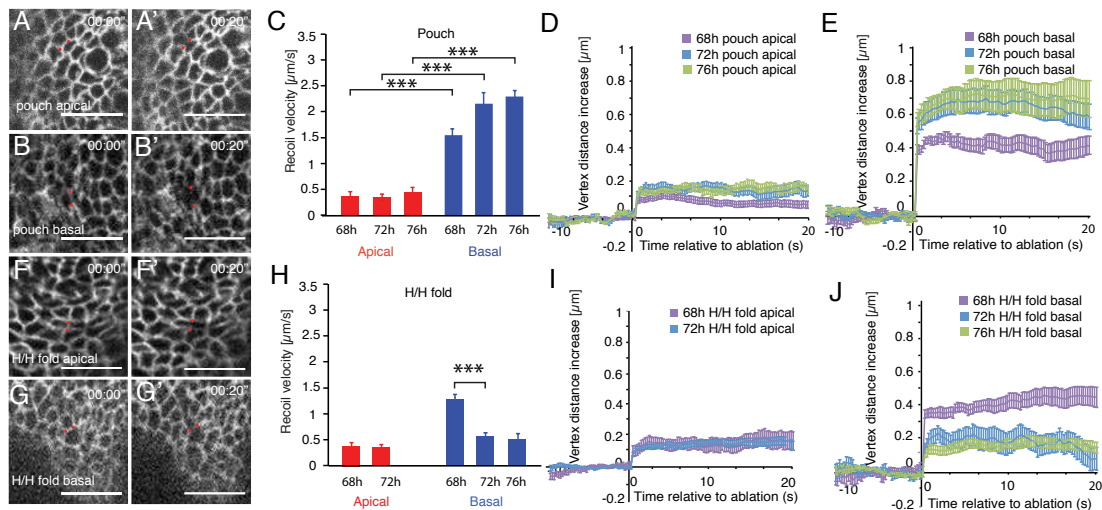

### **8.3.1 Basal cell bond tension is higher than apical cell bond tension**

Previous studies have shown that actomyosin enrichment on the apical bonds of wing disc generates apical bond tension (Landsberg et al., 2009). Here, I observed F-actin not only from apical side but also from basal side of wing disc. F-actin was visualized by Utrophin-GFP which is fluorescent F-actin probes based on the calponin homology domain of Utrophin (Utr-CH) (Burkel et al., 2007). I found actomyosin enrichment also on the basal bonds of wing disc (**Figure 13A, B**). To test whether mechanical tension is generated in the basal cellular bonds, I did laser ablation of single cell bonds at the basal most position with a focused laser beam to measure the mechanical tension which can be quantified by measuring the vertex displacement and Initial recoil velocity after laser ablation of cell bonds. The cellular bonds in a cultured wing disc were labeled by Indy-GFP. For comparison, I ablated apical cell bonds at the level of adherens junctions, as previously described (Landsberg et al., 2009). Laser ablation experiments were performed in the pouch outside the folds before and during the folding at about 68-76h AEL (**Figure 14 A-B**). I found an average initial recoil velocity of severed apical junctions of about 0.5  $\mu\text{m/s}$ , while the basal initial recoil velocity was significantly higher with about 1.5-2.5 $\mu\text{m/s}$  (**Figure 14 C**). The vertex distance increase after laser ablation was 3-5 fold higher for basal bonds cuts compared to apical bonds cuts (**Figure 14 D, E**). These findings suggest that basal cell bond tension is significantly higher than apical cell bond tension in the wing pouch region outside the folds.

**Figure 13. The distribution of myosin II and F-actin on the apical and basal surface of the wing disc**

(A-B'') Apical and basal views and cross-sectional images of two different 72h AEL wing disc co-expressing Utr-GFP and Sqh-cherry to visualize F-actin and MRLC, respectively. (A-B') Wing disc is mounted apical face to the objective. (B-B') Wing disc is mounted basal face to the objective. Dotted lines indicate the position of the corresponding cross-sections. Scale bars are 10  $\mu$ m.

**Figure 14. Wing disc basal bonds generate significantly higher tensions than their apical counterparts, and reduced in H/H fold cells**

(A-B') Wing disc pouch cells of 72h AEL larvae expressing Indy-GFP before and 20 seconds after ablation of a single cell edge at the apical (A) or basal (B) side of the epithelium. Red dots label the vertices of the ablated cell edge. Scale bars are 10 $\mu$ m.

(C) Initial recoil velocity in the pouch region for wing discs of the indicated stage. Recoil velocities are shown for ablations of apical and basal cell edges, as indicated. Mean and s.e.m. are shown. (n=15 cuts) (\*\*\*: p<0.001).

(D-E) The vertex distance increase after laser ablation for the apical (D) or basal (E) bonds in the pouch region for wing discs of the indicated stage.

(H) Initial recoil velocity in the H/H fold region for wing discs of the indicated stage. Recoil velocities are shown for ablations of apical and basal cell edges, as indicated. Mean and s.e.m. are shown. (n=15 cuts) (\*\*\*: p<0.001).

(I-J) The vertex distance increase after laser ablation for the apical (I) or basal (J) bonds in the H/H fold region for wing discs of the indicated stage.

### 8.3.2 The basal cell bond tension is reduced in H/H fold cells during H/H fold formation.

In the previous section we analyzed the basal cell bond tension in the pouch cells. I now turned to the fold cells to see, if their tension differs from the neighboring cells. To identify the H/H fold region we took advantage of 30A-Gal4 labeling H/H fold cells with CD8-mCherry (**Figure 15A**), and H/P fold region was identified by *CD8-mCherry* expression under *Doc-Gal4* driving (**Figure 15B**). I measured the apical and basal cell bonds tension in H/H fold cells by performing laser ablation experiments before (68hAEL) and during (72h-76hAEL) H/H fold formation. I found that the initial recoil velocity after ablation of the basal cell bonds at 68h AEL was 1.5  $\mu\text{m/s}$  in H/H fold cells and thereby not significantly different from the neighboring pouch cells. At 72h to 76h AEL, the recoil velocity of ablated basal bonds of H/H fold cells decreased to 0.5  $\mu\text{m/s}$ , which is similar to the level of apical cell bonds in H/H fold cells, but significantly lower than the level of basal cell bonds in neighboring pouch cells (**Figure 14 F-H**). The vertex distance increase after laser ablation for apical and basal bonds cuts in H/H fold cells show the similar tendency as the initial recoil velocity (**Figure 14 I-J**). So I conclude that basal tension of H/H fold cells are decreased during fold formation. The decrease in recoil velocity correlated with an increased basal cross section area of H/H fold cells during H/H fold formation (**Figure 8E and Figure 10C,H**). This suggests that H/H fold is not forming by apical constriction, but by a release in basal tension acting along basal cell bonds that leads to the widening of the basal cell area.

**Figure 15. 30A-Gal4 expressed in the H/H fold region and Doc-Gal4 expressed in the H/P region**

Top view and cross-section view of wing discs expressing Indy-GFP, 30A-Gal4, UAS-CD8-mCherry (A, A') and Indy-GFP, Doc-Gal4, UAS-CD8-mCherry (B, B'), respectively.

### 8.3.3 H/H pre fold cells have reduced levels of Collagen IV and integrin

I wondered what causes the lower basal bond tension in H/H fold cells compared to neighboring pouch cells during folding. To test if the extracellular matrix (ECM) that is localized at the basal membrane of wing disc cells was involved, I visualized Collagen IV which is one of the components of ECM, using a GFP protein trap in the Collagen IV  $\alpha 2$  chain, Viking-GFP (Buszczak et al., 2007). I found that Viking-GFP levels on the basal side were reduced by approximately 20% underneath the H/H fold cells (in a stripe of approximately 4 cells) compared to neighboring cells before and during fold formation (**Figure 16 A-D**). Likewise, integrin levels were reduced in H/H fold cells compared to neighboring cells before and during fold formation (**Figure 16 E-**

G).

**Figure 16. The distribution of ECM and integrin in the H/H and H/P fold region**  
 (A-C') Basal and cross-sectional views of wing disc at the indicated stages expressing Viking-GFP (Vkg-GFP) and Indy-GFP are shown. Green and purple arrows point to the H/H and H/P fold, respectively. Scale bars are 10  $\mu$ m.

 (E-G') Basal and cross-sectional views of wing disc expressing Indy-GFP at the indicated stages stained for  $\beta$ PS integrin. Green and purple arrows point to the H/H and H/P fold, respectively. Scale bars are 10  $\mu$ m.

### 8.3.4 Collagen removal leads to the loss of the H/H fold and decreases basal tension

A local decrease in collagen coincides with fold formation and decreased basal cell bond tension. Assuming that collagen plays a major role in this process, we would predict from these results that removing collagen would impact on fold formation and basal cell bond tension. To test that, I treated 76h AEL wing imaginal discs with collagenase and observed that the wing

disc completely lost the basal collagen after 60 min of collagenase treatment (**Figure 17 A-B''**). Following the collagen removal of wing discs, the basal area of wing disc cells increased significantly, while the apical area of wing disc cells almost did not change (**Figure 17 A-C**). This is consistent with the H/H fold cells having less basal collagen and bigger basal area than neighboring cells. Moreover, the H/H fold disappeared after collagenase treatment of wing imaginal discs. Consequently, the overall basal curvature of the wing disc was largely lost (**Figure 17 A-B''**).

In the wild type wing discs, H/H fold cells have less ECM, bigger basal area and simultaneously have less basal tension than neighboring cells. To test whether wing disc cells have less basal tension after collagen removal, I performed laser ablation experiments and found that the apical tension was not affected by the removal of ECM, while the basal tension was reduced significantly at the wing pouch cells after collagenase treatment (**Figure 17 D-E**). These findings suggest that the generation of basal tension in cells depends on their interactions with the basal ECM, and that the local decrease of basal tension in H/H cells is driven by a local reduction of collagen at the basal side of the folding cells.

**Figure 17. Collagenase treatment results in cell basal area increased and basal tension decreased**

(E) The vertex distance increase after laser ablation for the apical or basal bonds in the pouch region for 72h AEL wing discs before (control) and 60 min after addition of collagenase (collagenase).

### 8.3.5 Inhibition of Myosin II and F-actin activities mildly decrease basal cell bond tension

Apical cell bond tension depends on the actomyosin belt of cell bonds. I found a similar actomyosin enrichment on the basal bonds of wing disc (**Figure 9A, B**) and wondered whether basal cell bond tension depends on Myosin and F-actin. To test this hypothesis, we first impaired Myosin II activity by inhibiting Rho-associated protein kinase, a Myosin II regulator, with its inhibitor Y-27632. Indeed, after Y-27632 treatment, the levels of Myosin proteins at the apical and basal surface of wing disc are significantly decreased compared to control wing disc (**Figure 18 A-B**). Laser ablation experiments showed that basal bond tension of wing discs is mildly decreased 30%, while the apical bond tension is significantly decreased 50% after inhibition of Myosin activity (**Figure 18 E-F**). In addition to that, I also analyzed the role of F-actin in the generation of basal and apical bond tension. I used the drug Latrunculin, which leads to depolymerization of F-actin and thereby depleted the wing disc cells of F-Actin (**Figure 18 C-D**). I found that the basal bond tension is also mildly decreased, but apical bond tension is significantly decreased after depolymerizing F-actin (**Figure 18 G-H**). These results suggest that F-actin and Myosin do only have a minor role in the generation of basal tension, while basal tension clearly depends on the basal ECM.

**Figure 18. The role of actomyosin in the basal bonds tension generation**

### **8.3.6 Local reduction of collagen leads to local reduction of basal tension and is sufficient for epithelial folding**

Next, I wanted to test whether local reduction of collagen is sufficient to induce ectopic fold formation in the wing disc. Matrix metalloproteinase II (MMP2) is an enzyme, which is secreted by the cell and degrades Collagen IV. It thereby depletes Collagen IV and its receptor Integrin (Dominguez-Gimenez et al., 2007; Sui et al., 2012). I expressed MMP2 in a stripe of cells along the AP boundary to locally decrease Collagen. As expected, I found that Integrin levels were reduced at the basal side of the wing disc cells already after 12h of MMP2 overexpression (**Figure 19 A and A'**). Laser ablation experiments further show, that overexpression of MMP2 is not decreasing the apical but the basal cell bond tension within the cells expressing MMP2 already 12h after overexpression starts (**Figure 19 C-D**). At this time the ectopic fold is not formed yet, but deeply formed after overexpression of MMP2 for 24h (**Figure 19 B**). This is reminiscent of the situation in the H/H fold cells, where local reduction of ECM and basal cell bond tension precedes the formation of a fold (**Figure 19 H**). These results demonstrate that a local reduction of ECM components is sufficient for epithelial folding.

**Figure 19. A local reduction of ECM decreases basal cell bond tension and results in epithelial folding**

(A-A') Basal view of wing disc expressing MMP2 for 12 hours under the control of *dpp-Gal4, tub-Gal80ts*. Dpp expression strip is labeled by expressing CD8-mCherry (green), Integrin staining is shown in red. Integrin channel is shown (A').

(B) Cross-sectional view of wing disc expressing MMP2 for 24 hours under the control of *dpp-Gal4, tub-Gal80ts*. Dpp expression strip is labeled by expressing CD8-mCherry (green), F-actin staining is shown in red.

(C) Initial recoil velocity of control cells and cells expressing MMP2 for 12 hours. Recoil velocities are shown for ablations of apical and basal cell edges, as indicated. Mean and s.e.m. are shown. (n=15 cuts) (\*\*\*: p< 0.001).

(D) The vertex distance increase after laser ablation for the apical or basal bonds in the control cells and cells expressing MMP2 for 12 hours, as indicated. Mean and s.e.m. are shown. (n=15 cuts) (\*\*\*: p<0.001).

#### 8.4 F-actin pulsed accumulation at the lateral cell bonds of H/P fold cells increase lateral tension, driving cell shortening and H/P fold formation

H/P fold is formed after the H/H fold. I found several differences between H/H fold formation and H/P fold formation. Firstly, the basal deformation ( $d_b$ ) increased for the H/H fold while it does not for the H/P fold (**Figure 8 E**). Secondly, reduction of Myosin II activity prevents H/P, but not H/H fold formation (**Figure 9 D**). Thirdly, H/P fold cells did not show less ECM and

integrin at the basal surface compared with neighboring pouch cells before and during H/P fold formation (**Figure 16 A-G''**).

#### 8.4.1 H/P fold cells have comparable basal tension and slightly higher apical tension than neighboring pouch cells

To test whether H/P fold cells have less basal tension than neighboring cells I performed laser ablation experiment. I found recoil velocity of ablated basal cell bonds to be comparable to neighboring cells (**Figure 20 A and C**) This suggests that H/P fold cells have as high basal tension as their neighboring cells. By performing the similar laser ablation experiments at the apical side, I observed a slight increase in apical cell bond tension in H/P cells, which was still weaker than the basal cell bond tension (**Figure 20 A and B**). This is different from the situation in the H/H fold, where fold cells have lower basal cell bond tension than the neighboring cells.

**Figure 20. Apical and basal tension measurements in the H/P fold cells**

(A) Initial recoil velocity of neighboring cells and H/P fold cells in the 76h AEL wing discs. Recoil velocities are shown for ablations of apical and basal cell edges, as indicated. Mean and s.e.m. are shown. ( $n=15$  cuts) (\*\*\*:  $p < 0.001$ ).

(C) The vertex distance increases after laser ablation for the basal bonds in neighboring cells and H/P fold cells in the 76h AEL wing discs, as indicated. Mean and s.e.m. are shown. ( $n=15$  cuts) (\*\*\*:  $p < 0.001$ ).

#### 8.4.2 F-actin shows pulsatile enrichment at lateral interfaces of H/P fold cells during folding

I showed that the H/P fold cannot form when we inhibit myosin activity by expressing  $\text{sqh}^{\text{dsRNA}}$  (**Figure 9**). This suggests Myosin activity is necessary for H/P fold formation and made us look at the role of myosin and F-actin during H/P fold formation. Strikingly, I found that H/P fold cells displayed a highly

dynamic enrichment of F-Actin along their lateral interfaces, while in the neighboring cells F-actin levels are lower and stable at the lateral surfaces (**Figure 21 A-B**). The dynamic enrichment of F-actin correlated with pulsations in the apical-basal height of cells: Cells became shorter when F-actin accumulated at the lateral surface of the cell, and cells recover cell height when lateral F-actin accumulation pulses go away. (**Figure 21 C-D**). To understand the correlation of cell height with lateral F-actin accumulation in detail, I quantified apical-basal cell height and average lateral actin intensity in N=12 cross sections over durations of 22-60mins to study the cross correlation of actin intensity and cell height over time (**Figure 21 E**). In average I found a strong negative cross correlation with a time lag of around 22s (**Figure 21 E**). This shows that an increase in lateral F-actin is closely followed (with a delay of about 22s) by a decrease in cell height in the H/P fold cells. H/H fold cells on the contrary do not have dynamic lateral F-actin accumulations during cell shortening (**Figure 22 A-B**). H/H fold cells also showed no comparable cross correlation (**Figure 22 C**), suggesting that their decrease in height is not driven by lateral F-actin accumulation.

**Figure 21. F-actin enrichment at lateral interfaces of H/P fold cells is correlated to cell shortening during H/P fold formation**

(A-A') Middle (13  $\mu\text{m}$  below apical surface) xy-layer (A) and cross-sectional images (A') of a time-lapse movie of a cultured wing disc expressing Utr-GFP to label F-

actin. The region of the H/P fold is shown. Time is as indicated. Scale bars are 10  $\mu\text{m}$ .

### 8.4.3 Lateral actin enrichment increases lateral tension in H/P fold cells

To test if lateral actin enrichment increases lateral tension, I performed laser ablation experiments of lateral cell interfaces during F-actin accumulation (**Figure 23 A-B**). To do this, I mounted the wing disc with the lateral side face to the objective. I found that the initial recoil velocity and the final maximal displacement of severed junctions are strongly increased in H/P fold cells that have accumulated lateral F-actin compared to neighboring cells which is without F-actin accumulation (**Figure 23 C-D**). This suggests that dynamic

actin enrichment in H/P fold cells increases lateral tension leading to cell shortening and finally to H/P fold formation.

**Figure 23. Dynamic lateral F-actin enrichment in H/P fold cells increases lateral tension**

(A-B) Kymograph of cross-sections of Utr-GFP expressing neighboring cells (A) or H/P fold cells (B) before and after ablation of a lateral cell edge. The interval time per frame is as indicated. Scale bar is 10  $\mu\text{m}$ .

(C) Distance increase of opening F-actin fibers upon laser cutting of lateral cell edges of H/P fold cells (purple) and neighboring cells (grey) as a function of time after ablation. Mean and s.e.m are shown.  $n=15$ .

(D) Initial recoil velocity upon laser cutting of lateral cell edges of H/P fold cells (purple) and neighboring cells (grey). Mean and s.e.m. are shown. ( $n=15$  cuts) (\*\*\*:  $p < 0.001$ ).

#### 8.4.4 H/P fold cells undergo pulsatile apical contractions and basal contractions during fold formation

I wondered whether F-actin, besides the dynamic accumulation at the lateral interfaces, also shows dynamic accumulation at the apical and basal side of H/P fold cells. Interesting, I found H/P fold cells show dynamic apical and basal F-actin pulsed accumulation during fold formation, while neighboring cells do not (**Figure 24 A-C**). The dynamic enrichment of apical F-actin in H/P fold cells correlated with pulsatile changes in the apical area of cells: Cells decreased apical area when F-actin accumulated at the apical surface and apical area increased when the peak of apical F-actin accumulation is

gone (**Figure 24 D**). Consistent with that, I found a strong negative cross correlation between cell apical area and medial F-actin intensity (**Figure 24 E**). I did the similar analyses for the basal cell area in H/P fold cells (**Figure 24 H-I**). I found H/P fold cells not only undergo pulsatile apical contraction but also basal contraction during fold formation. However, these pulsations at the apical and basal surface do not seem to lead to cell shortening, as cell height is neither correlated with apical nor with basal area changes (**Figure 20 F-G and J-K**). These results suggest that H/P fold cells change cell height mainly by the lateral contraction forces generated by the lateral F-actin accumulation, but not by the apical or basal contractions.

**Figure 24. H/P fold cells undergo apical and basal constriction**

## 8.5 The role of the wingless signaling pathway during hinge fold formation

What is the signaling pathway upstream of the mechanical mechanism of hinge fold formation? Based on our studies, we know that H/H fold formation is due to less ECM in the H/H fold cells compared to neighboring cells. We were wondering which signaling pathway might control the difference in ECM distribution between fold and neighboring pouch cells. The wingless (*wg*) signaling pathway is required for the specification, growth, patterning, and morphogenesis of the pouch (Gonsalves and DasGupta, 2008). Within the wing hinge *wg* is expressed in two concentric rings, the inner ring (IR) in the distal domain and the outer ring (OR) in the proximal domain (Couso et al., 1993). The *wg* IR is induced in early third instar and the *wg* OR is induced during mid-third instar (Baker, 1988). *Wg* is required for the proliferation of hinge cells and can induce hinge overgrowths without causing repatterning when overexpressed. Reduction of *wg* gene activity in the wing hinge leads to underproliferation of this region and loss of distal hinge structures (Whitworth and Russell, 2003; Zirin and Mann, 2007). That implies a role of *wg* in hinge development.

### 8.5.1 The expression pattern of wingless in different developmental stages of wing discs

Firstly, I investigated *wg* expression pattern during hinge fold formation. Wingless (*Wg*) protein staining showed *Wg* is expressed in the pouch region at 68h AEL (**Figure 25 A**). Following the wing disc growth the level of *wg* is gradually decreasing at the dorsal and ventral compartment. Concomitantly it forms a protein gradient with high levels both adjacent to the dorsoventral compartment boundary and in a ring along the distal hinge from 72h AEL

larval stage onwards (**Figure 25 B**). The H/H fold is formed at the hinge region at 76h AEL (**Figure 25C**). The H/P fold is formed at the border between pouch and hinge at 80h AEL (**Figure 25D**). Both of the folds are forming parallel to wingless expression ring.

**Figure 25. The distribution of Wingless in the different developmental stages of the wing imaginal disc**

(A-F') Z-projection images of fixed wing discs of larvae of the indicated times after egg lay (AEL) stained for E-cadherin-GFP (green) and Wingless (red). (A'-F') Wingless channel is shown. Scale bars are 10  $\mu$ m.

### 8.5.2 Downregulation of Wg signaling in the hinge region did not disturb hinge fold formation

To test whether Wg signaling plays a role in the hinge morphology, we decrease wg expression in the posterior compartment by expressing *wg-RNAi* under the control of *hh-Gal4*. I found both Wg protein and Integrin are significantly decreased in the posterior compartment compared with anterior compartment (**Figure 26 A-B'**). This suggests that decreasing Wg in the cells can reduce Integrin levels at the basal cell membrane. I also decreased Wg transduction by expressing a dominant-negative form of the Wingless transducer T-cell factor (TCF) under the control of *dpp-Gal4* which is expressed at the A/P strip of wing disc. We found that an ectopic fold forms along the *dpp* expression strip in the pouch region (**Figure 26 C and C'**). That suggested decreased wg transduction in a strip of pouch region is sufficient to induce an ectopic fold. However, in the hinge region, decreasing wg protein or wg transduction did not disrupt hinge fold formation.

**Figure 26. Downregulation of *wg* signaling could decrease Integrin levels and induce ectopic fold formation in the pouch region, but did not affect fold formation in the hinge region**

(A-A') Z-projection of wing disc expressing *wg*-RNAi under the control of *hh-Gal4*, *hh* expression region is labeled by expressing CD8-mCherry (red), F-actin staining is shown in green, Wg protein is shown in blue. (A') Wingless channel is shown. Scale bars are 10  $\mu$ m.

(B-B') Basal Z-projection of wing disc expressing *wg*-RNAi under the control of *hh-Gal4*, *hh* expression region is labeled by expressing CD8-mCherry (red), Integrin staining is shown in green. (A') Integrin channel is shown. Scale bars are 10  $\mu$ m.

(C-C') Z-projection view and cross section view of wing disc expressing TCF<sup>DN</sup> under the control of *dpp-Gal4*. *dpp* expression strip is labeled by expressing CD8-mCherry (red), F-actin staining is shown in green. Scale bars are 10  $\mu$ m.

### 8.5.3 Upregulation of wingless signaling in the H/H fold region inhibits fold formation

Finally, I wondered whether upregulation of *wg* signaling in H/H fold cells could affect hinge fold formation. To test this, I overexpressed *wg* in the distal hinge using *zfh-Gal4* which is expressed in the hinge region and all the H/H fold cells. This causes upregulation of *wg* signalling in all H/H fold cells. Strikingly, we found that *wg* overexpression leads to a complete loss of the H/H fold (**Figure 27 A-B**). Furthermore, I increased wingless signaling transduction by expressing ArmS10 under the control of *dpp-Gal4* which expression covers only a part of the presumptive H/H fold. I found that H/H fold is inhibited cell autonomously only in the cells expressing ArmS10 (**Figure 27 C-E**). Cells expressing ArmS10 in the presumptive H/H fold region have narrower basal area and higher level of integrin compared with neighboring folds cells (**Figure 27 F-G**). This suggests that upregulation of *wg* in the H/H fold cells could increase the level of integrin, decrease basal area and inhibit folding.

Figure 27. Upregulation of wingless signaling in the H/H fold region inhibits fold formation

## RESULTS

(A-B') Z-projection view and cross section view of control wing disc or wing disc expressing *wg* under the control of *zfh-Gal4* whose expression region is labeled by expressing CD8-mCherry (red), F-actin staining is shown in green. Scale bars are 10  $\mu\text{m}$ .

(C-E) Z-projection view and cross section view of wing disc expressing *arm<sup>S10</sup>* under the control of *dpp-Gal4* whose expression region is labeled by expressing CD8-mCherry (red), F-actin staining is shown in green, Integrin is shown in blue. Dotted lines in Z-projection views indicate the position of the corresponding cross-sections. (C'-E') Integrin channel is shown. Scale bars are 10  $\mu\text{m}$ .

(F-G') The magnification images from white box of (C') in the control H/H fold region (F-F') or in the H/H fold region expressing *arm<sup>S10</sup>* (G-G'). (F-G) F-actin staining is shown. (F'-G') integrin staining is shown. Scale bars are 10  $\mu\text{m}$ .

## 9 DISCUSSION

Epithelial folding is one of the most important morphogenetic processes, which results in the transformation of simple 2D cell sheets into 3D complex organs. Epithelial folding has been extensively studied in the embryos of both vertebrates and invertebrates, and through this research, it has been discovered that actomyosin generates the mechanical force necessary to induce apical constriction which is involved in the process of epithelial folding (Martin et al., 2009; Roh-Johnson et al., 2012; Sawyer et al., 2010).

During the course of my research, I used *Drosophila* wing imaginal discs as a model to study the mechanical mechanism of epithelium folding. While it is known that these wing discs form three folds in the hinge region during the third instar stage of development, the process by which these fold formations occur is not yet understood. However, due to technical progress in the process of wing disc cultivation, we can now observe the folding process *ex vivo*. A comparison of fixed wing discs to the cultured wing discs revealed that they both developed into similar shapes during the same developmental stages, which suggests that the wing discs can develop properly in the cultured condition.

By using the culture method and laser ablation based tension measurement, I found two distinct mechanisms involved in the formation of the two folds. The H/H fold is induced by locally decreased basal tension. Collagen IV is reduced in a stripe at the center of the fold, resulting in a reduction of mechanical tension in the basal cellular cortex of cells. Local expression of Matrix metalloproteinase II (MMP II), which reduces the ECM, results in basal tension release and ectopic folding. The H/P fold is induced by an increase of lateral tension in pre-fold cells. Pulsed accumulation of F-actin at the lateral side of pre-fold cells increased the lateral tension, driving cell shortening and folding.

Our research shows two new mechanical mechanisms of folding, neither of which involved apical constriction. Two different mechanisms generate similar

morphologies of neighboring folds. This implies that the mechanical processes shaping a tissue cannot be deduced from the tissue morphology alone. Decrease of basal tension and increase of lateral tension may therefore represent two important mechanisms driving the folding of epithelia in different organisms.

### 9.1 Apical constriction is not important in hinge fold formation

Previous studies have shown that apical constriction is an important mechanism for fold formation in various organisms, such as ventral furrow formation and neuronal tube formation in embryos (Haigo et al., 2003; Martin et al., 2009). In these models, pre-fold cells firstly narrow the apical area to get wedge shape which facilitate the fold formation. However, in the wing discs, the ratio of apical cross-section length of pre fold cells ( $l_a$ ), and apical basal height of pre fold cells ( $h$ ) is approximately 1:20. Based on this kind of tall columnar shape of pre-fold cells, even pre-fold cells in the wing disc undergo apical constriction, yet it is still not enough to deform the cell to a wedge shape and induce folding. To test whether pre fold cells undergo apical constriction during hinge fold formation in the wing disc. I firstly quantified apical cell area from the apical projection of cell mesh. The apical areas of folding cells are apparently decreased. While due to the geometric bias of apical projection of cell mesh in the curved wing disc surface, especially the wing disc obtaining 3D shape after folding, we are difficult to obtain the “real” apical cell area of fold cells after folding). Moreover, there is less geometric bias for the apical projection of cell mesh before folding, because the apical surface of the wing disc is relatively flat, which shows that the apical area of pre-fold cells did not change before folding (**Figure 10 A-E**), and pre fold cells also didn't elongate along the folding direction (**Figure 10 F-G**). I also quantified cell shape changes from the cross section of the cultured wing disc during the fold formation, such as the apical and basal indentations ( $d_a$  and  $d_b$ ), the average apical and basal cross-section length of cells inside the folds ( $l_a$  and  $l_b$ ), and the average apico-basal height ( $h$ ) of the tissue surrounding the folds. I found  $l_a$  was gradually increased in both fold cells following the cell invagination (**Figure 8**). This implied that not only did the fold

cells not undergo apical constriction, but they actually increased in apical area during the fold formation. Taken together, I conclude that apical constriction is not the mechanical mechanism for hinge fold formation in *Drosophila* wing disc.

## **9.2 Cell proliferation is also not important for the hinge fold formation**

As I introduced before, cell division causes a series of cell shape changes and cytoskeleton remodeling that could also affect the tissue morphogenesis. Mitosis has been found to play an active role in the epithelial invagination of the *Drosophila melanogaster* tracheal placode (Kondo and Hayashi, 2013). Moreover, differences in the rate of cell proliferation in the tissue may generate compression force resulting in folding (Miller et al., 1994b). In the wing discs, Mao and colleagues has reported that differential proliferation rates can generate global patterns of mechanical tension that orient tissue growth (Mao et al., 2013). Therefore, it was important to test whether cell proliferation is important for the hinge fold formation. Through observation, I found that the notum and wing pouch have similar proliferation rates (**Figure 11**). Therefore, hinge fold formation is not due to the compression forces generated by different cell proliferation rate between notum and pouch. Next, I test whether cell mitosis affect hinge fold formation itself. So, I temporarily blocked cell division in the wing disc by using a temperature-sensitive allele of *cdc2*, While the three hinge folds still proceeded to develop properly, similar to the development process in the control wing disc (**Figure 12**). So I concluded that the cell proliferation is not required for the hinge fold formation in *Drosophila* wing disc.

## **9.3 Basal reduction of surface tension in folding cells, associated with local ECM degradation, leads to basal expansion and H/H fold formation**

As previously discussed, neither apical constriction or cell proliferation is necessary for hinge fold formation in the wing disc, therefore some other

potential mechanism must be responsible for the folding in the wing disc. Previous studies into the mechanical mechanism of folding have historically focused on the apical side of tissue (Martin et al., 2009), while forces generated at the basal and lateral surfaces have remained largely unstudied. As we know, apical actomyosin networks generate the constriction force necessary to drive the apical constriction that contributes to many folding processes (Martin et al., 2009). In the wing disc, actomyosin has been found to enrich on the apical bonds of wing disc and is responsible for generating apical bond tension. Apical tension of cells in the wing disc can be measured using laser ablation, and the tension was estimated by monitoring the recoil velocity of two cell vertexes after laser ablating the single cell bonds (Landsberg et al., 2009). Here, I imaged wing disc from basal side. I also found actomyosin enriched on the basal bonds of wing discs (**Figure 13**). After conduction laser ablation on the basal bonds, using the same method as for apical bonds, I found that basal bonds have 3-5 fold higher tension than apical bonds in the pouch region of wing disc (**Figure 14 A-E**). This presents an explanation for the basal bending curvature and shape of the wing pouch.

Interestingly, I found the basal tension is decreased to the level of apical tension in the H/H fold cells during folding (**Figure 14 F-J**). This implied that the basal tension decrease may promote H/H fold formation. The next step was to attempt to find out why H/H fold cells have less basal tension during folding. The ECM is widely present on the basal side of the epithelial sheet. Integrins is the basal membrane protein which physically links the ECM into the cytoskeleton. Integrins coupled with the ECM is important for the transmission of force during many morphogenetic processes (Haigo and Bilder, 2011; He et al., 2010). I found that integrin and the ECM component Collagen IV, are decreased at the basal side of pre H/H fold cells compared with neighboring cells (**Figure 16**). When the ECM was removed via drug treatment in the wing disc, the wing disc bent over towards the apical side, the formed H/H fold was lost and the basal area of the wing disc largely increased compared with the condition before drug treatment (**Figure 17 A-C**). This is consistent with the fact that less ECM coupled with basal expansion of pre H/H fold cells in the wild type situation. Moreover, basal tension is significantly

decreased in the wing disc cells after removal of the ECM (**Figure 17 D-E**). That indicated that the ECM is necessary for basal tension generation in the wing disc. I therefore conclude that a reduction of the ECM leads to reduction of basal tension in pre H/H fold cells. Furthermore, local removal of the ECM by ectopic expression of MMP2 in a stripe of wing disc also decreases the basal tension and is sufficient to induce ectopic fold formation (**Figure 19**). Taken together, I conclude the local reduction of ECM triggers a local decrease of basal bonds tension, driving the relaxation of the basal cell bonds and H/H fold formation. This is an interesting finding, since essentially epithelial bends have been described at the apical surface, via apical constriction.

Previous study has shown the ECM can contribute to cell and tissue shape in epithelia (Daley and Yamada, 2013). Recent studies have shown that the ECM component of collagen regulates the mechanical properties of the basement membrane (Pastor-Pareja and Xu, 2011). In line with our research shown here, the authors also described that the highly ordered columnar cells were expanded laterally or flattened when collagen levels were reduced in the wing disc. These imply that type IV collagen within basement membrane provides a constricting force on tissues (Pastor-Pareja and Xu, 2011). Moreover, it has been found that laminin-dependent basal constriction is required for the folding of the zebrafish embryonic brain. In laminin mutants, basal constriction does not occur, indicating an active role for the basement membrane in this process (Gutzman et al., 2008).

In my study, I found basal membrane ECM not only controls cell and tissue shape changes but also controls the basal force generation; less collagen decreasing the basal tension in pre fold cells results in basal expansion, driving H/H hinge fold formation. However, it is still unclear how ECM controls the basal tension generation. In general, tension generation is dependent on the actomyosin. Actomyosin contractions can generate forces on the underlying ECM substratum by pulling on integrins, and these forces can be transmitted to neighboring cells via deformation of the elastic ECM meshwork (Sen et al., 2009). In addition, the forces generated by the actomyosin

network result in many cellular behaviors, such as migration or cell deformation, all of which need cells to couple with the plasma membrane or the ECM via adhesion complexes. Based on these behaviors, I was curious about the role of ECM and actomyosin in the basal tension generation. So I inhibited the activity of F-actin or myosin via drug treatment in the wing disc. However, the basal tension decreased under these conditions, but not as significantly as when ECM was removed (**Figure 18**). The wing disc did not show basal expansion and did not lose fold after inhibition of the activity of F-actin or myosin as well. This indicated basal tension generation may partly depend on the F-actin and myosin, and the ECM may play a more complex role in the basal tension generation. The ECM is likely to modulate basal tension through its interaction with integrins in the basal cell membrane and subsequently regulate cytoskeletal function. The ECM is a dynamic network which may also generate tension itself at the basal membrane by assembling different components (Daley and Yamada, 2013). Further studies on how the ECM components are added, maintained and removed from basement membranes, and which signaling pathway control these changes will be especially intriguing.

#### **9.4 Pulsed accumulated F-actin in the lateral surface of pre H/P fold cells leads to increased tension along their lateral edges, driving H/P fold formation**

While the H/P fold forms only shortly after the H/H fold, unlike the H/H fold formation, the H/P fold cells did not show less ECM and integrin distribution at the basal membrane before and during folding (**Figure 16**). Additionally, pre H/P fold cells did not decrease the basal tension compared with neighboring cells (**Figure 20**). The implication is that pre H/P fold cells have no different mechanical property at the basal side compared with neighboring cells. The H/P and H/H folds may form by different mechanisms. Genetic manipulation of the myosin level in the wing disc showed myosin plays a more important role in the H/P fold formation compared to the H/H fold (**Figure 9**). So I observed the dynamic behavior of actomyosin in the pre H/P fold cells from

the 3D level. As we know, the motor protein myosin works along with the F-actin to generate forces by hydrolyzing ATP. Because the myosin protein is much smaller and moves faster than F-actin, it is easier to capture dynamic F-actin under microscopic scanning. Therefore, in my work, I only show the F-actin dynamic movement. Strikingly, Utr-GFP imaging revealed a highly dynamic accumulation of F-actin along the lateral interfaces of H/P fold cells, as well as pulsatile contractions of their apical-basal height. This was not the case for cells in the H/H fold. I quantified the correlation between F-actin intensity and changes of cell height at pre H/P fold cells, and found a negative correlation, indicating that an increase in lateral actin is closely followed by a decrease in cell height. More and more pre H/P fold cells undergo the pulsatile contractions along their apical-basal axis. Over time, H/P fold cell height decreased more significantly due to the neighboring cells pulling down on each other at the apical surface, after which a group of pre-fold cells decrease cell height over longer time scales, indicating a ratcheting mechanism similar to what has been previously described for the apical constriction of cells (Martin et al., 2009). However, we still do not know the cause of the ratchet formation. It could be due to the mechanical limitation of neighboring cells, or due to the contribution of some unknown pathways. Furthermore, laser ablation experiments of lateral cell edges showed that increased lateral actin accumulation in H/P fold cells leads to increased tension along their lateral edges (**Figure 23**). Thus, I conclude that increased lateral actin accumulation in H/P fold cells leads to increased tension along their lateral edges, driving cell shortening and the formation of the H/P fold.

In silico simulations of ventral furrow formation based on a computational vertex model, indicate that active cell shortening can induce deep epithelial invagination (Conte et al., 2008). Furthermore, the biomechanical analysis confirmed that mesodermal cell shortening forces are the primary cause for the furrow and have strong impact on the furrow depth (Conte et al., 2009). However, the molecular and cellular mechanisms for cell shortening remain to be elucidated. A recent study described that during the gastrulation of ascidian embryos, after actomyosin dependent of apical constriction, Myosin II relocalizes to the basolateral membrane, where it promotes cell shortening

and deepened endodermal invagination (Sherrard et al., 2010). In addition, Monier recently found that apoptotic cells, displaying a highly dynamic apico-basal myosin II cable, exert a transient pulling force upon the apical surface of the epithelium, which drives epithelium folding in the *Drosophila* leg disc (Monier et al., 2015). In my study, I found that dynamic F-actin accumulated along the lateral edge of pre H/P fold cells drives fold formation without cell death. H/P fold cells also displayed a highly dynamic accumulation of F-actin at their apical and basal areas that correlated with apical and basal cell constriction, respectively. These constrictions, however, were not obviously correlated with changes in cell height (**Figure 24**). But this indicated that H/P fold cells display a dynamic cytoskeleton structure. A recent paper by Lomakin et al has suggested that actomyosin accumulation in one part of a cell during migration causes depletion in another (Lomakin et al., 2015). In H/P fold cells, dynamic F-actin accumulation seems to go through the lateral side by running from apical to basal sides of cells or from basal to the apical side of cells cyclically. When lateral F-actin accumulation at the lateral edge of the cells results in cell shortening, and cell apical or basal F-actin flow goes away, the cells increase in apical or basal area to maintain constant volume. In contrast, when apical surface accumulated F-actin results in apical constriction, basal or lateral accumulated F-actin may go away to release the cell height and basal area.

Local relaxation of the cellular cortex is also important to epithelium morphogenesis. For example, during zebrafish hindbrain development, epithelial relaxation induced by reduced levels of Myosin II, is required for ventricular lumen expansion (Gutzman and Sive, 2010). These results suggest that actomyosin contractility needs to be balanced among apical, lateral and basal membranes, and leads the cell shape changes as well as epithelial tissue deformation. However, how spatio-temporal regulating F-actin accumulation at the different 3D regions of the cells control coordinated cell shape changes during folding requires further research in order to be better understood, and the role of ratchet formation in stabilizing fold cell shape during H/P fold formation should be considered in 3D level of the cells.

Furthermore, we know shrinkage of apical area by apical constriction needs an actomyosin network attachment with the adherens junctions to generate constriction force (Martin et al., 2009). However, it is yet unknown exactly how F-actin accumulation at the lateral and basal side of the attached plasma membranes generates the constriction force necessary to deform the cell. It will be interesting to find out what membrane associated proteins are necessary for F-actin to attach with in order to change cell shape.

### **9.5 The difference between H/H and H/P fold formation**

H/H and H/P folds are formed at almost the same time in the hinge region of wing discs. They have indistinguishable morphologies in the final shape. However, the process of their formation is largely different. First, before fold formation, pre H/H fold cells have a wider basal area than neighboring cells, that is correlated with less ECM and integrin at the basal side. Basal tension of pre H/H fold cells is also lower than neighboring cells. However, H/P pre fold cells have similar basal area and no difference in the level of ECM and integrin at the basal side compared with neighboring cells. Basal tension of H/P pre fold cells is similar with neighboring cells. While during fold formation, pulsed F-actin accumulation at the lateral surface generated lateral tension to drive pulsed shrinking of cell height. This was observed in H/P fold cells, but not in the H/H fold cells. This suggested two different mechanical mechanisms in the two neighboring folds formation. Interestingly, two fundamentally different mechanisms generate similar morphologies of neighboring folds. This implies that the mechanical processes shaping a tissue cannot be deduced from the tissue morphology alone.

### **9.6 The potential role of the Wingless signaling pathway during the hinge fold formation**

The Wingless (Wg) signaling pathway is required for the specification, growth, patterning, and morphogenesis of the wing disc (Sharma and Chopra, 1976). Within the wing hinge, *wg* is expressed in two concentric rings. It is required for the hinge development. Three hinge folds are formed parallel with the

inner ring of *wg* expression in the hinge region at early third instar. Wingless signal transduction has been shown to play a cell-autonomous role in promoting and maintaining the columnar shape of wing disc cells in the wing pouch region (Widmann and Dahmann, 2009b). However, the roles of Wg signaling in cell shape changes in the hinge region and whether Wg plays a role in the hinge fold formation have not been studied. Here, I genetically manipulate Wg signaling to observe the morphology changes in the hinge fold cells. We know Wg is required for the hinge development and a strong reduction of *wg* gene activity in the wing hinge leads to loss of distal hinge structures (Morata and Lawrence, 1977; Sharma and Chopra, 1976). So I mildly downregulated *wg* signaling by expressing *wg*-RNAi in the posterior compartment. This results in decreasing integrin at the basal side of the cells (**Figure 26 B**). When we reduced Wg signal transduction by expressing TCF<sup>DN</sup> at the *dpp* expression strip, it resulted in cell shortening and ectopic fold formation in the pouch region (**Figure 26 C**), which is the same observation as previous studies (Widmann and Dahmann, 2009b), while decreasing Wg signaling or Wg signal transduction in the hinge region did not affect hinge fold formation. In contrast, upregulation of Wg signaling or activation of Wg signal transduction in the H/H fold region decreases cell basal area, increases the level of integrin and inhibits H/H fold formation but not H/P fold formation (**Figure 27**). This is consistent with wider basal area and less integrin in pre H/H fold cells during the formation of the H/H fold (**Figure 16**). Even overexpression of Wg in the hinge region induces overgrowth (Neumann and Cohen, 1996), but we have found cell proliferation is not important for hinge fold formation (**Figure 12**). So overexpression Wg in hinge region inhibiting H/H fold formation is not due to the tissue over growth in this case. Moreover, I found the level of F-actin is not affected by regulating Wg, but integrin levels are significantly affected by regulating Wg. Therefore, we surmised that Wg induced cell shape change by regulating integrin levels. Furthermore, Wg is important for specifying cell fates within the wing disc. During early larval development, loss of Wg signaling transforms the wing structures into notum structures. Conversely, ectopic expression of Wg in the notum can result in the formation of wing-like structures (Klein, 2001). In contrast with its effects in the wing blade, Cohen has shown that Wg,

as a mitogen, affects cell proliferation, but not specific cell fates in the hinge region (Neumann and Cohen, 1996). While overexpression of Wg in the H/H fold cells inhibits fold formation, this may not be due to cell fate transformation, rather, it may be accomplished by regulating integrin levels to change cell shape. Therefore, we concluded that H/H fold formation needs to maintain low levels of Wg signaling activity at the fold cells. However, downregulation of Wg signaling in the hinge region did not inhibit hinge fold formation, which suggests the upstream signaling pathway for regulating hinge fold formation is more complicated and needs to be explored further.

### 9.7 Two distinct mechanisms drive H/H and H/P fold formation

Through my research, I revealed the process of H/H and H/P fold formation in the wing disc and found that H/H and H/P fold formations are driven by two distinct mechanisms (**Figure 28**). In previous studies, apical constriction was thought to be the main mechanical mechanism of epithelium folding. While, in the wing disc, we found the two hinge fold formations are independent of the apical constriction. First, wing disc cells have a super columnar shape with the ratio of apical cross-section length of pre fold cells ( $l_a$ ) and apical basal height of pre fold cells ( $h$ ) approximately 1:20, such that apical constriction cannot cause significant cell shape change in these cells. Second, we found basal tension is 3-5 fold higher than apical tension in these columnar cells in general, and basal tension depends on ECM. Because of this, we suggested two new mechanisms of epithelial fold formation. In H/H fold formation, a locally-defined decrease in basal tension, associated with local reduction of ECM density, leads to basal cell expansion in the H/H pre fold cells and promotes folding. While in the H/P fold formation, a lateral increase of surface tension associated with actin flows and pulsatile contractions, leads to a local reduction of tissue height in the H/P fold cells and promotes fold formation. Cell shortening and basal expansion is also required for the folding of the zebrafish embryonic brain (Gutzman et al., 2008). Basal decrease of tension and lateral increase of tension may therefore represent two important mechanisms driving the folding of epithelia in different organisms.

**Figure 28. The model of H/H and H/P fold formation**

Top. Scheme of a cross-sectional view of an unfolded epithelium. Note that basal tension is greater than apical tension. Basal tension depends on ECM.

The H/H fold and the H/P fold form through two distinct mechanisms.

Left. Prior to H/H fold formation (pre-fold) a local reduction of ECM leads to a release of basal tension. The decrease of basal tension results in the basal expansion of the pre-fold cells; cells adopt a wedge-like shape that drives fold formation.

Right. Prior and during H/P fold formation, fluctuations of F-actin accumulation at lateral cell edges leads to increased lateral tension driving pulsatile and ratcheted cell height contractions. Since apical tension is lower than basal tension, cell shortening leads to apical invagination and fold formation.

## 9.8 Future perspectives

I have observed the process of hinge fold formation in cultured wing discs and quantified the cell shape changes from cross-sections perpendicular to the fold direction by manual segmentation of the apical and basal tissue outlines. I also projected apical or basal cell mesh to observe apical or basal area changes. However, because of the geometrical bias of projection in the folded region after apical invagination, the real apical area and basal area is not correctly shown in the 2D projection of cell mesh. Therefore, a 3D reconstruction of the wing disc is required. To do this, we used a computational method of 3D reconstruction of the wing disc, which was developed by our collaborator David Breen (Breen et al., 2012). In this method, 2D projection cell meshes of the apical and basal surfaces of the wing disc are reconstructed to a 3D shape based on confocal image stacks. Apical and basal cross sectional cell area can be retrieved and visualized in 3D. I have suggested that H/H fold formation is driven by basal expansion, and that H/P folding is driven by cell shortening along the apical-basal axis, however, how cells undergo coordinated shape change to transform into wedge-like shapes during fold formation remains unclear without doing 3D reconstruction of cells over time. To explore this question, a 4D reconstruction of wing disc cells is required in the future. A 4D reconstruction tool called Embryo Development Geometry Explorer (EDGE) has been used to study *Drosophila* ventral furrow formation (Gelbart et al., 2012). This tool is optimized for analyzing the fast dynamics of whole-cell shape changes in three spatial dimensions plus time in planar sheets of cells. This tool can be utilized to quantify rapid whole-cell shape changes, over time, during hinge fold formation. While high quality Z-stack images of wing disc cells are necessary for 4D reconstructions. In future, it is important to improve the resolution of live imaging and decrease the photobleaching of wing disc during the imaging.

In this study, I found that a basal decrease of tension drives H/H fold formation, and basal tension depends on ECM. How ECM regulates basal tension is not known, and how interaction between ECM and actomyosin driving the force will be interesting to explore in the future. The pre H/H fold

cells have less ECM at the basal side compared with neighboring cells (**Figure 16**). Decreasing the ECM in the pouch region is sufficient to decrease the basal tension and drive ectopic fold formation (**Figure 19**). However, we do not know whether an increase of ECM in the H/H fold cells could inhibit fold formation. Since Collagen IV, a main component of the ECM, is secreted in the fat body in the *Drosophila* larvae and assembles at the basal side of wing disc (Pastor-Pareja and Xu, 2011), it is experimentally difficult to increase the ECM level in the H/H fold cells. In the future we can attempt to discover a method to increase ECM levels in the H/H fold cells. For example, we can try to culture the wing disc in the 3D collagen gel polymerized chamber (Matsumoto, 2010).

Recently, optogenetics has been used to control apical constriction during ventral furrow formation in *Drosophila* embryo (Guglielmi et al., 2015). Optogenetics is an innovative technique for optical control of cells, and has offered unique methods to manipulate cellular activity. Optogenetics provides millisecond-scale temporal precision, locally controlling actin polymerization so that we can inhibit or activate fast biological processing immediately. Based on this method, we can inhibit the lateral F-actin dynamic in the H/P fold cells during the folding process, in order to study how the spatial range of force integration between cells drives folding. We also can induce F-actin accumulation at the lateral surface of pouch cells, to see whether it is enough to induce ectopic fold formation.

Moreover, even though we have found the potential role of Wg signaling pathways in the hinge fold formation, it is still not clear which upstream genes directly control fold formation. In the future, it will be interesting to search for the genes which control less ECM levels or dynamic lateral F-actin activity in the pre-fold cells. For example, we can focus on the genes which are specifically expressed in the fold cells during fold formation, genes which encode the protein of ECM components and genes which control F-actin assembly. In the end, it will be very interesting to understand how this pattern of gene activities is converted into a pattern of cell mechanics and how changes in cell mechanics alter cell and tissue morphologies in general.

## 10 ACKNOWLEDGEMENTS

I am extremely grateful to my supervisor Prof. Dr. Christian Dahmann for offering me the PhD position so that I have chance to study and stay with my family in Dresden. Especially, I am very thankful to him for providing this excellent and interesting project. His expertise, generous guidance makes this project going smoothly and digging deeply.

I am also thankful to Prof. Dr. Frank Jülicher for his great advice and valuable discussion on this project.

Moreover, I would like to thank our collaborator Dr. Guillaume Salbreux and Dr. Silvanus Alt, who work on the 3D vertex model of this project. Their theory not only inspired me the direction of experiment but also gave a reliable theory supports. Especially, I would like to thank Dr. Silvanus Alt for helping me do some data analysis by Matlab.

I thank Dr. Natalie Dye and Dr. Suzanne Eaton for sharing the protocol for cultivating wing discs and C. Blasse and E. W. Myers for providing access to PreMosa before publication.

I thank Prof. Dr. Stephan Grill for kindly providing access to their laser ablation device.

I thank my TAC members Prof. Dr. Elisabeth Knust and Prof. Dr. Frank Jülicher that provided a valuable advice on my project.

Further, I would like to express many gratitude to the former lab members Daiki Umetsu, Katrin Rudolf, Katharina Landsberg and Franziska Aurich, and the current lab members Marcus Michel, Sonja Purkert, Lisa Bialas, Cagdas Göktas, Annegret, Sarah Poetschke and Veronika Faltin offer all the help not only on my PhD work but also on the normal life as a foreigner here. Thanks all of them offer me their friendship.

Last but not least, I thank my husband Yan Ge, who did a big sacrifice in his job to move with me, and give me a lovely home here. Thank him to give me all unlimited support and understanding during my PhD period.

Erklärung gemäß § 5.5 der Promotionsordnung

Hiermit versichere ich, dass ich die vorliegende Arbeit ohne unzulässige Hilfe Dritter und ohne Benutzung anderer als der angegebenen Hilfsmittel angefertigt habe; die aus fremden Quellen direkt oder indirekt übernommenen Gedanken sind als solche kenntlich gemacht. Die Arbeit wurde bisher weder im Inland noch im Ausland in gleicher oder ähnlicher Form einer anderen Prüfungsbehörde vorgelegt.

Ich erkläre hiermit, dass ich die Promotionsordnung der Fakultät für Mathematik und Naturwissenschaften der Technischen Universität Dresden anerkenne.
