Abstract

Background: Muscle-invasive bladder cancer (MIBC) is a heterogeneous disease, and gene expression profiling has identified several molecular subtypes with distinct biological and clinicopathological characteristics. While MIBC subtyping has primarily been based on messenger RNA (mRNA), long non-coding RNAs (lncRNAs) may provide additional resolution.

Methods: lncRNA expression was quantified from microarray data of a MIBC cohort treated with neoadjuvant chemotherapy (NAC) and radical cystectomy (RC) ($n = 223$). Unsupervised consensus clustering of highly variant lncRNAs identified a four-cluster solution, which was characterized using a panel of MIBC biomarkers, regulon activity profiles, gene signatures, and survival analysis. The four-cluster solution was confirmed in The Cancer Genome Atlas (TCGA) cohort ($n = 405$). A single-sample genomic classifier (GC) was trained using ridge-penalized logistic regression and validated in two independent cohorts ($n = 255$ and $n = 94$).

Results: NAC and TCGA cohorts both contained an lncRNA cluster (LC3) with favorable prognosis that was enriched with tumors of the luminal-papillary (LP) subtype. In both cohorts, patients with LP tumors in LC3 (LPL-C3) were younger and had organ-confined, node-negative disease. The LPL-C3 tumors had enhanced *FGFR3*, *SHH*, and wild-type p53 pathway activity. In the TCGA cohort, LPL-C3 tumors were enriched for *FGFR3* mutations and depleted for *TP53* and *RB1* mutations. A GC trained to identify these LPL-C3 patients showed robust performance in two validation cohorts.

Conclusions: Using lncRNA expression profiles, we identified a biologically distinct subgroup of luminal-papillary MIBC with a favorable prognosis. These data suggest that lncRNAs provide additional information for higher-resolution subtyping, potentially improving precision patient management.

Background

Bladder cancer has a global annual incidence of 430,000 patients, making it the fourth and tenth most common malignancy in men and women, respectively [1]. Approximately 25% of patients present with muscle-invasive bladder cancer (MIBC). The recommended treatment option

for MIBC is neoadjuvant cisplatin-based chemotherapy (NAC) followed by pelvic lymph node dissection and radical cystectomy (RC) [2, 3]. Despite this aggressive treatment regimen, the 5-year overall survival (OS) is only approximately 55% from the time of surgery.

In recent years, gene expression profiling has revealed that MIBC is a heterogeneous disease; like breast cancer, it can be stratified into different molecular subtypes [4–7]. At the highest level, there is a division into basal and luminal subtypes, with different models providing additional subdivisions [8, 9]. Stratifying MIBC by molecular subtype

has potential clinical value in terms of predicting both outcome and response to treatment, such as NAC or immunotherapy [10–12].

While most MIBC studies to date have exclusively used messenger RNA (mRNA) expression to differentiate molecular subtypes, the mammalian transcriptome is comprised of a diverse range of coding (mRNA) and non-coding RNAs. Long non-coding RNAs (lncRNAs) are mRNA-like transcripts that range in length from 200 nucleotides to over 100 kilobases and lack open reading frames [13]. They represent a significant fraction of the transcriptome, and, while it is unclear how many lncRNAs have biological function, their expression patterns can be specific to a particular biological or disease state [14, 15]. In the TCGA study, the lncRNA transcriptome divided the luminal-papillary subtype into two groups with distinct prognosis [12]. These findings suggest that lncRNA expression may offer additional resolution of molecular subtypes, potentially revealing additional prognostic information not captured by mRNA profiling.

In the present study, we aimed to expand these initial TCGA findings, further exploring the utility of lncRNA expression profiling for finer-grained molecular subtyping of MIBC.

Methods

Patient populations and expression data

For the present study, we analyzed four MIBC patient cohorts (Table 1). (1) NAC cohort: We compiled a cohort of 223 MIBC patients from seven institutions who had received neoadjuvant/induction chemotherapy followed by radical cystectomy (RC) for cT2-4aN0-3M0 urothelial carcinoma of the bladder [11]. Whole transcriptome profiling had previously been performed on formalin-fixed, paraffin-embedded (FFPE), pre-treatment tissue samples from transurethral bladder tumor resection (TURBT) in a Clinical Laboratory Improvement Amendments (CLIA)-certified laboratory (Decipher Biosciences, Inc., San Diego, CA) [16]. (2) TCGA cohort: RNA-seq data of 405 MIBC patients treated with RC in the absence of NAC was publicly available and previously analyzed by The Cancer Genome Atlas (TCGA) Research Network [12]. (3) PCC cohort: A prospective commercial cohort (PCC) consisting of the de-identified and anonymized gene expression profiles of 255 MIBC patients from the clinical use of the Decipher Bladder TURBT test that were available in the Decipher GRID registry (NCT02609269). Pathological staging and clinical outcome data were not available for this cohort. (4) UTSW cohort: The UT Southwestern (UTSW) cohort consisting of 94 MIBC patients from the UT Southwestern Medical Center who underwent RC without neoadjuvant therapy [17]. In this cohort, whole transcriptome profiling was performed on RC tissue samples. The NAC, PCC, and UTSW cohorts were all profiled on the GeneChip Human

Exon 1.0 ST Array (Thermo Fisher, Carlsbad, CA). The lymphocyte and normal bladder expression datasets were downloaded directly from the GTEx Portal (<https://gtexportal.org/>).

Unsupervised clustering using lncRNAs

For unsupervised clustering analysis (R package ConsensusClusterPlus), the normalized gene expression data for $n = 223$ samples (NAC cohort) was pre-processed by multi-analysis distance sampling (R package MADS) to identify highly variant lncRNA genes. We assessed unsupervised consensus clustering with sets of between 250 and 1500 variant lncRNAs. After critically evaluating outputs from ConsensusClusterPlus (tracking plots, delta plots, CDF plots), we judged that the 750 lncRNA four-cluster solution was the most appropriate and informative. The expression clustering analysis was done by a consensus partitioning around medoids (PAM) approach, using Pearson correlations, and 10,000 iterations with a 0.95 random fraction of lncRNAs in each iteration. We repeated this process with log-transformed, RNA-seq gene expression data (TCGA cohort) for $n = 405$ samples to see whether clustering of our *de novo* selected lncRNA genes would identify lncRNA clusters that were similar to those identified by the TCGA analysis [12]. We determined concordance of this cluster solution with the published lncRNA cluster solution using Cohen's kappa statistic.

Classification of tumors among molecular mRNA subtypes

We generated a classifier that was based on the published TCGA 2017 mRNA subtypes [12], to classify tumors from the NAC, PCC, and UTSW cohorts into basal/squamous, luminal, luminal-infiltrated, luminal-papillary, and neuronal mRNA subtypes. We introduced an additional category, "unknown," to provide a bin for tumors that did not fit the aforementioned subtyping structure. Furthermore, we applied the recently released consensus molecular classification by The Bladder Cancer Molecular Taxonomy Group to classify tumors from all four cohorts into six consensus mRNA subtypes: basal/squamous, luminal-papillary, luminal non-specified, luminal unstable, stroma-rich, and neuroendocrine-like [18].

Regulon analysis of lncRNA clusters

Regulon analysis involves calculations that transform a cohort's gene expression data into a functional readout that can inform on biological state [19, 20]. An initial step reconstructs regulatory units, each of which consists of a regulator, i.e., a gene whose product induces and/or represses a set of target genes, which we call a "regulon." A second step calculates the activity profile of a regulon across a cohort. As demonstrated for breast cancer [19], and in the TCGA MIBC study [12], subsequent steps may use activity profiles as a molecular covariate to

segregate clinical subtypes. In the work reported here, regulon activity profiles for both FGFR3 and SHH segregated FGFR3 and TP53 mutations, and the LPL-C3 tumors.

We used R package RTN v2.7.1 to calculate a transcriptional regulatory network from RSEM RNA-seq data for the TCGA-BLCA discovery cohort, as in Robertson et al. [12]. We used a set of 26 regulators: the 23 from TCGA work (*AR*, *EGFR*, *ERBB2*, *ERBB3*, *ESR1*, *ESR2*, *FGFR1*, *FGFR3*, *FOXA1*, *FOXM1*, *GATA3*, *GATA6*, *HIF1A*, *KLF4*, *PGR*, *PPARG*, *RARA*, *RARB*, *RARG*, *RXRA*, *RXRB*, *STAT3*, and *TP63*), with *RBI*, *SHH*, and *TP53* added. For calculating regulon activity profiles across a cohort, we required a regulon to have at least 15 positive and 15 negative targets.

We used regulon target genes from the discovery cohort to calculate regulon activities in the NAC validation cohort. For each regulon, we performed enrichment tests (Fisher's exact tests) to identify whether lncRNA clusters were enriched with samples of high or low regulon activity. We used RTNsurvival v1.6.0 and TCGA-BLCA mutation data [12] to generate oncoprint-like diagrams that showed, for the TCGA cohort, how regulon activity segregated TP53 and FGFR3 mutations, and LPL-C3 and LPL-Other samples.

Gene expression analysis

We created heatmaps and boxplots to visualize differences between tumors from lncRNA and mRNA subtypes, in

the expression of individual genes, gene signatures [5], and hallmark gene sets (from the molecular signature database hallmark gene set collection, MSigDB [21]). Hedgehog signaling activity was quantified by a signature based on target genes (*SHH*, *BMP4*, *BMP5*, *ID1*, *ID2*, *ID3*, *ID4*) as mentioned by Shin et al. [22]. *FGFR3* signaling was assessed by a gene signature from Sjö Dahl et al. [5]. Sample purity was calculated by the ABSOLUTE and ESTIMATE algorithms for the TCGA and NAC cohorts, respectively [23, 24]. Median fold changes (FC) and p values (using two-sided Wilcoxon rank-sum tests) were calculated for differential gene expression analyses. To identify lncRNAs enriched in immune cells, we filtered the GTEx datasets for lncRNAs with at least five median transcripts per million (TPM) higher expression in lymphocytes compared to a normal bladder. The candidate list of lncRNAs was compared to the 750 lncRNAs used for consensus clustering to generate a candidate list of immune-associated lncRNAs used for the clustering. The Immune190 signature score calculations have been previously described [25].

Statistical analyses

Statistical analyses were performed using R statistical software (R Foundation for Statistical Computing, Vienna, Austria). In the NAC and TCGA cohorts, patient and tumor characteristics were compared between subgroups by Fisher's exact tests and two-sided Wilcoxon rank-sum tests. p values for boxplot figures were determined by comparing LPL-C3 with LPL-other tumors by Wilcoxon rank-sum tests. The primary endpoint for the survival analysis was overall survival (OS). OS was calculated as the date of the most recent TURBT (NAC and PCC cohorts) or RC (TCGA and UTSW cohorts) till date of death from any cause. Patients who were lost to follow-up were censored at the date of last contact. The Kaplan-Meier method was used to estimate the statistical significance of differences between survival curves for patients of different molecular subtypes, using the log-rank test. After checking the proportional hazard assumption based on Schoenfeld residuals, we used multivariate Cox proportional hazard models to demonstrate the relationship of the genomic classifier's predicted subtype with OS, adjusting for clinical variables, including age, sex, and stage.

Discovery and validation of a genomic classifier

The NAC cohort was used to train a genomic classifier (GC) to predict luminal-papillary MIBC patients that had favorable prognosis (OS), as identified by the lncRNA clustering (LPL-C3). To make the model applicable to several platforms, we selected genes that were present in both the Illumina HiSeq platform (TCGA cohort) and Affymetrix Human Exon 1.0 ST Array (NAC, PCC, and UTSW cohorts) as the initial gene list (25,942 genes). Using this

gene list, the selection of genes for the GC was based on an overlap of gene sets that were created by differential gene expression analyses (median FC < -0.06 or > 0.1 , $p < 0.001$), in which we compared lncRNA clusters and mRNA subtypes. This resulted in a list of 69 candidate genes. The final gene set included 65 genes after removing highly abundant mitochondrial transcripts (seven genes) and adding three genes enriched in LPL-C3, determined from heatmaps generated in the study (*SHH*, *BMP5*, and *FGFR3*) (Additional file 1: Table S1). Next, we trained a 10-fold cross-validated, ridge-penalized logistic regression model (R package glmnet) consisting of 36 coefficients to predict LPL-C3 MIBC (Additional file 1: Table S1). This model was applied to RNA-seq data (TCGA) using quantile normalization. For the 65 genes, expression values from RNA-seq were normalized by quantile-quantile matching with the expression values in our training cohort (NAC) as implemented in R package preprocessCore. We used the R package OptimalCutpoints to select the optimal probability threshold (P_t), corresponding to the maximal specificity for identifying LPL-C3 MIBC patients in both NAC and TCGA cohorts. Finally, we selected a probability threshold (P_t) of 0.43, corresponding to a 98–68% specificity-sensitivity combination in the NAC cohort and a 96–55% specificity-sensitivity combination in TCGA cohort. After training and testing of the GC in NAC and TCGA cohorts, the classifier was locked for further independent external validation in the PCC and UTSW cohorts.

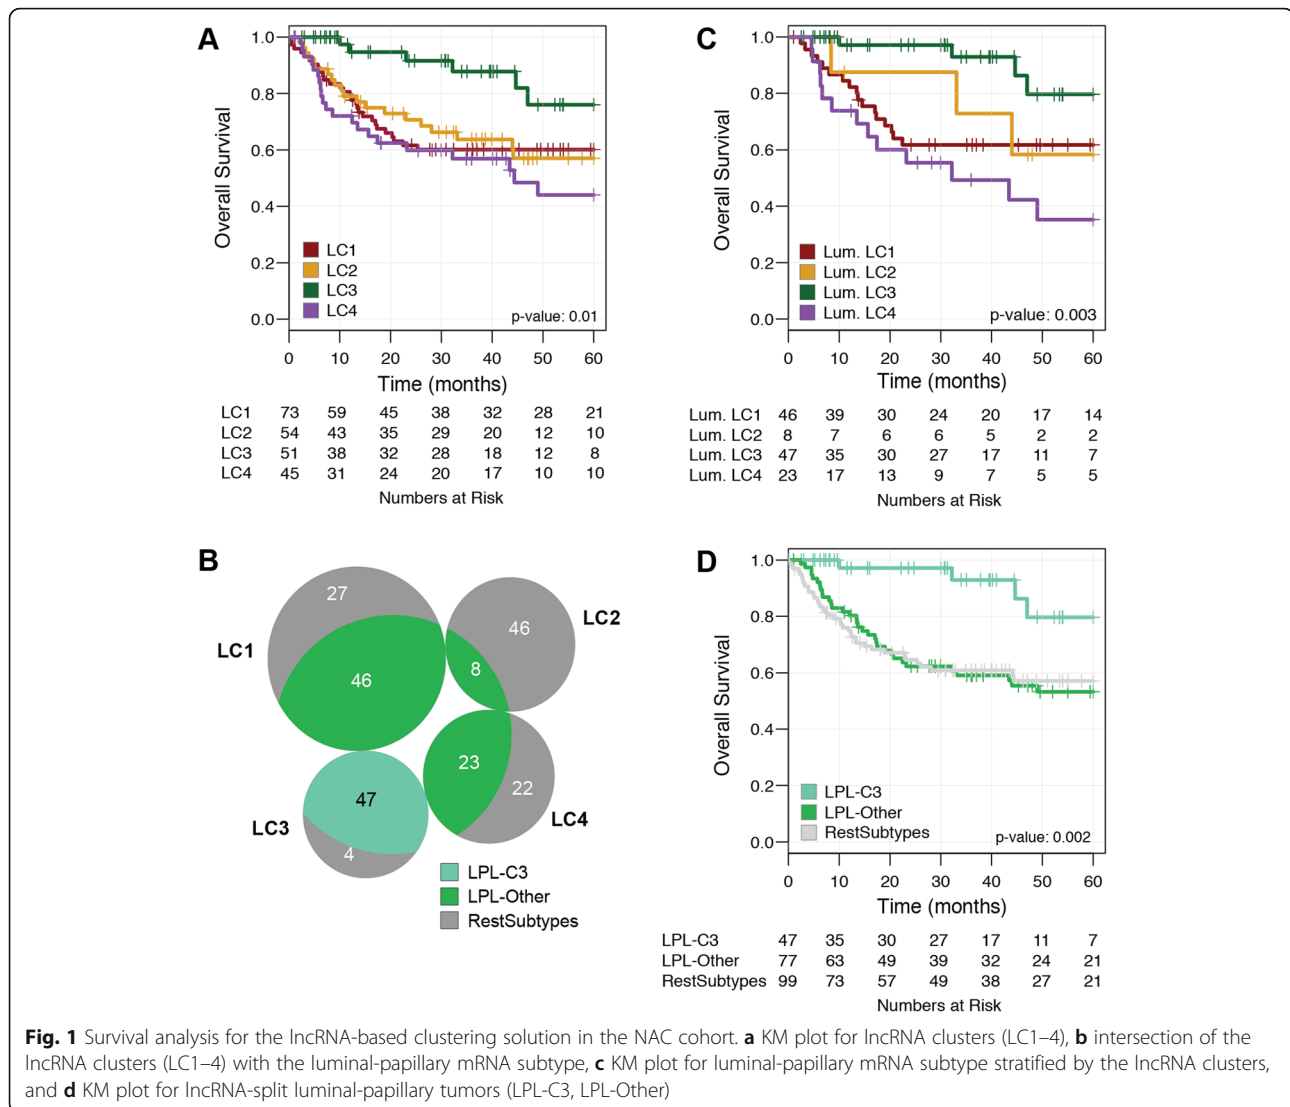

Results

lncRNA expression profiling subdivides the luminal-papillary mRNA subtype

To explore the lncRNA expression landscape of MIBC, we downloaded a microarray-based cohort of 223 bladder cancer TURBT samples treated with NAC and RC (NAC cohort). Unsupervised consensus clustering of 750 of the most highly variant lncRNAs resulted in a robust four-cluster consensus solution (Additional file 2: Figure S1). Survival analysis of the lncRNA-based consensus clusters (LC1–4) revealed that LC3 had significantly better prognosis than clusters LC1, LC2, and LC4 ($p = 0.01$) (Fig. 1a).

To assign the tumors in the NAC cohort to TCGA 2017 mRNA subtypes (luminal-papillary, luminal, luminal-infiltrated, basal squamous and neuronal), we applied our single-sample classifier (Methods), which revealed that these tumors were enriched for basal/squamous (33%) and luminal-papillary (54%) subtypes (Additional file 2: Figure S2a). Survival analysis showed that patients with luminal-papillary tumors had better outcomes than the other subtypes (Additional file 2: Figure S2b).

Comparing our lncRNA four-cluster solution and the classifier assigned TCGA subtypes, we found LC2 was strongly enriched (72%, 39/54) for tumors of the basal/

squamous subtype, whereas LC1, LC3, and LC4 contained only 23%, 4%, and 33% basal/squamous tumors, respectively ($p < 0.001$). Conversely, luminal-papillary tumors were enriched in LC3 (92%, 47/51) but were also present in LC1 (63%) and LC4 (51%) clusters ($p < 0.001$) (Fig. 1b). Considering only the luminal-papillary subtype ($n = 124$), we found patients in LC3 (38%) had favorable outcomes compared to other luminal-papillary tumors ($p = 0.003$; Fig. 1c, d), whereas stratifying the basal-squamous subtype by lncRNA clusters did not reveal differences in outcome ($p = 0.66$; Additional file 2: Figure S3). Given the enrichment of luminal-papillary tumors in LC3, we named this group of patients “Luminal-Papillary lncRNA Cluster 3 (LPL-C3),” and the other luminal-papillary tumors as “LPL-Other.”

Next, we repeated the consensus clustering in the TCGA cohort ($n = 405$) using the lncRNAs that were consistent between the array and RNA-seq platforms

(739/750). This resulted in a four-cluster consensus solution that was substantially concordant with the published TCGA lncRNA results [12] ($\kappa = 0.77$, $p < 0.001$, Additional file 1: Table S2). As in the NAC cohort, we identified a distinct lncRNA cluster (LC3) enriched in luminal-papillary tumors (74/88 patients, $p < 0.001$) with favorable prognosis ($p = 0.022$) (Additional file 2: Figure S4a-c and Additional file 1: Table S3).

The biological characteristics of LPL-C3 tumors are consistent with less-aggressive disease

To investigate the biological differences between the LPL-C3 and LPL-Other tumors, we generated a heatmap of genes associated with MIBC subtypes for both the NAC and TCGA cohorts (Fig. 2a, b). Many luminal markers (i.e., *PPARG*, *FOXA1*, and *GATA3*) were expressed at significantly higher levels in LPL-C3 than in LPL-Other tumors (Additional file 2: Figure S5A-C).

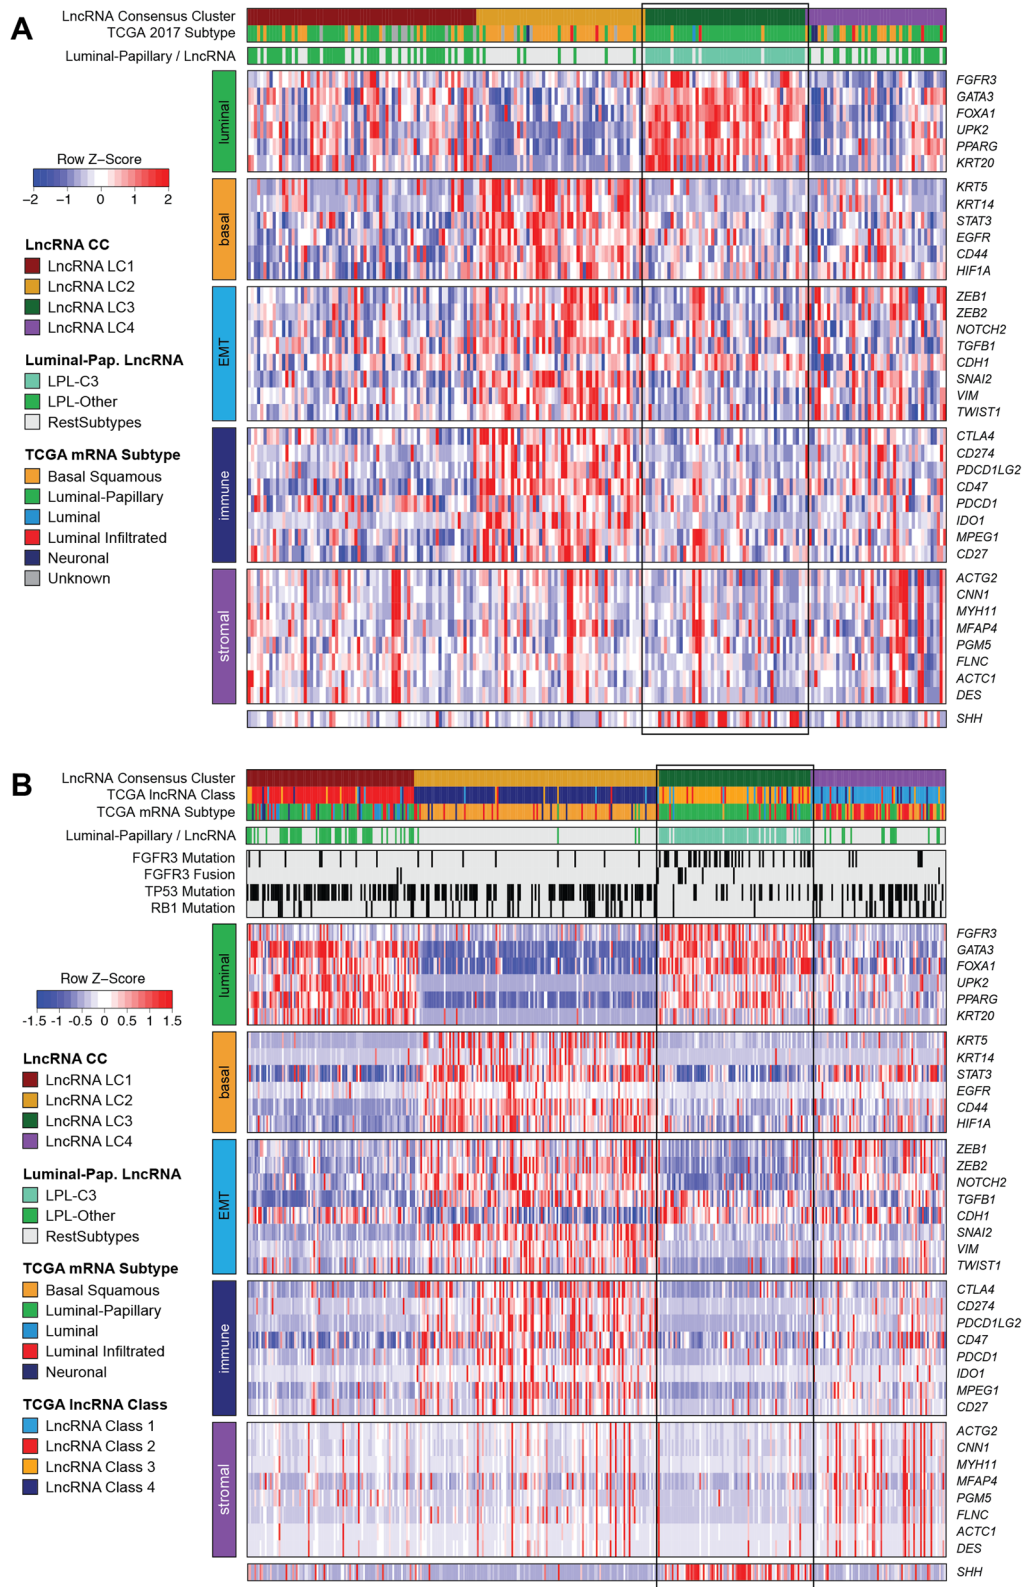

Fig. 2 (See legend on next page.)

(See figure on previous page.)

Fig. 2 Biological characterization of the lncRNA clusters using selected MIBC marker genes in the **a** NAC and **b** TCGA cohorts. For the NAC and TCGA cohorts, both the five TCGA subtypes (luminal-papillary, luminal, luminal-infiltrated, basal squamous, and neuronal, unknown) and the luminal-papillary subgroups (LPL-C3, LPL-Other and RestSubtypes) are indicated in the covariate tracks. In the TCGA cohort, the 2017 TCGA four-cluster lncRNA solution, *FGFR3*, *TP53*, and *RB1* mutation status and *FGFR3* fusion status, are also indicated in covariate tracks

These patterns were less evident in the TCGA cohort, with only *FOXA1* showing significantly increased expression ($p = 0.023$) (Additional file 2: Figure S5d-f). In both cohorts, all luminal-papillary tumors showed downregulation of basal (i.e., *KRT5/6*, *KRT14*) (Fig. 2a, b and Additional file 2: Figure S6) and immune-associated genes (i.e., *CD274*, *PDCD1LG2*) (Fig. 2a, b and Additional file 2: Figure S7).

Significant differences in expression of genes associated with epidermal-to-mesenchymal transition (EMT) were observed for LPL-C3 versus LPL-Other tumors in the NAC cohort (Additional file 2: Figure S8a-c). For example, *VIM* and *ZEB1* were less abundant and *CDHI* was more abundant in LPL-C3, indicating lower EMT activity in these tumors. Hallmark EMT signature scores were also significantly lower among the LPL-C3 tumors in the NAC cohort (Fig. 3a). However, in the TCGA cohort, EMT activity differences between LPL-C3 and LPL-Other tumors were not significant ($p = 0.5$), although both luminal-papillary subsets showed low levels of both EMT gene expression and EMT hallmark scores (Fig. 3e and Additional file 2: Figure S8d-f). Moreover, we found LPL-C3 tumors had the highest median purity in both cohorts (Additional file 2: Figure S9), suggesting a general lack of fibroblast infiltration, which may account for the low EMT scores (Additional file 2: Figure S10). As differential immune cell infiltration may have contributed to the lncRNA profiles, we generated a list of immune-enriched lncRNAs and compared these to the 750 initially used for clustering. Only 23 were leukocyte-associated and selected for clustering, although their expression was not limited to the immune-enriched CC2 (Additional file 2: Figure S11).

Higher expression of *SHH* and genes associated with urothelial differentiation (i.e., *UPK3A*, *UPK3B*) are features of luminal-papillary tumors [12, 22]. In both cohorts, LPL-C3 tumors had higher expression of *SHH* (Additional file 2: Figure S12) and *SHH*-BMP pathway activity signature scores (Fig. 3b, f).

Next, we sought to use regulon activities to further explore the differences in biology between the LPL-C3 tumors, the LPL-Other tumors, and the rest of the cohort [12, 20], using the TCGA cohort for discovery and the NAC cohort for validation. Regulon analysis returns a profile of the activity of a transcription factor (or similar regulator) across a cohort (Methods). Mean regulon activities for LC2 and LC3 subtypes were largely consistent between cohorts, though only weakly for LC1 (Fig. 4a).

Activated *SHH* and *FGFR3* regulon activity was associated with LC3 (LPL-C3) tumors and enriched with *FGFR3* mutations (Fig. 4b, c), consistent with the results of the gene expression analysis.

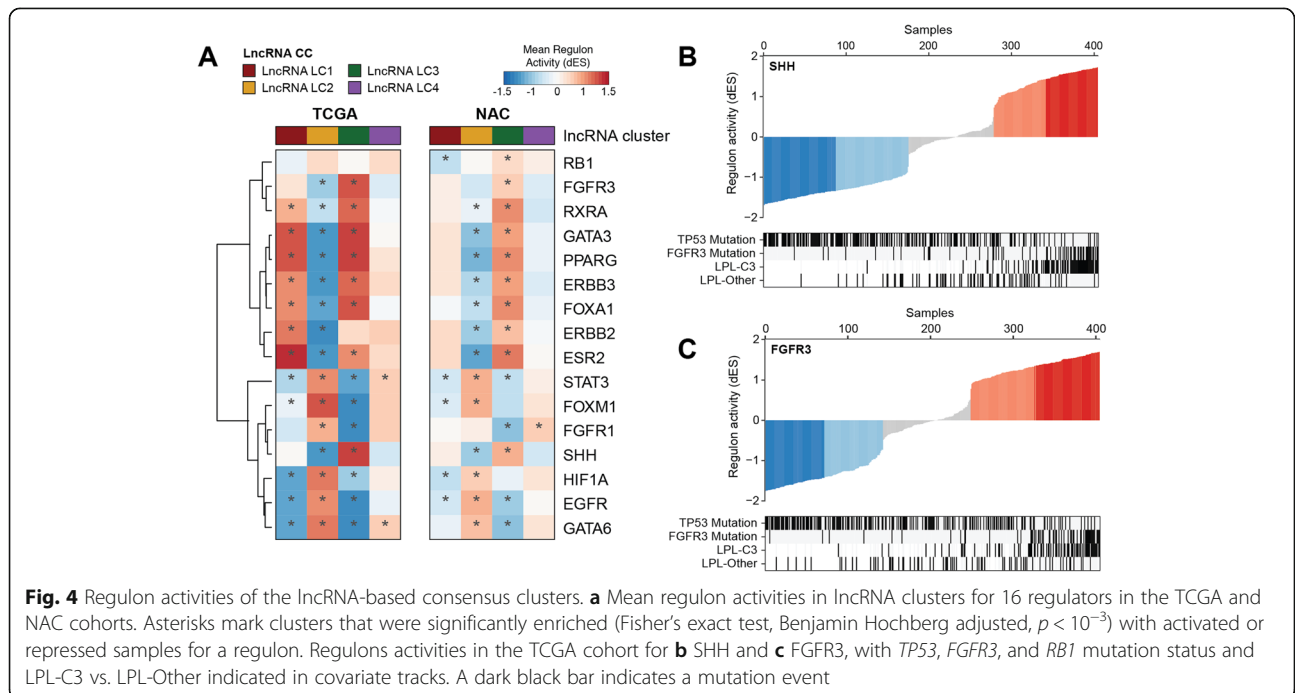

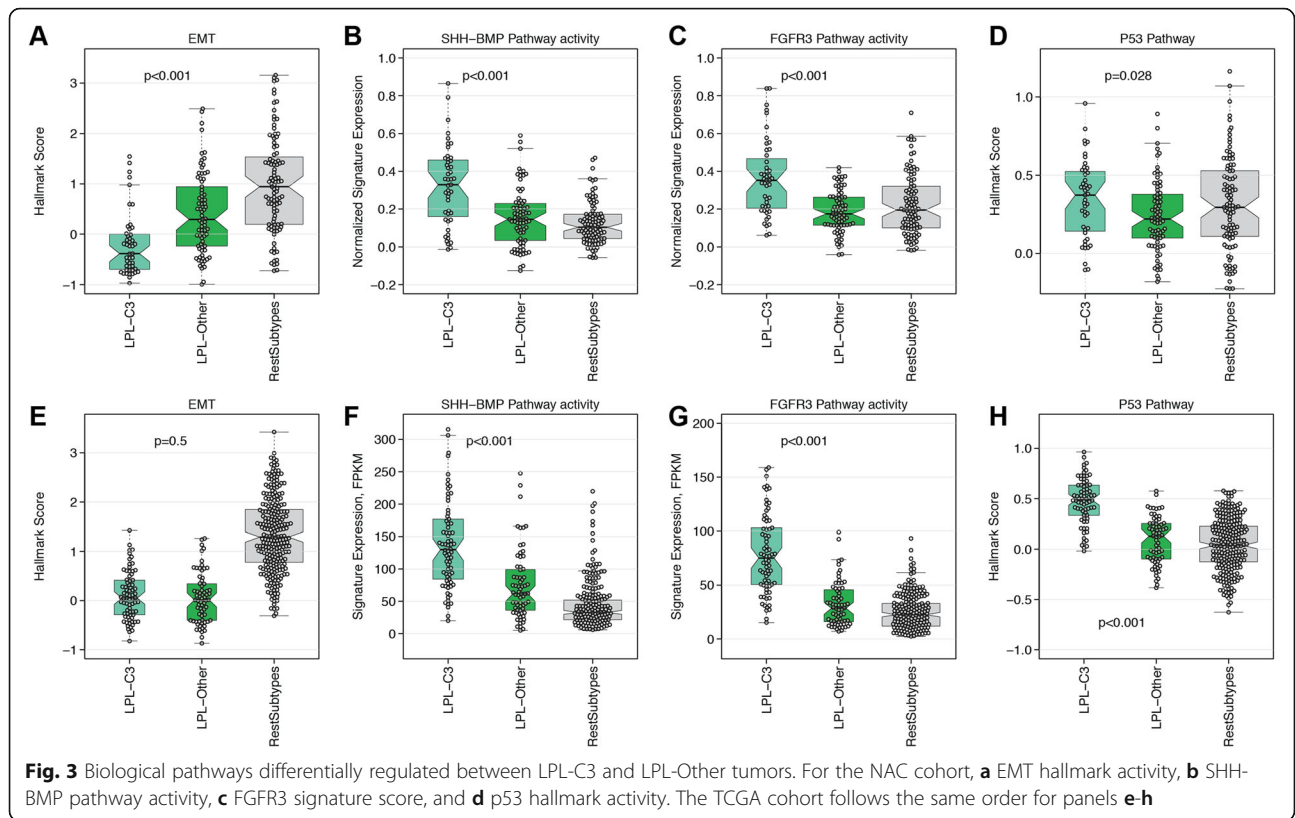

LPL-C3 tumors are enriched for *FGFR3* alterations and have wild-type p53 activity

We assessed a panel of 59 genes with mutation status reported in the TCGA cohort [12]. After adjusting for false discovery rate (FDR), we retained *FGFR3*, *TP53*, and *RB1*, whose rates of mutation differed ($p < 0.05$) between LPL-C3 and the rest of the cohort (Fig. 2b and Additional file 1: Table S4).

In the LPL-C3 tumors, the enrichment for *FGFR3*-mutations (33/74 cases, $p < 0.001$) correlated with both increased *FGFR3* gene expression and signaling activity (Additional file 2: Figure S13a, b). These tumors were also enriched for *FGFR3* fusions (6/74, $p = 0.02$; Fig. 2b), which was the only significant fusion event identified when comparing LPL-C3 and the rest of the cohort (Additional file 1: Table S5). Tumors with strongly activated *FGFR3* regulon activity were likewise enriched in *FGFR3* mutations, supporting this observation (Fig. 4c). Although *FGFR3* mutation status was not available for the NAC cohort, both the *FGFR3* gene expression and gene signature activity were significantly higher in the LPL-C3 tumors ($p < 0.001$) (Fig. 3c).

To examine if *TP53* mutation correlated with impaired p53 activity, we first compared expression of the p53 pathway hallmark scores between *TP53* mutated and wild-type patients within the TCGA cohort (Additional file 2: Figure S13c, d). The LPL-C3 tumors, which were depleted for *TP53* mutations, showed the highest p53 hallmark scores, which suggested functional p53 activity (Fig. 2b and Fig. 3h). Consistent with this, samples with high *SHH* and *FGFR3* regulon activities were depleted in *TP53* mutation (Fig. 4b, c). Unfortunately, the *TP53* regulon had insufficient (< 15) positive and negative targets and was therefore too small to support activity calculations. The *TP53* regulon was therefore excluded from the analysis. Although *TP53* mutation status was not available for the NAC cohort, the LPL-C3 tumors had higher p53 hallmark scores, suggesting these tumors may also be depleted for *TP53* mutations (Fig. 3g).

Although LPL-C3 tumors from the TCGA cohort were depleted for *RB1* mutations, *RB1* gene expression differed only non-significantly between LPL subgroups ($p = 0.054$) (Fig. 2b and Additional file 2: Figure S14a). In

contrast, LPL-C3 tumors from the NAC cohort had significantly higher expression of *RB1* ($p = 5.5 \times 10^{-4}$) (Fig. 2a and Additional file 2: Figure S14b). In contrast to SHH and FGFR3 regulon activities, tumors with higher RB1 regulon activity showed only weak depletion for *TP53* mutations in the TCGA cohort (Additional file 2: Figure S14c).

All genes and pathway activities of LPL-C3 tumors suggested that these tumors should be less clinically aggressive. Therefore, we compared the clinical features of luminal-papillary patients in the NAC cohort and found higher rates of organ-confined disease, including significantly lower pT-stage ($p = 0.047$) and fewer lymph node metastases ($p = 0.0016$) for LPL-C3 tumors (Table 2). Notably, LPL-C3 patients with clinical node involvement still had a good prognosis (Additional file 2: Figure S15). Similar observations were seen in the TCGA cohort, with lower ypT-stage ($p = 0.0043$) and fewer lymph node metastases in LPL-C3 patients ($p = 0.002$). In the NAC and TCGA cohorts, the median age of patients with LPL-C3 tumors was significantly lower (median age 58 vs. 63 years and 61 vs. 70 years, respectively; $p < 0.01$).

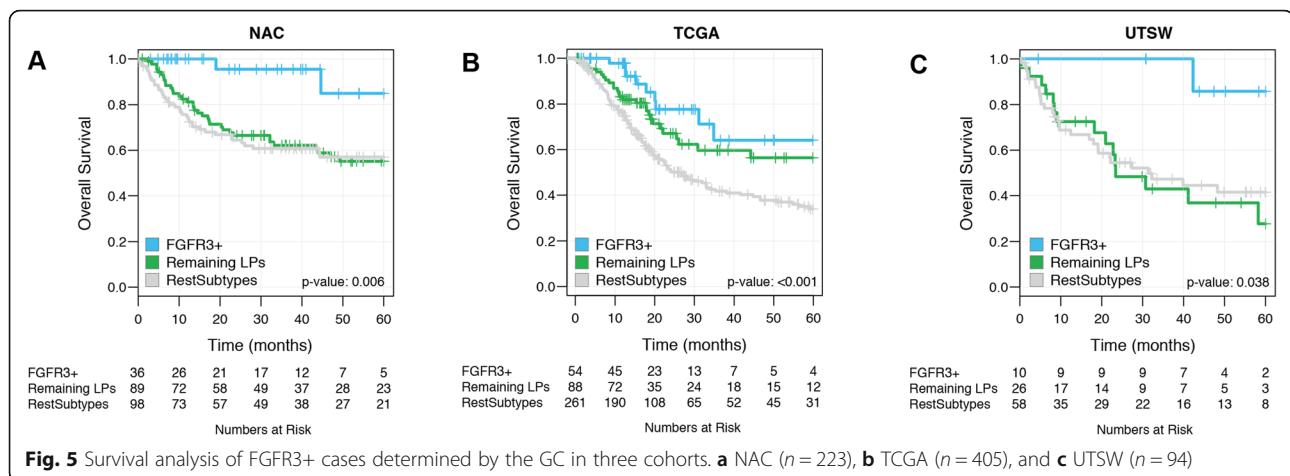

Development of a single-sample classifier to identify luminal-papillary MIBC patients with good prognosis

To provide utility as a prognostic model, we developed a single-sample genomic classifier (GC) to identify the good-prognosis luminal tumors with activated FGFR3 (FGFR3+). To be classified as FGFR3+, the tumor must also show enhanced SHH activity, higher p53 pathway activity, and lower EMT, consistent with the data shown above.

We identified 36/223 (16%) and 55/408 (14%) FGFR3+ cases in the NAC and TCGA cohorts, respectively. The majority of the FGFR3+ calls in both cohorts were of the luminal-papillary mRNA subtype (Additional file 1: Table S6). In both cohorts, patients with FGFR3+ tumors had better survival than other patients ($p = 0.001$ and $p = 0.003$ for NAC and TCGA, respectively) (Fig. 5a, b). As expected, we found the FGFR3, SHH, and p53 signature scores were significantly higher among FGFR3+ cases when comparing them to the other tumors. In the NAC cohort, EMT hallmark scores were significantly lower among FGFR3+ cases ($p < 0.001$), whereas FGFR3+ cases

yN0	39 (83%)	35 (45%)		61 (82%)	36 (53%)	
yN1–3	5 (11%)	24 (31%)		6 (8%)	17 (25%)	
yNx	3 (6%)	18 (23%)	0.0016	7 (9%)	15 (22%)	0.0020

from the TCGA cohort showed no significant difference in EMT activity (Additional file 2: Figure S16A-H). *FGFR3* was mutated in 25/55 FGFR3+ cases (45%) compared to 32/350 negative cases (9%) from the TCGA cohort ($p < 0.001$). The FGFR3+ cases were depleted for TP53 mutations in 15/55 (27%) compared to 180/350 (51%) negative cases ($p < 0.001$). Likewise, RB1 mutations were fewer in FGFR3+ cases, 0/55 (0%) compared to 70/350 (20%) of negative cases ($p < 0.001$).

To validate the classifier, we used an independent RC cohort (UTSW) of 94 patients, identifying 10 (11%) FGFR3+ cases (all luminal-papillary) with excellent prognosis (Fig. 5c) and expected biological character (Additional file 2: Figure S17a-d). Multivariable Cox regression analysis revealed that the GC was a significant survival predictor in the NAC TURBT cohort, but not in the TCGA and UTSW cohorts (Additional file 1: Table S7). The GC was also validated in a prospectively collected commercial cohort (PCC, $n = 225$), resulting in 24/225 (11%) FGFR3+ cases (21 luminal-papillary, 3 luminal) with genomic characteristics consistent with FGFR3+ cases from the other cohorts (Additional file 2: Figure S17f-i). Unfortunately, follow-up data were unavailable for this cohort and therefore outcomes could not be determined.

Comparison of the GC single-sample classifier to the consensus subtyping model

Finally, we also used the recently released consensus molecular classification of The Bladder Cancer Molecular Taxonomy Group to assign tumors from all four cohorts into the six consensus mRNA subtypes (Ba/Sq, LumNS, LumP, LumU, Stroma-rich, and NE-like). Intersecting the consensus subtype calls with the results of the GC revealed that our GC identified tumors from all three luminal subtypes (unstable, non-specified, or papillary), and only rarely the stromal-rich consensus subtype (Additional file 1: Table S8).

Discussion

Molecular characterization of MIBC by transcriptome profiling has revealed a range of subtypes with distinct clinicopathological characteristics, prognosis, and response to therapeutic regimens. Significant efforts have been invested in mRNA-based molecular subtyping of MIBC; however, mRNA transcripts represent only 1–2% of the transcriptome, which is dominated by ribosomal RNA and ncRNAs [26]. In non-muscle-invasive bladder cancer (NMIBC), lncRNA and mRNA expression appear to correlate with each other [27], although only TCGA has explored stratification of MIBC using the non-coding transcriptome [12].

In the present study, we selected a list of highly variable lncRNAs for consensus clustering and identified a subset of luminal-papillary MIBC patients with favorable prognosis (LPL-C3). This lncRNA-mediated subdivision of the luminal-papillary mRNA subtype was consistent with, though not identical to, the TCGA lncRNA clustering solution [12]. lncRNA expression has been described as highly specific to tissue, cell, or disease state, compared to mRNAs [28, 29]; these data support the utility of lncRNA expression in refining mRNA-based subtyping models. Although we observed differential immune infiltration in our lncRNA clusters, only a handful of lncRNAs highly expressed in lymphocytes were identified in our lncRNA set used for clustering, suggesting these were not major contributors to the signal driving the clustering solution.

As the current work was an independent analysis using a panel of *de novo* selected lncRNAs, these data demonstrate that the lncRNA transcriptome contains additional signal for the identification of a biologically distinct MIBC subgroup with potential clinical utility. This highlights a significant advancement over mRNA-based subtyping, where the additional granularity in the subtypes resulted in meaningful survival associations. Notably, LPL-C3 patients with clinically node-positive disease,

who would be expected to have *worse* outcomes, also were found to have surprisingly good outcomes. Thus, the identification of a group of patients with superior prognosis is a major finding that significantly advances the bladder cancer field.

The LPL-C3 tumors had genomic features consistent with less-aggressive disease, including wild-type p53 activity, FGFR3 activation, and lower EMT. LncRNAs have been implicated in the p53-regulatory network in colorectal, nasopharyngeal, and prostate cancers [30–32], where they function as regulators [33, 34]. Some of the lncRNAs that we used in our unsupervised clustering may reflect a wild-type p53 network, facilitating the identification of the LPL-C3 subgroup. Effective cell cycle/apoptosis regulation by p53 may confer a less-aggressive tumor and the favorable prognosis seen in patients with these tumors.

In bladder cancer, *TP53* and *FGFR3* mutations are reported to be mutually exclusive [35, 36]. In the TCGA cohort, tumors in the LPL-C3 group, while being depleted for *TP53* mutations, had *FGFR3* mutation rates five times higher than in other tumors. These tumors also showed higher levels of *FGFR3* gene expression, pathway activation, and regulon activity, consistent with the mutational activation of *FGFR3* [37]. Mutations in *FGFR3* have been reported in bladder cancer to be associated with a less-aggressive disease, lower-stage tumors, and improved prognosis, consistent with the data from our study [36, 38].

Other biological features may also explain the less-aggressive clinical course of patients with LPL-C3 tumors. In these tumors, we observed higher expression of *SHH* and downstream *SHH* targets, and higher expression of the *SHH* gene has been proposed to restrain bladder cancer progression [22, 39]. Moreover, in the NAC cohort, the LPL-C3 tumors had lower EMT activity, a feature known to be associated with less-aggressive cancer in many tumor types [40]. In the TCGA cohort, both LPL-C3 and LPL-Other tumors had lower EMT activity, suggesting this feature may be a characteristic of the luminal-papillary subtype.

Collectively, the luminal nature of the LPL-C3 tumors, the wild-type p53 activity, the high proportion of *FGFR3* mutations, *SHH*-BMP pathway activity, and lower EMT signature all support a less-aggressive tumor type and suggest a biological explanation for the favorable prognosis of patients with these tumors. However, the extent of the LPL-C3/*FGFR3*+ survival benefit differed between the NAC and TCGA cohorts, which may be caused by a different treatment regimen (NAC+RC versus RC only), as the survival curves of all four lncRNA clusters were shifted upwards in the NAC cohort. In contrast, *FGFR3*+ patients from the UTSW (RC only) cohort showed even better prognosis than *FGFR3*+ cases from the NAC

cohort, despite having had a different treatment regimen. Additionally, over half of the tumors in the TCGA cohort are pT3/T4, which may explain, at least in part, the less favorable outcomes seen for these patients.

While MIBC has a poor prognosis in general, identifying a subgroup of patients with excellent outcomes would be a major step in addressing the heterogeneous clinical behavior of this disease. In daily clinical practice, such patients could be offered a less invasive treatment. To provide clinical utility for our findings, we developed a stringent, single-sample classifier that identified *FGFR3*+ cases with high *FGFR3* activity and enrichment for *FGFR3* mutations/fusions. Early results from a phase II trial showed a 40% overall response rate in patients with *FGFR3*-mutated, metastatic urothelial cancer after treatment with erdafitinib, an *FGFR* inhibitor [41]. Consequently, *FGFR3*+ cases may be candidates for treatment with *FGFR3* inhibitors instead of NAC, as patients with luminal tumors may benefit less from NAC while still being exposed to chemotherapy-related toxicity [11].

This retrospective study has several limitations. First, DNA sequence data was unavailable for the NAC, UTSW, and PCC cohorts, so we were unable to accurately determine whether the LPL-C3 (or *FGFR3*+) cases were enriched for *FGFR3* mutations or depleted for *TP53* mutations. Although the *FGFR3* signature is a reasonable surrogate, and *FGFR3* regulon activities show promise as a complementary metric, availability of mutation calls for patients from all cohorts would strengthen the study. Second, the PCC cohort lacked clinical follow-up, so we were only able to evaluate the GC model calls based on genomics.

In the TCGA and UTSW cohorts, the HR, although not statistically below the *p* value threshold of 0.05, was consistently below 0.50 in all datasets tested, suggesting a protective status for *FGFR3*+ tumors. For UTSW, the cohort was small ($n = 94$) with only 10 *FGFR3*+ patients, which may explain why *FGFR3*+ status did not achieve significance in multivariable analysis. Given the reported trends, we anticipate that statistical significance may be achieved with additional patients. For the TCGA cohort, sufficient tumor tissue for the many different assays required by TCGA studies (copy number, RNA-seq, DNA methylation, etc.) may have resulted in the collection of larger, more bulky tumors which tend to exhibit a more aggressive clinical behavior. For our study, the *FGFR3*+ tumors may therefore be on the more aggressive side of the spectrum of the LPL-C3 tumors, resulting in a higher HR than observed in the NAC or UTSW cohort, and possibly explaining the lack of a significant *p* value in the TCGA survival analysis.

Given these factors, the GC will require additional prospective validation before it can be used clinically as a single-sample classifier for identifying luminal-papillary

MIBC patients with enhanced FGFR3 activity and favorable prognosis.

Conclusions

In summary, using the lncRNA transcriptome, we identified a subgroup of luminal-papillary MIBC patients that have very good outcomes. We characterized these tumors genomically, and biologically, and characterized the patients clinically. Further, we developed a single-sample genomic classifier to identify such tumors and validated it in two independent cohorts.

JJdJ, YL, CSG, MAAC, JLB, and EAG contributed to the analysis and interpretation of the data. JJdJ, AGR, RS, PCB, JLB, and EAG contributed to the drafting of the manuscript. JJdJ, AGR, RS, YL, ECZ, PCB, JLB, and EAG contributed to the critical revision of the manuscript for intellectual content. JJdJ, YL, CSG, and MAAC contributed to the statistical

analysis. ECZ, JLB, and ED obtained funding. JLB and EAG are responsible for the supervision. All authors read and approved the final manuscript.

Funding

Decipher Biosciences funded the original gene expression analysis of the patient tissue. No additional funding sources are reported.

Availability of data and materials

The datasets analyzed during the current study are available in the Gene Expression Omnibus repository (<http://www.ncbi.nlm.nih.gov/geo/>), under accession codes GSE87304 and GSE128702 [11, 17]. The TCGA RNA-seq data was available as part of the TCGA research network (<http://cancergenome.nih.gov/>) [12]. The PCC cohort is available for non-commercial research through a data usage agreement with the test manufacturer [17]. Requests can be made via email (partner@decipherbio.com). The lymphocyte and normal bladder expression datasets are available in the GTEx Portal (<https://gtexportal.org/>).

Ethics approval and consent to participate

Whole transcriptome profiling of the NAC, UTSW, and PCC cohorts has been performed on formalin-fixed, paraffin-embedded (FFPE), tissue samples in a Clinical Laboratory Improvement Amendments (CLIA)-certified laboratory (Decipher Biosciences Inc., San Diego, CA) in collaboration with academic institutions. The study used publically available data, the human ethics board of each institution approved the original studies, and all patients provided written consent to analysis of their tumor tissues [11, 17]. The studies were conducted in accordance with the ethical guidelines of the Declaration of Helsinki.

Consent for publication

Not applicable.

Competing interests

Three authors (YL, ED, EAG) are employees of Decipher Biosciences. The remaining authors declare that they have no competing interests.
