ABSTRACT

Objectives To estimate trends in HIV testing, positivity and prevalence in UK primary care for 2000–2015 as part of a wider investigation into reasons for late diagnosis of HIV.

Design Retrospective cohort study using the Clinical Practice Research Datalink (CPRD) which is derived from computerised clinical records produced during consultations in primary care.

Setting 404 general practices in England.

Participants 5 979 598 adults aged ≥16 years registered between 2000 and 2015 with 45 093 761 person years of observation.

Outcomes Annual HIV testing rates, proportion of positive tests and prevalence of HIV-infected people recorded in primary care 2000–2015.

Results HIV testing in primary care increased from 2000 to 2010, but then declined. Testing was higher in females than in males and in those aged 16–44 years compared with older adults. Rates per 100 000 in women aged 16–44 years were 177 (95% CI 167 to 188); 1309 (95% CI 1282 to 1336); 1789 (95% CI 1757 to 1821) and 839 (95% CI 817 to 862) in 2000, 2005, 2010 and 2015, respectively, and for non-pregnant women: 22.5 (95% CI 19 to 26); 134 (95% CI 125 to 143); 262 (95% CI 250 to 275); 190 (95% CI 179 to 201). For men aged 16–44 years rates were: 26 (95% CI 22 to 29); 107 (95% CI 100 to 115); 196 (95% CI 185 to 206); 137 (95% CI 127 to 146). Over the study period, there were approximately two positive results per 1000 HIV tests. Men were eightfold more likely to test positive than women. The percentage of HIV diagnoses among adults recorded in CPRD may be as low as 55% in London and 67% in the rest of the UK.

Conclusions HIV testing rates in primary care peaked in 2010 and subsequently declined. Access to testing was higher for women despite the prevalence of HIV being higher in men.

Implications and further research needed Opportunities remain in primary care for increasing HIV testing to prevent costly late diagnoses and decrease HIV transmission. Interventions to improve targeting of tests and increase adherence to HIV testing guidelines are needed in primary care.

INTRODUCTION

HIV testing in primary care is an important component of the strategy to diagnose HIV

Strengths and limitations of this study

- We investigated trends in HIV testing in primary care using high quality data from the Clinical Practice Research Datalink (CPRD) which is derived from computerised clinical records produced during consultations in primary care in England.
- CPRD provided anonymised primary care records on patients registered between 2000 and 2015 in 404 primary care practices in England which is likely to be representative of the general patient population.
- A limitation of the study is that not all general practices contribute data to CPRD and therefore we cannot know whether the sample was representative.
- A major strength of the study was the large number of patients, nearly 6 million, which allowed us to contrast trends in HIV testing rates in primary care by sex, age, deprivation, rural/urban location and whether in London or not.
- Data were available for 15 years of follow-up allowing us to show that HIV testing in primary care in England increased between 2000 and 2010, but then declined up to 2015.

earlier and reduce transmission of HIV. In 2015 there were an estimated 89 800 (95% credible interval (CrI) 87 100 to 94 800) people living with HIV in England of whom approximately 15% (CrI 12%–19%) were unaware of their infection.¹ Of those individuals newly diagnosed with HIV in 2015, 39% were diagnosed late, defined as having a CD4 count below 350 cells/mL within 3 months of diagnosis.² An estimated 1 in 4 of newly diagnosed individuals experienced a missed opportunity for an earlier diagnosis within the healthcare system in the preceding year.³ Late diagnosis of HIV is associated with increased hospitalisations, decreased life expectancy^{4–7} and higher treatment and care costs to the National Health Service (NHS).⁸ Importantly, individuals with undiagnosed HIV are likely to

be responsible for the majority of transmissions because successfully treated individuals are unlikely to infect others.⁹

Enhanced HIV testing is considered to be cost-effective in areas with a local diagnosed HIV prevalence that exceeds 2 per 1000 in adults aged 15–59 years.^{2 10} In these high HIV prevalence areas recommendations are an HIV test should be routinely offered to all new general practitioner (GP) registrations, those undergoing tests for other sexually transmitted infections or having blood tests for any reason, and all new hospital medical admissions.^{2 11} However, the majority of people with HIV seek medical care for a related condition several times prior to their HIV diagnosis.^{12 13} This may be presenting to general practice or hospital care. But without a high degree of clinical suspicion, the diagnosis is often missed.¹⁴ The British HIV Association (BHIVA) has published a list of indicator diseases that are more commonly found in those who are HIV positive than negative.¹⁵ HIV testing is recommended in these cases, but recent surveys suggest poor adherence to guidelines.^{16 17} Given the increase in HIV prevalence over time we would expect that there would be an increase in GP testing for HIV.

Evidence from systematic reviews shows that there are often many barriers to testing experienced by patients and equally by healthcare professionals (HCP).^{18–20} Patients presenting with clinical indicator conditions to their GP provide a valuable opportunity to diagnose HIV and avoid hospitalisations due to late diagnosis.²¹ Research has shown that the majority of patients (up to 75%) newly diagnosed with HIV had been seen in the healthcare system within the 12 months prior to their diagnosis resulting in a missed opportunity to test.^{12 14 22 23} Opt out HIV testing has been shown to be feasible, acceptable and cost effective in eight pilot studies conducted in community, primary and secondary care settings in high prevalence areas across England.²⁴ However, no recent evidence is available to know if HIV testing in primary care has been increasing and guidelines have been implemented over the country and not just in high risk areas.^{16 17}

HIV testing in primary care has been reported only for the years 1995–2005 using data from the UK General Practice Research Database (GPRD).²⁵ This study showed that testing in primary care remained low, but increased steadily. Our main objective was to analyse data from the same source collected between the years 2000 and 2015 to study if HIV testing trends continued to increase in primary care over this extended time period. In addition we investigated differences in HIV testing rates and HIV diagnosis by demographic characteristics and estimated the prevalence of HIV recorded in primary care and compared it with estimates from national surveillance.

METHODS

Population and data

We used data from the Clinical Practice Research Data-link (CPRD), previously known as the GPRD, which is derived from computerised clinical records produced

during consultations in primary care. The CPRD database contains information from GP practices in the UK using the Vision software system (roughly 9% of UK practices) who consent to data collection; the sample is broadly representative of the adult UK population.²⁶ Only GP practices in England are eligible for linkage to other data sets such as hospital admissions and practices can opt out of linkage. CPRD provided anonymised primary care records and linked secondary care and mortality records on patients registered between 2000 and 2015 in 404 primary care practices in England. Data were available on nearly 6 million people aged over 16 years old. GPs enter data on tests, diagnoses and symptoms using Read codes that are a hierarchical alphanumeric system similar to, but more extensive than International Classification of Disease (ICD) codes. The list of Read codes used to identify (1) HIV tests²⁵ (2) HIV diagnoses²⁵ (3) pregnancy/delivery/abortion²⁷ and (4) additional CPRD browser pregnancy medcodes is listed as appendices 1 to 4, respectively, in the online supplementary file. We used individual level quintiles of the Index of Multiple Deprivation (IMD), 2015.²⁸ Practices were classified as rural, urban conurbation or city/town at lower super output level (a small area geographic boundary of around 1500 people) in England based on Office for National Statistics classifications, 2011,²⁹ and as within or outside London. Ethnicity was grouped as Asian, Black African, Black Caribbean, Other, White and unknown based on linked Hospital Episode Statistics data.

We used national surveillance data from Public Health England (PHE) on testing in primary care derived from general practices that submit HIV tests to laboratories participating in the Sentinel Surveillance of Blood Borne Virus Testing (SSBBV). These practices cover 35% of England's primary care population. HIV testing data are captured from 66% of the primary care population in extremely high prevalence areas (>5/1000), 37% within high prevalence areas (>2/1000) and 29% within low prevalence areas. These data exclude any point of care tests carried out by GPs, and tests carried out as part of antenatal screening. The latest data available on testing rates and positivity were for 2015.³⁰ Data on HIV prevalence were derived from the HIV and AIDS Reporting System (HARS) and for earlier years the Survey of Prevalent HIV Infections Diagnosed (SOPHID) available from PHE.² These data were available up to 2015.

Patient and public involvement

Public and patients were not involved in the design of this study. Patient data from general practices were contributed via CPRD and PHE surveillance as stated earlier.

Statistical methods

HIV testing rate, positivity and prevalence of HIV recorded in primary care

Using data from CPRD we estimated the HIV testing rates for each year between 2000 and 2015, overall and by patient demographics. Testing rates were estimated

for males and females, for all ages and grouped by age (16–44, ≥45 years, chosen to match the study by Evans *et al*²⁵). We also estimated rates separately according to whether the practice was in London or not, and by type of location. For each calendar year, the denominator used to calculate the HIV testing rate was the number of patients who were in the CPRD cohort in that year satisfying the following inclusion criteria:

1. They were registered before 30 June of that year.
2. They did not transfer to another practice or die before 30 June of that year.
3. They were in the same practice for at least 6 months.
4. They had not previously tested positive for HIV.

The numerator was the number of HIV tests carried out within the relevant year. For each patient in the denominator, the number of tests was calculated, disregarding repeat tests that were within a 3-month period. Any test done or registered more than 90 days after the first recorded positive test was ignored.

As the majority of HIV tests in women are carried out as part of antenatal screening, analyses for females were repeated excluding these tests. We identified women who were pregnant using either delivery dates or Read codes as follows:

1. Delivery (birth) dates associated with the females in our data: An HIV test was considered antenatal if it occurred between 3 and 9 months before the recorded delivery date.
2. Read codes indicating any sign of pregnancy (antenatal): In this case an HIV test was considered antenatal if it occurred within 6 months from the day the Read code was recorded.
3. Read codes associated with the postpartum period: In this case the HIV test was considered antenatal if it occurred within 3–10 months before the corresponding record.
4. Read codes indicating any sign of miscarriage or abortion: An HIV test was recorded as antenatal if it occurred between 3 months prior to 3 months after the corresponding record.

The Read codes associated with pregnancy are listed in the online supplementary material. The antenatal HIV tests were excluded from the numerator and the corresponding patients were removed from the denominator for the related period as well.

We plotted the trends in HIV testing rates per 100 000 person years for 2000–2015 separately for men and women (including and excluding antenatal HIV tests) for all adults and restricted to those aged 16–44 years old. In addition, we calculated the annual proportion of HIV tests that were positive for each year to investigate whether testing improved in terms of targeting higher risk individuals during the later years.

For the years 2005, 2010 and 2015, we estimated and tabulated HIV testing rates and incidence rate ratios (IRRs) with 95% CI from Poisson models for males and females separately according to whether practice was in London or not, by age, ethnicity, IMD and by type of

Table 1 Patient and practice demographics

IMD, Index of Multiple Deprivation.

location. To validate our estimates of HIV testing rates recorded in CPRD, we compared them with those from national surveillance data collected by PHE for 2015.³⁰ Finally, we estimated the prevalence of diagnosed HIV recorded in CPRD and compared this with estimated prevalence from national surveillance data collected by PHE using SOPHID and HARS to determine the proportion of all HIV diagnoses that were recorded in CPRD. Data analysis was performed using STATA V.14.

RESULTS

Data were available on 5 979 598 distinct patients with 45 093 761 (males 22,155,768; females 22,937,630) person years of observation. The demographic characteristics of included individuals are shown in [table 1](#). There were less males (48%) than females (52%). Practices (15%) and individuals (16%) in the most deprived quintile of IMD were under-represented in CPRD. The total number of

Figure 1 Trend in HIV testing rates per 100 000 person years for the period 2000–2015 by gender and age group, with and without inclusion of antenatal testing.

HIV tests recorded in CPRD between 2000 and 2015 was 159 115 of which 357 (0.2%) were positive.

Trends in HIV testing rates 2000–2015 in primary care

Figure 1 shows the trend in HIV testing rates per 100 000 person years for the period 2000–2015 by gender and age group, with and without inclusion of antenatal testing. The main reason for HIV testing among women of child-bearing age was antenatal screening; the testing rates (per 100 000 person-years) in all women aged 16–44 increased from 177 (95% CI 167 to 188) in 2000 to 1789 (95% CI

1757 to 1821) in 2010 and then decreased to 839 (95% CI 817 to 862) in 2015, with the corresponding figures being 23 (95% CI 19 to 26), 262 (95% CI 250 to 275) and 190 (95% CI 179 to 201) when antenatal testing was excluded. For males the corresponding rates were 26 (95% CI 22 to 29), 196 (95% CI 185 to 206) and 137 (95% CI 127 to 146), which are lower than rates for females even when antenatal tests are excluded. HIV testing rates in primary care peaked in females in 2010 (figure 1) and have declined markedly since then. In men and women not tested antenatally, HIV testing rates increased until 2012–2013, but have declined since. Similar patterns were seen when data were restricted to those aged 16–44 years only, except that rates were much higher in younger adults compared with those aged 45 years and over (online supplementary table 1 all adults, online supplementary table 2 for those aged 16–44 years).

Trends in positive HIV diagnosis in primary care

Although the number of HIV tests was much higher in women, more men tested positive: 196/20,328 (0.96%) men compared with 161/138,787 (0.12%) women. This was skewed by a very low rate of positive diagnoses in younger females who were screened antenatally. The smoothed trend in the percentage of tests that were positive for men and women of different ages is shown in figure 2 (plot of raw data is shown in online supplementary figure). Percentage positive (excluding antenatal tests) was similar in men and women before 2005, but declined more sharply in women thereafter. The

Figure 2 Trend in the percentage of HIV tests that were positive for the period 2000–2015 by gender and age group, with and without inclusion of antenatal testing.

percentage of tests that were positive peaked around 2003 and has fallen sharply since 2010, indicating that there is no evidence of better targeting of testing to individuals in later years.

HIV testing rates in practices within and outside London, by age and deprivation index

HIV testing rates were twofold higher in London compared with outside London for both men and women in 2005 and this differential increased in 2010 and 2015. [Tables 2 and 3](#) give the testing rates for years 2005, 2010 and 2015 for males and females (excluding antenatal tests), respectively, stratified by whether the practices were in London or outside London. Data for all years between 2000 and 2015 are given for all adults (online supplementary table 1) and for adults aged 16–44 years (online supplementary table 2). In more recent years practices outside London but in conurbations had higher rates than those in cities or towns, which, in turn, had higher rates than rural practices. Although testing rates in men in London practices decreased between 2010 and 2015 overall from 273 (95% CI 251 to 295) to 246 (95% CI 225 to 266) per 100 000 person-years, there was evidence of a shift in targeting of testing since rates increased in older men from 151 (95% CI 127 to 176) to 180 (95% CI 154 to 206) per 100 000 person years and in the most deprived quintile from 415 (95% CI 351 to 480) to 565 (95% CI 487 to 643) per 100 000 person years. This targeting effect was also seen among women in London practices, but not in practices outside London. However, in 2015 in London it remained the case that older people were less likely to be tested: IRR for age ≥ 45 compared with 16–44 years was 0.59 (95% CI 0.50 to 0.71) for men and 0.46 (95% CI 0.38 to 0.55) in women. The corresponding IRRs for outside London were much lower: IRR for age ≥ 45 compared with 16–44 years was 0.37 (95% CI 0.32 to 0.43) in men and 0.18 (95% CI 0.16 to 0.21) in women. In contrast, by 2015 the most deprived group were two/threefold more likely to be tested than the least deprived, depending on gender and locality, with IRR for IMD quintile 5 versus 1 increasing markedly from 2005 to 2015 ([table 2](#) (males) and [table 3](#) (females)).

HIV testing rates and positivity according to national surveillance data

For comparison, national surveillance data for 2015 estimated that general practices in extremely high prevalence areas (defined as greater than 5/1000 population, comparable with 'London' in our CPRD study) carried out the highest number of tests per practice population 860 per 100 000 person years. This was nearly double the coverage rate of general practices in high diagnosed prevalence areas (defined as greater than 2/1000 population), which was estimated at 440 per 100 000 person years, and ten times the coverage rate among general practices in low diagnosed prevalence areas, which was estimated at 90 per 100 000 person years. The estimates of HIV testing rates from surveillance were higher than our

estimates from CPRD ([tables 2 and 3](#)). The proportion of positive tests among those tested in primary care estimated from SSBBV surveillance data was 0.4% in 2015.³⁰ This varied from 0.5% in very high prevalence areas to 0.2% in low prevalence areas and was consistent with our estimated positivity ([figure 2](#)).

Prevalence of recorded HIV in CPRD and comparison with national surveillance estimates

In 2015 the prevalence of diagnosed HIV recorded in CPRD was 2.8 per 1000 adult patients in London practices and 0.8 per 1000 in the rest of the UK ([table 4](#)). According to PHE surveillance, in 2015 HIV prevalence in UK was estimated to be 1.6 per 1000, and excluding undiagnosed HIV was 1.3 per 1000 population.² The HIV prevalence in London was estimated to be 4.7 per 1000, substantially higher than the rest of the UK at 1.1 per 1000. The corresponding observed prevalence, that is, excluding undiagnosed cases of HIV, was 4.2 and 0.9 per 1000 population in London and the rest of the UK, respectively.² However, these percentages are likely to be overestimated as children aged <16 years were not included in the CPRD calculations of prevalence but were included in PHE data. In general practices in London, prevalence of HIV recorded in CPRD was higher for males, older individuals, Black African ethnicity and most deprived quintile ([table 4](#)) with a similar pattern in practices outside London except that prevalence did not vary by age.

DISCUSSION

Statement of principal findings

Our analysis of CPRD data on GP consultations recorded on approximately 6 million people living in the UK over a 15-year period shows that the initial rise in HIV testing seen in primary care between 2000 and 2010 reversed with a significant drop in the testing rates for HIV in primary care from 2010. This is an unexpected finding as throughout this period prevalence of HIV has been increasing which should have engendered higher rates of testing in primary care, given the NICE recommendations on testing, which would increase with increased prevalence.^{31 32} HIV testing rates in primary care were higher in women than men throughout the study period, even when tests for antenatal screening were excluded, despite HIV prevalence being higher in men. This resulted in men being eightfold more likely to test positive than women in this setting. Over the 15-year period of the study, there were approximately two positive results per 1000 HIV tests. We did not find evidence of better targeting of HIV testing to individuals in more recent years as the percentage of tests that were positive peaked around 2003. Many individuals at high risk of HIV infection may choose to test in settings other than general practice, such as sexual health clinics, which might make it harder to target HIV testing among the population attending primary care.

IMD, Index of Multiple Deprivation.

The pattern of HIV testing has also changed over time. Testing was twofold higher in London than elsewhere and has increased in the groups and areas of high deprivation within London. This is reassuring as it also reflects the higher prevalence of HIV in these areas and indicates that HIV testing has become more geographically targeted. Overall, testing rates were higher in urban conurbations and cities than in rural areas reflecting the national prevalence figures.² Younger people were more likely to be

tested than those aged 45 years and over, which reflects the incidence pattern for HIV. However, our data show an increasing trend in the rate of testing among the older age group in London, but not elsewhere, which may have been driven by the recognition that among those with HIV infection the proportion diagnosed late is higher in older age groups.³³

In 2015, the prevalence of HIV recorded in CPRD was over threefold higher in London than elsewhere, but

overall was substantially lower than the prevalence of diagnosed HIV estimated from PHE surveillance.² This may be due to HIV-positive individuals not using primary care or to non-disclosure of their HIV status to their GP, not recording of the diagnosis on GP systems, or to CPRD not including sufficient practices with high HIV prevalence. CPRD is broadly representative of primary care in the UK, but the UK HIV epidemic is concentrated in cities with approximately half of HIV-positive individuals living in London.² The estimated percentage of HIV diagnoses among adults that were recorded in CPRD increased between 2005 and 2015 but was still substantially lower in London than elsewhere. This trend may reflect the ageing HIV population's greater requirement of primary care services, decrease in stigma of disclosure, or better transfer and recording in primary care of positive results of HIV tests carried out in other settings in later years.

Strengths and weaknesses of the study

This study is very large with data from nearly six million patients followed over 15 years with detailed primary care records. This detailed coverage enabled us to accurately measure HIV testing rates according to the important factors of deprivation, urbanisation, gender, ethnicity and age. Records were collected prospectively and electronically over a significant time period; therefore, we were able to show clearly the trends that have occurred. Our analysis and the data collection may be biased by several factors. The CPRD only includes a sample of general practices, but this is broadly representative of primary care in the UK, and, given the large numbers, this is a sufficient sample size for estimates of testing rates to be accurate. We have shown the CPRD slightly under-represents deprivation, in both individuals and GP practices. While this may be the case, given the very large sample size, we think that we can still draw valuable conclusions from this data. This study can only show the composite rates of testing in primary care. We were not able to categorise the different indications for an HIV test. What is clear, given the number of HIV positive patients, is that many patients will have been diagnosed in other healthcare settings, for example, PHE estimated that in England during 2016 5.9% and 7.3% of new diagnoses in men and women, respectively, were made in primary care.³⁴ This implies that estimates of the prevalence of diagnosed HIV based on diagnoses recorded in CPRD will be underestimates for the UK which we have shown by comparing with surveillance data from PHE.

Strengths and weaknesses in relation to other studies, discussing important differences in results

HIV testing in primary care in the Netherlands also decreased between 2010 and 2015 despite similar guidelines encouraging more pro-active screening for HIV.³⁵ Although HIV testing in primary care has declined, the rates of late diagnosis (CD4 count less than 350 cells/mL) have also declined from 50% in 2010 to 39% in 2015,³⁶ indicating a discordancy between the testing in primary

care and diagnosis. This indicates that increased testing has likely occurred in other settings. Earlier diagnosis may be due to better detection in secondary care, either from screening or testing those with indicator conditions, or through other routes such as sexual health clinics, insurance requests or specialist testing services. Moreover, if testing has become better targeted in primary care and incidence in the consulting population is decreasing then even without an increase in testing, those who get tested may be tested earlier in the course of HIV infection leading to reduced rates of late diagnoses. However, we have shown a significant decline in HIV testing in primary care since the previous analysis by Evans *et al*²⁵ on testing up to 2005, and therefore we can look at increased testing in primary care as an option to improve early HIV detection rates.

Meaning of the study: possible explanations and implications for clinicians and policymakers

Since 2015, UK and international treatment guidelines³⁷ for those diagnosed with HIV recommend immediate treatment with antiretroviral therapy due to findings from the START trial.³⁸ This change, together with pre-exposure prophylaxis, has resulted in a decline in HIV infection rates for the last 2 years³⁴. Nevertheless, there are still opportunities for diagnosing HIV earlier in primary care while testing rates remain very low. Current UK testing guidelines³⁴ recommend people attending general practices in areas of high HIV prevalence should be offered an HIV test at registration or when having a blood test if they have not had an HIV test in the past 12 months. People newly diagnosed with an HIV indicator condition should also be offered an HIV test. The aim is to diagnose HIV earlier as late diagnosis of HIV is associated with increased morbidity and mortality.^{7 39 40} There are benefits for diagnosing HIV earlier both for the individual in terms of quality of life and life expectancy⁶ and a wider societal benefit of reduced transmission and lower NHS treatment costs.

Unanswered questions and future research

Although it is a public health imperative, and target, to increase HIV testing and diagnosis, it is unclear how this could be implemented in primary care. A literature review undertaken of public and HCP attitudes towards HIV testing in the UK showed that a proactive offer of an HIV test by the HCP was an important factor which could help increase testing rates.²⁰ Reasons for low levels of HIV testing by the HCP include fear/concern of offending patients, inadequate knowledge/training on HIV, low awareness of current testing guidelines, underestimation of patient risk, insufficient time, competing priorities, perceived burdensome consent process and pre-test discussion.^{18-20 41} Studies indicate a need for education and training on HIV testing for HCP in primary care to overcome these barriers to testing.^{16 42} Adequate interventions are needed to address these barriers so individuals can receive a timely HIV test and with it the important

treatment benefits and care if found to be HIV positive. Another literature review has provided evidence that HIV indicator conditions have the potential to be used more effectively as triggers for earlier HIV testing.⁴³ Opt-out testing can facilitate increased HIV testing as has been evident from a trial in emergency care setting.⁴⁴ When blood tests are carried out for any reason in primary care, there could also be an opt-out HIV test. Computer prompts based on risk algorithms are another strategy to support HIV testing^{45–49} which could be based on electronic health records such as those in CPRD.

Although the results shown here are for a UK-based population the methodology may be applicable to other healthcare systems. They provide accurate testing rates and detection rates in primary care which are measures of HIV testing that can be used for international comparisons. A key element for preventing transmission and late diagnosis of HIV is testing in primary care, based on a screening strategy or indicator conditions.⁵⁰ These data inform us of the current situation on testing and will be useful in planning and evaluating interventions to improve this.

The data on the discrepancy between PHE and CPRD prevalence of HIV positive status being recorded are another finding of importance for planning. New testing strategies such as home test and rapid testing outside of standard healthcare settings may contribute to the decrease in testing in primary care. These need to have a strategy in their delivery to feed back to primary care to maximise the benefits to patients and their health networks.

CONCLUSIONS

HIV testing rates have declined in primary care in all age groups, although there has been a fall in late presentation. HIV testing rates are highest in London, and higher in urban areas than rural areas. Increased testing would likely increase the number of positive tests and help prevent late diagnosis. Further interventions to increase selectivity of testing (positive cases per test) may be required, either at the individual level using risk factors and HIV indicator conditions or at the practice level using knowledge of local HIV prevalence.
