4 *Xiphactinus audax* is the largest macropredatory osteichthyan ever known (Everhart  
5 et al., 2010). Some of the largest specimens exceed 5 m in total length, though the discovery  
6 of a few large, isolated teeth suggests that this teleost could reach even larger body sizes  
7 (Vavrek et al., 2016 and references therein). Fossil remains of this species have only been  
8 reported from the Upper Cretaceous of North America, across the Western Interior Basin  
9 (Schwimmer et al., 1997; Vavrek et al., 2016). The discovery of several virtually complete  
10 individuals in this area has provided valuable information about the anatomy, the dimensions,  
11 and the ecology of this species (Cope, 1872; Bardack, 1965). *Xiphactinus audax* displayed a  
12 tarpon-like body plan with a semi-lunate caudal fin and large caniniform teeth (Hay, 1898;  
13 Bardack, 1965; Carrillo-Briceño et al., 2012), suggestive of a highly active predatory lifestyle  
14 (Cavin et al., 2013). In fact, the emblematic ‘fish-within-a-fish’ specimen, containing an  
15 entire 2-m-long *Gillicus arcuatus*, provides evidence of the ability of *X. audax* to prey upon  
16 large, rapidly swimming fishes (Bardack, 1965).

32  
33 Predation entails a high energetic demand (Brown and Kotler, 2004). Ferrón et al.  
34 (2017) recently proposed that, because mass-specific metabolic rate decreases with increasing  
35 body size, highly active lifestyles (such as macropredation) cannot be maintained by an  
36 ectothermic metabolism over a specific body size. From this perspective, they argued that the  
37 punctual evolution of gigantism among macropredators was closely linked to metabolic-level  
38 shifts promoted by various factors (i.e., endothermy, highly efficient respiratory systems,  
39 warm temperatures, and high oxygen levels), and suggested that several extinct aquatic  
40 macropredators, including *Xiphactinus*, could have been meso- or endotherms on the basis of  
41 their body size and life history. Later, Ferrón (2017) established a useful methodology to  
42 assess the swimming energetics of extinct aquatic organisms, which can be used to interpret  
43 their metabolic levels and thermoregulatory strategies. This study presents an equivalent

## 10 MATERIALS AND METHODS

11  
12  
13  
14

15 The thermoregulatory strategy of *X. audax* was examined by comparing its estimated  
16 energy budget and cost of locomotion under an ectothermic and regionally-endothermic  
17 scenario at different water temperatures. This allowed for the determination of a range of  
18 potentially habitable water temperatures under each scenario (i.e., the temperature range is  
19 only viable when the estimated energy budget is greater than the cost of locomotion). In  
20 parallel, the actual range of water temperatures inhabited by this species was calculated from  
21 paleobiogeographical and paleoclimatic data. Comparison between potential and actual  
22 temperature ranges enabled exploration of the thermophysical strategy most likely adopted by

### 38 **Energy Budget Estimates**

39  
40  
41

42 Energy budget of *X. audax* was assessed using routine metabolic rate (RMR)  
43 estimates given that both parameters can be considered equivalent in a broad sense (Willmer  
44 et al., 2009; Clarke, 2013). RMR records of 24 active extant osteichthyans were compiled  
45 from FishBase (Oxygen Consumption Studies Tables; Froese and Pauly, 2017) and Watanabe  
46 et al. (2015) (Table S1 in Supplemental Data 1), and were temperature adjusted from 0°C to  
47 32°C (at 4°C increments) with a  $Q_{10}$  of 1.83 (according to Clarke and Johnston, 1999). Two  
48 additional analyses including species with different levels of activity were also undertaken  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60 (see Appendix S1 in Supplemental Data 1). Where multiple records of RMR and body mass

1  
2  
3 were available for the same species in FishBase the mean value was taken and subsequently  
4  
5 treated as a single data point. RMR records expressed in joules per second ( $J \cdot s^{-1}$ ) were  
6  
7 transformed to oxygen consumption units ( $mgO_2 \cdot h^{-1}$ ) assuming an oxycaloric value of 13.54  
8  
9  $J \cdot mgO_2^{-1}$  (following Brett and Groves, 1979). The scaling relationship between RMR and  
10  
11 body mass was independently established in ectothermic and regional endothermic taxa by  
12  
13 means of regression analysis, and differences between both groups were tested by ANCOVA  
14  
15 analysis in PASW Statistics software version 18.0.0. The RMR of *X. audax* was then inferred  
16  
17 at various temperatures in the ecto- and endothermic scenarios assuming body masses  
18  
19 between 1,300 kg and 1,430 kg. Mass range was established assuming a body volume of  
20  
21 1,300,000  $cm^3$  and a possible range of body densities from 1.0  $g \cdot cm^{-3}$  to 1.1  $g \cdot cm^{-3}$   
22  
23 (according to the typical values from living teleosts; see Lowndes, 1955, and Davenport,  
24  
25 1999). Body volume was calculated in Netfab Basic version 7.4.0 from a 3D virtual model of  
26  
27 *X. audax* (Supplemental Data 2; available for use under a Creative Commons license in the  
28  
29 Sketchfab platform, <https://sketchfab.com>) after scaling the model to 5.1 m total length  
30  
31 (following Shimada and Everhart, 2004).

#### 40 **Cost of Locomotion Estimates**

41  
42  
43  
44  
45 Costs of locomotion of *X. audax* were assessed from estimates of net cost of  
46  
47 swimming (NCS), as this is a suitable parameter for assessing energy expenditure of thrust  
48  
49 generation during swimming (Korsmeyer et al., 2002), and has been successfully utilized for  
50  
51 this purpose in both extant (Sundström and Gruber, 1998; Semmens et al., 2013) and extinct  
52  
53 groups (Ferrón, 2017; Ferrón et al., 2018). Power-performance curves for small fishes,  
54  
55 calculated using conventional respirometers, represent useful tools for inferring energy  
56  
57 expenditure in larger species (e.g., Sundström and Gruber, 1998; Semmens et al., 2013),  
58  
59  
60

1  
2  
3 particularly when the studied taxa share similar lifestyles (see references and a detailed  
4 discussion in Ferrón, 2017). Estimates of NCS for *X. audax* were calculated under  
5  
6 ectothermic and endothermic scenarios from power-performance curves from two extant  
7  
8 pelagic species, *Sarda chiliensis* (an ectotherm) (Sepulveda et al., 2003) and *Thunnus*  
9  
10 *albacares* (a regional endotherm) (Korsmeyer and Dewar, 2001), as the difference between  
11  
12 total metabolic rate (TMR, oxygen consumption at a particular swimming speed) and standard  
13  
14 metabolic rate (SMR, oxygen consumption at resting) (Appendix S2 in Supplemental Data  
15  
16 1). NCS values were inferred assuming a cruising swimming speed of  $3.65 \text{ m}\cdot\text{s}^{-1}$  (equivalent  
17  
18 to  $0.57$  body lengths per second,  $\text{BL}\cdot\text{s}^{-1}$ ), calculated from the method of Sambilay (1990) and  
19  
20 considering a body length of  $5.1 \text{ m}$  (Shimada and Everhart, 2004) and an aspect ratio of the  
21  
22 caudal fin of  $5.93$  (specimen FHSM VP-333 from Schwimmer et al., 1997:fig. 1; see  
23  
24 Appendix S2 in Supplemental Data 1 for further details on how this parameter was  
25  
26 calculated). NCS was considered identical for all temperature scenarios according to William  
27  
28 and Beamish (1990), Claireaux et al. (2006) and Ohlberger et al. (2007).

35  
36  
37

### 38 **Actual Temperature Range**

39  
40  
41  
42 The actual range of water temperatures inhabited by of *X. audax* was extrapolated  
43  
44 from a global map of Late Cretaceous mean sea surface temperatures (Tabor et al., 2016)  
45  
46 overlain with the current known paleobiogeographic distribution of this species (Vavrek et al.,  
47  
48 2016). The paleoclimatic map considered in this study constitutes the most recently published  
49  
50 global reconstruction of the Late Cretaceous, being based in multiproxy models that combine  
51  
52 both climatic modelling and isotopic records (see Tabor et al., 2016 for further detail).  
53  
54  
55  
56  
57

### 58 **Validation Test**

1  
2  
3  
4  
5  
6 The predictive power of the established framework for inferring thermophysiological  
7  
8 strategy in active pelagic osteichthyans was tested in a selection of living taxa from  
9  
10 simultaneous records of cruising swimming speeds, water temperatures, and body masses  
11  
12 (Table S2 in Supplemental Data 1). Two different validation tests were performed, the first  
13  
14 considering all RMR records from the original dataset for establishing the RMR scaling  
15  
16 relationship, and the second one performing a cross-validation analysis where the RMR  
17  
18 scaling regression was recreated without inclusion of the particular species being tested in the  
19  
20 each case.  
21  
22  
23  
24  
25

## 26 RESULTS

27  
28  
29  
30

31 Scaling relationship of RMR for both ectothermic and regional endothermic  
32  
33 osteichthyans fits well to a linear model ( $R^2_{\text{ecto}} = 0.95$ ;  $R^2_{\text{endo}} = 0.97$ ) (Fig. 1; see equations  
34  
35 calculated for each scenario in Appendix S3 in Supplemental Data 1). ANCOVA analysis  
36  
37 detected significant differences between both groups, suggesting that regional endothermic  
38  
39 osteichthyans exhibit a higher RMR than similar-sized ectotherms ( $p < 0.000$ ) (Fig. 1). Low  
40  
41 dispersion of the data allows for reliable RMR estimates for *X. audax* assuming ecto- and  
42  
43 endothermy under different temperature scenarios (Table 1). NCS values of  $57.09 \text{ mgO}_2 \cdot \text{h}^{-1} \cdot \text{kg}^{-1}$   
44  
45 and  $81.56 \text{ mgO}_2 \cdot \text{h}^{-1} \cdot \text{kg}^{-1}$  are predicted for *X. audax* swimming at  $0.57 \text{ BL} \cdot \text{s}^{-1}$   
46  
47 assuming ecto- and endothermy, respectively (Appendix S2 in Supplemental Data 1). When  
48  
49 contrasting RMR and NCS estimates, the model predicted that the range of potential habitable  
50  
51 water temperatures would vary depending on the thermophysiological strategy of *X. audax*  
52  
53 (Table 1). Thus, under the assumption of endothermy, this species could potentially live at  
54  
55 considerably colder temperatures (waters above  $4^\circ\text{C}$ ) than in an ectothermic scenario (waters  
56  
57  
58  
59  
60

1  
2  
3 above 28°C), which translates to disparate potential paleogeographical distributions (Fig. 2).  
4  
5  
6 When accounting for actual paleobiogeographic and paleoclimatic data, the estimated real  
7  
8 distribution and range of water temperatures (12–32°C) was inferred for *X. audax* that is  
9  
10 congruent with the endothermic scenario (compare Fig. 2B, C). Furthermore, the validation  
11  
12 tests support the high predictive power of this approach, as it is capable of correctly  
13  
14 determining the thermophysiological strategy of all the living species included (Table 2).  
15  
16  
17  
18

## 19 DISCUSSION

20  
21  
22  
23  
24 Regional endothermy is the ability of some living fishes to maintain the temperature  
25  
26 of certain body areas over that of the surrounding water (Block and Finnerty, 1994; Dickson  
27  
28 and Graham, 2004). Among chondrichthyans, regional endothermy has been documented  
29  
30 within alopiids (Weng and Block, 2004; Bernal et al., 2005; Sepulveda et al., 2005; Patterson  
31  
32 et al., 2011) and lamnids (Lowe and Goldman, 2001), and was likely present in two other  
33  
34 extinct families of lamniforms (Otodontidae and Cretoxyrhinidae) (Ferrón, 2017; see also  
35  
36 Maisey et al., 2017). Within osteichthyans, regional endothermy has been described in tunas  
37  
38 (tribe Thunnini, Scombridae), billfishes (Xiphiidae and Istiophoridae), and *Gasterochisma*,  
39  
40 although the last two taxa possess the ability to heat only the brain and the eyes (i.e., cranial  
41  
42 endothermy) (Block and Finnerty, 1994). Recently, whole-body endothermy has also been  
43  
44 recorded in the opah (*Lampris guttatus*) (Wegner et al., 2015). In the present study, a useful  
45  
46 methodology for predicting the most likely thermophysiological strategy of extinct  
47  
48 osteichthyans has been developed, also revealing the possible existence of endothermy in *X.*  
49  
50 *audax*, a basal teleost belonging to the extinct order Ichthyodectiformes (Nelson et al., 2016).  
51  
52 This study constitutes the first evidence of endothermy in a stem teleost (Arratia, 1999), and  
53  
54 would represent the earliest case of an endothermic taxon among osteichthyans, pushing the  
55  
56  
57  
58  
59  
60

1  
2  
3 appearance of this adaptation within this group back to the Turonian period (Late Cretaceous)  
4  
5 (Cavin et al., 2013). However, endothermy could also be present in other older large  
6  
7 ichthyodectiforms with similar macropredatory lifestyles.  
8  
9

10 Thermal niche expansion, promoted by oceanic cooling and tropical compression  
11 during the Late Paleocene and Early Eocene, has been proposed as the most likely  
12 explanation for the radiation and diversification of extant endothermic fishes (Dickson and  
13 Graham, 2004; but see also Ferrón, 2017). The selective pressures that drove the evolution of  
14 endothermy in *X. audax* cannot be reliably assessed until it is known whether this adaptation  
15 evolved in this species punctually or, conversely, if it was a generalized condition among  
16 ichthyodectiforms, and was also present in older forms. The thermal niche expansion  
17 hypothesis itself seems insufficient for explaining the evolution of endothermy in this group,  
18 given the warm climate and the reduced vertical and latitudinal temperature gradients present  
19 during most of the Jurassic and Cretaceous (Huber et al., 1995; Jenkyns et al., 2012;  
20 Giorgioni et al., 2015). Notwithstanding, other selective pressures acting in unison in a similar  
21 way to endothermic cretoxyrhinid sharks (Ferrón, 2017) could offer more convincing  
22 explanations. In this sense, competition with other predators, most of them endothermic taxa  
23 with higher prey capture rates (Wegner et al., 2015), and the elevated cruising speed  
24 hypothesis should be also considered in future studies. These are possible related factors  
25 given the evolution, rapid radiation, and diversification of various endothermic groups during  
26 the Cretaceous period (Everhart, 2005; Motani, 2009; Bernard et al., 2010; Harrell et al.,  
27 2016; Ferrón, 2017; Pimiento et al., 2019), the cosmopolitan distribution of the  
28 ichthyodectiforms, and their body and caudal fin morphology, which is suggestive of high  
29 locomotory capacity (Cavin et al., 2013). In any case, it is important to emphasize that niche  
30 expansion, competition, and elevated cruising speeds are not mutually exclusive hypotheses  
31 (see Watanabe et al., 2015; Wegner et al., 2015).  
32  
33

58  
59  
60

1  
2  
3  
4 Marine predators have experienced a tendency toward larger, faster, and more mobile  
5  
6 forms from the Paleozoic to the present (Vermeij, 2002). Extant communities of marine  
7  
8 vertebrates, especially those inhabiting comparatively high latitudes, usually include highly  
9  
10 active meso- or endothermic top predators such as tunas, lamnid sharks, birds, or marine  
11  
12 mammals (Cairns et al., 2008). The results presented here provide evidence of *X. audax*  
13  
14 representing an endothermic taxon, which constitutes further evidence supporting endothermy  
15  
16 already being a common trait among Cretaceous marine vertebrate top predators, including  
17  
18 ichthyosaurs (Bernard et al., 2010), mosasaurs (Bernard et al., 2010; Harrell et al., 2016),  
19  
20 cretoxyrhinid sharks (Ferrón, 2017), and now ichthyodectiform osteichthyans. In fact,  
21  
22 representatives from the majority of these taxa coexisted not only temporally, but also  
23  
24 geographically in non-tropical latitudes, as occurred in the Western Interior Sea (Shimada and  
25  
26 Everhart, 2004; Myers and Lieberman, 2010). Altogether, these aspects highlight the  
27  
28 singularity of Cretaceous marine ecosystems, where vertebrate predator communities not only  
29  
30 acquired unprecedented levels of taxonomic diversity (Walker and Brett, 2002), but were also  
31  
32 characterized by the independent evolution of highly active lifestyles and energetically costly  
33  
34 thermophysiological strategies among phylogenetically distant taxa.  
35

## 43 CONCLUSIONS

44  
45  
46  
47 This study presents a useful approach for assessing the thermophysiological strategy  
48  
49 of extinct osteichthyans by comparing energy budgets and cost of locomotion estimates under  
50  
51 ecto- and endothermic scenarios. By applying this framework, the presence of endothermy is  
52  
53 supported in *X. audax*, the largest macropredatory osteichthyan ever known. This finding  
54  
55 constitutes the first evidence of endothermy in a stem teleost, and represents the earliest case  
56  
57 of an endothermic taxon among osteichthyans—pushing the appearance of this adaptation in  
58  
59  
60

1  
2  
3 such groups back to the Late Cretaceous. These results also highlight the singularity of  
4  
5 Cretaceous marine ecosystems, further supporting that vertebrate predator communities were  
6  
7 already dominated by endothermic taxa belonging to several phylogenetically distant groups  
8  
9 during this period.  
10

#### 14 15 ACKNOWLEDGMENTS

16  
17  
18  
19 I want to thank the two anonymous reviewers and editor L. Sallan for providing  
20  
21 thoughtful and valuable comments on the manuscript. I thank artist Julian Johnson-Mortimer,  
22  
23 whose work appears in Supplemental Data 2. I am also grateful to K. R. Harrold for her role  
24  
25 in the proofing process. H.G.F. is a recipient of a Marie Skłodowska-Curie Individual  
26  
27 Fellowship (H2020-MSCA-IF-2018-839636).  
28

FIGURE 1. Routine metabolic rate (RMR) scaling relationships established for living ecto- and regionally endothermic osteichthyans (in green and red, respectively) temperature adjusted to 16 °C. [planned for column width]

FIGURE 2. **A**, paleogeographic reconstruction of the entire Late Cretaceous globe and Western Interior Basin (zoomed, below), indicating mean sea surface temperatures (SST) (modified from Tabor et al., 2016). The range of potential habitable water temperatures (i.e., range of water temperatures within which energetic budget surpasses the net costs of swimming) and potential paleobiogeographic distribution of *Xiphactinus audax* are shown assuming **B**, ectothermy (in green) and **C**, endothermy (in red). Fossil occurrences of this taxon, representing its real distribution, are denoted with asterisks (according to Vavrek et al., 2016). [planned for page width]

TABLE 2. Routine metabolic rate (RMR) and net cost of swimming (NCS) estimates predicted from the established framework for living active pelagic species assuming ectothermy and regional endothermy. Note that ectothermy is discarded as a likely strategy in *Thunnus* species, as NCS exceeded RMR under an ectothermic scenario. *Istiophorus platypterus* and *M. nigricans* can be considered ectothermic fishes in terms of locomotion performance, because these species exhibit only eye and brain warming (i.e., cranial endothermy) and do not possess warmed red muscle.
