Cover: A crack that developed during hot-pressing of a high-purity polycrystalline spinel compact. The color change indicates uniaxial tensile stress, likely caused by a combination of differential sintering and preferential MgO evaporation. In turn, this resulted in grain coarsening and a lower CTE offset by a smaller lattice parameter and a volume reduction. Dark spots at lower left are aggregates of abnormal grains radiating from an unknown impurity source (5X obj, 50X mag, polarized light, full-wave retardation plate).

Erklärung zur Dissertation

Hiermit versichere ich die vorliegende Dissertation ohne Hilfe Dritter nur mit den angegebenen Quellen und Hilfsmitteln angefertigt zu haben. Alle Stellen, die aus Quellen entnommen wurden, sind als solche kenntlich gemacht. Diese Arbeit hat in gleicher oder ähnlicher Form noch keiner Prüfungsbehörde vorgelegen.

Darmstadt, den 20 September 2018

(Marc Rubat du Merac)

Acknowledgments

I sincerely thank my advisor, Hans-Joachim Kleebe for his support and patience, without which this work would not have been completed. I am also deeply indebted to Ivar Reimanis. I thank my wife, Melanie Slemko for her support in difficult times. I thank my parents, Jacques and Adine Rubat du Merac for their support and encouragement, and my grandfather, Jacques Tricand de la Goutte, for inspiration. The research was conducted with the help of many others and I thank Tim Jochum (hot-press, ICP), Scott Pawelka (instrumentation), Anne Cenadella (HIP), Subramanian Ramalingam (particle-size analysis), Shai Meir (spinel articles), Ulrike Kuntz, Gary Zito and John Chandler (electron microscopy), Frank Anderson and Steve Govorchin (LA-ICP), Pat Taylor (HSC), Charlene Smith (fluorescence spectroscopy, WDS), Mike Sanders (dilatometry, STA-MS), Harvey Guthrey (FIB), Brian Gorman and Maria Romanes (STEM-EDS), Leo Molina and Stefan Lauterbach (STEM-EELS), Mathis Müller (TEM specimens), Jason Stoke (ellipsometry), Joseph Tsai and Ingo Sethman (AFM), Yi Ke (Raman spectroscopy), Tod Gross (EFM), Santhana Moorthy (SIMS, PIES), Shen Dillon and Ling Fen (SIMS); Ryan O'Hayre, Jinhua Tong, Chung Min An, and Chan Young Kim (EIS); Aidan Seawalt and Anthony Linenberger (various experiments), Rishi Raj and John Francis (FAST), David Olson and Gerard Martins (scientific advice and inspiration), and to all my colleagues for lively conversations.

Abstract

Transparent ceramics have unique properties that can enable applications that no other materials can and they have recently engendered renewed interest due to scientific and technological advances. Polycrystalline magnesium aluminate spinel is one promising transparent ceramic with an exceptional combination of properties that is at the forefront of these developments. However, the powder-processing-property relationships of transparent spinel fabrication are still poorly understood, precluding repeatably obtaining components with acceptable properties at reasonable cost. In particular, interfaces, such as surfaces and grain boundaries, often govern densification and final properties, yet little is known of how they are affected by stoichiometry, impurities, additives, and processing parameters, and consequently how they affect microstructure during processing. In this light, the interfaces of transparent spinel compacts were studied with the goal of understanding their properties and behaviors.

Spinel powders with different stoichiometries and impurity and LiF additive contents were prepared and extensively characterized. Starting powders were densified into transparent compacts by hot-pressing, hot-isostatic pressing and pressureless sintering under a variety of processing conditions designed to elucidate the behavior of their interfaces, especially in relation to microstructure evolution and opto-electronic properties. Dense compacts were examined by optical and electron microscopy and various spectroscopic methods. Grain boundaries and surfaces were examined by optical microscopy, scanning and transmission electron microscopy, convergent-beam electron diffraction, energy- and wavelength-dispersive X-ray spectroscopy, electron-energy loss spectroscopy, secondary-ion mass spectroscopy, parallel-ion electron spectroscopy, atomic-force microscopy, and electrochemical impedance spectroscopy. In turn, the features of interfaces were related to starting powders, processing, and bulk properties.

Crystallite surfaces and grain boundaries were found to be highly sensitive to small differences in stoichiometry and impurity and additive content, which altered their free energy, diffusion, lattice parameter, and mechanical, optical, and electronic properties. The interface energies of stoichiometric compositions were quantified and found to be more conducive to densification. However, enhanced interface transport for Al_2O_3 -rich compositions caused

coarsening, resulting in larger grain size and precluding densification without pressure while assisting it with pressure. Stoichiometry was also observed by way of gradients at interfaces and on a compact scale, which resulted in associated microstructure and property gradients. Impurities in starting powders and carbon contamination from processing segregated at grain boundaries and significantly affected microstructure, were the main source of optical scatter and absorption, and increased conductivity. Dielectric properties were found to be a complex function of microstructure, stoichiometry, impurities, and additives, and higher conductivity for dense compacts compared to single crystals was attributed to conductance along impurity-rich magnesium-depleted grain boundaries, especially for Al_2O_3 -rich stoichiometry.

The LiF sintering additive was found to have a powerful, complex, and multi-faceted effect. Fluorine reacted with impurities to form volatile species, which could be removed by careful processing to render transparency, and it also reacted with spinel to form magnesium fluoride and oxide, thus altering stoichiometry. Whereas, lithium incorporated into the lattice and altered interface energies, diffusion, and conductivity. The net effect was (i) a shift towards Al_2O_3 -rich composition, (ii) the removal of impurities, (iii) accentuation of grain-boundary and compact-scale stoichiometry and microstructure gradients, (iv) enhanced interface transport and grain growth, (v) reduced densification temperature and enhanced densification with pressure-assisted sintering, (vi) coarsening and inhibited densification without pressure, (vii) grain-boundary embrittlement, (viii) grain-boundary optical scatter, (ix) opacity when processing trapped LiF and its by-products, and (x) lower conductivity due to decreased grain-boundary area and impurities, and the formation of conductance-inhibiting point defects.

The work demonstrated how interfaces were affected by starting powders and processing parameters and in turn how this affected microstructure, fracture behavior, and opto-electronic properties. The findings shed light on many of the intricacies of transparent spinel fabrication, enabling a better understanding of powder-processing-property interactions and giving guidance on how to tailor processing and microstructure to yield desired bulk properties.

List of Symbols

(g)	Gas phase
(l)	Liquid phase
(s)	Solid phase
[]	Concentration
	Field-parallel
⊥	Field-perpendicular
a	Lattice parameter
A	Absorptance, ampere, area, cross-sectional area, interfacial area
Å	Ångström
ABF	Annular brighfield
AC	Alternating current
Ac Mix	Acoustic mix
Add	Addition
AFM	Atomic force microscopy
Ann	Anneal
APS	Average particle size
BET	Brunauer-Emmett-Teller surface area
BF	Brightfield
BR	Biaxial ring-on-ring flexure test
C	Capacitance
C_0	Open cell capacitance
C_{bulk}	Bulk capacitance
C_{eff}	Effective capacitance
$C_{\text{gb-L}}$	Series grain-boundary capacitance
CBED	Convergent-beam electron diffraction
CCD	Charge couple device
CIP	Cold isostatic press
CP	Cold Press
CPE	Constant phase element

CRSS	Critical resolved shear stress
CTE	Coefficient of thermal expansion
d	Size of scattering center, grain boundary width, groove depth
d_{\parallel}	Field-parallel grain-boundary width
d_{\perp}	Field-perpendicular grain-boundary width
d_{50}	Average particle diameter
D	Grain size
D_B	Grain boundary diffusivity
D_V	Volume diffusivity
DF	Darkfield
DFT	Density functional theory
DI	Depth-sensitive indentation
dn/dT	Refractive index change with temperature
$dn/d\lambda$	Refractive index homogeneity
DSC	Differential scanning calorimetry
e	Electron, electron charge, base of natural logarithm
E	Modulus of elasticity, electric field
E_a	Activation energy
E_F	Formation energy
E_g	Bandgap energy
EBSD	Electron backscattered diffraction
ED	Electron diffraction
EDS	Energy-dispersive X-ray spectroscopy
EELS	Electron energy loss spectroscopy
EFM	Electrostatic force microscopy
EIS	Electrochemical impedance spectroscopy
erg	10^{-7} Joules
eV	Electron volt
f	Frequency
f_{\max}	Resonant frequency
F-	Two trapped electron color center
F+	Single trapped electron color center

FAST	Field-assisted sinter
FD	Freeze dried
FIB	Focused ion beam
FOLZ	First-order Laue zone
g	Gram
GB, gb	Grain boundary
GB1	Green body 1
GB2	Green body 2
GC	Gelcast
GDMS	Gas-discharge mass spectroscopy
GHz	Gigahertz
GPa	Gigapascal
GS	Average grain size
h	Hour, electron hole, Planck's constant
H	Spacing of reciprocal lattice planes
HIP	Hot isostatic press
HK	Hardness Knoop
HP	Hot press
HRTEM	High-resolution transmission electron microscopy
HV	Hardness Vickers
Hz	Hertz
i	Inversion parameter
I	Indentation
I_0	Incident intensity
I_A	Absorption
I_{DT}	Diffuse transmittance
I_{ILT} , ILT	In-line transmittance
I_{RD}	Diffuse reflectance
I_{RS}	Specular reflectance
I_{RT}	Reflected transmittance
I_T , IT	Total forward transmittance
I_{TT}	Total transmittance

IBR	Intrinsic birefringence
ICP	Inductively-coupled plasma
IE	Impulse excitation
Im	Imaginary
IR	Infrared
j	Square root of -1
J	Joule
k	Boltzmann's constant
K	Kelvin
kN	Kilo Newton
L	Camera length, thickness (EIS)
l	Liter
L_0	Initial side length
$L_{compact}$	Length of compact
L_i	Instantaneous side length
L_{std}	Length of standard
LA	Laser ablation
lbs	Pounds
LVDT	Linear variable differential transformer
m	Meter
m_0	Electron mass
M	Modulus (EIS)
m/z	Mass-to-charge ratio
Max	Maximum
mg	Milligram
MHz	Megahertz
min	Minutes
ml	Milliliter
mol%	Mole percent
MPa	Megapascal
mPa	Milli Pascal
MS	Mass spectroscopy

n	Refractive index, neutron
n_c	Constant phase element exponent
N	Newton
NAA	Nuclear activation analysis
NMR	Nuclear magnetic resonance
Null	Perfect lattice
obj	Objective lens
OES	Optical emission spectroscopy
OM	Optical microscopy
P	Pressure application
Pa	Pascal
PC	Polycrystal
PEG	Polyethylene glycol
PIES	Parallel-ion electron spectroscopy
PLM	Polarized light microscopy
p_{O_2}	Oxygen partial pressure
ppm	Parts per million
ppmv	Parts per million volume
ppmw	Parts per million weight
P_s	Fractional sintered density
PS	Pressureless sinter
PVA	Polyvinyl alcohol
p_x	Partial pressure of species formed during reduction
Q	Constant phase element parameter
r	Grain radius, radius of first-order Laue zone
r_0	Initial grain radius
R	Reflectance, resistance, distance between SAD reflections
R'	Thermal shock parameter
R_{bulk}	Bulk resistivity
R_D	Diffuse reflectance
R_S	Specular reflectance
R_{S1}	Reflectance from a single surface

R_{S2}	Reflectance from two surfaces
R_T	Total reflectance
RC	Resistor-capacitor
Re	Real
rel	Relative
RF	Radio frequency
RGA	Residual gas analyser
RIT	Real in-line transmittance
rms	Root-mean squared
RS	Reactive sinter
s	Seconds, inter-ridge distance
S	Seimens, Scatter
SA	Surface area
SAD	Selected-area diffraction
SBR	Stress birefringence
SC	Single crystal, slip cast
SEM	Scanning electron microscopy
SPS	Spark-plasma sinter
STA	Simultaneous thermal analysis
STEM	Scanning transmission electron microscopy
t	Thickness, time
T	Temperature
T_{Amb}	Ambient temperature
TEM	Transmission electron microscopy
TFT	Total forward transmittance
TGA	Thermogravimetric analysis
TOF-SIMS	Time-of-flight secondary-ion mass spectroscopy
u	Anion parameter
US Mix	Ultrasonic mix
UV	Ultraviolet
UV-Vis-IR	Ultraviolet-Visible-Infrared
V	Volts

V-	Trapped hole color center
V_0	Voltage amplitude
Vac	Vacuum
v_{gb}	Grain boundary volume fraction
V_i	Instantaneous volume
Vis	Visible
W	Watt
W_0	Initial weight
WDS	Wavelength-dispersive spectroscopy
wt%	Weight percent
x	Stoichiometry $MgO:xAl_2O_3$
XRD	X-ray diffraction
YAG	Yttrium aluminum garnet
Z	Impedance
Z_0	Impedance magnitude
ZA	Zone axis
ZL	Zero-loss
α	Absorption coefficient
α_L	Linear coefficient of thermal expansion
γ	Interfacial energy
γ_{gb}	Grain boundary energy
γ_s	Surface energy
Δ	Change
δ	Loss tangent
ΔL	Linear displacement
$\Delta L/L_0$	Linear shrinkage per unit length
ϵ	Dielectric constant
ϵ_0	Permittivity of free space
ϵ_{bulk}	Bulk permittivity
ϵ_{gb}	Grain boundary permittivity
θ	Dihedral angle
κ	Thermal expansion coefficient

λ	Wavelength
ξ	Anisotropy ratio
ρ	Resistivity
ρ_{bulk}	Bulk resistivity
ρ_g	Green density
$\rho_{\text{gb}\perp \text{ sp}}$	Specific field-perpendicular grain-boundary resistivity
ρ_i	Instantaneous density
ρ_t	Total resistivity
ρ_{th}	Theoretical density
σ	Conductivity, stress
σ_0	Conductivity pre-exponential constant
σ_{bulk}	Bulk conductivity
$\sigma_{\text{bulk series}}$	Bulk conductivity using the series model
σ_{gb}	Grain boundary conductivity
$\sigma_{\text{gb}\parallel \text{ sp}}$	Specific field-parallel grain-boundary conductivity
$\sigma_{\text{gb}\perp \text{ sp}}$	Specific field-perpendicular grain-boundary conductivity
σ_{sc}	Single-crystal conductivity
σ_{series}	Conductivity across the bulk and grain boundaries
σ_t	Total conductivity
σ_T	Transition stress
τ	Time constant
ν	Poisson's ratio, volume fraction (EIS)
φ	Phase shift
Φ	Diameter, phase shift
Φ_f	Final diameter
Φ_i	Instantaneous diameter
Φ_o	Initial diameter
Ψ	Dihedral angle
ω	Angular frequency
ω_{max}	Angular frequency at imaginary maximum

CHAPTER 1 INTRODUCTION

Advances in powder synthesis, processing and scientific understanding have enabled overcoming some of the limitations of polycrystalline ceramics, such as their brittle nature and the difficulty of fabricating dense compacts. In turn, these developments have garnered a renewed interest in transparent ceramics due to their unique functional properties, such as high hardness, chemical inertness, thermal resistance, and high transmission over a wide range of wavelengths. Polycrystalline magnesium aluminate spinel has been at the forefront of these developments due to its isotropic crystal structure and an attractive combination of physical properties. However, there remains a significant lack of understanding of the properties and behaviors of the interfaces of spinel as a function of stoichiometry, impurities, and additives, and how these change during processing. Interfaces, such as surfaces and grain boundaries, largely govern sintering, densification and microstructure evolution in ceramics and other polycrystalline materials, and they can significantly affect the physical properties of bulk compacts. In this light, the properties and behaviors of the interfaces of spinel compacts made using a variety of starting powders with different stoichiometries, impurity contents, additive contents, and using different processing methods and parameters were examined using a wide-range of analytical methods.

1.1 Motivation

The motivation for the research was to understand the structure-processing-property relationships involved in the fabrication of transparent spinel, in order to improve the mechanical and optical properties of bulk compacts and thus widen applications. The goal was to characterize and understand interfaces, in particular how they are affected by stoichiometry, impurities, LiF additive and processing, and in turn, to understand how this affected bulk properties.

1.2 Objectives

Specific objectives included; (i) characterizing interfaces, (ii) determining the effect of stoichiometry, LiF additive, impurities, and processing parameters on their properties, and (iii) determining the effect of interfaces on sintering, densification, microstructure evolution and bulk mechanical, optical, and electronic properties.

1.3 Summary of Work

Experiments were designed to elucidate the role of interfaces in the processing-structure-property relationships of transparent spinel, with attention paid to identifying relationships between variables spanning the entirety of processing. To enable identifying these relationships, starting powders and bulk compacts were extensively characterized. Starting powders with different stoichiometries and impurity and LiF additive contents were characterized by X-ray diffraction, inductively-coupled plasma in combination with optical-emission and mass spectroscopy, carbon-sulfur and nitrogen determination, optical and electron microscopy, particle-size analysis, and Zeta potential. Sintering behavior was assessed by dilatometry and hot-press ram displacement analysis, and chemical interactions by thermal analysis combined with mass spectroscopy and thermodynamic simulations. Compacts were densified by hot-pressing, pressureless sintering and hot-isostatic pressing. Dense compacts and interfaces were characterized using optical microscopy, scanning electron microscopy in combination with energy and wavelength-dispersive spectroscopy and electron-energy backscatter spectroscopy; transmission electron microscopy in combination with convergent-beam electron diffraction, energy-dispersive X-ray spectroscopy, and electron energy-loss spectroscopy; secondary-ion mass

spectroscopy, parallel-ion electron spectroscopy, and atomic-force microscopy. Optical properties were assessed by spectrophotometry, ultraviolet laser fluorescence, and Raman spectroscopy, and dielectric properties with electrochemical impedance spectroscopy. Interface properties were then related to starting powder properties, processing parameters, microstructure evolution, and optoelectronic properties.

1.4 Structure of Thesis

The thesis contains six chapters, references, and personal information:

1. Chapter 1 is an introduction consisting of the motivation, goals, and objectives.
2. Chapter 2 is a background on the processing and properties of transparent spinel.
3. Chapter 3 discusses the experimental methods.
4. Chapter 4 presents combined results and discussion.
5. Chapter 5 is a general discussion of the results.
6. Chapter 6 is a summary of the main findings.
7. “References” lists references cited.
8. “Personal Information” contains personal information.

Four articles were published based on the research: “The Role of LiF and Impurities in the Sintering and Optical Properties of Transparent Polycrystalline MgAl_2O_4 Spinel”,¹ published in the International Journal of Applied Ceramic Technology, “50 Years of Research and Development Coming to Fruition; Understanding the Complex Interactions during Processing of Transparent Magnesium Aluminate (MgAl_2O_4) Spinel”,² published as an invited feature in the Journal of the American Ceramic Society, “Electrochemical Impedance Spectroscopy of Transparent Polycrystalline MgAl_2O_4 Spinel”,³ published in the Journal of the American Ceramic Society, and “Interface Energies in Transparent Non-Stoichiometric Spinel Determined by Thermal Grain-Boundary Grooving”, to be submitted for publication in the Journal of the European Ceramic Society, and a related article “Enhanced Fracture Toughness in Non-stoichiometric Magnesium Aluminate Spinel through Controlled dissolution of Second Phase Alumina” was published in the Journal of the American Ceramic Society.

CHAPTER 2 BACKGROUND

This chapter provides a detailed background on the processing and properties of polycrystalline transparent spinel, which are crucial to understanding interfaces and their interactions. Section 2.1 is a general introduction, Section 2.2 discusses properties, Section 2.3 discusses processing, Section 2.4 discusses stoichiometry, Section 2.5 discusses impurities and additives, Section 2.6 discusses processing parameters, and Section 2.7 is a summary.

2.1 Introduction

The quest for materials to satisfy demanding optical applications combined with scientific and technological advances have spurred a resurgent interest in transparent polycrystalline ceramics.⁴⁻¹¹ Transparent ceramics have a unique combination of properties that is not obtainable with other materials,¹² and unlike single crystals, they can be formed into complex near-net shapes from commercially-available powders at lower cost.¹³ Transparent polycrystalline spinel is an especially promising and rapidly-maturing technology. However, although it has been studied for over 50 years, highly-transparent components with acceptable mechanical properties have only recently been reliably fabricated at reasonable cost.^{4,10,13-17} Spinel is difficult to sinter to the near-theoretical density required for transparency and fabrication is complicated by variable stoichiometry and high sensitivity to powder and processing parameters.^{1,4,8} These difficulties, combined with a poor understanding of synthesis-processing-structure-property relationships, have hindered development.⁴ Key to recent success is an emerging understanding of complex, multi-scale, multi-variable interactions occurring during green-body formation and sintering.^{8,18,19} In particular, particle-size characteristics, stoichiometry, and impurities play a decisive role in determining compact properties and successful fabrication entails tracking these variables from synthesis to the finished product.

Magnesium aluminate spinel (MgAl_2O_4 , spinel) is a naturally-occurring, often twinned, cubic mineral with octahedral habit.²⁰ It is transparent to opaque and exhibits various colors, most notably red due to chromium impurity.²⁰ The general chemical formula $(\text{Mg,Fe})(\text{Al,Cr})_2\text{O}_4$ is a common constituent of peridotite, the main mineral comprising the Earth's upper mantle.²¹ The spinel structure is the prototype for the larger spinel group, with formula unit AB_2X_4 , where A and B are cations with net charges of +2 and +3, respectively, and X is an anion with a net charge of -2.²² A wide range of cations, including aliovalent substitutions, can occupy the A and B positions, with iron (Fe^{2+} and Fe^{3+}) occupying both in magnetite (Fe_3O_4). The X anion is typically oxygen, but can be occupied by sulfur or other aliovalent anions. This large variety of elemental substitutions leads to a wide range of minerals and compounds with the spinel structure and also to a wide range of substitutions and point-defects in polycrystalline compacts.

Spinel has a combination of isotropic cubic structure, low density, high hardness, erosion resistance, high strength, transparency from the near-UV (ultra-violet) to the mid-IR (infra-red), and high-temperature stability possessed by few materials.^{4,23} Transparent non-oxides such as ZnS, ZnSe, Si₃N₄, and SiC possess good IR-transmittance, but have so far exhibited lower visible transmittance.²³ Alkaline and alkali-metal halides like MgF₂, and also glasses and glass-ceramics, have lower mechanical and thermal properties.²³ Competing transparent ceramics include sapphire and polycrystalline Al₂₃O₂₅N₅ (AlON), Al₂O₃, MgO, cubic ZrO₂, Y₂O₃, Y₂Al₅O₁₂ (YAG), and diamond.^{6,11,19,23-30} Sapphire and AlON have excellent mechanical and optical properties, but are denser, harder to polish, more expensive to produce, and birefringence in sapphire requires single crystal use.^{4,13,31} In addition, these ceramics have a lower IR absorption edge and transmission at the 4.8 μm exhaust signature wavelength used for IR-sensing, especially at higher temperature.¹² ZrO₂ has a higher IR absorption edge than spinel, but also higher density, and lower hardness, erosion resistance and visible transmittance.²³⁻²⁵ YAG and Y₂O₃, used in laser applications, both have high transmittance and wider transmission windows than spinel, and Y₂O₃ lower emittance.^{6,11,23-26,30} However, they are significantly denser, have lower hardness and erosion resistance, and are more expensive.^{6,11,23-26,30} Polycrystalline MgO and Al₂O₃ have excellent mechanical properties, but MgO has poor visible transmittance²³ and polycrystalline Al₂O₃, although showing promise for IR windows and domes, is translucent in thick sections due to birefringence, even with nanometer-sized grains.^{23-25,27} Single crystal and polycrystalline diamond produced by chemical vapor deposition have excellent optical and mechanical properties, but they are difficult and expensive to fabricate and are not yet commercially available.^{23,28,29}

Until recently, spinel had only been used sporadically in military applications such as transparent armor, IR-transparent windows for missile launchers and reconnaissance pods, and transparent domes for IR-seeking missiles.^{4,32,33} However, it is now being used or considered for windows for UV lithography, spacecraft, barcode scanners, watches, night-vision systems, high-temperature sight-glasses, and laser ignitors.^{10,13,15,34-40} Moreover; multi-spectral windows for imaging, ranging, and targeting in ground, sea, and air vehicles.¹⁴ In addition; UV, miniaturized, and refractive index lenses; laser and scintillator hosts, and laser Q-switches.^{8,10,13,15,34-40}

Spinel was first synthesized accidentally in the mid-18th century⁴¹ but polycrystalline spinel only found commercial use starting in the 1960's, mainly as refractory brick material for the steel-making industry and with limited use as anode and catalyst support material.^{19,42} Transparent spinel development began in the 1960's in the U.S. and The General Electric Co. (Fairfield, CT, USA) was first to successfully fabricate visibly transparent material, which also had an IR-transmittance >60% at ~3 mm thickness.⁴ Compacts were cold-pressed (CP) from calcined Al₂O₃ and MgO powders with Li₂O and SiO₂ additives, embedded in powder of similar stoichiometry in a molybdenum enclosure, and sequentially pressureless sintered (PS) up to 1900°C in H₂.^{12,43,44} Development continued in the 1970's–1990's with hot press (HP), HP/hot isostatic press (HIP), and fusion-cast spinel (which suffered from residual stress), however production was fraught with difficulties.⁴ Initially, obtaining high transparency was an issue, but then reproducibility and optical defects became prime concerns.⁴ These were attributed to small differences in powder stoichiometry and impurity content that often precluded transparency, a condition which only improved once higher-quality powders became available.⁴ Sintering additives were initially necessary for transparency, but they interfered with transmittance, and LiF emerged as the most useful additive.⁴ Since the 1990's, many of the inherent issues with achieving transparency were solved and interest shifted towards optimizing processing, lowering cost, and improving mechanical properties, mainly through grain-size reduction.^{4,8,45}

Translucent or transparent spinel has since been produced by PS,^{43,46-48} HP,^{1,33,49,50} HP/HIP,^{13,51-57} PS/HIP,^{13,34,38,45,54,58-61} spark plasma sintering (SPS),⁶²⁻⁶⁷ field-assisted sintering (FAST),¹⁸ fusion casting,⁶⁸ and melt-casting⁶⁹ sometimes in combination with reactive sintering (RS).^{51,57,58,70} However, nearly all commercial manufacture is currently with HP/HIP or PS/HIP, producing components up to 10 cm thick and 50 cm in diameter, and larger windows up to 0.52 m² by diffusion edge-bonding of smaller panes.^{16,56} LiF (0.25–4 wt%) is typically required for transparency with pressure-assisted sintering (HP, HP/HIP, and SPS), but with the advent of high-purity nano-powders and improved pre-treatment, the trend is towards not using additives.^{4,8,36} The ultimate goal is pressureless sintering without HIP, but only translucency has been achieved and all commercial fabrication uses pressure to increase sintering kinetics (HP, SPS) or close residual pores (HP, HP/HIP, PS/HIP, SPS).^{4,8} Electric fields (SPS, FAST) increase kinetics and reduce grain size, but geometry is limited and sintering rates comparable to HP appear necessary for high transparency.⁸ Increasing kinetics by irradiating powders and

microwave sintering^{44,70} have also been attempted without significant success.⁷¹ Despite progress achieved, considerable headway remains, including increasing reproducibility, scaling-up fine grain-size technologies, grain-boundary engineering with new additives, lowering absorption near absorption edges, and lowering cost. In addition, many questions remain only partially answered, such as the causes of grain growth, absorption, and optical defects, as well as the specific role of stoichiometry, defect chemistry, and sintering additives.

2.2 Physical Properties

This section discusses the physical properties of transparent spinel, including thermodynamics (Section 2.2.1), crystal structure (Section 2.2.2), interfaces (Section 2.2.3), diffusion (Section 2.2.4), and electronic (Section 2.2.5), optical (Section 2.2.6), and mechanical properties (Section 2.2.7), and describes the physical requirements for various applications (Section 2.2.8).

2.2.1 Thermodynamic Properties

Spinel is the only intermediate compound of the MgO-Al₂O₃ phase system (Fig. 2.1).^{72,73} Formation from its constituents is exothermic and occurs by cation counter-diffusion through a stationary oxygen lattice^{71,74} with an accompanying ~5-8 vol% expansion.^{19,75} Although spinel forms a line compound of equal mol% MgO and Al₂O₃ at equilibrium below ~1200°C, it has increasing solubility with temperature, especially for Al₂O₃, as described by x in MgO: x Al₂O₃, with a maximum range of $0.6 \leq x \leq 9.1$.⁷² The solid-solubility end-member on the Al₂O₃-rich side is the highly-defected cubic γ -Al₂O₃ polymorph.⁷⁶ In practice, single-phase variable stoichiometry $\sim 1 \leq x \leq 3$ is quenched in with moderate cooling rates ($< 5^\circ\text{C}/\text{min}$).^{1,4,73,76,77}

The vapor pressure of Mg or MgO over spinel is up to 10^3 times higher than that of Al₂O₃,⁷⁸ resulting in Mg/MgO loss and variable stoichiometry during sintering. Mg/MgO loss is greater at high temperature and low oxygen partial pressure ($p\text{O}_2$),⁷⁹⁻⁸¹ and reducing conditions favor the decomposition of MgO(g) into Mg(g) and O₂(g).^{75,82} Stoichiometry may also be affected by formation of AlO₂ gas, which is exacerbated by carbon present in graphitic furnaces. Variable stoichiometry affects virtually every property and is both a source of complexity and a key to understanding spinel (Section 2.4).

2.2.2 Crystal Structure and Defects

In spinel, the larger O^{2-} anions form a cubic close-packed sub-lattice, rendering isotropic properties, and the cations occupy only $\frac{1}{4}$ of the interstices (Fig. 2.2). The cubic symmetry is visualized by considering a larger unit cell composed of 8 $MgAl_2O_4$ formula units with the lattice parameter (a) determined by the cations. In normal spinel, larger Mg^{2+} cations occupy $\frac{1}{8}$ of the smaller tetrahedral interstices and smaller Al^{3+} cations occupy $\frac{1}{2}$ of the larger octahedral interstices, dilating anions from their ideal cubic arrangement, characterized by the anion parameter (u). The structure can accommodate significant cation site-exchange, characterized by the inversion parameter (0 [normal] $\leq i \leq 1$ [inverse]), with $i \sim 0.1-0.6$ for synthetic spinel.^{22,85}

A wide variety of point defects exist in spinel and defect chemistry is a key parameter that influences many properties (Sections 2.4-2.6).^{22,76,86-90} In turn, it is affected by stoichiometry, impurities, additives,³⁶ mechanical treatment,⁹¹ irradiation,⁹² sintering atmosphere,^{75,79-83} temperature,⁹³ and applied pressure.^{22,76,86-90}

Fig. 2.2: Unit cell of spinel depicting symmetry (shaded) and octahedral and tetrahedral interstices.¹⁵

Intrinsic point defects in Kroger-Vink notation include:

Point defects in high-bandgap ionic compounds like spinel are typically charge-compensated by ionic rather than electronic defects, with interstitial (Frenkel) and anionic defects (O_i'' , $V_O^{\bullet\bullet}$) less favorable than Schottky defects due to strain in the close-packed anion lattice.⁹⁴ Cation inversion (antisite) is the predominant intrinsic point defect in spinel and is self-compensating:⁹²

Inversion causes variation in u , affecting the path of diffusing species and altering the equilibria of other defects.²² For example, Eq. (2.5) combines with Eqs. (2.1-2.4) to replace V_{Al}''' with $V_{Mg}'' + Mg_{Al}'$ or V_{Mg}'' with $V_{Al}''' + Al_{Mg}^{\bullet}$. Inversion is induced by heating to higher temperature and has been quantified by X-ray diffraction (XRD),⁹⁵ nuclear magnetic resonance (NMR),^{93,96} electron spin/paramagnetic resonance,⁹⁷ neutron diffraction,⁹⁸ optical absorption,⁹⁹ Raman spectroscopy,^{100,101} and simulations.^{92,102}

Extrinsic point defects are created by stoichiometry (Eqs. 2.6 and 2.7) introduced during synthesis or caused by Mg/MgO volatilization (Eq. 2.8). Sintering in graphitic furnaces adds an additional reaction affecting defect equilibrium by generating oxygen vacancies (Eq. 2.9).

The consensus is that excess aluminum occupies magnesium sites and excess magnesium occupies aluminum sites, but experimental studies are contradictory as to compensating defects. XRD and magic-angle NMR indicate $V_{Al}^{\prime\prime\prime}$ are preferred in Al_2O_3 -rich spinel,^{98,103} although $V_{Mg}^{\prime\prime}$ may exist simultaneously and the viability of $O_i^{\prime\prime}$ is not addressed. In MgO-rich compositions, enhanced sintering is explained by charge-compensation with $V_O^{\bullet\bullet}$,^{50,90,94,104} with possible confirmation by optical methods.^{99,105} Simulations also conflict as to compensating defects (Table 2.1), indicating aluminum defects may be even less favorable than oxygen defects. Oxygen interstitials have the highest mobility even though their formation energy is higher and Schottky defects have the lowest formation energy apart from inversion. Simulations also indicate that charged defects attract oppositely-charged defects, leading to defect associates, with lower formation energies noted for defect pairs, trimmers, and cluster.^{106,107} Simulations indicate impurities lower defect formation energies, and aliovalent substitutions require charge-compensating defects that likely affect properties similarly to stoichiometry.¹⁰⁸ UV irradiation affects lower-energy defects such as electron-hole recombination, gamma-ray irradiation induces point defects such as inversion, and neutron irradiation induces higher-energy defects such as cation and oxygen vacancies.^{92,99,105,109-112}

Line defects such as dislocations are commonly observed and likely serve as pathways for diffusion and have a significant effect on densification during pressure-assisted sintering (Section 2.6.2). Dislocations move primarily on {110}, {111}, and sometimes {100} planes, depending on stoichiometry, and slip occurs along <110> directions,^{113,114} while cleavage is typically along {111} planes.¹¹⁵⁻¹¹⁹

2.2.3 Interface Properties

Interfaces comprise the surfaces of powder crystallites and polycrystalline bodies and the internal boundaries between grains and secondary phases. Unlike the bulk, surface atoms have unsatisfied bonds and experience unbalanced attractive forces, resulting in lattice strain, surface reconstruction, and a difference in free energy, which makes them prone to adsorption by impurity species. Grain boundaries are the structural discontinuities between regions with different lattice orientation within polycrystalline bodies and are often likened to arrays of

dislocations that accommodate the lattice mismatch. However, grain boundaries also often have associated chemical and defect chemistry gradients, space-charge layers and strain fields, and a difference in free energy, which like surfaces make them prime sites for defect and impurity segregation. Interfaces have a strong and often controlling influence on sintering, microstructure evolution, and mechanical, thermal, optical, and electronic properties. The properties of interfaces of transparent spinel, their interactions with variables that affect them throughout processing, and their effect on bulk properties is the central theme of this work.¹²⁰

Planar defects, such as grain boundaries and surfaces (and their associated energies), can govern sintering, densification, and microstructure evolution while also significantly impacting physical properties (Sections 2.2.8, 2.4.4, 2.5, 2.6.1, 2.7.2).¹²¹ The surface energy (γ_s) of spinel varies with orientation (Table 2.2),¹²²⁻¹²⁹ resulting in the faceted octahedral habit observed for crystallites¹²² and polycrystal grains.¹¹⁹ Recent studies indicate {100} planes have the lowest energy,^{123,125,126,128,129} whereas {111} are frequently observed cleavage, twin, and crystal surface planes.^{122,130-132} Moreover, simulations predict Mg-terminated surfaces have lower energy,¹²⁸ whereas high-temperature annealing in oxygen suggests Al-O terminations are more favorable.^{127,133,134} The latter indicates an influence from stoichiometry that also likely applies to grain-boundary energy.¹²⁹ The grain-boundary energy (γ_{gb}) of spinel has been estimated based on calorimetry¹²⁹ and thermal grooving¹³⁵ from which γ_{gb} can be found if γ_s is known (Table 2.2). The γ_{gb} also varies with orientation and {111} grain-boundary plane orientations are observed at twice the frequency of {100} orientations.¹¹⁹ Published γ_{gb} ,¹²⁹ γ_{gb}/γ_s ratios¹³⁵ and recent γ_s ¹²⁵ values for low-energy planes suggest the grain-boundary energy for pure stoichiometric spinel ranges from 0.5 – 1.6 J/m². However, complicating matters is that interface energies are also affected by impurities, additives, and sintering atmosphere.^{127,129,135} Grain-boundary mobility is another important variable affecting microstructure evolution and it is generally low in spinel compared to other oxides.⁷⁶ Other planar defect such as twins, which are commonly observed in natural spinel, are rarely observed in synthetic material.¹³⁶

2.2.4 Diffusion Properties

Mg²⁺ has the highest diffusivity of the constituent ions and Al³⁺ is slightly lower (Fig. 2.3).¹³⁷⁻¹³⁹ Ionic transport occurs by a defect-assisted interstitial mechanism that is accentuated by V_{Mg}'' in Al₂O₃-rich stoichiometry ($2Al_2O_3 \rightarrow 2V_{Mg}'' + 4Al_{Al}^x + 6O_O^x + 2V_O''$).^{138,140-142} O²⁻ diffusivity is orders of magnitude lower than cation diffusivities, as expected for the largest ion and the close-packed lattice.¹⁴³⁻¹⁴⁶ Sintering experiments indicate similar activation energies to that of O²⁻ self-diffusion, indicating it is rate-limiting.^{50,94,104,147} However, the O²⁻ grain-boundary diffusivity is expected to be rate-limiting as it may be lower.¹³⁹ Understanding is complicated because of the dependence of diffusion on stoichiometry and planar defects, which both vary during sintering.^{76,86,89,139} O²⁻ diffusion is expected to be higher in MgO-rich compositions due to

the higher oxygen vacancy concentration indicated by sintering experiments. However, studies indicate either a slight increase¹⁴³ or much higher¹⁴⁵ O²⁻ diffusion for Al₂O₃-rich compositions.

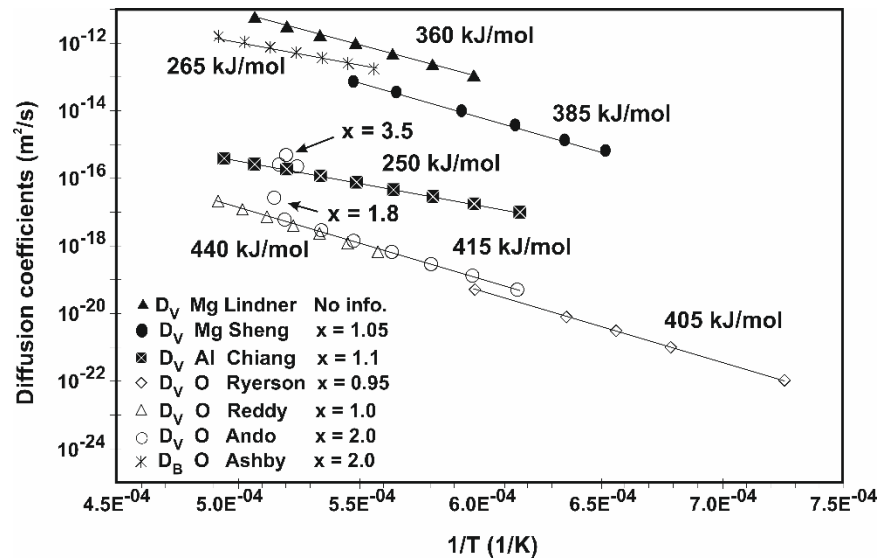

Fig. 2.3: Diffusion coefficients for spinel species, adapted with permission.^{139,145}

2.2.5 Electronic Properties

Spinel is a wide, direct band-gap¹⁴⁸⁻¹⁵⁰ insulator with the lowest conductivity of the spinel series.¹⁵¹ It exhibits mainly ionic, mixed ionic-electronic conduction^{137,141,151-154} with transference numbers from 0.5 to 1 reported between 500°C and 1000°C.^{137,152} Conductivity varies with an Arrhenius relation from $\sim 10^{-12}$ S/cm at 500°C to $\sim 10^{-4}$ S/cm at 1600°C and activation energies vary from 0.4 eV to 2.6 eV.^{137,151,154} Although Mg²⁺ ions have the highest self-diffusivity, it is unclear whether they or magnesium vacancies (V''_{Mg}) are the main charge carriers.^{137-140,142,152,153,155} Al³⁺ diffusivity is up to several decades lower^{138,139,156} and O²⁻ diffusivity is lower still,^{139,143-145} with conductivities expected to mirror diffusivities. Polycrystalline conductivity is generally 1-2 decades higher than for single crystals, tentatively attributed to higher conduction along grain-boundaries.^{140,142,151,157-159} O²⁻ grain-boundary conductivity is higher than in the bulk¹⁶⁰ but cation grain-boundary conductivities have not been reported.¹³⁹ However, cations are likely the main grain-boundary charge carriers as single-crystal and polycrystalline conductivities are not greatly influenced by oxygen partial pressure.^{140,142,152} Grain-boundary conductivity is likely affected by Mg-depletion, which is suggested to result in a negative core enriched in V''_{Mg}

compensated by a positive space-charge layer composed of $\text{Al}_{\text{Mg}}^{\bullet}$.^{86,89,161,162} Surface conduction also contributes to conductivity, with protons hopping along surface-adsorbed hydroxyl ions being the main charge carriers at low temperature and high relative humidity in porous oxygen-sensor compacts.^{163,164} Conductivity is also highly dependent on porosity, grain size, and impurities.¹⁵⁴

2.2.6 Optical Properties

Spinel has a wide transmission window ($\sim 190 \text{ nm} < \lambda < 6000 \text{ nm}$) that is limited by the UV and IR absorption edges (Fig. 2.4). IR transmission decreases starting at $\sim 4\text{-}5 \mu\text{m}$ and reaches zero by $\sim 7 \mu\text{m}$, with an IR absorption edge up to $\sim 1 \mu\text{m}$ lower for Al_2O_3 -rich compositions.⁴ Some transparency is also exhibited in the microwave range (70 GHz–105 GHz, 2-4 mm).¹²

Fig. 2.4: Typical transmission spectrum for transparent polycrystalline spinel.^{4,15,165}

The total intensity transmitted through a window is the total forward transmittance (TFT, I_T), while that within a narrow cone ($3^\circ\text{-}5^\circ$) along the incident direction is the in-line transmittance (ILT, I_{ILT}), the difference between the two is the diffuse transmittance (I_{DT}), or forward scatter. The ILT best characterizes the intensity and accuracy with which the spatial relationship and resolution of image details are transmitted. However, most optical imaging applications require high ILT along a narrower cone and the real in-line transmittance (RIT) is defined for an aperture of $\sim 0.5^\circ$.²⁴ In highly transparent compacts with an RIT of $>95\%$ theoretical (or $>82.2\%$ measured), transmittance becomes nearly thickness-independent as in window glass, with the term translucent used for $\text{RIT} < 95\%$.^{24,61,166} Three main factors reduce

transmittance within the transmission window: (i) reflectance (R), (ii) scatter (S), and (iii) absorptance (A) (Fig. 2.5). The relationship between incident radiation of intensity I_0 and transmitted radiation I_T is given by:

$$I_0 = I_T + R + S + A = 1 \quad (2.10)$$

For stoichiometric spinel at $\lambda = 532$ nm, the specular reflectance from a single surface (R_{S1}) is $\sim 7\%$, implying a minimum theoretical reflectance (R_{S2} , two surfaces including multiple reflections) of $\sim 13\%$ for a window, limiting the maximum theoretical ILT without anti-reflective coatings to $\sim 87\%$.²³ The diffuse reflectance (R_D) can be minimized by ensuring planarity and smoothness. The refractive index (n) and reflectivity increase with decreasing wavelength, significantly reducing the theoretical ILT below $\lambda \approx 200$ nm.²⁵

Fig. 2.5: Light transmission through a polycrystalline spinel compact.

Scatter is thickness-dependent and caused by phases with different n (pores, precipitates, and impurity and additive phases), regions with variable n (variation in stoichiometry and stress), and variation of n along different crystallographic directions. Light-scattering models are mostly based on Mie theory,⁶ with approximations dependent on the size of the scattering center (d) relative to the wavelength (λ): (i) Rayleigh-Gans-Debye scatter ($d > \lambda$), (ii) Mie scatter ($d \approx \lambda$) and (iii) Rayleigh scatter ($d < \lambda/10$). Scatter scales to d^2 for Mie scatter and to d^6/λ^4 for Rayleigh scatter.^{25,67} Porosity is a main source of scatter in spinel, the most detrimental being

pores the size of the transmitted wavelength.¹⁶⁷ Using a numerical Mie model¹⁶⁸ at $\lambda = 600$ nm, 0.1% porosity (1000 parts per million, ppm) of 400 nm diameter pores reduces theoretical ILT to nearly zero for an 0.8 mm thick polycrystalline compact with $n = 1.76$.¹⁶⁷ Even 0.01% (100 ppm) of 400 nm diameter pores at $\lambda = 600$ nm or of 40 nm pores at $\lambda = 200$ nm reduces theoretical ILT to ~50% for a 1 mm thick spinel compact.^{24,169} For imaging applications, only very thin windows tolerate smaller pores (<100 nm), even at longer IR wavelengths.¹⁷⁰ Reducing the pore size by half reduces Rayleigh scatter by one order of magnitude⁶ and thus pore concentration and size reduction are one of the main goals of fabrication. Scatter also occurs due to inclusions, impurity phases, and cracks.^{1,4,51} Grain boundaries and point defects contribute minimally to scatter at visible and IR wavelengths due to the small thickness (<5 nm) and size, respectively.¹⁶⁷

Another source of scatter in spinel is intrinsic birefringence (IBR, ~50 nm/cm) at UV wavelengths due to the refractive index difference along the more densely-packed <111> unit cell cube diagonals versus the <001> cube edges.^{25,35} However, IBR is ~0 in polycrystalline compacts.³⁵ Stress birefringence (SBR) also occurs due to local strain variation and is in the order of ~5 nm/cm.³⁵ The refractive index of spinel does not change significantly with λ , as indicated by the low Abbé number (~60),²⁵ resulting in reduced chromatic aberration.¹⁰ Its variation with temperature is also low ($dn/dT \sim 3 \times 10^{-6} \text{ K}^{-1}$ from 3 to 5 μm).¹⁰

Absorption in spinel arises from several sources and even ppm volume fractions of absorbing centers can lead to opacity in thicker compacts. As for scatter, absorption is thickness-dependent and obeys a Beer-Lambert relationship (Eq. 2.11). In the case of scatter, the absorption coefficient (α) is dependent upon a volume fraction and a scattering cross-section. The sensitivity of transmittance to ppm volume fractions of scattering or absorbing centers is arguably the main challenge of transparent spinel fabrication.

$$I_T = I_0 e^{-\alpha t} \quad (2.11)$$

2.2.7 Mechanical Properties

The fracture toughness of spinel ranges between ~1.4-2.0 $\text{MPa}\cdot\text{m}^{1/2}$,^{7,171-173} with an apparent Hall-Petch dependency for coarse grains (~ >50 μm).^{7,39} Lower toughness has been correlated with inter-granular fracture, predominantly in coarse-grained microstructures,⁷ probably due to

grain-boundary embrittlement by residual LiF, impurities, and residual stress (Fig. 2.6).¹ Somewhat in contrast, coarse-grained microstructures exhibit limited *R*-curve behavior due to frictional grain-bridging and grain-wedging.¹⁷² Thus, strengthening grain boundaries should improve toughness. Strength decreases for inter-granular fracture that persists in coarse-grained microstructures.^{114,171,173} In fact, weak boundaries of large grains have been proposed to serve as critical surface flaws.^{173,174} Porosity and second phases do not necessarily serve as limiting flaws in highly-transparent compacts as they demand <0.01% porosity and second phases typically smaller than ~50 nm.⁸ Coarse-grained microstructures have long been recognized as a source of lower strength, but fine-grained, highly-transparent spinel compacts have only recently been produced.^{60,64,175,176} Microstructure refinement exhibits significant hardness increases for grain sizes less than ~1 μm and a Hall-Petch relation is observed.^{173,174,177,178} Despite the relevance to projectile erosion during penetration,^{10,177} the mechanism for hardness changes in spinel is not known.¹⁷⁹ Nevertheless, reducing grain size is one of the main goals of transparent spinel processing. However, for transparent armor, cost outweighs small additional hardness gains associated with fine grain sizes and sizes in the hundreds of microns are often acceptable.⁴ Relatively little is known about the effect of grain size on ballistic performance due to the complexity of failure.¹⁸⁰ Spinel is susceptible to moisture-assisted crack growth, but the effect is significant mainly for coarse-grained microstructures.⁷ It appears that no slow crack growth studies for single crystals exist. Nonetheless, the results demonstrate the importance of grain boundaries in dictating strength.

Fig. 2.6: Fracture surfaces of spinel showing mixed-mode inter- and trans-granular fracture for hot-pressed (a) lower-purity powder and (b) higher-purity powder, without additives.¹ With LiF addition, fracture becomes predominantly inter-granular.

2.2.8 Physical Requirements

Spinel physical requirements depend on the application. Requirements for transparent armor are high ILT in the visible range, compatibility with near-IR (0.4-0.92 μm) night-vision and thermal imaging systems,¹⁰ low areal density, high hardness, multi-hit capability, and low cost due to the volumes required.^{14,23} In the case of spacecraft windows, fracture strength and toughness are more important.⁷ Requirements for IR windows and domes are high RIT in the atmospheric windows from the UV to the mid-IR, possibly transmittance in the microwave region,¹³ low absorption near the IR absorption edge and especially at 4.8 μm , low emissivity, flexural strength, impact and erosion resistance, thermo-mechanical stability, low dn/dT , and thermal shock resistance.^{10,23} Military requirements are increasingly calling for multi-spectral capability¹⁴ and tri-mode multi-spectral seeker domes satisfying additional RF shielding requirements¹⁸¹ have been successfully fabricated.^{165,182,183} Transmittance requirements are most stringent for imaging applications, with sensor windows requiring error of $<1/10$ of λ over the aperture size.¹⁰ UV lithography components require high RIT, especially near the UV absorption edge but less stringent mechanical properties. UV and IR absorption edges need to be pushed towards theoretical energies and absorption near the edges lowered to enable UV-lithography and increased demands for IR-targeting applications.³⁵ A combination of low Abbé number combined with a high refractive index compared to glasses can enable miniaturized lenses¹⁰ and refractive index variation with stoichiometry may enable flat graded refractive-index lenses. Properties of polycrystalline spinel compacts are summarized in Table 2.3.

Table 2.3: Physical Properties of Transparent Polycrystalline Spinel.

Property	Value
Melting point (°C)	2105°C–2135°C ^{19,165,182}
Lattice parameter (<i>a</i> , 3.0 > <i>x</i> > 1.0, Å)	8.797–8.808 ²²

2.3 Processing

This section introduces the key processing variables (Section 2.3.1), and describes the effect of powder synthesis (Section 2.3.2), green-body formation (Section 2.3.3), and particle-size characteristics (Section 2.3.4) on microstructure evolution (Section 2.3.5) and compact properties.

2.3.1 Key Processing Variables

Spinel is inherently difficult to sinter due to: (i) low oxygen lattice-diffusion requiring high sintering temperature, (ii) Mg/MgO volatilization causing stoichiometry variation and gradients, (iii) a propensity for coarsening possibly exacerbated by a high grain-boundary to surface-energy ratio, surface-energy anisotropy, and LiF additive, and (iv) extreme sensitivity to impurities, additives, processing parameters, and compact size. These issues accentuate the difficulty in attaining the near-theoretical density required for transparency. In addition, the multitude of fabrication variables combined with property variation with stoichiometry further complicates processing, and in turn understanding. The crux of transparent spinel fabrication lies in understanding the complexities of fabrication, and in particular of green-body formation and of interactions during sintering between material, microstructure, compact, and process variables, from the nanometer to the compact scale (Fig. 2.7). In particular, three variables are key to successful processing: (i) particle-size characteristics, (ii) stoichiometry, and (iii) impurities. Gross deficiencies in these variables cannot be compensated for by adjusting processing parameters and achieving transparency entails controlling them throughout processing. Post-treatment and finishing are not described here, but grinding and polishing can be the most time-consuming and expensive step for components like missile domes¹⁸¹ and new methods are being explored to reduce costs.⁸

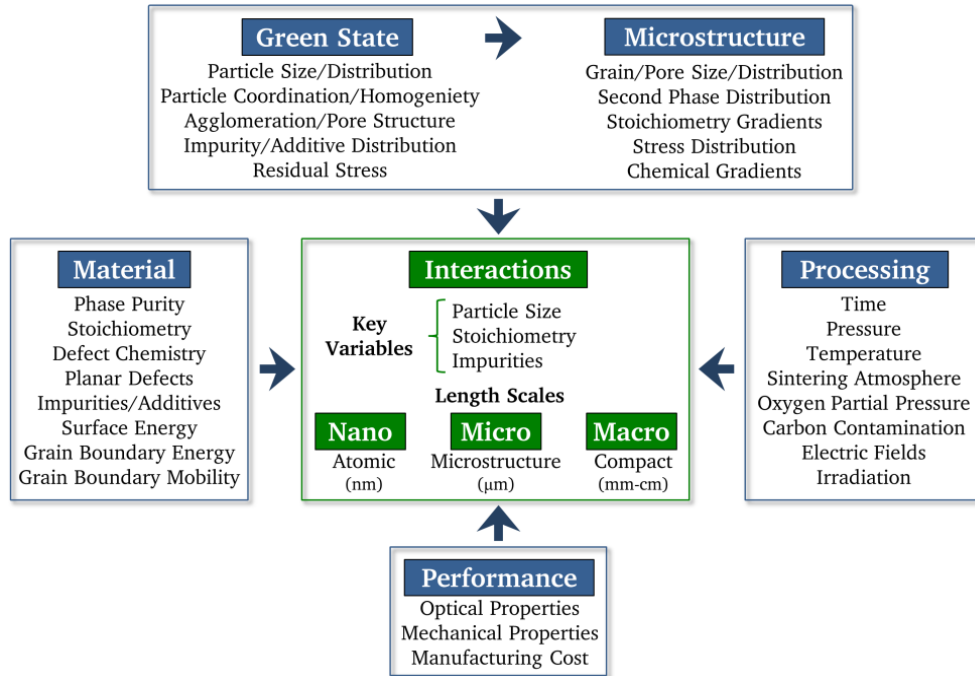

Fig. 2.7: Fabrication and Key Variables.

2.3.2 Powder Synthesis

Spinel has been synthesized from a wide variety of precursors (metals, oxides, hydroxides, chlorides, nitrates, carbonates, sulfates, and alkoxides) and methods (mechanical alloying, freeze drying, spray drying, solid-state sintering, sol-gel, hydrothermal, co-precipitation, gelcasting, flame-spray pyrolysis, self-propagating high-temperature synthesis, chemical vapor deposition, atomic layer deposition, and plasma spray).^{4,19} Acceptable powders for transparent spinel fabrication typically require nanometer-sized particles with a high surface area ($>10 \text{ m}^2/\text{g}$)⁴⁵ to provide a high driving force for sintering. In addition, it is desirable to have a narrow particle-size distribution, minimal agglomeration,⁴⁵ adequate flow properties,^{8,34,45} stoichiometry control,^{1,77} minimal impurities, and cost matching the intended application. However, powder properties are difficult to characterize in practice. Particle-size analysis by laser scattering can be flawed due to inadequate dispersion and shielding of smaller particles by larger ones,⁴⁵ and microscopy samples only small volume fractions, possibly missing large inclusions. Stoichiometry is difficult to quantify by chemical analysis and XRD with an accuracy that reflects the processing sensitivity to it.¹ Volatile impurities such as carbon, nitrogen, and sulfur are

difficult to quantify and are often not quoted by suppliers.¹ These issues make it difficult to pinpoint problems caused by starting powders that occur later during processing.⁵⁵

2.3.3 Green Body Formation

The green-body state determines the sintering activity and it is profoundly influenced by particle size characteristics.⁴⁵ The goal of synthesis, pre-treatment, and shaping is obtaining green bodies composed of fine, uniformly-sized particles with high coordination and homogeneity.⁴⁵ Achieving this may require involved particle sizing, such as centrifugation, filtration, and sedimentation.⁴⁵ Perfect packing of spheres yields theoretical pore-size distributions of $\sim 1/5^{\text{th}}$ of particle size. Yet even with optimal processing pore sizes are at least twice that, likely reflecting particle packing resembling GB1 in Fig. 2.8.⁴⁵ Nevertheless, defect-free, homogeneous, highly-coordinated green bodies with narrow pore-size distributions like GB1, when obtained with high-purity nano-powders, allow sintering forces alone to achieve high densification (>95%) at temperatures up to 200°C lower than less optimal bodies.⁴⁵ With additional pressure, full density has been reached without additives while exhibiting high transparency and nanometer-sized grains.⁴⁵ The best results have been obtained using flame-spray pyrolysis powders, whose better flow properties³⁴ likely contribute to higher coordination and smaller pore-size distributions.⁴⁵ Consolidation methods yielding the best results are shaping from aqueous or organic slurries or colloidal suspensions using organic dispersants combined with slip or gel-casting.^{6,45} However, these methods require drying, solvent debinding, or lengthy thermal cycles to ensure complete, defect-free organics outgassing.^{13,34} Optimal dispersion of binders, dispersants, and sintering additives, typically added during milling or wet processing, is also essential.^{36,45} Alternatively to wet processing, high solids-loading slurries have been spray or freeze-dried¹⁸⁴ into better-flowing powders consisting of soft-agglomerate granules,³⁴ which have been dried and cold-pressed into acceptable green bodies.³⁴ However, cold-pressing or CIP require high loads ($\sim 100\text{-}500$ MPa) to achieve high green densities, and cold-pressing introduces density gradients due to friction from die walls. Acceptable green bodies have also been obtained by additionally milling or freeze-drying more agglomerated powders followed by dry or wet consolidation.⁴⁵

Fig. 2.8: Green bodies made using two different powder/processing routes (pink diamonds represent impurities or additives): (GB1) fine, narrow particle-size distribution powder leading to narrow pore-size distribution, and (GB2) agglomerated, wide particle-size distribution powder leading to wide pore-size distribution, large inter-agglomerate pores, and inhomogeneous additive dispersal.

2.3.4 Particle Morphology

Smaller particles result in smaller green-body inter-particle pores and sizes $<50\text{-}60\text{ nm}$ decrease PS/HIP temperature $<1400^\circ\text{C}$, improving compact visible and near-IR transmittance and mechanical properties.⁴⁵ However, small size and high surface-area increase susceptibility to agglomeration from weak attractive forces, such as friction-induced charging during dry-milling or hydrogen-bonding during aqueous processing.^{8,45,49} High surface-area powders also provide more residence sites for adsorbed gases, water, and impurities and may be more susceptible to chemical reactions.^{55,185} Nanometer-sized powders are also more expensive, are cumbersome to handle, require large volume reduction, and are difficult to disperse and to sieve to uniform particle-size.³⁴ In addition, compacts HP/HIPed with nanometer-sized powders ($<50\text{ nm}$) exhibit reduced UV-transmittance and higher refractive-index variation due to a concentration of nanometer-sized pores ($<400\text{ nm}$) that is one order of magnitude higher than for similarly-made compacts using coarser powders ($\sim 70\text{-}120\text{ nm}$).^{45,170} A balance between particle-size, agglomeration, and attaining high green-body particle-coordination and homogeneity leads to an optimal particle-size.⁴⁵ The lower size-limit with HP/HIP using high-purity powders without additives for maximum transmission at low HIP temperatures ($<1300^\circ\text{C}$) and fine grain-size ($<500\text{ nm}$) with current technology is near $\sim 55\text{ nm}$.⁴⁵ However, even with careful processing, 50-200 ppm nanopores have been observed to survive HIP up to 1700°C .⁴⁵ For lower-cost, high-volume applications, lower purity powders, or high additive contents, the optimal size for HP or

HP/HIP is perhaps $>70\text{-}120\text{ nm}$.^{1,45,49} Even larger particle or aggregate size ($>1\text{-}10\text{ }\mu\text{m}$) may be desirable as coarser powders attain closed porosity at higher temperatures and enable increased outgassing of volatile impurities and additives.¹⁸⁶

Agglomeration is the most detrimental powder-size characteristic as inter- and intra-agglomerate pores are frequently orders of magnitude larger than intrinsic crystallites (Fig. 2.9).^{45,186} Dense agglomerates differentially sinter; enlarging inter-agglomerate porosity, inducing stresses that can cause cracking, and forming solid skeletons (even during calcining) that limit particle re-arrangement during consolidation and sintering.¹⁸⁵ These can be difficult to remove without resorting to higher pressures or temperatures, where excessive grain growth occurs, and at worst impossible to remove.¹⁸⁵ In addition, lower-temperature sintering and tortuous diffusion paths in dense agglomerates trap volatile species.¹⁸⁴ Some of these features result in optical defects such as pore clusters,³⁴ large impurity/additive phases,¹ and microstructural inhomogeneity.¹⁸⁶ Agglomerates are best dealt with before green-body formation, and are typically broken down by mechanical milling, ultrasonic or acoustic methods, or removed by sieving.⁴⁵ The best case, although difficult to achieve in practice, is forming soft agglomerates that can be broken by sintering stresses alone.³⁴

Fig. 2.9: Agglomerates in (a) synthesized,⁴⁵ and (b) commercial sulfate-derived powders.

Wide particle-size distributions are also detrimental and result in wide pore-size distributions in green bodies, making it impossible to tailor sintering regimes that close all pores simultaneously.¹⁸⁶ They also exacerbate Ostwald ripening and microstructural coarsening. Conversely, narrow particle-size distributions allow higher green-body coordination and homogeneity, lower sintering temperature, and similar-sized particles have similar driving forces for grain growth, resulting in finer-grain size.^{45,186}

2.3.5 Microstructure Evolution

Microstructure evolution during sintering is strongly affected by the green-body state, and also by stoichiometry, impurities, additives, and processing parameters (Sections 2.4-2.6). Particle re-arrangement in the initial sintering stages is inhibited by green bodies like GB2 in Fig. 2.8 and aided by liquid phases (Section 2.5.2) and pressure (Section 2.6.2). Higher surface and vapor transport compared to bulk transport in initial stages result in coarsening, which is exacerbated by green bodies like GB2 and LiF addition, and inhibited by high heating rates (Sections 2.5.2, 2.6.1, 2.6.4). Coarsening is also strongly affected by interface energies. The driving force for sintering is the reduction of excess interfacial energy¹⁸⁶ which is accomplished by transforming surfaces into grain boundaries (resulting in densification), or by reducing surface area by coarsening (without shrinkage);

$$\Delta(\gamma A) = \Delta\gamma A + \gamma\Delta A, \quad (2.4.1)$$

where γ is the interfacial energy and A is the interfacial surface area.¹²¹ High surface energy drives both processes, but high grain boundary versus surface energy favors coarsening and also makes it less favorable for grain boundaries to advance into pores.¹²¹ Interface energies are in turn affected by stoichiometry, impurities, additives, and processing parameters (Sections 2.4-2.6).

Volatile species outgassing during initial and intermediate sintering stages is essential to obtaining transparency (Section 2.5) and is inhibited by differential sintering. Differential sintering occurs on a compact-scale as surfaces sinter more rapidly than the interior due to exposure to higher temperatures and shorter diffusion paths for densification-impeding volatile species to escape.¹⁸⁶ Compact-scale differential sintering traps volatile species in compact interiors, restricting grain size (Fig. 2.10), and if impurity concentration is high enough, scattering second phases form that display as a hazy central region in compacts.¹ Differential sintering is exacerbated by green bodies like GB2 in Fig. 2.8, high heating rates that engender high temperature gradients, large sample size resulting in longer diffusion distances, sintering atmosphere that can cause Mg/MgO loss, and any variable that accelerates sintering or lowers sintering temperatures (Sections 2.4-2.6).¹⁸⁶ Green bodies like GB1 in Fig. 2.8 attain closed porosity homogeneously, but do so at lower temperature and trap higher boiling-point volatiles.

Fig. 2.10: (a) Optical microscopy image of microstructure of 2 mm thick hot-pressed stoichiometric spinel compact, and (b) similarly processed compact, but 4 mm thick and with pressure applied at a lower temperature.¹

Once closed porosity is attained in the final stage of sintering, densification slows as the sintering stress decreases and mass transport is forced along slower grain boundary and lattice paths. As pore content and size diminish, the pinning effect of remaining porosity on grain boundaries decreases, leading to grain growth. Increasing kinetics with higher temperature (Section 2.6.1) or applied fields (Section 2.6.4) exacerbates grain-boundary mobility and grain growth and can cause pore occlusion, which is virtually impossible to remove. Thus, long sintering times or pressure (Section 2.6.2) are used to close remaining pores.

2.4 Stoichiometry

This section describes; the effect of stoichiometry on properties (Section 2.4.1), stoichiometry gradients (Section 2.4.2), stoichiometry-related defect chemistry (Section 2.4.3), and the effect of stoichiometry on grain growth (Section 2.4.4) and densification (Section 2.4.5).

2.4.1 Effect on Properties

Stoichiometry affects virtually every property of spinel and its spatial and temporal variation during sintering greatly increases processing complexity.^{4,8,52,55,61,76,77,86,89,94,99,170,187-191} However, as the cubic structure and transparency are retained,⁷⁷ astoichiometry offers opportunities to vary properties⁷⁷ and may enable graded-property compacts.¹⁰ Transparent components have successfully been made with $0.98 < x < 3.0$,^{4,76,77} with MgO and Al₂O₃ precipitates (Fig. 2.11) typically observed beyond this range.^{1,7,73,76} Precipitates scatter wavelengths on the scale of their size and of strain fields that surround them and they also affect mechanical properties.¹

Mechanical properties comparable to stoichiometric compositions have been observed for $x = 1.2$.⁷⁷ However, other studies report increased hardness (up to $x = 2.0$),¹⁹² fracture strength (up to $x = 2.0$),¹⁹² and fracture toughness (up to $x = 1.3$ ¹⁹² and $x = 2.0$ ^{52,188}) for Al_2O_3 -rich stoichiometry. Increased fracture toughness in one case was attributed to transgranular fracture and greater plasticity at grain boundaries,¹⁸⁸ whereas in another increased properties were attributed to hard Al_2O_3 precipitates and associated crack deflection and bridging.¹⁹² However, other studies indicate Al_2O_3 precipitates and Al_2O_3 -rich grain boundaries decrease mechanical properties due to residual stress and intergranular fracture,⁷ and Al_2O_3 -rich compositions exhibit substantial hardness decrease above $x > 2$.¹⁷⁷ Nevertheless, Al_2O_3 -rich compositions ($x = 2$) appear less sensitive to microcracking and display higher transmission and fracture toughness compared to stoichiometric compositions when using reactive sintering and HP/HIP.^{51,52} High transmittance for Al_2O_3 -rich stoichiometry has also been obtained using reactive-sintering with PS/HIP ($2 < x < 2.5$), with opacity observed for $x < 1.8$.⁵⁸ However, with HP/HIP of precalcined powders, the best transmittance was noted for $x = 1.2$.⁷⁷ Although advantageous in yielding high transparency and fracture toughness in some instances, astoichiometry has major drawbacks of precipitation and scattering for MgO-rich compositions, and a lower IR absorption edge, densification rate, and hardness for Al_2O_3 -rich compositions. Stoichiometric compositions likely still yield the best combination of densification and properties.¹⁷⁰

Fig. 2.11: (a) MgO precipitates (arrows) in $x \sim 0.995$ hot-pressed compact¹ and (b) Al_2O_3 precipitates (arrows) and Al_2O_3 -rich grain boundaries in HP/HIP compact,⁷ reproduced with permission.

2.4.2 Stoichiometry Gradients

Mg/MgO evaporation occurs preferentially at surfaces, causing stoichiometry gradients in grains,^{76,86,89} and it is exacerbated by: (i) high temperature, (ii) low pO_2 , (iii) reducing conditions, and (iv) LiF addition.^{36,93} Stoichiometry gradients between grain boundaries and cores^{76,86,89,139} may cause scatter at UV wavelengths as the lattice parameter decreases with Al_2O_3 -rich stoichiometry according to Vegard's law,⁷⁶ implying a concomitant change in refractive index.¹⁹³ Differences in thermal expansion between Al_2O_3 -rich boundaries and grain cores may also cause residual stress and grain-boundary embrittlement as Al_2O_3 -rich stoichiometry is reported to have a lower coefficient of thermal expansion.^{1,194} Preferential Mg/MgO loss at compact surfaces causes compact-scale stoichiometry gradients.^{80,81} As Mg/MgO volatilization is compensated by oxygen vacancies [Eq. (2.8)], densification of the compact exterior is enhanced, exerting a backstress that opposes densification of the interior.⁸¹ Interior densification is further inhibited by species diffusing along the slower paths of the densified exterior.⁸¹ With pressureless sintering, by the time Mg/MgO loss leads to Al_2O_3 -rich stoichiometry and exterior densification slows, there is already increased porosity in the interior, entrapped pores in the coarsened Al_2O_3 -rich zone, and a gradient towards smaller grain size in the compact interior (Fig. 2.12).⁸¹ In addition to porosity, transmittance may be further reduced by refractive index inhomogeneity due to the stoichiometry gradient. The microstructural features that distinguish this effect are obscured in later stages and for thinner compacts.⁸¹ MgO volatilization can be reduced via pressureless sintering in air, embedding compacts in powder of similar stoichiometry, shielding with refractory foils, or introducing inert atmosphere once closed porosity is reached during vacuum sintering.

Fig. 2.12: Composite SEM cross-section of pressureless-sintered stoichiometric spinel compacts, reproduced with permission.⁸¹

2.4.3 Defect Chemistry and Grain-Boundary Mobility

Astoichiometry is especially relevant for interfaces, which are a key determinant of microstructure evolution. Al_2O_3 -rich grain boundaries and triple junctions have been observed in polycrystalline compacts (Fig. 2.13a), even for MgO-rich compositions.^{18,76,86,89,139} Stoichiometry gradients imply defect-chemistry gradients and suggest a space-charge layer surrounding a charged grain-boundary core (Fig. 2.13b). However, disagreement exists as to the charge-compensating defects.^{76,86,89} Chiang and Kingery argued that in stoichiometric and Al_2O_3 -rich compositions, anion defects were unlikely due to the close-packed anion lattice and cation interstitials were also unlikely as charge-compensation is expected by cation vacancies.^{76,86} As anti-sites are the predominant intrinsic defects, only $\text{Al}_{\text{Mg}}^\bullet$ remain to account for Al_2O_3 -rich boundaries. They suggested a positive space-charge layer enriched in $\text{Al}_{\text{Mg}}^\bullet$ adjacent to a negative grain-boundary core, assumed to consist of cation vacancies or oxygen interstitials, as these are more likely to reside there. Based on thermodynamic considerations, Nuns *et al.* also suggested a positive space-charge with segregated $\text{Al}_{\text{Mg}}^\bullet$ and assigned a negative grain-boundary core, but based on simulations¹¹⁵ assumed it to be composed of V_{Mg}'' .¹⁶² For MgO-rich compositions, Chiang and Kingery again assumed a positive space-charge, this time occupied by $\text{Al}_i^{\bullet\bullet}$ to account for Al_2O_3 -rich stoichiometry at the boundaries. However, Ting and Lu argued that charge-compensation by cation interstitials in MgO-rich compositions contradicted increased densification^{189,195,196} attributed to $V_{\text{O}}^{\bullet\bullet}$.^{50,81,104,147} Based on the Brouwer equilibrium diagram (Fig. 2.14a) they argued MgO-rich stoichiometry was charge-compensated by $V_{\text{O}}^{\bullet\bullet}$. Based on proton diffusion experiments, optical absorption, and density measurements, Okuyama suggested that both cation interstitials and $V_{\text{O}}^{\bullet\bullet}$ charge-compensate MgO-rich stoichiometry.⁹⁰

Uncertainty also exists as to grain-boundary mobility variation with stoichiometry. Chiang and Kingery noted 10^2 to 10^3 higher grain-boundary mobility in MgO-rich compositions and decreasing mobility, after a slight initial increase, with increasingly Al_2O_3 -rich compositions (Fig. 2.14b).^{76,86} Reduced mobility was attributed to solute drag caused by segregated native cation defects. Uematsu *et al.* noted a large initial increase, followed by a decrease in grain-boundary mobility for increasingly MgO-rich compositions and a steadily increasing mobility for Al_2O_3 -rich compositions.¹⁹⁷ Chiang and Kingery noted the discrepancy may be due to different experimental conditions; they used reducing H_2 atmosphere and packed compacts in powder of

similar stoichiometry enclosed in molybdenum foil, restricting MgO loss and solute segregation, whereas Uematsu *et al.* used open H₂ atmosphere, where Mg/MgO volatilization occurs.^{86,198}

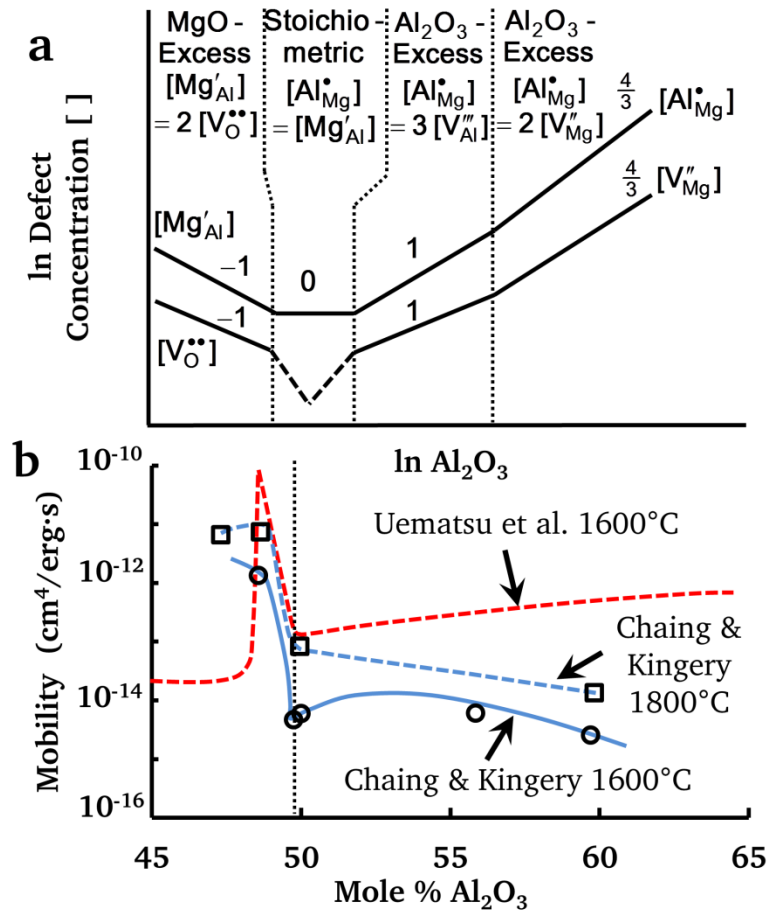

Fig. 2.14: (a) Brouwer diagram and (b) log grain-boundary mobility versus stoichiometry; adapted from Ting & Lu,⁸¹ Chiang & Kingery,⁷⁶ and Uematsu et al.¹⁹⁷ with permission.

2.4.4 Grain Growth

Grain-boundary mobility and grain growth are related and abnormal grain growth has been observed in MgO-rich^{76,80,86} and more prevalently in Al₂O₃-rich compositions.^{47,59,76,80,81,86,196,199} However, it occurs primarily at surfaces, where Mg/MgO volatilization is greater.^{76,80,86} MgO-rich compositions generally display smaller grain size, even though mobility is greater,^{1,47,59,147,190,196} possibly influenced MgO precipitate drag. On the other hand, smaller grain size is also observed in stoichiometric compositions, where MgO precipitates are not expected.⁷⁷ These discrepancies, including those discussed in Section 2.4.2, highlight the sensitivity of spinel to small variations in stoichiometry, processing, and experimental conditions, and indicate a complex defect chemistry. In order for accurate comparisons, stoichiometry,

defect chemistry, sintering atmosphere, Mg/MgO outgassing, and impurity content all need accurate spatial and temporal quantification. In the case of grain-boundary mobility and grain growth in ceramics, there is growing evidence that triple junctions and quadruple points play a determining role,^{200,201} yet for spinel they are often entirely overlooked. The variation in interface energy with stoichiometry, with relevance to coarsening and densification, has also not been quantified. The remaining uncertainty as to the mechanisms occurring at interfaces requires further research as it precludes enabling greater control over densification and properties.

2.4.5 Densification

Stoichiometry strongly affects densification and deformation, and pressureless-sintered MgO-rich compositions densify one order of magnitude faster⁹⁴ and attain higher densities than Al₂O₃-rich compositions (Fig. 2.15),^{94,104,189,195,196} attributed to higher oxygen vacancy concentration.^{50,81,90,94,104,139,147,189} The effect of stoichiometry in pressure-assisted sintering is discussed in Section 2.6.2.

Fig. 2.15: Compact density as a function of time for pressureless-sintered compacts with various stoichiometries ($0.8 < x < 1.5$), adapted with permission.⁹⁴

2.5 Impurities & Additives

This section describes the effect of impurities (Section 2.5.1) and sintering additives (Section 2.5.2) on processing and properties.

2.5.1 Impurities

Impurities affect interface energy and grain-boundary mobility, and are a key determinant of microstructure and properties. Even a few ppm impart color²⁴ and tens to hundreds of ppm can cause absorption over a broad range.^{49,99,109,117,202} The tolerable impurity content depends on the specific impurity, processing, and compact size. Generally, starting powders require ~99.99% purity, <500 ppm cation impurities,^{8,46} and removal of higher vapor pressure volatiles.¹ Even in thin compacts (<2 mm), as little as 0.1 wt% of remnant impurity or additive can cause opacity (Fig. 2.16).^{1,8,46} Impurities are present in MgO and Al₂O₃ constituents, due to incomplete removal of precursors, binders, and processing fluids, and are inadvertently introduced during processing.¹ As temperature increases during sintering, adsorbed gases, water vapor, organic binders and dispersants, hydroxides, sulfates, sintering additives, and others outgas at different temperatures.¹ Their removal requires knowledge of outgassing behavior, as assessed by vacuum gauge,¹² thermal analysis,¹ or residual gas analysis.¹ Volatiles are more easily trapped when inhomogeneously distributed, present in dense agglomerates (GB1 in Fig. 2.8) or in green bodies that attain closed porosity at lower temperatures (GB2 in Fig. 2.8), in which case powders may need to be pre-coarsened to reduce sintering activity.¹ Incomplete volatile impurity removal is exacerbated by high heating rates, insufficient holds, differential sintering, and larger compacts.¹ Volatile impurities are also trapped by pressure application, use of sintering aids, and applied electric fields, all of which lower densification temperature.^{1,186} Vacuum sintering is beneficial in removing most volatiles, whereas air sintering allows formation of volatiles from organics, carbon, and sulfur, although it may result in swelling as in Al₂O₃.²⁰³ High volatilization temperature species like sulfates 1050°C-1250°C require careful attention to remove during pressure-assisted sintering.¹

Fig. 2.16: Impurity phases causing opacity in 2 mm thick compact (inset) hot-pressed with high-purity spinel powder; (a) amorphous impurity (C,S,K) phase at grain boundary¹ and (b) decorated grain boundary.¹ (c) Amorphous phase at triple junction in HIP compact (all images TEM-BF).

Impurities (C, S, Si, Ca, Fe, K, Ti, Na, F, Li, lanthanide cations, and likely others) segregate at surfaces and later reside at grain boundaries.^{1,18,57,76,86,89,135,139,204} Some studies suggest impurities have little effect on grain-boundary mobility and grain growth.^{76,86} However, more recent studies indicate the opposite,^{1,8} with some impurities restricting grain growth by solute drag¹ and others forming liquid phases or increasing surface diffusion and enhancing grain growth (LiF, CaO).^{1,46} Impurities also modify interface energies. For example, TiO₂ increases the grain boundary relative to surface energy and exacerbates coarsening.¹³⁵ As the microstructure coarsens during sintering and grain-boundary area decreases, segregated impurities concentrate¹⁷⁶ and further affect grain-boundary mobility, microstructure evolution, and strength, and can cause fracture behavior to change from transgranular to intergranular.¹ In high concentration, impurities and additives form second phases, especially at triple junctions, pinning grain boundaries, opposing densification if they have high vapor pressures, causing scatter and absorption, and reducing mechanical properties.¹ In addition, preferential surface volatilization causes impurity and additive gradients that result in compact-scale microstructure gradients (Fig. 2.12).¹ Impurities like LiF and some transition-metal cations appear to have some solubility in spinel and incorporate into the lattice, creating defects that affect diffusion and optical properties.^{1,99} The effect of impurities on grain-boundary strength has not been systematically studied,¹³⁵ but additives like Y₂O₃ refine grain size, and increase hardness, flexure strength, and erosion resistance.¹⁷⁴ Composite compacts made with Si₃N₄ nanodispersoids have

recently demonstrated enhanced mechanical properties while still retaining >70% IR transmittance.²⁰⁵

2.5.2 Sintering Additives

Sintering additives and impurities are inextricably linked, demonstrated by the need for additives with impure powders and the ability to sinter high-purity powders to transparency without them. Many sintering additives have been used to produce translucent or transparent spinel, including $\text{Li}_2\text{O} + \text{SiO}_2$,⁴³ CaO ,^{46,206} $\text{LiF} + \text{NaF}$,²⁰⁴ LiF ,^{4,50,207} $\text{LiF} + \text{CaCO}_3$,^{208,209} AlCl_3 ,²¹⁰ AlF_3 ,¹⁹ Na_3AlF_6 ,²¹¹ and B_2O_3 .⁵⁹ However, LiF (~0.25-4 wt%) is the only sintering aid that consistently enables obtaining highly transparent spinel²¹² and likely most commercially manufactured transparent spinel is made with LiF . LiF melts at ~850°C, wets spinel,⁶⁵ spreads over surfaces by capillarity,⁶⁵ and likely aids densification by particle rearrangement and liquid-phase sintering.^{50,212-215} Near its melting point and in sufficient quantity, LiF reacts²¹⁶ with spinel and forms a eutectic with MgF_2 at ~740°C.^{36,50,215,216} The products may enhance densification by solution re-precipitation (Eqs. 2.12 and 2.13).^{50,209} Highly defected reprecipitated grains (Figs. 2.17 and 2.18) may have higher diffusion, enhancing densification.^{50,217}

Fig. 2.17: Hot-pressed spinel/LiF/spinel sandwich structure and highly-defected grains revealed by etching.²¹²

Fig. 2.18: HIP spinel compact with LiF; (a) Fluorine-rich xenomorphic grain (TEM-brightfield) and (b) coffee-bean contrast (arrow, STEM-ABF).²¹⁷

LiF is unique in that lithium and fluorine are highly reactive and can substitute for magnesium and oxygen, respectively, with a valence difference of one. It has even been suggested that a requirement for sintering additives is the ability to create both cation and anion vacancies.¹⁸⁴ Auger electron spectroscopy,²⁰⁴ optical absorption²¹⁸ secondary ion mass spectroscopy, transmission electron microscopy,²¹⁷ and sintering experiments⁵⁰ indicate lithium and fluorine are both incorporated in the lattice (Eq. 2.14).²¹⁵ If fluorine reacts with impurity cations (see below), then only lithium remains to create defects (Eq. 2.15).⁶⁵ The resulting oxygen vacancies may explain the ~ 200 kJ/mol^{50,208} and $\sim 200^\circ\text{C}$ ^{65,208} lower densification activation energy and temperature, respectively. Enhanced formation of spinel during reactive sintering^{57,65} has been partially attributed to vacancies caused by lithium incorporation in Al_2O_3 that allow higher cation diffusion.²¹⁹

Fluorine forms volatile compounds with many impurity cations, which along with LiF have volatilization temperatures below that at which spinel compacts typically reach closed porosity, enabling their removal. LiF removes carbon,^{65,220} sulfur, iron, calcium, and likely other impurities¹ in the vapor phase (Eqs. 2.16-2.18) and hence LiF addition must be tailored to impurity content. Less LiF is also required with alumina-rich powders.⁶¹ LiF also lowers magnesium content^{1,208} due to MgF_2 evaporation and perhaps Eq. (2.14).

LiF vaporizes between 1000°C and 1400°C and above 1200°C it coarsens spinel crystallites.²²¹ The slopes of the grain-growth curves in Fig. 2.19 indicate vapor-phase transport,²²¹ which requires the formation of magnesium and aluminum-containing volatile species, likely similar to that observed for LiCl.²¹⁹ Although coarsening is detrimental to densification, it is mitigated in pressure-assisted sintering, especially if surface diffusion or grain-boundary diffusional creep is enhanced²¹³ and as long as pores migrate as fast as grain boundaries.^{184,185,222} Large or exaggerated grain size and lack of intragranular porosity with LiF indeed suggest enhanced surface or vapor-phase diffusion.^{49,219} In addition, wetting, reaction with spinel, and defect creation suggest interface-energy modification. High surface energy favors pore-boundary attachment and may decrease the ratio of grain boundary to surface energy, favoring densification.²²² Atomic force microscopy and grain-boundary grooving experiments indicate surface mobility is increased and the interface energy ratio is altered by LiF.

Fig. 2.19: Log-log plot of grain-size change versus time for air-sintered spinel powders with 1 wt% LiF at 1000°C, 1100°C, and 1200°C, SEM images of air-sintered spinel powders (a) without LiF and (b) with LiF.²²¹

LiF also counteracts dark color observed in spinel compacts processed in graphitic furnaces by removing carbon and possibly color centers, as suggested by EIS studies.^{3,18} To work effectively, LiF must be evenly distributed^{213,216} and must leave the compact as it has a different refractive index. LiF can be trapped if too much is used (accelerating sintering)⁶¹ and hold times are insufficient (especially in larger compacts), with high-sintering activity powders, or with pressure application forcing densification to lower temperatures.¹ Excess or trapped LiF accumulates at grain boundaries and triple junctions and results in scatter (Fig. 2.20)^{1,53,57,207,214,216} and possibly restricted grain size.⁴⁹ Formation of lithium aluminate and/or Mg/MgO evaporation may also result in MgO-rich regions with poor transmission.^{207,216}

In addition to coarsening and scatter, a major drawback of LiF is grain-boundary embrittlement and intergranular fracture (Fig. 2.21). Although LiF will likely continue to be used in bulk applications; where lower-cost powders are not required or for more stringent applications the trend is to minimize or eliminate LiF entirely. Figure 2.22 shows typical microstructures with and without LiF for various processing methods.

2.6 Processing Parameters

This section describes the effect of temperature (Section 2.6.1), pressure (Section 2.6.2), sintering atmosphere (Section 2.6.3), and electric fields (Section 2.6.4) on processing and properties and also discusses the causes of absorption (Section 2.6.5).

2.6.1 Temperature and Heating Rate

Temperature and heating rate are used to control microstructure evolution during processing.¹ High heating rates are beneficial in attaining temperatures where lattice and grain-boundary diffusion and diffusion-assisted dislocation motion and grain-boundary creep are active, avoiding the formation of densification-resistant sintering necks and grain coarsening by surface or vapor transport mechanisms. However, excessive heating rates provide insufficient time for volatiles removal and enhance compact-scale differential sintering.¹ High cooling rates can also be detrimental by causing residual stress and cracking. High sintering temperatures enable greater diffusion, allowing deformation mechanisms to become active, but are limited by degradation of spinel at $\sim 1650^\circ\text{C}$ in vacuum.¹² To avoid grain growth, carbon contamination, and Mg/MgO volatilization, the lowest possible sintering temperatures are used that still allow densification within reasonable times.

2.6.2 Pressure

Although transparent spinel was first made by PS,⁴³ to date only small, thin compacts made with high-purity nanometer-sized powders CP at high pressures have been PS to translucency using high temperatures or long sintering times with various atmospheres.^{18,46-48} Attempts with larger compacts lead to cracking and opacity, possibly due to density gradients, differential sintering, pore coarsening, and swelling.¹⁸ Consequently, spinel is invariably densified using pressure. Pressure provides an additional driving force for densification, driving mass transport from regions of higher compressive stress at interparticle contacts and adjacent to pores, to regions of lower stress.¹⁸⁶ Densification also occurs by plastic flow assisted by dislocation motion and diffusional creep along dislocations (Fig. 2.23) and grain boundaries.⁸⁷ Pressure lowers sintering temperature, allowing finer grain size.^{186,223} In PS/HIP, high pressure (>150 MPa) is applied to remove the last few percent porosity at high temperatures ($>1600^\circ\text{C}$), where grain

boundary and lattice diffusion and deformation mechanisms are all active, although exaggerated grain growth also occurs. Very high pressures (2-5 GPa) and low temperatures ($<800^{\circ}\text{C}$) have been used to obtain transparency while maintaining small grain size ($<100\text{ nm}$).²²³ However, transparency is degraded by porosity and strain, the latter having low recovery at such temperatures.^{38,223} Application of pressure at too low a temperature during sintering traps volatile species.^{1,186}

Based on the wide range of stress exponents reported in creep experiments, opinions vary as to the dominant deformation mechanism and the underlying reason for strain softening and hardening. However, there is agreement that dislocations and grain boundaries are critical and oxygen diffusion is in some form rate-limiting. Dominant mechanisms have been attributed to slip,²²⁴ dislocation glide,¹⁹¹ dislocation creep,²²⁵ grain-boundary sliding,^{226,227} diffusional

Fig. 2.23: Dislocations in a HP stoichiometric spinel compact, adapted with permission.⁸⁸

creep,²²⁸ or some combination of these,²²⁷ and control attributed to glide,²²⁴ dislocation climb,^{191,225} interface-reaction diffusion,²²⁶ and oxygen-lattice diffusion.^{227,228} Lack of consensus as to the dominant deformation mechanism is likely due to its variability, which depends on the densification method and also on the density and distribution of planar defects, grain size, stoichiometry, impurities, additives, temperature, pressure, and strain rate, which all vary during processing.^{50,208,229,230} In hot-pressing, Nabarro-Herring diffusional creep dominates at lower temperatures ($<1350^{\circ}\text{C}$) with a transition to dislocation glide at higher temperatures ($>1450^{\circ}\text{C}$).²³⁰ During deformation, the effective pressure changes from an initially high value due to stress concentration at inter-particle contacts (early stage) to a lower value as densification proceeds (late stage).⁸⁷ In the case of hot-pressing, the predominant densification mechanism changes at a critical stress (σ_T), from climb-controlled dislocation creep at high effective stress

(early stage) to Nabarro-Herring diffusional creep controlled by oxygen lattice diffusion, possibly in combination with grain-boundary sliding^{229,230} at low effective stress (late stage).⁸⁷

In Al₂O₃-rich stoichiometry, the critical resolved shear stress (CRSS) for dislocation motion is up to several orders of magnitude lower^{4,87,113,231} than for stoichiometric compositions. For example, the CRSS drops from ~1 GPa for $x = 1$ to ~100 MPa for $x = 1.7$ and ~20 MPa for $x = 3-3.5$.²³¹ Al₂O₃-rich compositions thus give enhanced densification with lower applied stress early during pressure-assisted sintering, so long as the CRSS is within the range of contact stresses. However, as sintering progresses, the effective stress decreases and transition to diffusion control occurs, in which Al₂O₃-rich stoichiometries display lower densification rates (attributed to lower O²⁻ diffusion). During hot-pressing, the transition stress from dislocation to diffusion control decreases with increasing Al₂O₃-rich stoichiometry, consistent with decreased oxygen vacancy concentration ($\sigma_T = 25$ MPa for $x = 1.15$ versus $\sigma_T = 40$ MPa for $x = 0.92$ at 1450°C).⁸⁷ Hence, although Al₂O₃-rich stoichiometries initially densify more rapidly, they require longer time, higher temperature, or greater pressure to reach full density (>300 min at 1450°C and 12 MPa, >1500°C and 300 min for 25 MPa, >12 MPa and 300 min for 1550°C).⁸⁷ In contrast, for MgO-rich stoichiometry the transition to diffusion control occurs at higher stress (earlier during densification) and as they densify at higher rates in this regime, they achieve full density at even low effective stress within reasonable times (2 h at 12 MPa). For stoichiometric compositions using HP, ~33 MPa is just enough to attain full density at 1550°C.⁵⁰ Impurities, additives, and atmosphere likely affect the deformation mechanism, although their effect has not been systematically studied.

2.6.3 Atmosphere

Sintering atmospheres including vacuum, air, oxygen, hydrogen, helium, argon, and combinations have been used to obtain transparent spinel. Vacuum provides a greater driving force for removing volatile species and is typically used with HP, SPS, and with graphitic furnaces. However, vacuum exacerbates Mg/MgO volatilization at higher temperatures. Reducing atmospheres are beneficial in removing sulfur,¹ but exacerbate color center formation, and CO atmosphere causes carbon contamination. Air or oxygen assists in binder burnout and formation of volatile oxide impurities.²⁴ For PS, higher densification rates initially occur with vacuum sintering compared with air sintering⁸¹ due to Mg/MgO loss and differential sintering,

but densification rates are eventually surpassed by air sintering.⁴⁵ Sintering atmospheres other than air have found limited benefit in the case of PS.^{44,45}

2.6.4 Electric Fields

Applied electric fields enable high heating and densification rates,²³² lower sintering temperature, and attaining fine grain size.^{18,67} Many mechanisms have been proposed,²³²⁻²³⁵ including enhanced diffusion at grain boundaries early during sintering,^{67,232,234,235} although the exact cause is not known with certainty. Applied electric fields lower the flow stress, possibly by reducing the electrochemical potential of rate-controlling vacancies in the space-charge adjacent to grain boundaries,²³⁶ perhaps with relevance to the discussion in Section 2.4.2. SPS is one FAST technique that has enabled the rapid fabrication of transparent spinel compacts with fine grain size. Densification starts as low as $\sim 850^{\circ}\text{C}$ - 950°C and can be complete by $\sim 1200^{\circ}\text{C}$.^{67,176} The densification mechanism is attributed to grain-boundary sliding accommodated by interface-reaction (controlling) and oxygen-lattice diffusion.²³⁷ However, despite benefits, high heating rates with SPS exacerbate differential sintering and allow insufficient time for pore elimination.¹⁷⁶ In addition, grain-boundary mobility appears to increase, resulting in occluded porosity, a feature not usually observed in HP. The pulsed field also appears to enhance diffusion of carbon and/or CO gas from graphite fixtures, leading to absorption (Section 2.6.5), which in the case of SPS zirconia has been attributed to oxygen vacancies²³⁸ and carbon.²³⁹ LiF addition has been used to counteract dark color, but it requires lower heating rates to ensure its removal. As with hot-pressing, addition of pressure lowers the densification temperature, exacerbating compact-scale differential sintering. In addition, due to increased CO gas concentration, high pressure or application of pressure at too low a temperature traps CO in pores, further increasing absorption.^{66,176} Due to enhanced sintering, pressure also forms stronger bonds for a given temperature, making it more difficult to remove intervening porosity.⁶⁴ Consequently, applying pressure at higher temperature where increased diffusion and deformation takes place leads to smaller residual pores.²⁴⁰ Increased trapping of pores, occluded porosity, and absorption with SPS relegates heating rates to those used in hot-pressing.^{64,202} In addition, as with HP, shapes and sizes are limited. Thus, although demonstrating promise, SPS has significant hurdles to overcome before becoming competitive. Pressureless FAST suffers from similar problems to SPS as high densification rates trap everything from pores to binders, additives, and impurities.¹⁸

2.6.5 Absorption

Dark color is observed in spinel compacts sintered in graphitic furnaces (HP, HIP, and SPS, Fig. 2.24),^{1,64-66,202} and several sources have been identified;

1. Gross inclusions.
2. Organic additives and binders.
3. Transition metal impurities.
4. Al₂O₃ formation at spinel-graphite interfaces.
5. Carbon precipitation from trapped CO/CO₂ gas in pores.
6. Diffusion and precipitation of carbon from graphitic components.
7. Color center formation by reduction of spinel in reducing atmospheres.

Gross inclusions in starting powders, graphite foil flakes, atmospheric dust, and remnant organic precursors and binders, can result in significant absorption and/or can decompose into pore clusters.^{1,241} As little as 0.01 wt% transition-metal impurities such as Mn, Cr, and Fe cause significant absorption, and even 10-50 ppm can result in color and detrimental absorption at shorter wavelengths.^{8,24,49,99,112,117} Absorption occurs due to electronic transitions, charge-transfer transitions, and intervalence charge transfer ($\text{Fe}^{2+} \leftrightarrow \text{Fe}^{3+}$, absorbs at 194 and 258 nm).^{99,109,117} Absorption over the entire visible spectrum requires overlapping absorption bands from multiple impurities present in sufficient quantity; not likely the case for high-purity powders.⁸ Charged defects, such as antisites (absorb at 300, 328 nm) and vacancies, can trap electrons or holes, forming F-centers (two trapped electrons, absorbs at 200-233 nm), F⁺ centers (single trapped electron, absorbs at 260-270 nm) and V-centers (trapped hole, absorbs at 391 nm).^{24,99,111,242-244} These defects can interact with impurities and modify absorption characteristics. Vacancies and color centers can form under reducing conditions present in graphitic furnaces,^{8,24,66,109,242,243} and their presence is supported by experiments with single and poly-crystals that exhibit dark color when reduced with H₂ under carbon-free conditions.²⁴⁵

CO₂ or CO (above ~500°C, depending on $p\text{O}_2$) gas is present in graphitic furnaces^{24,79,246,247} and in open porosity early during sintering. It becomes trapped in pores in later stages, and with increased pressure and/or decreasing temperature precipitates as carbon or graphite, possibly by stress graphitization (Eq. 2.19 and Fig. 2.25).^{65,202,248,249} Individual carbon atoms may also migrate along grain boundaries, perhaps exacerbated by applied fields during SPS, and

accumulate into particles at grain boundaries and triple junctions.^{8,202} Spinel also reacts with carbon at interfaces to form Al_2OC , which contributes to absorption.⁸³ Use of polished vitreous graphite dies alleviates absorption in HP and allows components with modest optical properties to be used without subsequent polishing.²⁵⁰ Although often only present in detectable quantities at triple junctions, the presence of carbon has been unequivocally demonstrated in alumina and spinel compacts and models confirm absorption between $0.2\text{--}2.0\ \mu\text{m}$.^{65,202,248}

Fig. 2.24: Increased absorption in SPS compacts with; (a) increasing heating rate,⁶⁴ (b) sintering temperature,¹⁷⁶ (c) temperature of pressure application,²⁴⁰ and (d) applied pressure.⁶⁶

Fig. 2.25: (a) Carbon-rich phase at triple junction in spinel compact, (b) HRTEM image of graphitic carbon at triple junction in spinel compact.²

Increasing absorption with temperature in HP and SPS compacts and with Al_2O_3 -rich stoichiometry in HP compacts is consistent with increased carbon diffusion and Al_2O_3 formation, respectively. Absorption is also observed in MgO-rich compositions, possibly at Al_2O_3 -rich grain boundaries or due to greater oxygen vacancy and color center concentration. The possibility of absorption due to magnesium and its compounds has not been addressed. Absorption at the periphery of HP compacts and decreased absorption with increased shielding is consistent with carbon contamination from contact with graphite foil or graphitic components. In SPS compacts, increasing absorption with heating rate, with applied pressure, and with decreasing temperature of pressure application is consistent with differential sintering of compact exteriors, trapping CO containing pores, in which CO subsequently transforms to carbon. LiF effectively removes dark color in HP and SPS compacts, with lithium possibly playing a larger role. Pre-heating^{58,62} and postannealing in air have been shown to remove dark color in SPS and PS/HIP compacts,²³⁵ indicating either reaction of oxygen with carbon or neutralization of oxygen vacancies with no distinguishing between them.

2.7 Summary

Consensus is emerging that successful fabrication of transparent spinel, and likely transparent ceramics in general, entails a holistic approach. All material and processing variables need consideration, quantification, and tracking, through every step of fabrication. For spinel, increased attention must be paid to three variables that play a critical role during processing: (i) particle-size characteristics, (ii) stoichiometry, and (iii) impurities. In addition, effects that occur from the nanometer-scale to the compact scale must be considered. In this respect, scaling technologies for larger or thicker components is arguably one of the most challenging aspects of fabrication and size is also a major limitation for techniques such as HP and SPS. Although large-scale variables such as agglomeration and gross inclusions are tackled first since they have an immediately visible impact on optical properties, atomic-scale variables such as point defects and color centers, may in some cases be controlling and cannot be overlooked. In between these scales are effects of gradients in stoichiometry, impurities, microstructure, and residual stress. Despite the complexity of the spinel processing system, the identification of key variables, attention to multiscale effects, and understanding of the complexities of green-body formation and interactions that occur during sintering has enabled production of large, transparent components using a variety of methods (Table 2.3). However, significant progress remains, particularly in scaling-up fine grain-size technologies, strengthening grain boundaries, pushing absorption edges towards the theoretical limits, and lowering cost. In addition, understanding still lacks regarding the causes of grain growth and absorption, and the specific role of impurities, additives, and point defects. Variable stoichiometry, although a source of complexity, is a potentially powerful tool to control processing and properties. However, understanding of stoichiometry gradients on microstructural and compact scales also lacks. Perhaps with a deeper knowledge of these issues and with optimal powders and green bodies and careful use of atmosphere, additives, electric fields, and other methods, it may be possible to achieve the ultimate goal of pressureless sintering.

CHAPTER 3 EXPERIMENTAL METHODS

Spinel powders were examined by X-ray diffraction (XRD), optical and polarized-light microscopy, scanning electron microscopy (SEM) in combination with energy-dispersive X-ray spectroscopy (EDS), transmission electron microscopy (TEM) in combination with selected-area diffraction (SAD), carbon-sulfur and nitrogen determination, inductively-coupled plasma in combination with mass and optical-emission spectroscopy (ICP MS/OES), laser scattering particle-size analysis, and Zeta potential (Section 3.1). Powders were mixed with additives (Section 3.2) and chemical interactions during thermal treatment were examined by simultaneous thermal analysis in combination with mass spectroscopy (STA-MS) (Section 3.3) and verified with thermodynamic simulations (Section 3.4). Coarsening studies were conducted and densification was assessed by variable-atmosphere dilatometry (Section 3.5) and hot-press displacement analysis (Section 3.6). Dense compacts were made by hot pressing (HP) (Section 3.6) and pressureless-sintering (PS) (Section 3.7), sometimes combined with hot-isostatic pressing (HIP), and were subject to quenching experiments (Section 3.8). Compact density was determined by the Archimedes method and mercury pycnometry (Section 3.9) and chemistry with ICP OES/MS (Section 3.10). Compacts and interfaces were examined with optical and polarized-light microscopy (Section 3.11), SEM in combination with EDS, wavelength-dispersive X-ray spectroscopy (WDS), and electron-backscatter diffraction (EBSD) (Section 3.12), TEM in combination with EDS and convergent-beam electron diffraction (CBED), scanning TEM (STEM) in combination with EDS and electron energy-loss spectroscopy (EELS) (Section 3.13), time-of-flight secondary-ion mass spectroscopy (TOF-SIMS), nano-SIMS, and TEM in combination with SIMS (parallel-ion electron spectroscopy: PIES) (Section 3.14), Raman spectroscopy (Section 3.15), ultraviolet-visible-infrared (UV-Vis-IR) spectrophotometry (Section 3.16), atomic-force (AFM) and electrostatic-force (EFM) microscopy (Section 3.17), and electrochemical impedance spectroscopy (EIS) (Section 3.18).

3.1 Powder Characterization

Spinel powders with $x = 0.95, 0.995, 1.0, 1.05, \text{ and } 1.50$ from three different sources were used. S30CR “sulfate powder” (lot #601113, Baikowski, Charlotte, NC, USA) is synthesized from aqueous sulfates and contains ~ 800 ppm sulfur. Nanocerox “alkoxide powder” (lot #4CZ143B1, Nanocerox, Ann Arbor, MI, USA) is synthesized by flame-spray pyrolysis of metal-organic precursors and contains < 100 ppm impurities. Powders “hydroxide powder” with $x = 0.95, 1.0, \text{ and } 1.5$ were synthesized by mixing $\gamma\text{-Al}_2\text{O}_3$ (SPA-Gamma, AF grade, SASOL North America, Tuscon, AZ, USA) and $\text{Mg}(\text{OH})_2$ (99% grade, Noah Technologies, San Antonio, TX, USA) in an aqueous slurry, drying by rotary evaporation and in vacuum, milling with high-purity alumina media, sieving with 58-mesh nylon screens, and calcining in high-purity alumina crucibles at 1000°C for 2 h.

Powders were examined by XRD (X'Pert, Philips, Eindhoven, The Netherlands). Impurity content was determined by diluting ~ 0.1 g samples in 4-40 ml of spectroscopic grade H_3PO_4 in Teflon beakers, dissolving by microwave digestion, and examining by ICP-OES (Spectro Arcos, Spectro, Kleve, Germany; 3000 ICP-OES, Perkin Elmer, Waltham, MA, USA). Sulfur and carbon content were determined by placing powder samples into nickel baskets with tungsten-tin and/or iron accelerants in a combustion infrared-absorption analyzer (CS-400, LECO, St. Joseph, MI, USA) that was calibrated with a standard prior to each run. Nitrogen content was determined by placing powder samples in a nitrogen-oxygen thermal conductivity determinator (TC-456, LECO). Powders were also examined using polarized-light microscopy (PMG3, Olympus, Tokyo, Japan).

Powder particle-size was determined by SEM (Quanta 600i, FEI, Hillsboro, OR, USA; JSF-7000, JEOL, Tokyo, Japan), TEM (CM12, CM200, Philips), and laser scattering (S3500, Microtrac, York, PA, USA). The TEM camera length was calibrated with silicon and MoO_3 standards, powders were dispersed in ethanol in glass beakers in an ultrasonic bath and scooped onto lacy polymer/carbon grids, SAD powder ring patterns were indexed, and intensities and lattice spacings calculated and matched to ICDD (International Center for Diffraction Data) PDF files. Average particle size was calculated using diameters for at least 50 particles. The laser scattering analyzer was calibrated with a silica standard and powder samples were dispersed in water using Darvan[®] C-N (ammonium polymethacrylate). Particle colloid-stability was assessed

by dispersing powders in water and measuring the Zeta potential (Zetasizer Nano ZS, Malvern Instruments, Worcestershire, UK).

3.2 Powder Treatment Experiments

Additions of 0.05 – 10 wt% LiF (99.99% metal basis, Lot #20307, Puratronic, Alfa Aesar, Ward Hill, MA, USA) were added to sulfate and alkoxide powders and 0.05 and 0.1 wt% Al₂O₃ (99.99%, 20 nm average particle size, CoorsTek, Golden, CO, USA) was added to alkoxide powder, corresponding to $x = 0.998$ and 0.996 , respectively. Additives and powders were weighed to ± 0.1 mg, poured into a Nalgene bottle filled with methanol (40 % solids loading), mixed ultrasonically with a tungsten horn (CPX 130, Cole Parmer, Vernon Hills, IL, USA) for 1 min with a power setting of 40 W, solvent was removed by rotary evaporation (R-210, Büchi Labortechnik AG, Flawil, Switzerland), powders were dried in ambient conditions for 3 days and were subsequently ground with an agate mortar and pestle and sieved through 100 or 425 steel mesh sieves using a vibratory mixer. As a control on the mixing method, powders without additives were also similarly processed. Mixing additives by ball-milling in methanol or water with high-purity Al₂O₃ media and dry acoustic mixing (Resodyne, Butte, MT, USA) yielded compacts with poor transmission and so ultrasonic mixing followed by rotary evaporation was selected as standard processing.

3.3 STA-MS Experiments

STA (STA 409, Netzsch, Selb, Germany), combining differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA), was conducted on powder samples to determine thermal behavior. To analyze evolved gases, an atmospheric residual gas analyzer (Cirrus, MKS, Andover, MA, USA) equipped with a 100-channel quadrupole MS operated at 40 eV, was connected to the STA chamber via a 3.175 mm stainless steel capillary heated to $\sim 250^\circ\text{C}$ with resistive tape. Analyte powder was poured into an alumina crucible and weighed to ± 0.1 mg. The crucible was placed in the STA chamber, which was filled with air or evacuated and back-filled three times with ultra-high purity argon. The chamber was heated at $5^\circ\text{C}/\text{min}$, $10^\circ\text{C}/\text{min}$, or $20^\circ\text{C}/\text{min}$ to 1450°C . The analyzer software output pressures based on calibrated counts for each mass-to-charge (m/z) ratio, which were divided by total pressure to obtain partial pressures and expressed as ideal gas vol% or ppm volume percent (ppmv). Species of equal mass were

differentiated based on species known to be present, known chemical interactions, and species predicted by Gibb's energy minimization simulations using thermodynamic software.

Calibration runs were performed with empty crucibles in argon and served as correction files for STA and as a baseline for residual gas analysis. These indicated weak endotherms at 185°C associated with vaporization of adsorbed water and at 425°C associated with organics and an instrument-related endothermic rise above 500°C. STA-MS indicated 99.96 vol% argon species, with the remainder being atmospheric gases and water vapor, confirming effective sealing. Argon species (^{36}Ar , ^{38}Ar , ^{39}Ar , ^{40}Ar) concentrations matched isotopic distributions with weak signals (<0.01 vol%, 100 ppmv total) for charge-to-mass ratios (m/z) 20 (Ar^{++}), 41 (ArH^+), and 80 (Ar_2^+).²⁵⁸⁻²⁶¹ Weak signals (<100 ppmv total) for m/z 14 (N^+), 16 (O^+), 28 (N_2^+), and 32 (O_2^+) matched atmospheric gas concentrations and fragmentation patterns.^{262,263} Weak signals (<200 ppmv total) for m/z 17 (OH^+) and 18 (H_2O^+) were consistent with water vapor and increased slightly >1300°C.²⁶³ Weak signals (10 ppmv) for m/z 44 (CO_2^+ , N_2O^+) between 400°C and 1000°C were likely evaporation or combustion of organics, and for m/z 30 (NO^+) and 44 (CO_2^+ , N_2O^+) >1000°C were consistent with thermal N_2O formation and fragmentation patterns.²⁶³⁻²⁶⁷ Small (20-30 ppmv), sharp increases in m/z 20 and 32 >1350°C were of unknown origin. STA-MS of empty crucibles in air indicated atmospheric gases and water vapor in expected concentrations. Duplicate runs applying the calibrations were performed in air and in argon for; pure LiF; alkoxide powder with 0 wt%, 1 wt%, and 10 wt% LiF; and sulfate powder with 0 wt% and 1 wt% LiF, and with MgF_2 and LiAlO_2 , which are products of a reversible reaction between LiF and spinel.

3.4 Thermodynamic Simulations

Thermodynamic simulations were conducted using HSC Chemistry (Outototec, Espoo, Finland) to determine chemical interactions between starting powders, impurities, additives and the processing atmosphere. Simulations are based on thermodynamic equilibrium calculations using an internal thermochemical database. Solid and gaseous species arising from chemical interactions between starting constituents (MgO , Al_2O_3 , MgAl_2O_4 , LiF, Li_2O , AlF_3 , LiAlO_2 , MgF_2), impurities (C, S, Ca, Fe, MgSO_4 , $\text{Al}_2(\text{SO}_4)_3$), and atmospheres (air, O_2 , N_2 , argon), were selected from the software database. Initial species concentrations, atmosphere, pressure, and temperature (typically 25°C to 1500°C) were input, Gibb's energy minimization simulations were

conducted, and the software output plots of species concentration as a function of temperature. Simulations did not take into account kinetics, stoichiometry, solubility for species in spinel, or mixed-metal oxides and point defects.

3.5 Dilatometry Experiments

Dilatometry was conducted to assess sintering behavior as a function of powder, LiF addition, and atmosphere. 0.350 g powder samples were weighed with an analytical balance (BA 210S, Sartorius, Elk Grove, IL, USA) with an accuracy of ± 0.0001 g, poured into a 6.35 mm diameter cylindrical steel die lubricated with a solution of 5 wt% stearic acid and polyvinyl alcohol, and hydraulically cold-pressed to 530 MPa, yielding cylindrical compacts with an aspect ratio of $\sim 1:1$. Cold-pressed compacts were re-weighed and dimensions measured using a micrometer. Compacts were loaded into a horizontal dilatometer (402C, Netzsch) with alumina spacers placed between samples and the alumina pushrod and backrest. A force of 30 mN was applied to the push-rod and temperature was ramped at $2^\circ\text{C}/\text{min}$ to 1500°C . Atmosphere was either uncirculated ambient air or argon with 2% H_2 using flow rate of 20 l/min, in which case the dilatometer chamber was evacuated with a rotary vacuum pump and backfilled three times prior to starting. Compacts were subsequently re-weighed and dimensions re-measured.

The dilatometer recorded linear displacement (ΔL) as a function of time and temperature. Displacement was corrected for system thermal expansion by applying a calibration correction using an alumina standard. The error due to length and linear coefficient of thermal expansion (linear CTE, α_L) differences between the standard ($L_{std} = 10$ mm, $\alpha_{L, Al_2O_3} = 8.1 \cdot 10^{-6} \text{ K}^{-1}$)^{23,268} and samples ($L_{compact} = 6$ mm, $\alpha_{L, Spinel} = 8.0 \cdot 10^{-6} \text{ K}^{-1}$)²³ was corrected for. Displacement was normalized by length by dividing by the initial compact length. Sample thermal expansion was subtracted from displacement based on the sintered compact thickness. It was desired to display sintering behavior as a function of temperature (T) in terms of fractional sintered density (P_s) rather than linear shrinkage ($\Delta L/L_0$);¹⁸⁶

$$P_s = \frac{\rho_i}{\rho_{th}}, \quad (3.5.1)$$

where ρ_i is instantaneous density and ρ_{th} is theoretical density. If no mass loss occurs, then instantaneous density is initial weight (W_0) divided by instantaneous volume (V_i);

$$\rho_i = \frac{W_0}{V_i} \quad (3.5.2)$$

If shrinkage is isotropic, the ratio of initial volume to instantaneous volume (V_0/V_i) is equal to the ratio of the volume of a cube with initial side length (L_0), to that of a cube with instantaneous side length (L_i). Thus,

$$P_s = \frac{\left(\frac{W_0}{V_i}\right)}{\rho_{th}} = \frac{\left(\frac{W_0}{V_0}\right) \times \left(\frac{V_0}{V_i}\right)}{\rho_{th}} = \frac{\left(\frac{W_0}{V_0}\right) \times \left(\frac{L_0}{L_i}\right)^3}{\rho_{th}} \quad (3.5.3)$$

Since (W_0/V_0) is the green density (ρ_g);

$$P_s = \frac{\rho_g}{\rho_{th}} \left(\frac{L_0}{L_i}\right)^3 \quad (3.5.4)$$

Noting that $L_i = L_0 + \Delta L$ and that ΔL is negative for sintering;

$$\frac{L_0}{L_i} = \frac{1}{\left(\frac{L_i}{L_0}\right)} = \frac{1}{\left(\frac{L_0 + \Delta L}{L_0}\right)} = \frac{1}{\left(1 + \frac{\Delta L}{L_0}\right)} \quad (3.5.5)$$

Thus;

$$P_s = \frac{\rho_g}{\rho_{Th}} \frac{1}{\left(1 + \frac{\Delta L}{L_0}\right)^3} \quad (3.5.6)$$

For cylindrical compacts, shrinkage was anisotropic and the thickness (L) shrank more than the diameter (Φ) due to geometry and cold-pressing density gradients. Thus, $L_0/L_i > \Phi_0/\Phi_i$ and $V_0/V_i \neq L_0^3/L_i^3$, so $V_i = L_i \times L_i \times L_i'$, where L_i' is a radial direction with anisotropic shrinkage. If Φ_0 is the initial diameter and Φ_i is the instantaneous diameter;

$$\frac{V_0}{V_i} = \left(\frac{L_0}{L_i}\right) \times \left(\frac{\Phi_0}{\Phi_i}\right) \times \left(\frac{\Phi_0}{\Phi_i}\right) = \left(\frac{L_0}{L_i}\right)^3 \times \left(\frac{L_i}{L_0} \times \frac{\Phi_0}{\Phi_i}\right)^2 = \frac{1}{\left(\frac{L_i}{L_0}\right)^3 \left(\frac{L_0}{L_i} \times \frac{\Phi_0}{\Phi_i}\right)^2} = \frac{1}{\left(1 + \frac{\Delta L}{L_0}\right)^3 \xi^2}, \quad (3.5.7)$$

where ξ is the anisotropy parameter. Since Φ changed less per unit increase in temperature (or time) than L , assuming a similar temporal shrinkage behavior for L and Φ ;

$$\Phi_i \approx \Phi_0 - \left(\frac{L_i - L_0}{L_F - L_0} \right) (\Phi_0 - \Phi_F) = \Phi_0 - \left(\frac{\Delta L}{L_F - L_0} \right) (\Phi_0 - \Phi_F) \quad (3.5.8)$$

Thus;

$$\xi = \left(\frac{L_0}{L_i} \times \frac{\Phi_i}{\Phi_0} \right) \approx \left(\frac{L_0}{L_i} \times \frac{\Phi_0 - \left(\frac{\Delta L}{L_F - L_0} \right) (\Phi_0 - \Phi_F)}{\Phi_0} \right) \quad (3.5.9)$$

and

$$P_s = \frac{\rho_G}{\rho_{Th}} \frac{1}{\xi^2 \left(1 + \frac{\Delta L}{L_0} \right)^3} \quad (3.5.10)$$

Eq. (3.5.10) was applied to calculate fractional sintered density as a function of time and temperature. The onset of sintering was determined from the temperature associated with the intersection of tangents to the linear portions of the displacement curves before and after the onset. The temperature of maximum sintering rate was determined by differentiating the normalized displacement versus temperature curves with respect to temperature. Where applicable, the onset of closed porosity was estimated from the attainment of 92% theoretical density for the fractional density versus temperature curves.¹⁸⁶

3.6 Hot Press Experiments

Hot-pressing was used to achieve densification with a minimum of steps. Powders were poured into a graphite die lined with graphite foil (99.5%, GrafTech, Lakewood, OH, USA) with graphite foil spacers placed above and two below the powder. The graphite foil was cleaned and edges were smoothed to avoid contamination from graphite particles. To study the effect of sample size, three die sizes were used; 12.7 mm, 25.4 mm, and 38.1 mm. Powder amount was varied to study the effect of sample thickness; 1.5 g or 3.5 g (25.4 mm die), 9 g or 12 g (25.4 mm die), and 12 g (38.1 mm die). To eliminate the effect of carbon contamination from graphite foil and dies, a high-purity alumina die was constructed, in which alkoxide powder was hot-pressed with and without molybdenum foil. The graphite or alumina dies were placed in an instrumented hot press (Thermal Technology Inc., Santa Rosa, CA) with a water-cooled, stainless steel chamber and graphitic elements. The hot press chamber was evacuated using rotary and diffusion pumps and vacuum levels were monitored with an ion gauge (Model 563, Varian).

Vacuum levels deteriorated to ~ 13 mPa between 50°C and 300°C , but were < 1.3 mPa for the remainder of the runs. Temperature was recorded with a type C (tungsten/rhenium) hafnia-insulated thermocouple in the hot zone. Ram displacement was measured using a linear variable differential transformer (LVDT). Pressure was measured using a strain-gauge pressure-cell calibrated to a maximum load of 222 kN.

The starting hot-press regime was based on prior research^{49,269} and consisted of ramping temperature from ambient to 1550°C . A heating rate of $10^\circ\text{C}/\text{min}$ was used to avoid grain growth. The minimum controllable instrument pressure of 3 MPa was applied at the outset to prevent plunger damage during subsequent pressure application. A 60 min hold was used at 400°C to ensure volatile species outgassing. A 5 min hold was used at 900°C , presumably to allow LiF to melt and spread by capillarity.^{49,269} A 15 min hold was used at 1200°C , presumably to allow interaction between LiF and spinel.^{49,269} A 60 min hold was used at the sintering temperature of 1550°C to ensure complete densification. A slower cooling rate of $6^\circ\text{C}/\text{min}$ was used to avoid thermal shock. A pressure of 35 MPa was applied at 1200°C upon heating and maintained during sintering. Reports indicated that applying pressure at lower temperature (1100°C) resulted in opacity, presumably because of trapped volatile impurities and LiF.^{49,269} Applying pressure at higher temperature (1300°C) was also reported to result in opacity, presumably due to evaporation of LiF without interaction.^{49,269} Pressure was maintained until 900°C upon cooling, presumably to avoid pore coarsening.^{49,269}

Hot-press parameters from the initial regime were varied and optimized. Heating rates of $2^\circ\text{C}/\text{min}$, $3^\circ\text{C}/\text{min}$, $6^\circ\text{C}/\text{min}$, and $10^\circ\text{C}/\text{min}$ were used to optimize volatile species outgassing while minimizing grain growth. High-temperature intermediate holds at 900°C , 1050°C , 1150°C , and 1200°C were used to determine the optimal LiF interaction and outgassing. Maximum sintering temperatures of 1200°C , 1300°C , 1400°C , and 1550°C were used to determine the minimum temperature at which densification could be achieved. The temperature of pressure application was found to be an important parameter^{49,269} and temperatures of 800°C , 900°C , 1100°C , 1200°C , 1300°C , and 1400°C were used. A pressure of 60 MPa was also used to gauge the effect on microstructure and optical properties. Although optimal parameters depended on the starting powder and sample size, the regime shown in Fig. 3.1 “standard processing” was

generally used. The variation of processing and hot-press parameters is summarized in Table 3.1.

Fig. 3.1: Standard hot-press profile including ramp at 6°C/min to 1550°C with 1 h hold at 400°C, 0.25 h hold at 1200°C, 1 h hold at 1550°C, application of 35 MPa at 1200°C and removal at 900°C. Modified regime with pressure applied at 900°C (dashed line).

Vacuum, temperature, ram displacement, and pressure voltages were acquired and recorded by a data acquisition system every second, averaged to one value per 10 seconds, and imported into Excel. Thermocouple voltage was converted to temperature using a linear best-fit to a Type-C thermocouple voltage calibration.²⁷⁰ Load-cell strain-gauge voltage was converted to load using a linear best-fit to a manufacturer's calibration and converted to pressure by dividing by the plunger cross-sectional area. LVDT voltage was converted to displacement using a linear best-fit to an empirical calibration, and where necessary corrected for pressure and thermal expansion. Strain due to pressure was assumed to occur mainly in the graphite components due to the lower modulus (E) than the steel rams ($E_{ISO\ 63\ Graphite} \approx 12\text{-}20\ \text{GPa} \ll E_{Stainless\ Steel} \approx 195\ \text{GPa}$),^{271,272} and subtracted from displacement. Although the modulus of graphite varies with temperature, a value of 19 GPa correlated well with observations. The system linear thermal expansion was estimated from the displacement for a standard hot press run without a compact, and subtracted from displacement. The calculated system linear CTE ($\alpha_{L\ System} = 5.6 \cdot 10^{-6}\ \text{K}^{-1}$) closely matched experimental values. For higher accuracy, displacement values for the standard run without a compact were subtracted from identical standard runs with compacts. Compact linear thermal expansion was estimated based on the fully-densified thickness and $\alpha_{L\ Spinel}$ and subtracted from displacement. Compact density was calculated from corrected displacement,

measured compact final thickness and density, and was plotted as percent theoretical. Vacuum thermocouple and ion gauge voltages were converted to pressure based on manufacturer's conversions. For each hot press run, calibrated temperature, pressure, displacement, density, and vacuum levels were plotted as a function of time. The sintering onset temperature and temperature at which closed porosity occurred were determined in the same manner as for dilatometry experiments.

Subsequent to hot-pressing, compacts were ground using SiC grinding discs to 600-grit and polished on glass platens using napless nylon cloths and Al₂O₃ polishing media diluted in water down to 0.05 μm. When higher grain contrast was required, a final polish with colloidal silica and vibratory polishing was used. Compacts had diameters of 12.7 mm or 25.4 mm and were ~2 mm thick (1.5 g of powder) or ~5 mm thick (3.5 g of powder) after polishing.

Table 3.1: Variation of Processing Parameters.

Parameter	Range
Powder synthesis	Sulfate, Alkoxide, Hydroxide
LiF Addition (wt%)	0, 0.05, 0.25, 1.0, 10
Al ₂ O ₃ addition (wt%)	0, 0.05, 0.1
Other additives	Li ₂ O, AlF ₃
Mixing method	None, ball mill, acoustic, ultrasonic
Die size (mm)	12.7, 25.4, 38.1
Powder amount (12.7 mm die, g)	1.5, 3.5
Powder amount (25.4 mm die, g)	6, 9, 12
Powder amount (38.1 mm die, g)	11
Die material	Graphite, Al ₂ O ₃
Shielding type	Graphite foil, molybdenum foil
Sintering method	Pressureless, hot press
Atmosphere	Vacuum, air, argon + 2% H ₂
Temp. ramp rate (°C/min)	2, 3, 6, 10
Max. sintering temp. (°C)	1200, 1300, 1400, 1550
Hold at sintering temp. (min)	60, 120, 180
Intermediate hold temp. (°C)	900, 1050, 1150, 1200
Intermediate hold time (min)	15, 60, 120
Temp. pressure applied (°C)	800, 900, 1050, 1100, 1200, 1300, 1400
Max. Pressure (MPa)	35, 60

3.7 Pressureless Sinter - HIP Experiments

Pressureless sintering experiments were conducted to assess scaling-up transparency achieved with dilatometry to larger specimens and to gauge the effect of powder synthesis and properties on subsequent hot-isostatic pressing (HIP). 1.5 g of sulfate or alkoxide powder was poured into a 12.7 mm diameter steel die and cold-pressed at 175 MPa using a hydraulic press. Cold-pressed compacts were sintered in air in a vertical furnace with MoSi₂ elements (Deltech, Denver, CO) at 2°C/min to 1550°C, with a 1 hour hold at 1550°C, and a ramp to ambient at 10°C/min. Compacts were cut in half with a diamond saw and HIPed in a graphite furnace in argon at 5°C/min to sintering temperature with a 2 h hold at 300°C. One half of each sample was HIPed at 1550°C for 10 h, and the other at 1650°C for 15 h.

3.8 Quenching Experiments

Quenching experiments were conducted to determine whether impurities and additives segregated at grain boundaries could be re-dissolved into the matrix to alter fracture behavior. Samples from compacts hot pressed with sulfate powder with 1 wt% LiF were heated in an air furnace to 1200°C and quenched in water at ambient temperature. The samples were sectioned with a diamond saw and the slices obtained were fractured and the surfaces examined with SEM and compared to those of un-quenched samples.

3.9 Density Measurement

Compact densities were calculated using the Archimedes method and ASTM B962 and C373. Compacts were boiled in de-ionized water for 5 h, weighed to ±0.1 mg with an analytical balance (BA 210S, Sartorius) with adjustments made for ambient temperature and pressure. Density was also assessed using mercury pycnometry (Spy-2, QuantaChrome, Boynton Beach, FL, USA). However, although relative values between samples appeared accurate, calculated densities were higher than theoretical, likely due to the large chamber size compared to samples.

3.10 Chemical Spectroscopy

Laser ablation inductively coupled plasma optical emission and mass spectroscopy (LA-ICP OES/MS; Spectro-Arcos, Spectro; 820 MS, Varian; LSX-500 LA, Cetac, Omaha, NB) was used to

quantify impurity content within and among compacts. Two compacts hot pressed with 3.5 g of sulfate powder and pressure applied at 1200°C were analyzed; one without LiF and one with 1 wt% LiF. Compacts were sectioned using a diamond saw, yielding semi-cylinders. For each compact, two areas were analyzed; the center of a face and the geometric center. Prior to LA-ICP a compact hot pressed so as to maximize retained impurity content was analyzed with LA-ICP and also dissolved using spectroscopic-grade phosphoric acid and microwave digestion for analysis by solution ICP-OES to establish a reference. The spectral counts of the ICP analyses were integrated and the element counts normalized by dividing them by the aluminum, magnesium, or gallium counts. The normalized counts from LA-ICP were compared to those from solution-ICP to establish absolute concentrations. Major species (Na, Mg, Si, S, Ca, and Fe) concentrations were determined by OES and trace species (Li, B, Cu, Zn, Zr, Ga, Se, I, Ba, W) concentrations by MS. Alumina levels were obtained by difference, lithium content was measured directly and LiF content estimated from it, and boron content was too low to establish a calibration curve.

3.11 Optical Microscopy

Compact microstructures were examined using optical microscopy (OM; PMG 3, Olympus), with a 10X eyepiece, 10X-50X objective lenses, and a top-mounted digital camera (PX-CM, Paxcam, Villa Park, IL, USA). Decorated grain boundaries, second phases, inclusions, and other optical defects were observed by focusing the image plane in the interior of transparent compacts. Images with annotated calibrated scale bars were imported into Image J image analysis software (National Institute of Health, Bethesda, MD, USA). Average grain size was calculated using the circle-intercept method and ASTM E112. Grain boundary surface area per unit volume was calculated by modeling grains as tetrakaidecahedrons with diameters equal to the measured average grain size.²⁷³ Total grain boundary area for each grain size type was calculated by multiplying the grain boundary surface area per unit volume for each grain size type (matrix grains, sub-micron grains, abnormal grains) by the area fraction of that type determined from Image J analysis of SEM images. Compacts were also examined with polarized light microscopy (PLM; AxioScope A1, Zeiss, Oberkochen, Germany) using a full-wavelength green-light filter to examine birefringent features and residual stress.

3.12 Scanning Electron Microscopy

The microstructure and chemistry of polished compacts, fracture surfaces (which ensured the retention of brittle second phases and showed fracture mode), and of precipitate collected from the periphery of compacts subsequent to hot-pressing, were examined with SEM (JSF-7000, JEOL) in combination with EDS and WDS. Crystallographic texture in polished compacts was examined using EBSD. The volume percent of phases and fracture features were determined using Image J.

3.13 Transmission Electron Microscopy

Transmission electron microscopy (TEM; CM200, CM12, Phillips; JEM 2100F, JEOL) and scanning TEM (STEM, Tecnai G2 F20 S-Twin, FEI; JEM ARM 200F, JEOL) were performed on specimens that were dimple-ground and ion milled (Duo Mill 600, Gatan, Warrendale, PA, USA) with argon, or alternatively on lift-outs prepared with a dual-beam focused ion beam (FIB; Helios 600i; FEI). To preserve phases that dissolve in water, dimpled specimens were ground using an ethanol-based lubricant (Lubricant Yellow, Cloeren Technology, Wegberg, Germany). Compacts were examined in brightfield (BF) and centered dark-field (DF) modes and by electron diffraction (ED), selected-area electron diffraction (SAD), and convergent beam electron diffraction (CBED), and chemical composition was examined using energy-dispersive X-ray spectroscopy (EDS) and electron energy loss spectroscopy (EELS).

Changes in lattice parameter at grain boundaries were assessed by performing CBED on FIB samples. The TEM camera length was calibrated with silicon and polycrystalline aluminum standards using;²⁷⁴

$$R = \lambda L, \quad (3.13.1)$$

where R is the distance between SAD reflections, d is the crystal lattice spacing, λ is the electron wavelength, and L is the camera length. The TEM voltage was determined by collecting CBED patterns for a silicon single crystal and matching central-disc Kikuchi line patterns of low-index zone axes to simulated patterns with JEMS (EPFL, Lausanne, Switzerland) electron diffraction simulation software²⁷⁵ using;

$$\lambda = \frac{h}{(2m_0eV)^{1/2}}, \quad (3.13.2)$$

where λ is the electron wavelength, h is Planck's constant, m_0 is the electron mass, e is the charge of one electron, and V is the TEM voltage. CBED patterns were collected at grain interiors and grain boundaries of FIB samples. The relationship between electron wavelength, TEM camera length and voltage, and lattice parameter is given by;

$$\frac{1}{H} = \left(\frac{2}{\lambda}\right)\left(\frac{\lambda L}{r}\right)^2, \quad (3.13.3)$$

where H is the spacing of reciprocal lattice planes parallel to the electron beam, λ is the electron wavelength, L is the camera length, and r is the measured radius of the first-order Laue zone (FOLZ) ring. The lattice parameter was calculated from;

$$\frac{1}{H} = \frac{a_0(U^2 + V^2 + W^2)^{1/2}}{P}, \quad (3.13.4)$$

where a_0 is the lattice parameter, U , V , and W are the zone axis plane indices, $P = 1$ when $(U + V + W)$ is odd and $P = 2$ when $(U + V + W)$ is even.

Lattice parameter variation across grain boundaries using TEM-CBED could not be determined with certainty either because the variation gradient was too shallow or too narrow, or because the electron beam probe size was larger than the features being investigated. In addition, accuracy was limited by beam asphericity noted in FOLZ circles.

STEM-EDS/EELS maps were collected at several grain boundaries and triple-junctions of FIB lift-outs from hot-pressed sulfate powder compacts with LiF and were imported into Digital Micrograph (Gatan, Warrendale, PA). Relative intensity ratios for Mg, Al, and O peaks from EDS spectra were plotted versus distance from the grain-boundary core. The zero-loss (ZL) peak was removed and a power-law background subtraction was applied to EELS spectra. The Mg-L_{2,3} (51 eV), Al-L_{2,3} (73 eV), Mg-L₁ (88 eV), Al-L₁ (118 eV), C-K (284 eV), O-K (532 eV), Mg-K (1305 eV), and Al-K (1560 eV) edges were extracted and quantified. The Li-K (55 eV) edge was not identifiable, likely due to the low edge/background ratio intensity combined with low concentration and overlap with the Mg-L_{2,3} edge. The F-K (685 eV) edge was similarly not identified, likely due to low concentration. Mg-K (1305 eV) and Al-K (1560 eV) edges were too

weak to be accurately resolved. Edge intensity ratio variation across grain boundaries were plotted versus distance from the grain-boundary core for the following combinations: Mg-L_{2,3}/Al-L_{2,3}, Mg-L₁/Al-L_{2,3}, Mg-L_{2,3}7O-K, Mg-L₁/O-K, and Al-L_{2,3}/O-K.

3.14 Secondary-Ion Mass Spectroscopy

Knowledge of the distribution of lithium in sintered samples can give insights into its role during densification and how it affects interfaces. However, it is not easily detectable by EDS or TEM-EELS. Time-of-flight secondary-ion mass spectroscopy (TOF-SIMS) is one of few methods capable of quantifying its distribution with relatively high spatial resolution. TOF-SIMS (Phi Thrift III, Physical Electronics, Chanhassen, MN, USA) ⁷Li⁺ mapping was performed on the polished surfaces of samples hot-pressed with sulfate powder with (i) no LiF using the standard profile with 35 MPa applied at 1200°C, (ii) 1 wt% LiF addition and pressure applied at 1100°C during hot-pressing, and (iii) 1 wt% LiF addition and pressure applied at 900°C during hot-pressing. Application of pressure at a lower temperature during hot pressing was expected to trap more LiF and to result in sufficient lithium content for detection. Compacts were coated with 200 nm of copper to reduce charging. A liquid-metal ion (Au, Ce) or oxygen source was used for the ion beam and the manufacturer quoted ~1 ppm species and ~1 μm spatial resolution. For the compact without LiF, SIMS was conducted over an area of 50 μm², using 32 s analyze time, 10 s sputter time, and no charge compensation. For compacts with LiF, SIMS was conducted over an area of 25 μm², using 16 s analyze time, 10 s sputter time, and charge compensation. Lithium counts were normalized by the sum of magnesium and aluminum counts and plotted as a function of analysis time. Surface scans at the bottom of ion craters were conducted for 30 min for the compact without LiF and for 8 min for compacts with LiF. SIMS ⁷Li⁺, ²⁵Mg²⁺, and ²⁷Al³⁺ 50 x 50 μm maps were also performed on a polished sample hot-pressed with sulfate powder and 1 wt% LiF addition using the standard profile using a different SIMS instrument (IMS 6f, Cameca, France) and a SIMS instrument with a higher lateral resolution of 50 nm (Nano-SIMS 50L, Cameca, France).

PIES (Parallel-ion electron spectroscopy; LIMS, Esch-sur-Alzette, Luxembourg) consists of a SIMS instrument (with high sensitivity for low atomic-weight elements) placed within a TEM (with high spatial resolution of microstructural and crystallographic features). PIES ⁷Li⁺

mapping was conducted on a FIB lift-out from a sample hot-pressed with sulfate powder and 1 wt% LiF using the standard profile.

3.15 Raman Spectroscopy

Confocal Raman spectroscopy (Alpha 3000, WiTec, Ulm, Germany), using a Nd:YAG laser emitting light at 532 nm, was used to probe point-defect structure, determine the chemistry of second phases and inclusions, and to examine fluorescent behavior, both on the surface and within the interior of polished compacts. Raman shift as a function of wavelength was recorded for various compacts, spinel single crystals, and graphite, and compared to published spectra.

3.16 Spectrophotometry

UV-Vis.-IR Spectrophotometry (Lambda 950, Perkin Elmer; Cary 5G, Varian) was used to measure transmittance, reflectance, and fluorescence of surface ground and polished compacts. In-line transmittance (I_{ILT}) was measured from 175 nm to 3000 nm by placing samples between the radiation source and detector. Total transmittance (I_{TT}), total reflectance (I_{RT}), and diffuse reflectance (I_{RD}) were measured from 175 nm to 3000 nm using an integrating sphere. For total transmittance, samples were placed at the integrating sphere entrance aperture and a reflective plug placed at the sample reflection measurement location. For total and diffuse reflectance, samples were placed at the rear sample reflection measurement location, which was set to include specular reflectance within the sphere for total reflectance measurement, or to reflect it out the entrance aperture for diffuse reflectance measurement. For all measurements, 0% and 100% transmittance baselines were set by measuring transmittance with the source blocked and without a sample, respectively. For the 100% reflectance measurement a highly reflective polytetrafluoroethylene standard was used. Sample fluorescence was measured using a 6 W continuous wave UV source with and without a UV filter (9683) and measurement was made at 90 degrees to the incident light using a fiber-coupled detector.

Incident, transmitted, reflected, and absorbed intensities are related by;

$$I_0 = I_{TT} + I_{RT} + I_A = I, \quad (3.16.1)$$

where I_0 is the incident intensity, I_{TT} is the transmitted intensity, I_{RT} is the reflected intensity, and I_A is the absorbed intensity. Total transmittance is the sum of in-line and diffuse transmittance;

$I_{TT} = I_{ILT} + I_{DT}$, and total reflectance is the sum of specular and diffuse reflectance; $I_{RT} = I_{RS} + I_{RD}$. Diffuse transmittance (I_{DT} , or forward scatter) was calculated from the difference between total (I_{TT}) and in-line transmittance (I_{ILT}). Specular reflectance (I_{RS}) was calculated from the difference between total (I_{RT}) and diffuse reflectance (I_{RD}). Absorptance (I_A) was calculated as the incident intensity minus total transmittance and total reflectance. Where different thickness compacts were compared, values were normalized per unit thickness.

3.17 Thermal Grain-boundary Grooving Experiments

Stoichiometry affects nearly every property of spinel (Section 2.4), and it was expected to affect surface¹³⁴ (γ_s) and grain-boundary¹²⁹ (γ_{gb}) energies, which strongly influence densification.¹²¹ LiF was also expected to influence interface energies due to its reactivity with spinel and its effect on processing and properties (Section 2.5.2). In this vein, the relative γ_{gb}/γ_s ratio was quantified from thermal grain-boundary grooves imaged using atomic-force microscopy (AFM) for compacts made from powders with $x = 0.95, 1.0, \text{ and } 1.5$ and with $x \sim 1.05$ with and without 1 wt% LiF.

Grain-boundary grooving can be used to extract interface energies from thermally-etched polished surfaces. When a surface intersected by a grain boundary is exposed to temperatures where diffusion occurs, interface energies equilibrate to form a groove bounded by accommodating ridges, which deepen the groove by continually flattening to minimize surface energy.²⁷⁶ If surface energy is isotropic, the grain boundary perpendicular, and torque terms are disregarded, the groove profile is described by;

$$\gamma_{gb} = 2\gamma_s \cos(\Psi/2), \quad (3.17.1)$$

where γ_{gb} and γ_s are the grain boundary and surface energies per unit area, respectively, and Ψ is the internal dihedral angle.²⁷⁶ Thus, finding Ψ permits determining γ_{gb}/γ_s . The dihedral angle can also be found from;

$$s \approx 4.73d \tan(\Psi/2), \quad (3.17.2)$$

where s is the inter-ridge distance and d is the groove depth.²⁷⁶

Ψ , s , and d can be determined from surface topography maps made using AFM. However, AFM resolution is limited by the probe-tip radius. Due to groove convexity, slope measurements

overestimate Ψ , underestimating γ_{gb}/γ_s . Although d can also be underestimated, the error associated with measuring s and d is less than for measuring Ψ at the groove root.²⁷⁶ To reduce the relative depth measurement error, deeper grooves are preferable. However, since surface reconstruction occurs concurrently with grooving, the optimal thermal treatment is a balance between maximizing groove depth using long anneal times or high temperatures and minimizing surface reconstruction using short anneal times or low temperatures.

Ψ varies considerably as it depends on (i) inter-grain lattice misorientation, (ii) grain-boundary plane orientation, (iii) surface plane orientations, (iv) proximity to triple lines where grooves widen, (v) interface stoichiometry, (vi) precipitates, (vii) impurity content, (viii) and thermal treatment time, temperature, and atmosphere.^{135,277} Thus, valid statistics require sufficient grain boundary groove profiles.

Hydroxide powders with $x = 0.95, 1.0, \text{ and } 1.5$ (S.A. $\sim 10\text{-}20 \text{ m}^2/\text{g}$, Ca $\sim 30\text{-}35$, Na $\sim 0\text{-}460$, K $\sim 20\text{-}640$, Si $\sim 60\text{-}155$ ppm) were hot-pressed at 1600°C and 35 MPa for 5 h under a vacuum of $5 \cdot 10^{-2} \text{ Pa}$ and hot-isostatic pressed at 1850°C and 200 MPa for 5 h in argon to ensure complete solid solution.¹¹ Dense, transparent compacts were ground with SiC papers, polished with diamond slurries to $1 \mu\text{m}$, and final polished with $0.05 \mu\text{m}$ colloidal silica. To maximize groove depth, minimize surface reconstruction, and replicate typical processing conditions, polished compacts were thermally-etched for 1 h at 1450°C in argon and rapidly cooled. Thermal grain-boundary grooves were imaged by AFM (XE-100, Park Systems, Santa Clara, CA, USA) in intermittent contact mode with aluminum-plated pyramidal silicon cantilever tips (910M, ACTA, AppNano, Mountain View, CA, USA) with a radius of curvature $< 10 \text{ nm}$. AFM resolution was verified using a silicon grid (TGX01P, MikroMasch, Sofia, Bulgaria) with $1.15 \times 3 \mu\text{m}$ lateral and $0.110 \pm 0.004 \mu\text{m}$ vertical features. Polished surfaces prior to etching had a root-mean-squared roughness of $< 5.00 \text{ nm}$.

At least fifteen acceptable boundaries were mapped for each stoichiometry. Groove profiles were rejected when grain-height or groove-slope differentials on either side of boundaries were excessive ($> 40 \text{ nm}$ and $> 20^\circ$, respectively) or when grooves were shallower than the AFM tip radius. AFM maps, typically $< 30 \times 30 \mu\text{m}$, were corrected for tilt and at least three perpendicular line profiles were acquired for each boundary (XEP software, Park Systems),

resulting in at least 45 profiles per stoichiometry. Dihedral angles were determined using best-fit tangents on either side of grooves and also by measuring inter-ridge widths and groove depths. The γ_{gb}/γ_s ratio was calculated using Eqs. 3.17.1 and 3.17.2 and values were averaged for each boundary and stoichiometry.

Polished sulfate powder compacts hot-pressed with and without 1 wt% LiF using the standard using were thermally etched for 15 min at 800°C in a vertical drop-down furnace and quenched in air. Surface roughness maps were generated at selected sites by AFM (Nanoscope 310D, Digital Instruments, Tonawanda, NY, USA). Dihedral angles were measured from line scans generated using the AFM software. Due to inadequate thermal etch parameters and excessive surface roughness for samples without LiF, only five grain boundaries were examined for each condition. Electrostatic-force microscopy (EFM) was performed on polished compacts hot-pressed with and without LiF to try to detect changes in dielectric constant across grain boundaries. However, no changes were detected, either due to low instrument sensitivity or because the chemical gradients were too small, too shallow, or non-existent.

3.18 Electrochemical Impedance Spectroscopy Experiments

Electrochemical impedance spectroscopy (EIS) can be used to probe the dielectric properties of solids and interfaces.²⁷⁸ The motivation for performing EIS was to characterize interfaces and gain insights into the cause of grain-boundary embrittlement¹ and short-wavelength scatter^{1,216} in compacts processed with LiF from a defect-chemistry perspective. Degraded properties were tentatively attributed to LiF-induced MgO-depletion⁷⁸ as the smaller lattice parameter for MgO-deficient stoichiometry¹⁶¹ was expected to cause strain and refractive index variation at grain boundaries. Since 20 – 50 nm wide Mg-depleted zones have been observed at boundaries without LiF, even for MgO-rich stoichiometry (Section 2.4.2),^{81,86,89,161,162} the reaction of LiF with spinel forming volatile MgF_2 ¹ was expected to exacerbate MgO-depleted grain boundaries to the extent where they affected fracture properties and scattered visible wavelengths. Few EIS studies were found for polycrystalline spinel,^{152,157,163,279} and none for fully-dense or transparent spinel, and so EIS was conducted between 500°C and 900°C in oxidizing and reducing atmosphere on fully-dense polycrystalline spinel compacts hot-pressed with different powders and with and without LiF, and the dielectric properties determined were related to intrinsic microstructure.

Four compacts hot-pressed using the standard processing were analyzed; an apparently more oxidized, cream-colored (“white”) sulfate powder compact, an identically processed but apparently more reduced (“dark”) sulfate powder compact, a transparent sulfate powder compact hot-pressed with 1 wt% LiF, and a transparent alkoxide powder compact (Section 3.1). Polished (to 0.05 μm grit-size) cylindrical ($\sim 12.7 \times 2$ mm) hot-pressed compacts were glued with CrystalbondTM to a steel plate placed on a magnetic-bed surface grinder and ground with a 600-grit diamond grinding wheel to ~ 1.0 mm thickness. The ground side was re-polished to ~ 0.7 mm thickness using successively finer Al_2O_3 media to 0.05 μm grit-size. Compact thickness was measured at five locations with a micrometer. Gold electrodes ~ 7 mm or ~ 10 mm in diameter were magnetron sputtered on each side through a circular stencil using a setting of 20 mA for 8 min. Silver or platinum wire leads were tied to silver mesh, which was glued to the electrodes using silver adhesive paint cured at 200°C for 30 min. Electrode leads were threaded through a 2-bore alumina tube, leaving the sample hanging freely at one end. The 2-bore alumina tube was inserted through an UltraTorrTM fitting mounted on a ported steel flange attached to a larger-diameter closed-end alumina tube. A type-K thermocouple was inserted through an UltraTorrTM fitting and positioned adjacent to the sample. Gas inlet and outlet alumina tubes were fitted through two other UltraTorrTM fittings. The assembled EIS rig was placed in a tube furnace and thermocouple leads were connected to a thermocouple reader. The gas inlet tube was connected to a synthetic air cylinder or argon with 2% H_2 , set to a flow rate of 70 cm^3/m controlled by a mass-flow controller. The furnace was ramped to 900°C and sequentially cooled at 50°C intervals to 500°C with temperature allowed to stabilize at each interval. A potentiostat (Reference 3000, Gamry, Warminster, PA, USA) applied an alternating voltage (AC) of 100 mV rms from 0.1 Hz to 1 MHz at ten points per decade and recorded impedance (Fig. 3.2).

Fig. 3.2: Schematic of EIS Apparatus.

Impedance is given by;

$$Z = Z_0 e^{j\omega t} = \text{Re}[Z] - \text{Im}[Z] = \frac{V_0 \cos(\omega t)}{i_0 \cos(\omega t - \phi)}, \quad (3.18.1)$$

where Z is impedance, $j = \sqrt{-1}$, V_0 is voltage amplitude, i_0 is current amplitude, $\omega = 2\pi f$ is angular frequency, f is AC frequency, t is time, and ϕ is phase shift. The real and imaginary impedance components were normalized for sample-electrode geometry by multiplying by A/L (where A and L are the electrode cross-sectional area and separation, respectively) and plotted on Nyquist (Cole-Cole) plots, yielding resistivity on the real axes. Impedance arcs were simulated and fitted using Zview[®] (Scribner Associates, Southern Pines, NC, USA) electrochemistry software by modeling samples as two parallel resistor-capacitor (RC) circuits and a Warburg element in series, representing bulk, grain-boundary, and sample-electrode impedances (Fig. 3.3).²⁷⁸ Capacitors were replaced with constant phase elements (CPE's) to model impedance non-linearity, with CPE impedance given by;

$$Z(\omega) = Q^{-1}(j\omega)^{-n_c}, \quad (3.18.2)$$

where Q and n_c are CPE parameters, and the response is purely capacitive when $n_c = 1$.^{278,280,281} Fitted equivalent-circuit resistances and CPE parameters were used to calculate resistivity;

$$\rho = RA/L, \quad (3.18.3)$$

conductivity;

$$\sigma = 1/\rho, \quad (3.18.4)$$

and effective capacitance;

$$C_{eff} = R^{((1-n_c)/n_c)} Q^{(1/n_c)} \quad 282 \quad (3.18.5)$$

Fig. 3.3: Idealized Nyquist plot (a) and equivalent circuit representing a polycrystalline solid with electrodes (b), dashed line represents additional parallel grain-boundary conductivity and its effect. Z is impedance, f is AC frequency, ω is angular frequency, R is resistance, C is capacitance, and subscripts ‘e’ refer to electrode, ‘gb’ to grain boundaries, and ‘ \perp ’ to field-perpendicular and ‘ \parallel ’ to field-parallel boundaries.

Separate arcs were attributed to different impeding mechanisms based on their time constants or capacitances.²⁸³ Time constants were determined from arc maxima, where;

$$\omega_{\max}\tau = 2\pi f_{\max}\tau = 1, \quad (3.18.6)$$

where ω_{\max} is the resonant angular frequency at the maximum, τ is the time constant, and f_{\max} is the resonant frequency at the maximum.²⁷⁸ Since $\tau = RC$ for parallel RC-circuits, capacitance was also calculated from resonant frequency and resistance values using;

$$2\pi f_{\max} = 1/RC \quad (3.18.7)$$

Modulus plots of $\text{Im}(M)$ versus f (where $M = j\omega C_c Z$, $C_c = \epsilon_0 A/L$ is the empty cell capacitance and ϵ_0 is the vacuum permittivity) were also constructed to emphasize components with smaller capacitances when separate arcs were not resolved in Nyquist plots.^{278,283}

Specific conductivities were calculated using the series brick-layer model (series model), which assumes cubic grains with intervening boundaries and $\sigma_{\text{gb}} \ll \sigma_{\text{bulk}}$, ignores parallel conductance, and since resistivities add for series elements gives;

$$\rho_t = \rho_{bulk} + \rho_{gb\perp} \quad \text{or} \quad \frac{1}{\sigma_t} = \frac{1}{\sigma_{bulk}} + \frac{v_{gb}}{3\sigma_{gb\perp sp}}, \quad (3.18.8)$$

where $\sigma_t = 1/\rho_t = 1/(R_t(A/L))$ is total conductivity, $\sigma_{bulk} = 1/\rho_{bulk} = 1/(R_{bulk}(A/L))$ is specific bulk conductivity, the bulk volume fraction is assumed to equal unity, $v_{gb} \approx 3d/D$ is the grain-boundary volume fraction (where d is grain-boundary width and D is grain size), $\sigma_{gb\perp sp} = 1/\rho_{gb\perp sp}$ is *specific* conductivity across field-perpendicular grain boundaries, and the 1/3 in the last term corresponds to the fraction of perpendicular grain boundaries (the 2/3 parallel boundaries are ignored).^{278,284} The v_{gb} calculated in this model underestimated that calculated considering tetrakaidecahedral grains, especially for samples with bi-modal grain-size distributions. The effective impeding perpendicular grain-boundary width (d_{\perp}) was assumed to correspond to the grain-boundary core and estimated at ~ 1 nm by TEM for all compacts. Where grain-boundary arcs were well-resolved, d_{\perp} was also estimated using;

$$d/D \approx C_{bulk}\epsilon_{bulk}/C_{gb\perp}\epsilon_{gb}, \quad (3.18.9)$$

assuming $\epsilon_{bulk} \approx \epsilon_{gb}$.²⁷⁸ Using this relation and $\epsilon_{bulk}\epsilon_0 = C_{bulk}(L/A)$, bulk permittivity was estimated using;

$$\epsilon_{bulk} = C_{gb\perp}(d/D)(L/A)(1/\epsilon_0)^{278} \quad (3.18.10)$$

Activation energies for conductivity were calculated using;

$$\sigma = (\sigma_0/T)e^{-E_a/kT}, \quad (3.18.11)$$

where σ is conductivity, σ_0 is a pre-exponential constant, E_a is the activation energy for conductivity, k is Boltzmann's constant, and T is temperature.¹²⁰

Higher than expected conductivities compared to single crystals of similar stoichiometry, both in this study using the series model (Eq. 3.18.8) and in the literature, suggested the presence of enhanced conductivity *along* field-parallel grain-boundaries (dashed lines in Fig. 3.3), while still assuming reduced conductivity *across* boundaries. The *specific* conductivity along field-parallel grain boundaries ($\sigma_{gb\parallel sp}$) that would be required to reduce bulk conductivity from comparable single-crystal values (σ_{sc}) to observed values using the series model ($\sigma_{bulk\ series}$) was estimated using the complete brick-layer model, in which conductivities add for parallel elements and resistivities add for series elements, giving;

$$\sigma_t = \sigma_{series} + \sigma_{parallel} \quad \text{or} \quad \sigma_t = \frac{1}{\frac{1}{\sigma_{bulk}} + \frac{v_{gb}}{3} \frac{1}{\sigma_{gb\perp sp}}} + \frac{2v_{gb}\sigma_{gb\parallel sp}}{3}, \quad (3.18.12)$$

where σ_t is observed total conductivity, σ_{series} is conductivity across the bulk and intervening boundaries, $\sigma_{parallel}$ is conductivity along grain boundaries, σ_{bulk} was set equal to σ_{sc} , $\sigma_{gb\perp sp}$ was set equal to $\sigma_{sc}(\sigma_{gb\perp sp \text{ obs}}/\sigma_{bulk \text{ series}})$ (assuming the series model ratio valid), v_{gb} is the grain-boundary volume fraction, and $\sigma_{gb\parallel sp}$ is the specific field-parallel grain-boundary conductivity. The effective grain-boundary width contributing to parallel conduction (d_{\parallel}) was assumed to correspond to higher conductivity in Mg-depleted regions and estimated at 20 nm for samples without LiF based on STEM-EDS studies on slightly Al_2O_3 -rich^{86,89,162} and MgO-rich⁸⁶ compacts. Although a wider effective grain-boundary width was expected due to increased Mg-deficiency in the sample with LiF, the same 20 nm width was used as literature estimates were unavailable.

CHAPTER 4 RESULTS AND DISCUSSION

This chapter presents combined results and discussion for starting powders (Section 4.1), bulk samples (Section 4.2), and interfaces (Section 4.3). A general discussion tying together the conclusions from this chapter is given in Chapter 5.

4.1 Starting Powders

Since they largely determine the sintering and densification behavior, microstructure evolution, and properties of polycrystalline ceramics and their interfaces, starting powders were characterized to enable making inferences on processing-structure-property relationships. Sulfate and alkoxide-derived powders were examined by X-ray diffraction (XRD), polarized-light microscopy, scanning electron microscopy (SEM) in combination with energy-dispersive X-ray spectroscopy (EDS), transmission electron microscopy (TEM) in combination with selected-area diffraction (SAD), carbon-sulfur and nitrogen determination, inductively-coupled plasma in combination with mass and optical-emission spectroscopy (ICP OES/MS), particle-size analysis by laser scattering, Zeta potential analysis (Section 4.1.1), and simultaneous thermal analysis in combination with mass spectroscopy (STA-MS) (Section 4.1.2), with chemical interactions verified by thermodynamic simulations (Section 4.1.3). Sintering behavior was assessed by dilatometry and by examining hot-press displacement (Section 4.1.4). Hydroxide-derived powders were only used for thermal grain-boundary grooving experiments and their properties were obtained from the group who synthesized them.

4.1.1 Powder Characterization

Properties for aqueous sulfate-derived (“sulfate”), alkoxide-derived flame-spray (“alkoxide”), and reaction-sintered hydroxide-derived (“hydroxide”) powders are shown in Table 4.1.

Table 4.1: Spinel Powder Properties.^a

Property	Sulfate	Alkoxide	Hydroxide
Crystallite Size (nm)	50, 35 ^h	58, 30 ^h	-
Agglomerate Size (d_{50} , μm)	0.2, 0.3 ^h	0.1-0.3 ^h	2.7-3.2 ^e
Surface Area (BET, m^2/g)	30	29	12-20 ^e
Stoichiometry	$n \sim 1.05^b$	$n \sim 0.995^d$	$n \sim 0.95, 1.0, 1.5^e$
Element/Detection Method	ICP (ppm)	GDMS (ppm)	ICP (ppm)

^fCarbon-sulfur and nitrogen determination.

^gPrivate communication.²⁸⁸

^hSEM and TEM.

ICP OES/MS for sulfate powder indicated similar trace impurities (Si, S, Ca, Cr, Fe Cu, Zn) to reported values and also trace amounts of Li, V, Ni, Ga, Sr, Zr, I, and Ba.²⁸⁷ However, some results are not shown due to uncertainty in dilutions and normalization standards. Carbon and sulfur content measured by infrared absorption were higher than reported, attributed to remnant organic synthesis and sulfate species for alkoxide and sulfate powder, respectively. High nitrogen content for sulfate powder was attributed to atmospheric nitrogen adsorption on the high surface-area powders and the analysis was not repeated for alkoxide powder. Values for hydroxide powders were based on communications with the researchers who manufactured them.^{55,77} XRD for sulfate and alkoxide powders showed only peaks corresponding to spinel, indicating stoichiometric composition within the instrument resolution of $\sim 1\%$. However, sulfate powder was determined Al_2O_3 -rich ($\sim \text{MgO}:1.06\text{Al}_2\text{O}_3$) based on LA-ICP OES/MS (Section 4.1.2) and alkoxide powder MgO-rich ($\sim \text{MgO}:0.995\text{Al}_2\text{O}_3$) based on image analysis of MgO nodules in hot-pressed compacts (Section 4.3.2).²⁸⁷ Particulate and filamentous contaminants up to millimeters in size were observed by optical and polarized-light microscopy and micron-sized agglomerates (Fig. 4.1) by SEM in sulfate and alkoxide powders. Crystallites varied from rounded to faceted and had an average size of ~ 35 nm for sulfate and ~ 30 nm for alkoxide powder, with few crystallites up to 100 nm in diameter (especially alkoxide powder) and agglomerates joined by sinter-necks up to ~ 300 nm in diameter (Fig. 4.2 and Fig. 4.3). Intensities, positions, and calculated lattice spacings of indexed SAD ring patterns for both powders matched spinel ICDD PDF Files 00-021-1152 and 00-005-0672²⁸⁹ (Fig. 4.4).

Fig. 4.1: Sulfate powder (a) agglomerates and (b) crystallites (SEM).

Fig. 4.2: Sulfate (a) and alkoxide (b) powder crystallites (TEM-BF).

Fig. 4.3: Sulfate (a) and alkoxide (b) powder crystallites (HRTEM).

Fig. 4.4: Indexed electron-diffraction patterns for (a) sulfate and (b) alkoxide powder (TEM).

Laser-scattering particle-size results varied widely depending on dispersion, but were similar to reported values. Mercury pycnometry results are not shown as values were unreasonable, likely because the chamber volume was much larger than the powder samples. Sulfate powder had a Zeta potential of +13.5 mV and alkoxide powder -0.6 mV, the low values indicating both

powders formed an unstable colloidal suspension and had a tendency to flocculate. SEM indicated LiF was well-dispersed by the various mixing methods, although LiF crystallites were significantly larger than spinel crystallites (Fig. 4.5).

Fig. 4.5: Sulfate powder mixed with LiF (a,²²¹ b) (SEM).

Sulfate powder with LiF coarsened when heated in air above 900°C, whereas no coarsening was observed when heating with or without LiF under vacuum, even up to 1200°C (Fig. 4.6). This indicated a vapor-phase transport that was consistent with delayed sintering onset observed by dilatometry (Section 4.1.4) and larger grain-size in compacts hot-pressed with LiF addition (Sections 4.3.1 – 4.3.2).

Fig. 4.6: Sulfate powder with 1 wt% LiF heated at 1200°C for 1 h in (a) vacuum and (b) air²²¹ (SEM).

Although sulfate and alkoxide powders had similar stoichiometry and particle-size characteristics, higher impurity content, agglomeration, and slight Al₂O₃-rich stoichiometry for sulfate powder rendered it less prone to attaining theoretical density and high transparency. Whereas, the high carbon content of alkoxide powder rendered it more likely to exhibit absorption. Sulfate powder could be improved by processing in H₂ to remove sulfur, and alkoxide powder by annealing in oxygen to combust remnant carbon.

4.1.2 Thermal Analysis

Sulfate and alkoxide powders exhibited minimal thermal activity and lost <2% and <1% of their initial mass, respectively, attributed mainly to adsorbed water vaporization (Fig. 4.7).

Fig. 4.7: STA (DSC + TGA) for sulfate and alkoxide powders in argon at 5K/min ramp.

Sulfate powder with LiF lost mass concomitant with the amount added plus adsorbed water (Fig. 4.8). The LiF melting and vaporization endotherms were discernible, especially for 10 wt% LiF addition, for which the vaporization endotherm was split into peaks at 1100°C and 1175°C, possibly indicating an exotherm in between. The reason for the slight initial mass increase noted for samples with LiF is unknown. Simultaneous thermal analysis (STA) of pure LiF in argon showed melting (850°C) and vaporization (1000°C – 1400°C) endotherms, the latter concomitant with complete mass loss, consistent with reports in the literature.²¹⁶ STA of MgF_2 and LiAlO_2 , by-products of the reaction between LiF and spinel, in argon indicated 15% mass loss between 1000°C and 1350°C, corresponding to the 16 wt% LiF calculated to form along with spinel (Fig. 4.9). An endotherm at 740°C was likely the formation the eutectic liquid $\text{MgF}_2\text{:LiF}$, an exotherm at 760°C may have been the formation of spinel, and a small endotherm at 1270°C was consistent with the melting of unreacted MgF_2 (T_M 1263°C).

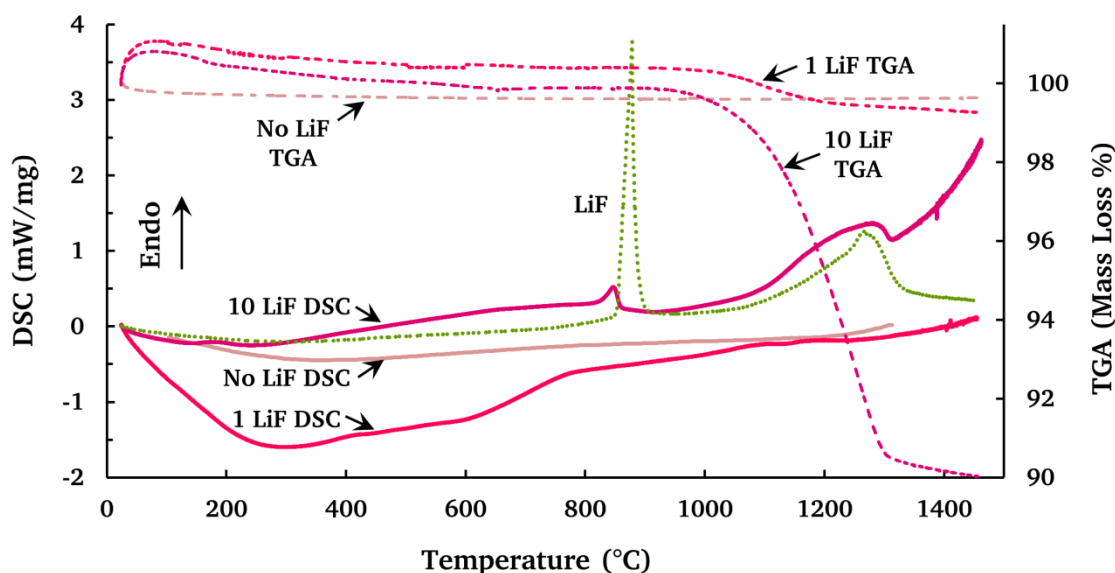

Fig. 4.8: STA for sulfate powders with 0, 1, and 10 wt% LiF addition in argon at 5-20 K/min with LiF DSC at 20% scale superimposed for reference.

Fig. 4.9: STA for LiF and $\text{MgF}_2 + \text{LiAlO}_2$ in argon at 10-20 K/min.

STA combined with mass spectroscopy (STA-MS) for pure LiF in argon indicated argon isotopes and trace water vapor, the latter consistent with the hygroscopy of LiF. Weak signals for m/z 16 (O^+) and 44 (CO_2^+ , N_2O^+) $>700^\circ\text{C}$ and between 1150°C and 1500°C were coincident with the melting and vaporization of LiF, respectively. Signals for m/z 7 (Li^+), 19 (F^+), and 26 (LiF^+) were not detected despite complete mass loss, suggesting LiF condensed on the vapor-

transfer capillary, reacted with the crucible or atmospheric gases, passed through undetected, or formed species that were neutral, negatively-charged, or with greater molecular weight than the detection limit ($m/z = 100$). Lithium may have outgassed as masses 16 (O, Li_2H_2), 30 (NO, Li_2O), and 44 (N_2O , CO_2 , Li_4O^{2+}) detected within its vaporization range and fluorine gas may not have ionized and been obscured by ^{38}Ar . STA-MS for MgF_2 and LiAlO_2 in argon indicated argon isotopes and trace atmospheric gases and water vapor. Weak (30 ppmv) m/z 2 (H_2) peaks at 675°C and 975°C were of unknown origin. As for pure LiF, no signals were observed for m/z 7 (Li^+), 19 (F^+), 26 (LiF^+), 38 (F_2^+), or 62 (MgF_2^+).

STA-MS for alkoxide powder in argon indicated argon isotopes and trace atmospheric gases and water vapor. Weak m/z 44 (CO_2^+) signals <400°C indicated residual organics or carbon, possibly flame-spray pyrolysis synthesis remnants. STA-MS for sulfate powder in argon indicated mainly argon isotopes and trace atmospheric gases and water vapor, which yielded distinct peaks up to 0.4 vol% at 100°C and 150°C upon vaporization. Weak (<100 ppmv) m/z 44 (CO_2^+) peaks at 150°C and 675°C were likely evaporation or combustion of organic contamination. Similar results were obtained in air for alkoxide and sulfate powders with mainly atmospheric gases detected. STA-MS for sulfate powder with 1 wt% LiF in argon indicated mainly argon isotopes and trace atmospheric gases and water vapor. Water vapor signals occurred throughout, with peaks up to 0.2 vol% between 100°C and 350°C consistent with vaporization. A secondary peak with an associated endothermic rise between 650°C and 750°C may have been LiF-assisted decomposition of a magnesium or aluminum hydrate. A weak m/z 44 (CO_2^+) signal <800°C peaking at 300°C (50 ppmv), associated with weak m/z 16 (O^+ , CH_4^+) and 32 (O_2^+ , CH_3OH^+) signals, was likely the evaporation or combustion of methanol used in mixing. Distinct m/z 32 (O_2^+ , S^+), 48 (SO^+), and 64 (SO_2^+) peaks (20 ppmv, 20 ppmv, and 150 ppmv, respectively) coincident with the vaporization endotherm of LiF at 1075°C (Fig. 4.10), along with their fragmentation patterns, were consistent the decomposition of the intermediate synthesis product $(\text{Mg,Al})\text{SO}_4$ and the release of SO_2 , consistent with thermodynamic simulations (Section 4.1.3).

Fig. 4.10: STA-MS for m/z 32, 48, and 64 shown at a finer scale for (a) sulfate-derived powder without LiF and (b) with 1 wt% LiF in argon.

STA-MS correctly indicated m/z signals for atmospheric gases and water vapor and argon and its isotopes throughout the runs. However, some species were likely obscured by outgassing of species of the same mass, such as Ar-40 and MgO, and neither LiF nor its constituents were detected. Nevertheless, STA-MS helped identify chemical reactions with LiF and determine the outgassing behavior of volatiles (including LiF by TGA). A main finding was the repeatable obtainment of m/z signals consistent with the fragmentation of SO_2 within a narrow temperature range centered at 1075°C , and concomitant with an endothermic rise, only for sulfate powder with LiF. This confirmed a vapor-phase reaction between LiF and unreacted magnesium and/or aluminum sulfates and was corroborated by thermodynamic simulations (Section 4.1.3) and ICP (Section 4.2.2). This reaction identified the cleansing mechanism of LiF, whereby it reacts with impurities to form volatile species that can be removed, and partially answered why LiF was required to obtain transparency with sulfate powders. The outgassing behavior of LiF and volatiles such as water vapor helped direct the proper pressure-temperature regime to ensure their removal and enable attaining transparency.

4.1.3 Thermodynamic Simulations

Gibb's energy minimization equilibrium composition simulations in vacuum and air using HSC predicted the reaction of MgAl_2O_4 and LiF to form MgF_2 and LiAlO_2 , consistent with reports

in the literature (Eq. 4.1).^{50,212} In air, the products were predicted to form above 1000°C along with LiF gas and trace amounts of AlF₃, and Li₂F₂ above 1200°C. Simulations with equal amounts of LiF and spinel in vacuum (replicating the hot-press environment) indicated a lower reaction temperature of ~750°C, consistent with the formation of a eutectic with MgF₂ and lower-temperature sintering onset indicated by dilatometry (Section 4.1.3). Simulations with MgF₂ and LiAlO₂ in vacuum predicted the reformation of spinel, consistent with reports in the literature.^{50,212} Simulations with Mg(SO₄), Al₂(SO₄)₃, and LiF in vacuum predicted the formation of MgF₂, LiAlO₂, MgAl₂O₄, and SO₂ (Eq. 4.2), consistent with STA-MS. Although, it is likely these reactions involved mixed-metal sulfides (Eq. 4.3 and 4.4), which HSC does not simulate. Simulations also confirmed the reaction of LiF or MgF₂ with calcium and iron (Eq. 4.5 and 4.6) were energetically favorable, consistent with lower concentrations for these impurities observed by ICP in compacts hot-pressed with LiF (Section 4.2.2). Simulations with spinel and carbon indicated the formation of aluminum oxy-carbides, which hot-press experiments with Al₂O₃ additions indicated are likely partly responsible for absorption (Section 4.2.3).

4.1.4 Dilatometry

Despite using the same cold-pressing conditions, 55% green density was achieved with alkoxide powder and only 51% with sulfate powder (Fig. 4.11). Cold-pressed alkoxide powder densified more readily and reached near-theoretical density, aided by the higher green density, the small size of samples, and the slow ramp rates during dilatometry. Whereas, cold-pressed sulfate powder samples reached <95% density and <60% with LiF addition. Densification curves for oxidizing and reducing atmosphere showed little difference, but alkoxide powder samples sintered in H₂ were more transparent than air-sintered samples.

Fig. 4.11: Fractional sintered density relative to theoretical as a function of temperature for dilatometry with cold-pressed sulfate and alkoxide powder samples (inset).

Fractional theoretical sintered density (Fig. 4.12) calculated from displacement corrected for thermal expansion mismatch and pressure strain during hot-pressing indicated sulfate and alkoxide powder compacts deviated from pure thermal expansion at $\sim 1000^\circ\text{C}$, with alkoxide powder compacts shrinking more. Significant shrinkage occurred upon pressure application (sharp drops at 900°C and 1200°C), lowering the temperature at which closed porosity was attained (92% density - dashed line in Fig. 4.12). Compacts hot-pressed with LiF deviated from pure thermal expansion at $\sim 600^\circ\text{C}$, 400°C lower than without LiF, with a sintering onset at $\sim 800^\circ\text{C}$. The latter was consistent with the formation of the $\text{MgF}_2:\text{LiF}$ eutectic and its lower onset temperature in reducing conditions, as indicated by thermodynamic simulations. The $\sim 200^\circ\text{C}$ lower sintering onset compared to dilatometry ($>1000^\circ\text{C}$) indicated the nominal 3 MPa pressure applied prior to full pressure application, as opposed to negligible pressure for dilatometry, was enough to overcome coarsening and force densification to lower temperatures.

Dilatometry confirmed the detrimental effect lower green density on densification for sulfate powder compacts, the former attributed to non-optimal particle coordination and agglomeration. Incomplete densification was also attributed to swelling caused by volatile impurities and coarsening due to Al_2O_3 -rich stoichiometry. These shortcomings demonstrated why sulfate powder required LiF to remove impurities and pressure-assisted sintering to close inter-

agglomerate pores. Dilatometry also demonstrated that pressure-assisted sintering was required with LiF addition due to the coarsening it induces. Higher green densities for alkoxide powder compacts and densification-enhancing MgO-rich stoichiometry resulted in complete densification and highly-transparent compacts. Although less accurate than dilatometry, hot-press displacement showed that pressure causes significant shrinkage and lowers the temperature at which closed porosity is attained, potentially trapping impurities and additives with higher volatilization temperatures. Whereas LiF-induced coarsening retarded densification without pressure during dilatometry, only 3 MPa was enough to overcome coarsening and lower densification temperature by several hundred degrees. This finding, in combination with observed coarsening behavior, suggests spinel compacts hot-pressed with LiF densify by pressure directing surface and vapor transport from inter-particle contacts to voids, contrary to the detrimental nature of these transport mechanisms without pressure.

Fig. 4.12: Hot-press fractional theoretical sintered density versus temperature corrected for pressure and thermal expansion as a function of powders and LiF addition. Dashed line indicates closed porosity at 92% theoretical density (~1250-1350°C).

4.2 Bulk Compacts

Bulk compacts were characterized to relate bulk properties to starting powders, processing, microstructure, and interfaces. The stoichiometry, impurity content, microstructure, grain size, fracture mode, and optical properties of bulk samples made by pressureless sintering and hot-pressing, sometimes in combination with hot-isostatic pressing (HIP), using powders with

varying stoichiometries and impurity contents derived from sulfates, alkoxides, and hydroxides, with and without LiF and Al₂O₃ additions, were characterized (Sections 4.2.1 – 4.2.4) and correlated with interface properties and behaviors (Section 4.3).

4.2.1 Dense Compacts

Detailed examination was conducted on compacts hot-pressed with 35 MPa applied at 1200°C using (i) sulfate powder, (ii) sulfate powder with pressure applied at 900°C instead of 1200°C, (iii) sulfate powder with 1 wt% LiF, (iv) alkoxide powder, and (v) alkoxide powder with 0.25 wt% LiF, and compacts hot-pressed and HIPed using hydroxide powders with (vi) $x = 0.95$, (vii) $x = 1.0$, and (viii) $x = 1.5$ (Fig. 4.13 and Fig. 4.14). All compacts were >99.5% dense based on Archimedes density measurement and porosity was not observed.²³

Fig. 4.13: Compacts hot-pressed using the standard profile with (a) sulfate powder, (b) sulfate powder with 1 wt% LiF, (c) sulfate powder with 1 wt% LiF but with pressure applied at 900°C, (d) alkoxide powder and (e) alkoxide powder with 0.25 wt% LiF (compacts 10 mm above template).

Fig. 4.14: Samples cut from hot-pressed and HIPed hydroxide powder compacts with $x = 0.95$ (a), 1.0 (b), and 1.5 (c) (10 mm above template).

Despite similar or greater impurity content compared to sulfate powder, compacts made using hydroxide powders were transparent, likely due partly to the presence of different impurity species and HIPing, which sometimes also increased transparency in sulfate powder compacts. Stoichiometric hydroxide powder compacts had the highest transparency, with scatter in non-stoichiometric compacts likely caused by MgO and Al₂O₃ precipitates.

Sulfate compacts were opaque, whereas identically-processed higher-purity alkoxide compacts were transparent (Fig. 4.15). Since porosity was not observed, impurities likely caused opacity. When processed with 1 wt% LiF, sulfate powder compacts were clear and transparent (Fig. 4.16). However, every processing variable impacted the transparency of compacts with LiF. Acoustic mixing or ball milling, ramping at 10°C/min instead of 6°C/min during hot-pressing, and larger sample size (especially thickness), all increased scatter, suggesting impurities and/or LiF as the source of degraded transparency. Applying pressure at too low a temperature also degraded transparency (Fig. 4.17) and yielded opaque compacts when applied below 900°C. This also pointed to impurities and/or LiF since pressure can force densification to occur below the volatilization temperature of some species. The best results were obtained by adding 1 wt% LiF by ultrasonic mixing in ethanol followed by rotary evaporation, ramping at 6°C/min, and applying pressure at 1200°C during hot-pressing (“standard profile”).

Fig. 4.15: Sulfate (a) and alkoxide (b) powder compacts hot-pressed using the standard profile (10 mm above template).

Fig. 4.16: Sulfate powder compacts (a) without and (b) with 1 wt% LiF hot-pressed using the standard profile (10 mm above template).

Fig. 4.17: Sulfate powder compacts with 1 wt% LiF hot-pressed with pressure applied at (a) 1200°C and (b) 900°C (10 mm above template).

The highest transparency for alkoxide powder compacts was obtained using a maximum sintering temperature of 1400°C, and in contrast to sulfate powder compacts, by applying

pressure at 900°C instead of 1200°C during hot-pressing. These observations support that without volatile transparency-inhibiting impurities, densification can be forced to lower temperature without adverse effect. Despite better results using these processing parameters, compacts made using the standard hot-press profile were examined in detail to compare with sulfate powder compacts. LiF addition eliminated absorption, but it increased scatter much more than for sulfate powder compacts (Fig. 4.18), strongly suggesting the lower densification temperature for alkoxide powders trapped more LiF. LiF addition was scaled to S, Fe, and Ca impurity content, with the calculated optimal of 0.05 wt% yielding the least scatter.

Fig. 4.18: Alkoxide powder compacts hot-pressed using the standard profile with (a) 0 and (b) 0.25 wt% LiF addition (10 mm above template).

Transparency differences between compacts strongly suggested (i) impurities in sulfate powder caused scatter (opacity) and absorption (grey tint), (ii) trapped LiF or its by-products caused scatter, (iii) ball or acoustic mixing caused agglomeration, (iv) higher temperature ramps and pressure application forced densification to lower temperature, trapping species with higher volatilization temperatures, and (v) precipitation in stoichiometric powders increased scatter.

4.2.2 Laser-Ablation Inductively-Coupled Plasma (LA-ICP OES/MS)

ICP-OES/MS by laser ablation on compacts hot-pressed using the standard profile with sulfate powder with and without 1 wt% LiF showed a decreasing concentration of iron, sulfur, and calcium from the geometric center to exterior surfaces (Table 4.2). This gradient may also have been present for species below the detection limit of ICP. In compacts processed with LiF, magnesium content was lower, impurity concentrations were lower (sometimes by an order of magnitude), and approximately half of the added lithium remained. STA-MS, TEM (Section 4.3.2), and SIMS (Section 4.3.5) indicated that most of the fluorine left the system, with only minor amounts remaining as MgF_2 in isolated triple junctions. Thus, the remnant lithium was likely not LiF. The high silica concentration suggested contamination from glassware during

processing, although no detectable correlation was found with microstructure or optical and electronic properties.

Table 4.2: LA ICP-OES/MS at the Geometric Center and Exterior Surface of Compacts Hot-Pressed with Sulfate Powder with and without LiF and Pressure Applied at 1200°C.

Species	Units	No LiF Center	No LiF Surface	LiF Center	LiF Surface
Al ₂ O ₃	wt%	73.6	72	74	74.2
MgO	wt%	26.2	27.8	25.4	25.3
CaO	ppm	93	32	19	4
SiO ₂	ppm	1,211	1,428	1,208	764
Fe ₂ O ₃	ppm	323	81	16	25
S	ppm	272	468	339	34
LiF	ppm	-	-	14,545	11,794
MgO:nAl ₂ O ₃	Ratio	1.10	1.02	1.15	1.16

Lower impurity and magnesium concentrations with LiF addition were consistent with reactions forming volatile fluorides indicated by STA-MS and thermodynamic simulations. Impurity gradients were consistent with differential sintering, in which compact exteriors attained closed porosity before interiors (in part due to volatile impurity outgassing), trapping remnant impurities and LiF in compact interiors. Lower iron, calcium, and sulfur concentration with LiF addition was consistent with SEM-EDS of precipitate found on the exterior surfaces of compacts after hot-pressing, which were found to be composed of iron, calcium, and sulfur. Lower impurity content was also consistent with the disappearance of impurity-decorated aggregates of submicrometer grains (Section 4.3.2) and increased transmittance (Section 4.2.3) in sulfate powder compacts. Lower iron concentration was consistent with the disappearance of an iron-rich phase in alkoxide powder compacts with LiF. Lower magnesium content with LiF addition was consistent with the formation and evaporation of MgF₂ and the coarsening behavior of the resulting Al₂O₃-rich composition. The results also showed why applying pressure at lower temperatures when hot-pressing compacts with LiF addition resulted in opacity (Section 4.2.1), as it forces densification to lower temperatures, trapping LiF and its reaction products.

4.2.3 Spectrophotometry

Transmittance, reflectance, scatter, and absorptance for hot-pressed and HIPed hydroxide powder compacts, and for selected sulfate and alkoxide powder compacts hot-pressed with 1.5 g of powder with and without LiF and with pressure applied at 1200°C are shown in Fig. 4.19 – Fig. 4.22 up to 750 nm, with transmittance relatively constant in the IR (not shown). For sulfate powder compacts without LiF, in-line transmittance was negligible, forward scatter increased in the visible, reaching up to ~40% in the IR, and absorptance peaked to 95% at 250 nm and remained above ~45% in the IR. For sulfate powder compacts with 1 wt% LiF, in-line transmittance was greater than 80% (theoretical ~87%)²⁹⁰ between 500 nm and 2500 nm, forward scatter was up to ~40% at 200 nm, and absorptance was negligible. For alkoxide powder compacts without LiF, forward scatter peaked at 20% at 270 nm and was negligible at longer wavelengths, whereas absorptance was significant over the visible, peaking near 90% at 210 nm and remaining above 35% in the IR. Sulfate powder compacts hot-pressed with 1.5 g of powder with pressure applied at 900°C displayed much lower in-line transmittance than when pressure was applied at 1200°C, being greater than 80% only between 1200 and 2500 nm. Compacts hot-pressed with 3.5 g of powder displayed significantly lower in-line transmittance. Sulfate powder compacts hot-pressed with LiF and standard processing subjected to UV-laser irradiation exhibited fluorescence that fit one Gaussian peak at 710 nm and a smaller one at 757 nm (Fig. 4.23), similar to some reports.²⁹¹

Fig. 4.19: Total (red) and in-line (dashed red) transmittance, total (blue) and diffuse (dashed blue) reflectance, scatter (dashed green), and absorptance (dashed pink) versus wavelength for sulfate powder compacts hot-pressed with the standard profile.

Fig. 4.20: Total (red) and in-line (dashed red) transmittance, total (blue) and diffuse (dashed blue) reflectance, scatter (dashed green), and absorptance (dashed pink) versus wavelength for sulfate powder compacts with 1 wt% LiF hot-pressed with the standard profile.

Fig. 4.21: Total (red) and in-line (dashed red) transmittance, total (blue) and diffuse (dashed blue) reflectance, scatter (dashed green), and absorptance (dashed pink) versus wavelength for sulfate powder compacts with 1 wt% LiF hot-pressed with pressure applied at 900°C instead of 1200°C.

Fig. 4.22: Total transmittance for hot-pressed and HIPed hydroxide powder compacts with $x = 0.95$ (blue), 1.0 (green), and 1.5 (purple).

Fig. 4.23: UV-laser induced fluorescence for a sulfate powder compact hot-pressed with 1 wt% LiF performed with shorter (blue) and longer (pink) integration time. Gaussian fit (black) deconvolution (dotted) yielded two peaks at 710 nm and 757 nm (arrows).

Low transmittance for sulfate powder compacts without LiF was consistent with an amorphous impurity phase of varying areal extent decorating grain-boundaries in aggregates of submicrometer grains (Section 4.3.2). For sulfate powder compacts with LiF, scatter at short wavelengths was consistent with isolated impurity phases and pockets of remnant MgF_2 of the same size as the wavelength of the scattered light (Section 4.3.2). Ramping at $10^\circ\text{C}/\text{min}$, application of pressure at 900°C , or using 3.5 g of powder instead of using 1.5 g of powder, ramping at $6^\circ\text{C}/\text{min}$, and applying pressure at 1200°C , trapped more LiF and impurities (Section 4.2.2, 4.3.2), increasing scatter enough to cause opacity in some compacts. The fluorescence observed with LiF addition was not consistent with that observed for common impurities in spinel, LiF, or MgF_2 . Scatter at short wavelengths in alkoxide powder compacts was consistent with MgO nodules and strain fields that surrounded them (Section 4.3.2), while absorption was consistent with carbon contamination (Sections 4.2.1 and 4.2.4).

4.2.4 Raman Spectroscopy

Raman spectra for transparent hot-pressed sulfate and alkoxide powder compacts and a stoichiometric single-crystal matched reported spectra for spinel (Fig. 4.24).^{100,101} Sulfate powder compacts exhibited a peak at 525 cm^{-1} , which was absent in compacts with LiF, suggesting the removal of an impurity species (Fig. 4.24a). These compacts also exhibited fluorescence at higher wave numbers. The broad shoulder at 350 cm^{-1} and peak at 680 cm^{-1} in

Fig. 4.24b are associated with a low inversion parameter²⁹² and these were more prominent for the single crystal. Raman spectra for alkoxide and sulfate powder compacts without LiF closely matched the single-crystal spectrum, whereas those with LiF had features associated with a higher inversion parameter. Spectra for dark spots in sulfate and alkoxide powder compacts with and without LiF matched spectra for graphite foil and pyrolytic graphite, indicating these features were caused by carbon or organic contamination.

Fig. 4.24: Raman spectra for (a) compacts hot-pressed with sulfate powder with and without 1 wt% LiF, and (b) a spinel single crystal and compacts hot-pressed with sulfate powder with 1 wt% LiF and with alkoxide (“flame-spray”) powder (arrows indicate features associated with low inversion).

4.3 Interfaces

The surfaces and grain boundaries of transparent spinel compacts made using powders with different stoichiometries and additives were examined by optical and polarized-light microscopy (Section 4.3.1), scanning electron microscopy (SEM) in conjunction with energy-dispersive X-ray spectroscopy (EDS) and electron-backscatter diffraction (EBSD) (Section 4.3.2), transmission (TEM) and scanning TEM (STEM) in conjunction with selected-area diffraction (SAD),

convergent-beam electron diffraction (CBED) (Section 4.3.4), EDS, and electron-energy loss spectroscopy (EELS) (Section 4.3.3), time-of-flight secondary-ion mass spectroscopy (TOF-SIMS) (Section 4.3.5), parallel-ion electron spectroscopy (PIES) (Section 4.3.6), atomic-force (AFM) (Section 4.3.7), and electrochemical impedance spectroscopy (EIS) (Section 4.3.8). Interface properties were correlated to stoichiometry, impurity and additive content, microstructure, processing conditions, and bulk properties.

4.3.1 Optical Microscopy

The microstructure of compacts hot-pressed with the standard profile (35 MPa applied at 1200°C) consisted of equiaxed micron-sized matrix grains with an average size of 10 μm for sulfate powders (Fig. 4.25a) and 4 μm for alkoxide powders (Fig. 4.25b), and abnormal grains up to hundreds of microns in diameter that were more prevalent near surfaces (Fig. 4.26). Addition of 1 wt% LiF to sulfate powders more than doubled grain size to 24 μm (Fig. 4.27) and 0.25 wt% LiF to alkoxide powders quadrupled it to 16 μm (Fig. 4.28). For compacts hot-pressed with sulfate powder with 1 wt% LiF, applying pressure at 900°C instead of 1200°C resulted in a bi-modal matrix grain-size distribution with smaller average grain size (Fig. 4.29). Some abnormal grains in sulfate and alkoxide powder compacts with and without LiF appeared to radiate from a point-source and the interface between these and matrix grains was planar (Fig. 4.30), suggesting the presence of an impurity liquid phase at processing temperature.

Fig. 4.25: Matrix grains in compacts hot-pressed with pressure applied at 1200°C using (a) sulfate powder and (b) alkoxide powder (optical microscopy 10X, 20X obj.).

Fig. 4.26: Abnormal grains in compacts hot-pressed with pressure applied at 1200°C using (a) sulfate powder and (b) alkoxide powder (optical microscopy 10X obj.).

Fig. 4.29: Microstructure of compacts hot-pressed using sulfate powder with 1 wt% LiF with pressure applied at (a) 1200°C and (b) 900°C (optical microscopy 20X obj.).

Fig. 4.30: Abnormal grains in compacts hot pressed with (a) sulfate powder with 1 wt% LiF (note planar interfaces) and (b) alkoxide powder appearing to originate from a point-source (optical microscopy 20X, 10X obj.).

Submicrometer-sized defects were observed at grain boundaries of sulfate powder compacts hot-pressed with the standard profile (Fig. 4.31a). These features were not observed with 1 wt% LiF addition (Fig. 4.31b). However, similar defects were observed (Fig. 4.32a), as were larger acicular micron-sized grain-boundary defects (Fig. 4.32b), when sulfate powder with 1 wt% LiF was hot-pressed with pressure applied at 900°C. This strongly suggested trapping of impurity and additive species by the lower temperature pressure application. By focusing into transparent compacts hot-pressed with LiF, grain boundaries were visible throughout the thickness due to optical scatter (Fig. 4.31b inset), requiring scattering features spanning hundreds of nanometers. Finding the cause of this scatter was a main motivation for examining grain-boundaries in greater detail using TEM (Sections 4.3.2 – 4.3.4), SIMS (Sections 4.3.5 and 4.3.6), AFM (Section 4.3.7), and EIS (Section 4.3.8).

Fig. 4.31: (a) Submicrometer-sized grain-boundary inclusions in compact hot-pressed with sulfate powder using the standard profile and (b) grain-boundary scatter (arrows) in identically-processed compact with 1 wt% LiF (optical microscopy 10X obj.).

Fig. 4.32: (a) Submicrometer-sized inclusions and (b) grain-boundary phase in compact hot-pressed with sulfate powder with 1 wt% LiF and pressure applied at 900°C (optical microscopy 50X obj.).

Secondary phases were not detected by optical microscopy in alkoxide powder compacts, likely due to the low impurity content. However, micron-sized optical defects such as inclusions and pore clusters were observed by focusing into transparent sulfate and alkoxide powder compacts. Alkoxide powder compacts contained spherical opaque defects that degraded transparency (Fig. 4.33a). These were typically associated with abnormal grains, which appeared to radiate outwards from the defects, suggesting an impurity source. Local strain fields associated with these defects were indicated by polarized-light microscopy. Although care was taken during preparation, flakes from the graphite liners were observed and pore-clusters (Fig. 4.33b) appeared to be the advanced stage of decomposition of these flakes or of other organic-based contaminants.

Fig. 4.33: (a) Spherical optical defect surrounded by abnormal grains in alkoxide powder compact without LiF, and (b) pore-cluster in sulfate powder compact with LiF (optical microscopy 10X obj.)

A crack in one compact hot-pressed with alkoxide powder and 0.05 wt% Al_2O_3 addition was surrounded by a zone of reduced absorption (Fig. 4.34). The color-change adjacent to the crack under polarized light indicated uniaxial tensile strain, which was estimated to be in the single-digit MPa's using a Michel-Levy chart and also by applying enough pressure to make the birefringence vanish. The grain-size near the crack was larger than in the surrounding matrix and the boundaries of grains adjacent to the crack were decorated by a second phase (Fig. 4.35). Since no major impurities were detected by SEM-EDS and TEM-EDS, the second phase was attributed to porosity caused by MgO vaporization or by CO/CO_2 formation arising from carbon contamination from the graphite foil or hot-press fixtures. Similar tensile strain was indicated under polarized light at surfaces of compacts hot-pressed with sulfate and alkoxide powders with and without LiF. The cause of the strain was not conclusively determined, but may have been associated with MgO evaporation or differential sintering.

Fig. 4.34: Crack exhibiting reduced absorption that occurred while hot-pressing an alkoxide powder compact (a, white box), with color-change under polarized light indicating strain birefringence (b) (optical microscopy, 5X obj., full-wavelength filter).

Fig. 4.35: Grain-size in the crack region was larger (a, 20X obj.) and boundaries were decorated by a secondary phase (b, optical microscopy, 50X obj.).

4.3.2 Electron Microscopy

Compacts hot-pressed with sulfate powder and pressure applied at 1200°C (dark and opaque, Section 4.2.1, Fig. 4.13a) displayed a bi-modal grain size distribution consisting of $\sim 20 \mu\text{m}$ matrix grains and $\sim 6 \text{ vol}\%$ aggregates with an average size of $\sim 5 \mu\text{m}$ composed of grains with an average size of $\sim 0.4 \mu\text{m}$ (Fig. 4.36). By modeling grains as tetrakaidecahedrons, the total grain-boundary area of the submicrometer grains was estimated to be more than twice that of the matrix grains. The fracture mode was predominantly transgranular for matrix grains and intergranular for submicrometer grains and for the interface between matrix grains and submicrometer-grain aggregates (Fig. 4.36b). FIB lift-outs (Fig. 4.37) confirmed this interface was planar (Fig. 4.38) and electron-diffraction and EDS showed it was decorated by a partially-wetting impurity-rich (C, S, Si, K) amorphous phase (Fig. 4.39) that also occupied all or part of triple junctions within the aggregates (Fig. 4.40). Roughly 120-degree dihedral angles indicated similar grain-grain and grain-amorphous phase interface energies within aggregate triple junctions. However, boundaries of submicrometer grains intersected the submicrometer-grain-aggregate matrix-grain interfaces nearly perpendicularly (Fig. 4.41), suggesting wetting by the amorphous phase along the entire interface. Boundaries of submicrometer grains exhibited strain-contrast resembling dislocation arrays (Fig. 4.42), whereas matrix grain-boundaries were generally clean (Fig. 4.43). Grain-boundary impurity concentration outside of the amorphous phase was below the detection limit of TEM-EDS, typically $< 1,000 \text{ ppm}$ per species.

Fig. 4.41: Near-perpendicular intersection of submicrometer-grain boundary with the interface between matrix grains and submicrometer-grain aggregates (a, arrow) in sulfate powder compact with boundary deviating to intersect at right angles (b, arrow) (TEM-BF).

Fig. 4.42: Dark-contrast features resembling dislocation arrays at boundaries of submicrometer grains in compact hot-pressed with sulfate powder and pressure applied at 1200°C (a, b) (TEM-BF).

Fig. 4.43: Clean, (a) atomically-rough and (b) smooth matrix grain boundaries in compact hot-pressed with sulfate powder and pressure applied at 1200°C (HRTEM).

Compacts hot-pressed with 1.5 g of sulfate powder with 1 wt% LiF and pressure applied at 1200°C (transparent, Section 4.2.1, Fig. 4.13b) displayed predominantly intergranular fracture (Fig. 4.44a). The grain-size distribution was uniform, but aggregates of small grains remained (Fig. 4.44b). The grains within the aggregates were micrometer-size, as opposed to submicrometer-size for compacts without LiF. Due to reduced grain-boundary area associated with grain growth, impurities in the aggregates concentrated into polyhedral submicrometer-sized Fe, Ni, C, and Ga-rich triple junction and grain-boundary phases that were detectable by SEM-EDS (Fig. 4.45c,d). Matrix grain-boundaries were generally clean (Fig. 4.46a) but a wetting amorphous phase was occasionally observed (Fig. 4.46b).

Fig. 4.44: Fracture surface of compact hot-pressed with sulfate powder with 1 wt% LiF and pressure applied at 1200°C showing (a) matrix grains with interspersed smaller-grain aggregates (arrows, b) (fracture surface, SEM).

Fig. 4.45: Polyhedral (a) and partially-wetting (b) Fe, Ni, C, and Ga-rich secondary phases (arrows) in smaller-grain aggregates of compact hot-pressed with sulfate powder with 1 wt% LiF and pressure applied at 1200°C (fracture surface, SEM).

Fig. 4.46: Clean grain-boundary (a) and with amorphous phase (b) in compact hot-pressed with 1.5 g of sulfate powder with 1 wt% LiF and pressure applied at 1200°C (HR-TEM, TEM-BF).

Compacts hot-pressed with 1.5 g of sulfate powder and 1 wt% LiF and with pressure applied at 900°C (hazy, Section 4.2.1, Fig. 4.13c) were shown by chemical analysis to contain more impurities and additives. Occasional mottled-contrast fluorine-rich phases at triple-junctions were determined to be MgF_2 by electron diffraction (Fig. 4.47b). Matrix grain-boundaries were generally clean, but a 1 nm thick disordered zone (Fig. 4.48) suggested the presence of a wetting phase, and this was supported by through-focus Fresnel ridge imaging indicating the presence of two parallel interfaces (Fig. 4.49). TEM of matrix grain-boundaries occasionally showed strain contrast, more so than in compacts hot-pressed without LiF (Fig. 4.50) and dislocation arrays were also occasionally observed within grains. STEM-EDS across matrix grain boundaries indicated S, Ca, and C segregation at the boundary core (Fig. 4.51).

Fig. 4.47: Clean (a) and mottled-contrast fluorine-rich (MgF_2) phase (b) at matrix-grain triple junctions in compact hot-pressed with sulfate powder with 1 wt% LiF and pressure applied at 900°C (TEM-BF).

Fig. 4.48: Matrix grain-boundaries of compact hot-pressed with sulfate powder with 1 wt% LiF and pressure applied at 900°C showing disorder at the interface (a, b) (HRTEM)

Fig. 4.49: De-focus ($\pm 3.5 \mu\text{m}$) of a grain-boundary of compact hot-pressed with sulfate powder with 1 wt% LiF and pressure applied at 900°C showing Fresnel fringes with reversed contrast (a, b) (TEM)

Fig. 4.50: Dislocation arrays (a) and strain-contrast at a grain-boundary (b) in a compact hot-pressed with sulfate powder with 1 wt% LiF and pressure applied at 900°C (TEM)

Fig. 4.51: Drift-corrected STEM-EDS profile scan across a matrix grain boundary of a compact hot-pressed with sulfate powder with 1 wt% LiF and pressure applied at 900°C showing C, Ca, and S segregation at the core (~0.035 μm).

The fracture surfaces of compacts hot-pressed with alkoxide powder with pressure applied at 1200°C (Fig. 4.13b,d) were predominantly transgranular (Fig. 4.52a), whereas they were intergranular for compacts with LiF addition (Fig. 4.52b), as observed for sulfate powder compacts. In compacts without LiF, irregularly-disseminated clusters of white-contrast particles ~100 nm in diameter and occupying less than 0.5 vol% were determined by SEM-WDS to be iron-rich (Fig. 4.53a) and were attributed to steel flaking-off from the flame-spray nozzle. This phase was absent in compacts hot-pressed with LiF (Fig. 4.53b), indicating iron removal, as observed for sulfate powder compacts. Nodules ~125 nm in diameter were determined by SEM-WDS to be at least 88% MgO and confirmed by TEM-EDS and TEM-SAD to be pure MgO (Fig. 4.54), indicating LiF exacerbated MgO-rich stoichiometry in alkoxide powders. The nodules were more prevalent at grain boundaries and in compacts with LiF, occupying ~0.9% of the grain boundaries (0.27 vol% or 0.08 wt%). Lighter contrast surrounding the nodules in SEM-BS suggested the adjacent matrix may have been Mg-depleted (Fig. 4.54a). The spherical shape of the nodules indicated a high interface energy between the nodules and the spinel matrix, despite both having similar cubic crystal structures and primitive unit cell lattice parameters ($\alpha_{Mgnesia} = 4.212$, $\alpha_{Spinel} = 4.404$ nm).²⁷²

Fig. 4.52: Fracture surfaces of compacts hot-pressed with pressure applied at 1200°C with (a) alkoxide powder (a) and alkoxide powder with 0.25 wt% LiF (b) with arrows showing MgO nodules (SEM).

Fig. 4.53: Fe-rich phase in compact hot-pressed with alkoxide powder (a) and larger grain-size and absence of Fe-phase in compact hot-pressed with alkoxide powder with 0.25 wt% LiF (b) (SEM).

Fig. 4.54: MgO nodules (arrow) surrounded by light-contrast indicative of Mg-depletion in compact hot-pressed with alkoxide powder with 0.25 wt% LiF (SEM) and high-magnification of MgO nodule (b) (TEM-BF).

Fracture surfaces of quenched sulfate and alkoxide powder compacts hot-pressed with LiF exhibited a larger fraction of transgranular fracture than un-quenched compacts (Fig. 4.55 and 4.56), possibly indicating additives and impurities diffused from grain boundaries into the lattice.

Fig. 4.55: Fracture surfaces for (a) hot-pressed compact with sulfate powder with 1 wt% LiF and (b) same compact after quenching (SEM).

Fig. 4.56: Fracture surfaces for (a) hot-pressed alkoxide powder compact with 0.25 wt% LiF and (b) same compact after quenching (SEM).

No preferential grain orientation was observed for sulfate or alkoxide powder compacts with or without LiF by SEM-EBSD (Fig. 4.57). Grain-sizes were consistent with those calculated from optical and SEM images and the average misorientation angle was 45° (Fig. 4.58, Fig. 4.59).

Fig. 4.57: EBSD pole maps for polished sulfate-powder compacts without (a) and with 1 wt% LiF (b) oriented perpendicular to the hot-pressing direction (inset: color-coded pole orientation).

Fig. 4.58: EBSD grain misorientation angles for compact hot-pressed with sulfate powder (a) without LiF and (b) with 1 wt% LiF, both showing preferred 45° orientation (first bar in graphs is instrument noise).

Fig. 4.59: EBSD grain misorientation angles for compact hot-pressed with sulfate powder without LiF (a) and alkoxide-powder compact with 0.25 wt% LiF (b), exhibiting strikingly similar orientation profiles with preferred 45° orientation (first bar in graphs is instrument noise).

Impurity-phase filled triple-junctions and intergranular fracture of grains in submicrometer-grain aggregates in hot-pressed sulfate powder compacts indicated impurities were present at the boundaries, even though they were not detected by TEM-EDS (but detected by STEM-EDS). The glassy structure and distribution of the secondary-phase at interfaces between aggregates and matrix grains suggested it formed from a eutectic liquid that partially de-wet upon cooling. Partially-filled triple-junctions in the aggregates suggested the unfilled portions were previously occupied by a vapor associated with the eutectic melt. In turn, the impurity phase and its vapor at triple-junctions were expected to pin grain boundaries and inhibit densification at processing temperature, explaining the small grain size. Planar interfaces between the aggregates and matrix grains along which fracture propagated, combined with the amorphous phase where submicrometer-grain boundaries intersected the interface and the near-perpendicular orientation of the intersections, suggested remnants of the wetting phase remained along the entirety of the interfaces. The varied areal extent of these wetted or partially-wetted interfaces made them likely candidates responsible for scatter causing opacity, with amorphous-phase filled triple junctions contributing to scatter at shorter wavelengths. Transgranular fracture of matrix grains in these compacts and in hot-pressed alkoxide compacts was consistent with those grain boundaries having lower impurity content.

The larger grain-size in compacts hot-pressed with sulfate powder with LiF was consistent with coarsening caused by LiF-induced (i) impurity removal, (ii) increased surface and vapor transport, and (iii) shifting of stoichiometry to Al₂O₃-rich. The distribution of small-grain regions in these compacts indicated they corresponded to submicrometer-grain aggregates in compacts

without LiF. However, the grains within these regions coarsened due impurity removal and enhanced mass transport associated with LiF. Concomitantly, even though total impurity content decreased (at least for S, Ca, and Fe), local impurity concentration increased with decreasing grain-boundary area associated with coarsening for both small and matrix grains, resulting in secondary-phases visible by SEM. The change in matrix-grain fracture from transgranular to intergranular with LiF addition was consistent with a wetting-phase occasionally observed at boundaries. Application of pressure at a lower temperature during hot-pressing trapped more impurities, LiF, and their by-products. As a consequence, impurities became detectable at grain-boundaries by STEM-EDS, triple-junctions filled with MgF_2 were observed, and the wetting grain-boundary phase was more prevalent. Where the wetting phase could not be discerned by HRTEM, through-focus Fresnel fringes indicated it was present and <1 nm thick. Considerably more strain contrast was observed at boundaries in these compacts (how LiF affects this is unknown), which together with the wetting phase likely contributed to grain-boundary scatter visible by optical microscopy. LiF resulted in similar coarsening and embrittlement in alkoxide powder compacts. Moreover, since the alkoxide powder was slightly MgO-rich, reaction of LiF with spinel caused the formation of MgO nodules, which along with their associated strain fields contributed to short-wavelength scatter observed by spectrophotometry.

4.3.3 Electron Energy-Loss Spectroscopy (STEM-EELS)

A typical zero-loss extracted, background-subtracted STEM-EELS spectrum from a grain-boundary area scan of a FIB lift-out from a compact hot-pressed with sulfate powder with 1 wt% LiF and standard processing is shown in Fig. 4.60. The extracted zero-loss peak was ~ 2 eV at full-width half-maximum, indicating limited energy resolution. The low-loss spectrum indicated the Mg- $L_{2,3}$ (51 eV), Al- $L_{2,3}$ (73 eV), and Mg- L_1 edges (88 eV) (Fig. 4.61), and the high-loss spectrum the C-K (284 eV) and O-K edges (532 eV) (Fig. 4.62). The Li-K edge (55 eV) was not resolvable, likely due to low signal and overlap with the Mg- $L_{2,3}$ edge. The F-K, Mg-K, and Al-K edges were not observed. STEM-EDS indicated strong Mg, Al, and O peaks and weaker C, S, Si, and possibly Fe, K, and Ca peaks. Ratios of integrated intensities for typical STEM-EDS peaks and STEM-EELS edges for Mg, Al, and O (Fig. 4.63) did not indicate stoichiometry gradients, contrary to literature reports of Mg-depletion in compacts processed without LiF. Chemical gradients had been expected based on the wetting phase and Fresnel fringe and strain contrast observed by TEM in these compacts. It is possible gradients were shallower and larger than the

~50 nm STEM scans. Indeed, light-scattering at boundaries observed by optical microscopy (Section 4.3.1) indicated the causing features were on the order of visible wavelengths.

Fig. 4.60: Typical zero-loss removed, background-corrected (green line) EELS spectrum with the Mg-L_{2,3} (51 eV), Al-L_{2,3} (73 eV), and Mg-L₁ (88 eV) edges visible (red rectangle indicates selected fit region for background subtraction).

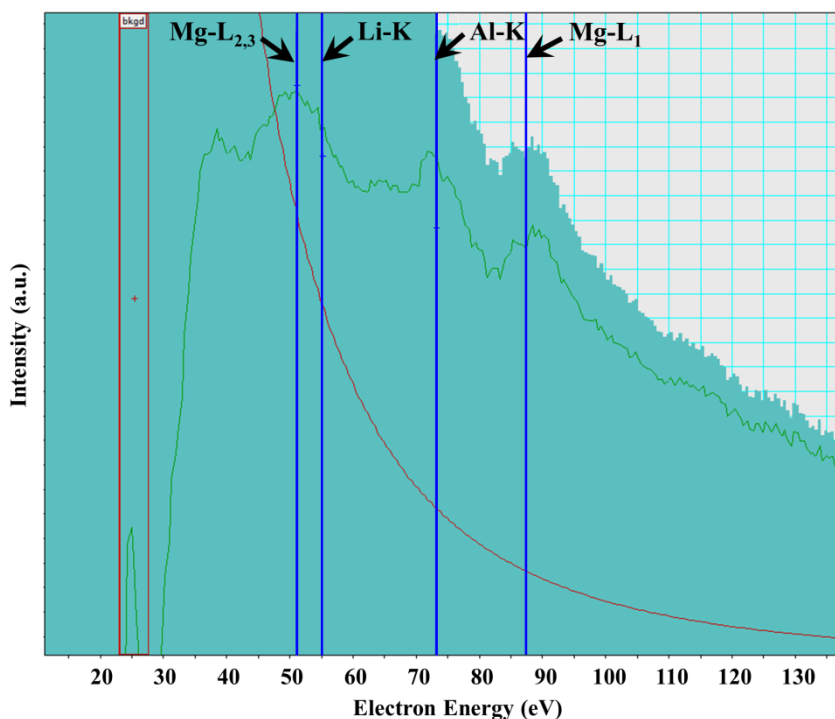

Fig. 4.61: Typical low-loss region of zero-loss removed, background-corrected EELS spectrum showing the Mg-L_{2,3} (51 eV), Al-L_{2,3} (73 eV) and Mg-L₁ (88 eV) edges.

Fig. 4.62: Typical high-loss region of zero-loss removed, background-corrected EELS spectrum showing well-defined C-K (284 eV) and O-K (532 eV) edges.

Fig. 4.63: FIB lift-out (a) from a compact hot-pressed with sulfate powder with 1 wt% LiF and standard processing, grain-boundary area scan (b), and STEM-EELS (c) and STEM-EDS (d) intensity ratios across the boundary (dashed line indicates boundary core).

4.3.4 Convergent-Beam Electron Diffraction (TEM-CBED)

TEM-CBED (TEM convergent-beam electron diffraction) patterns taken from grain interiors and boundaries of FIB lift-outs (Fig. 4.64, Fig. 4.65) from compacts hot-pressed with sulfate powder with and without 1 wt% LiF are shown in Fig. 4.66 and Fig. 4.67. The calculated lattice parameters were significantly larger than reported values for spinel (8.0898 Å), attributed to microscope parameters (voltage, camera length) used for calculations that changed after the calibration to determine these parameters was performed. Additionally, even with optimal convergence, the beam probe-size was wider than the grain-boundary core, resulting in contributions from adjacent grains. Moreover, beam-circularity anisotropy manifested by aspherical first-order Laue zones (FOLZ) patterns decreased measurement accuracy. Nevertheless, the results are included because microscope parameter calibration error similarly affected all measurements, allowing comparative analysis. Moreover, the results were consistent within samples and indicated a smaller lattice parameter for the sample with LiF, consistent with MgO-depleted stoichiometry, and possibly a slightly smaller lattice parameter at grain boundaries, indicative of a stoichiometry gradient.

Fig. 4.64: FIB lift-outs from compacts hot-pressed with sulfate powder without LiF (a) and with 1 wt% LiF (b).

Fig. 4.65: FIB lift-outs from compacts hot-pressed with sulfate powder without LiF oriented along the [011] zone axis (a) and with sulfate powder with 1 wt% LiF oriented along the [001] zone axis (b), with arrows indicating CBED locations.

Fig. 4.66: CBED patterns from grain interiors and grain-boundaries for compacts hot-pressed with sulfate powder (a,b), the first-order Laue zones are indicated by the white dashed lines.

Fig. 4.67: CBED patterns from grain interiors and grain-boundaries for compacts hot-pressed with sulfate powder with 1 wt% LiF (a,b), the first-order Laue zones are indicated by the white dashed lines.

4.3.5 Secondary-Ion Mass Spectroscopy (TOF-SIMS)

TOF-SIMS ${}^7\text{Li}^+$ maps of polished surfaces of samples hot-pressed with sulfate powder with; (i) the standard profile with 35 MPa applied at 1200°C, (ii) 1 wt% LiF addition and pressure applied at 1100°C, and (iii) 1 wt% LiF addition and pressure applied at 900°C are shown in Fig. 4.68 and Fig. 4.69. Lithium segregation was not detected within the instrument resolution of $\sim 1\ \mu\text{m}$. In compacts with LiF addition, applying pressure at 900°C forced densification to occur below the temperature of LiF volatilization ($\sim 1100^\circ\text{C}$), resulting in higher lithium content (Fig. 4.69b). Apart from an initial instrument-related decrease, lithium concentration was unchanged with depth-profiling (Fig. 4.70), indicating uniform lithium distribution within grain interiors.

Fig. 4.68: SIMS ${}^7\text{Li}^+$ maps for a 50 x 50 μm area of a sample hot-pressed with sulfate powder without LiF using the standard profile (a), and a 25 x 25 μm area of a sample hot-pressed with sulfate powder with 1 wt% LiF (b).

Fig. 4.69: SIMS ${}^7\text{Li}^+$ maps for 25 x 25 μm areas of sample hot-pressed with sulfate powder with 1 wt% LiF with pressure applied at 1100°C (a) and at 900°C (b) during hot-pressing.

Fig. 4.70: SIMS ${}^7\text{Li}^+$ depth profiles corresponding to maps in Fig. 4.68 and Fig. 4.69.

SIMS ${}^7\text{Li}^+$, ${}^{25}\text{Mg}^{2+}$, and ${}^{27}\text{Al}^{3+}$ mapping performed with a different instrument (IMS 6f, Cameca, France) on the polished surface of a sample hot-pressed with sulfate powder and 1 wt% LiF addition using the standard profile (Fig. 4.71, the same sample as for Fig. 4.68b) indicated no Li, Mg, or Al segregation observable within the instrument resolution.

Fig. 4.71: $50 \times 50 \mu\text{m}$ SIMS (a) ${}^7\text{Li}^+$, (b) ${}^{25}\text{Mg}^{2+}$, and (c) ${}^{27}\text{Al}^{3+}$ maps for sulfate powder sample with 1 wt% LiF hot-pressed using the standard profile.

SIMS performed on a $50 \times 50 \mu\text{m}$ area on the polished surface of a sample hot-pressed with sulfate powder and 1 wt% LiF addition using the standard profile (the same sample as for Fig. 4.68b and Fig. 4.71) using an instrument with a higher lateral resolution of 50 nm (Nano-SIMS 50L, Cameca, France) revealed lower-intensity features indicative of lower lithium content on the ${}^7\text{Li}^+$ map, which were consistent with the size and morphology of grain-boundaries for this sample ($\overline{GS} \sim 12 \mu\text{m}$) (Fig. 4.72a, arrows). Unfortunately, these features could not be directly

correlated to the microstructure of the scanned area. No similar signal-intensity features were detected for $^{25}\text{Mg}^{2+}$ (Fig. 4.72b).

Fig. 4.72: Nano-SIMS (a) $^7\text{Li}^+$ and (b) $^{25}\text{Mg}^+$ maps of a $50 \times 50 \mu\text{m}$ area on the polished surface of a sample hot-pressed with sulfate powder and 1 wt% LiF addition using the standard profile, arrows indicate features consistent with grain-boundaries.

4.3.6 Parallel-Ion Electron Spectroscopy (PIES)

PIES (Parallel-ion electron spectroscopy; LIMS, Esch-sur-Alzette, Luxembourg) conducted on a FIB lift-out from a sample hot-pressed with sulfate powder and 1 wt% LiF using the standard profile is shown in Fig. 4.73. $^7\text{Li}^+$ distribution appeared uniform and no grain-boundary or triple-junction segregation was detected (Fig. 4.73b). However, the resolution of this method is currently below that of nano-SIMS. TEM-EDS of the triple-junction at the lower left of the FIB lift-out in Fig. 4.73a only indicated signals for Mg, Al, and O and only one composition was detected by principle component analysis (Fig. 4.74b).

SIMS confirmed increased lithium content when pressure was applied at a lower temperature during hot pressing, consistent with LA ICP-OES/MS and TEM observations. The uniform distribution of lithium indicated by depth-profiling was contrary to studies indicating the presence of lithium and fluorine only at grain boundaries.²⁰⁴ However, this finding was consistent with studies suggesting lithium and/or LiF is distributed throughout grains²¹² and with thermal-grooving experiments (Section 4.3.7) suggesting LiF-induced defects were present in the bulk. Nano-SIMS suggested possible lithium depletion at grain-boundaries, although this could

not be verified separately. Although instrument resolution was limiting, the results had important implications for conductivity (Section 4.3.8).

Fig. 4.73: (a) Composite TEM brightfield image of a FIB lift-out from sample hot-pressed with sulfate powder with 1 wt% LiF using the standard profile, grain boundaries indicated by arrows, and (b) PIES ${}^7\text{Li}^+$ map.

Fig. 4.74: (a) TEM brightfield image of triple-junction at lower left of FIB lift-out in Fig. 4.73, and (b) intensity map of triple-junction area.

4.3.7 Atomic-Force Microscopy (AFM)

AFM tips accurately replicated test grid features (Fig. 4.75a) and polished compact surfaces exhibited minimal roughness (Fig. 4.75b). Thermal etching revealed grain boundaries and the grain size of hot-pressed and HIPed compacts using hydroxide powders with $x = 0.95, 1.0,$ and 1.5 (Section 4.2.1, Fig. 4.14) used for analysis ranged from $0.5 - 5 \mu\text{m}$. Many boundaries were unusable because of (i) shallowness, (ii) grain-height differentials caused by tilted boundaries, (iii) waviness caused by surface reconstruction, and (iv) grain-boundary precipitates in stoichiometric compositions, which obscured groove slopes and ridges. Results based on acceptable boundaries (Fig. 4.76) are shown in Table 4.3. Thermal-grooves were also imaged for compacts hot-pressed with sulfate powder ($n \sim 1.05$) with and without LiF (not shown).

Interface-energy ratios and standard deviations were similar to reported values.^{129,135} However, they were likely all somewhat similarly affected by starting powder impurities. Compared to stoichiometric, γ_{gb}/γ_s was 28% lower for MgO-rich and 51% lower for Al_2O_3 -rich powder compacts. The Mullins approach yielded expected^{135,276} $\sim 17\text{-}36\%$ higher γ_{gb}/γ_s values. Based on reported γ_s for lower-energy $\{100\}$ planes,^{123-127,129} direct groove-slope measurements indicated γ_{gb} ranged from 0.8 to 1.8 J/m^2 ($1.0 - 2.2 \text{ J/m}^2$ for the Mullins approach) with lower values corresponding to MgO-rich and higher values to stoichiometric compacts.

Fig. 4.75: AFM topography images of (a) calibration grid, showing excellent feature replication, and (b) polished sample surface with minimal roughness.

Fig. 4.76: AFM topography image of an optimal thermal grain-boundary groove ($x = 1.0$).

Table 4.3: Grain-boundary to Surface Energy Ratio (γ_{gb}/γ_s) as a Function of Stoichiometry for Hydroxide-powder Compacts.

x	Direct slope measurement	Mullins approximation
0.95	0.52 ± 0.23	0.63 ± 0.23

Pressureless sintering studies in reducing and oxidizing atmosphere indicate enhanced densification for MgO-rich spinel (suggesting lower γ_{gb}/γ_s)^{121,186} and coarsening for Al₂O₃-rich spinel (suggesting higher γ_{gb} , and thus higher γ_{gb}/γ_s)^{121,186}.^{2,94} Although γ_{gb}/γ_s was lower for MgO-rich spinel compared to stoichiometric, it was lower yet for Al₂O₃-rich spinel. This lack of

correlation for Al₂O₃-rich spinel suggested factors other than interface energies may have dominated densification.

Lower γ_{gb}/γ_s for MgO-rich spinel, along with increased bulk diffusion attributed to oxygen vacancies⁹⁴ and grain-boundary drag caused by intrinsic defects^{86,161} and precipitates,² likely contributes to enhanced densification. However, only limited grain-boundary stoichiometry variation was expected. Although complete solubility exists for $x = 0.95$ at the processing temperature of 1850°C,⁷² MgO precipitation, which is preferentially at boundaries,² likely occurred during cooling. Moreover, MgO solubility is <1 mol% ($n \sim 0.96$) at the thermal-grooving temperature of 1450°C,⁷² and boundary precipitates were observed. In addition, MgO-depletion at boundaries^{86,161,162} likely further shifted stoichiometry. Thus, spinel in the groove region was likely near-stoichiometric, suggesting γ_{gb}/γ_s is strongly sensitive to MgO-rich stoichiometry. However, it is not known whether lower γ_{gb}/γ_s was due to lower γ_{gb} or higher γ_s .

Near-stoichiometric boundaries were not expected in Al₂O₃-rich spinel. Despite some observed precipitation, Al₂O₃ solubility is still ~ 59 mol% ($n \sim 1.44$) at 1450°C.⁷² Moreover, MgO-depletion was expected to further shift boundary stoichiometry to Al₂O₃-rich. The lower γ_{gb}/γ_s suggests either lower γ_{gb} , or that γ_{gb} increases are accompanied by proportionally larger γ_s increases. Reports indicate impurities lower γ_{gb} ,¹²⁹ and it may be similarly lowered by intrinsic defects ($Al_{Mg}^{\bullet}, V_{Al}^{\prime\prime}, V_{Mg}^{\prime\prime}$)^{86,89,98,103,162} that accommodate boundary strain energy. Moreover, higher γ_s for Al₂O₃-rich spinel is suggested by reports indicating Al-terminated surfaces have higher energy.^{123,125-128} Since γ_s correlates with modulus and fracture, higher γ_s is also suggested by higher elastic constants and fracture toughness for Al₂O₃-rich single crystals.¹²⁴ Thus, lower γ_{gb}/γ_s may be due to higher γ_s and possibly lower γ_{gb} , but the latter is not associated with coarsening. If not interface energies, increased surface diffusion is a prime candidate to explain coarsening. Studies indicate higher grain-boundary diffusion and higher O²⁻ bulk diffusion in Al₂O₃-rich spinel,^{139,145,293} and surface diffusion may similarly be higher. However, increased surface diffusion presumably also affects groove profiles and γ_{gb}/γ_s measurements, especially when using the Mullins approach, shedding some uncertainty on the results.

Thermal grooves for the compact hot-pressed with sulfate powder were poorly-formed, suggesting an insufficient thermal etch, which along with differential grain etching and high roughness precluded accurate grain-boundary groove-slope determination. The contrastingly

smooth surface of the compact hot-pressed with sulfate powder with 1 wt% LiF indicated a much higher surface energy and/or surface diffusion, consistent with observations of coarsening of powder crystallites that were thermally-treated in air with LiF addition. That smooth surfaces were observed several hundred micrometers away from boundaries suggested defects associated with LiF contributing to surface-energy changes or enhanced surface transport were present in the bulk, with relevance to TOF-SIMS results (Section 4.3.5) and EIS (Section 4.3.8).

4.3.8 Electrochemical Impedance Spectroscopy (EIS)

Properties of EIS samples prepared from compacts hot-pressed with alkoxide and sulfate powders with and without LiF (Fig. 4.77) were described in Sections 4.1 – 4.3, but they are repeated here to emphasize structure-property relationships. Samples were estimated to have a theoretical density >99.5% and less than 0.05% porosity based on optical microscopy, SEM, TEM, and spectrophotometry. Hot-pressed sulfate-powder samples were opaque and one was darker (“dark”) than the other (“white”) due to reduction caused by vacuum fluctuations during hot-pressing. Stoichiometry was estimated slightly Al₂O₃-rich ($x \sim 1.06$) by LA-ICP OES/MS. Microstructure consisted of matrix grains ($\overline{GS} = 12 \mu\text{m}$) and ~6 vol% aggregates of sub-micron grains ($\overline{GS} < 0.5 \mu\text{m}$) accounting for ~70% of the grain-boundary area and in which grain boundaries were decorated with an impurity phase. The sample hot-pressed with sulfate powder with LiF was transparent and stoichiometry was estimated at $x \sim 1.16$. Grain-size ($\overline{GS} = 25 \mu\text{m}$) was uniform with areas of smaller micron-sized grains comprising <1 vol% and occasional secondary-phases at triple junctions. Whereas fracture was transgranular for samples without LiF, it was intergranular for the sample with LiF, indicative of chemical differences at the boundaries. Grain boundaries were devoid of secondary-phases, but grain-boundary scatter was observed by optical microscopy, Fresnel fringes and strain contrast were observed by TEM, and STEM-EDS indicated higher grain-boundary impurity content (C, Ca, S, Si) compared to matrix grains of compacts without LiF. However, LA-ICP OES/MS indicated lower total impurity content and ~0.5 wt% remnant lithium, while TEM-EDS indicated fluorine, especially at triple junctions, and SIMS indicated uniform lithium distribution in the bulk. Unlike compacts without LiF, grain-boundary stoichiometry gradients were not observed by STEM-EDS/EELS over the ~50 nm wide scans. The hot-pressed alkoxide-powder sample was transparent but dark with uniform grain size ($\overline{GS} = 4 \mu\text{m}$), occasional MgO nodules ~150 nm in diameter, and slightly MgO-rich stoichiometry estimated at $x \sim 0.995$ based on the volume fraction of MgO nodules.

EIS results for sulfate-powder samples are shown in Fig. 4.78 – Fig. 4.80, a comparison at 850°C is shown in Fig. 4.81, and insets show high-frequency regions and Zview[®] simulation fits for higher temperatures. All EIS spectra were depressed semi-circles with centers below the real axis, indicating distributed capacitance, with good fits simulated using CPE's with $0.75 < n_c < 1$ (n_c refers to the CPE parameter). The spectra displayed increasing low-frequency tails with good fits simulated using Warburg elements with phase angles varying from $\pi/5$ to $\pi/8$. The sample hot-pressed with LiF displayed two well-resolved arcs at higher temperatures. Samples hot-pressed without LiF displayed single arcs, but bulges were noted below $\sim 50 \cdot 10^3$ Hz and better fits were obtained using two parallel RC-circuits in series, one representing grain boundaries. High-frequency arc intercepts were consistently near zero, indicating negligible electrode resistance, whereas low-frequency intercepts decreased with increasing temperature, indicating increasing conductivity following an Arrhenius relation (Fig. 4.82). The alkoxide-powder sample displayed single elongated arcs with much higher impedance (Fig. 4.83). Unresolved, elongated arcs were also noted for the sulfate-powder sample with LiF at lower temperatures. Unfortunately, the equipment did not permit high enough temperatures to resolve separate arcs for the alkoxide-powder sample. All sample spectra were unchanged in reducing conditions, indicating oxygen ions were not the main charge-carriers, consistent with other reports.¹⁵⁴ However, degradation of the gold electrodes in reducing conditions sometimes erroneously indicated lower impedance. Modulus plots did not reveal any additional arcs or features. Calculated properties based on both the series and complete brick-layer models are shown in Table 4.4.

Fig. 4.77: Hot-pressed sulfate powder EIS samples with sputtered gold electrodes (without leads) made from (a) transparent compact with 1 wt% LiF, (b) dark-grey (“dark”) opaque compact without LiF (note smaller electrode), and (c) light-grey (“white”), opaque compact without LiF. The alkoxide-powder sample had nearly-identical geometry to (a) and (c).

Fig. 4.78: EIS spectra for the dark sulfate-powder sample. Impedance is normalized for geometry (indicating resistivity on the real axis), arrows indicate low-frequency bulges, and Zview[®] simulation fits are shown as solid red lines.

Fig. 4.83: EIS spectrum for the transparent alkoxy-powder sample at 850°C with EIS spectra for sulfate-powder samples shown for comparison. Spectra for lower temperatures are not shown due to high scatter.

Total conductivities for all samples were one decade or higher than reported values for single crystals of similar stoichiometry.^{141,142,154} Although consistent with reported polycrystalline values,¹⁵⁴ lower values were expected due to impeded conduction across stoichiometry gradients, space-charge layers, and especially the core of grain boundaries.^{86,89,161} Electrodes were well-aligned, and leakage and surface transport were not expected to increase conductivity to such extent.^{278,294} This suggested higher bulk conductivity than for comparable single crystals and/or

a parallel grain-boundary conductance contribution. Impurities and carbon contamination from the graphitic furnace could have contributed to the former, but higher than expected conductivity was also observed in the high-purity alkoxide-powder sample and carbon contamination alone would not explain the decades conductivity differences between samples subjected to similar hot-pressing conditions. Furthermore, impurities and carbon should have greater impact on grain-boundary conductivity, where they have been detected.^{1,2}

Values in italics are uncertain due to poorly-resolved grain-boundary arcs.

In contrast, parallel grain-boundary conductance was suggested by small grain-size in some samples and high reported grain-boundary ionic conductivity.¹⁶⁰ Grain-boundary conductivity is typically discounted due to a small conductive width, but wider Mg-depleted grain-boundary zones would result otherwise. Moreover, higher conductivity at boundaries is not unexpected for normal ionic materials without significant defect concentrations typical of solid electrolytes, and enhanced conductivity along field-parallel grain-boundaries has been observed in other ceramics²⁹⁵⁻²⁹⁷ and should be accentuated by current-line detouring along easy paths (Fig. 4.84).²⁹⁸ Parallel conductance decreases calculated values for bulk and grain-boundary conductivity if unaccounted for by considering only a series model (Eq. 3.18.8), but the resulting equivalent circuit (Fig. 3.3b) and Eq. 3.18.12 cannot be solved without knowing at least two specific conductivities. However, assuming bulk conductivities were unchanged (equal to comparable single-crystals), estimating the intervening grain-boundary conductivity based on this value and the series model bulk to grain-boundary conductivity ratio, and using Eq. 3.18.12 with grain sizes and boundary widths from Table 4.4, the specific field-parallel grain-boundary conductivity required to reduce total conductivity to that observed was estimated at $\sim 2 \times 10^{-3} - 1 \times 10^{-5}$ S/cm for samples without LiF and $\sim 2.4 \times 10^{-4}$ S/cm for the sample with LiF. Although parallel conductance could not be unequivocally confirmed, the results strongly suggest it was responsible for the high observed conductivity, perhaps with a contribution from an impurity-related increase in bulk conductivity.

Near-zero high-frequency arc intercepts, arc capacitances consistent with bulk values for oxides,^{78,283} and the absence of other high-frequency arcs in modulus plots, imply the single arcs in sulfate-powder samples without LiF were mainly due to bulk impedance. Intervening grain-boundary impedance was not expected to contribute to the arcs at higher frequencies due to the larger time-constant, with differences of less than one decade typically required for merging arcs.²⁷⁸ Two decades higher than expected bulk conductivity calculated using the series model was attributed to conduction along Mg-depleted, field-parallel grain boundaries, likely accentuated by current-line detouring through impurity-rich regions of submicrometer grains.²⁹⁸ The contribution from impurities was deemed likely due to their concentration at boundaries. Increased magnesium loss due to reducing conditions in the graphitic furnace^{2,75,79-81,83} and carbon contamination likely also contributed to increased grain-boundary conductivity, especially for the darker sample.

Fig. 4.84: Possible conduction mechanisms in polycrystalline spinel, “E” represents the AC field direction. (a) sulfate-powder sample without LiF, (b) sulfate-powder sample with 1 wt% LiF, (c) alkoxide-powder sample without LiF. Dashed arrows indicate current lines. Vertical arrows besides conductivity symbols indicate relative magnitudes. Shaded regions indicate relative effective grain-boundary widths and differing conductivities due to Mg-depletion, V''_{Mg} , and/or Li'_{Mg} .

Bulk impedance arcs in sulfate-powder samples without LiF imply intervening field-perpendicular grain-boundary impedance, even if parallel conduction exists, as suggested by low-frequency arc bulges. It is unlikely the bulges were due to sample-electrode effects, such as partial blocking, as bulge capacitances were similar to those for grain-boundary arcs in samples with LiF and to expected values for grain boundaries in oxides.^{278,283} Simulations using the series model confirmed good fits with a larger bulk impedance and a smaller series grain-boundary impedance ($C_{bulk} = 10^{-12}$ F and $C_{gb} = 10^{-9}$ F at 850°C). Assuming an effective resistive width of 1 nm, *specific resistivity across field-perpendicular grain-boundaries* (using the series model) was several decades lower than for the bulk, attributed to poor transport across the core. However, as separate arcs were not fully-resolved, grain-boundary properties for these samples involve

uncertainty and grain-boundary capacitances were not used to independently calculate grain-boundary widths. Arc non-linearity in these and other samples was attributed to microstructural variation, with possible contributions from surface and coating heterogeneities, slow adsorption reactions, and non-uniform potential and current distribution.^{278,280} The low-frequency tails were attributed to sample-electrode effects.²⁷⁹

Different dielectric properties for the sulfate-powder sample with LiF were expected given microstructure, fracture, and optical property differences compared to without LiF addition. The two well-resolved arcs at higher temperatures were attributed to bulk and grain-boundary impedances as capacitances matched typical values for these components.^{278,283} Higher than expected total conductivity than for comparable single crystals using the series model was attributed to field-parallel grain-boundary conduction. However, lower total conductivity compared to without LiF addition was partly attributed to larger grain-size and lower impurity content per unit volume (even though matrix grain-boundary impurity content was higher). Larger grain-size was expected to reduce the field-parallel grain-boundary contribution, thus increasing the conductance contribution across (and corresponding impedance from) the bulk and intervening grain boundaries. Although bulk conductivity was lower than without LiF addition, arc capacitances were similar and high-frequency intercepts were still near zero.

Higher activation energy for bulk conductivity and a different ratio of bulk to grain-boundary conductivity in the sulfate-powder sample with LiF compared to without LiF suggested other factors besides grain size and parallel conductance affected conductivity. Lower bulk and especially grain-boundary conductivities were also attributed to scatter and point-defect trapping caused by the incorporation of lithium. Although LiF shifts stoichiometry to more conductive Al₂O₃-rich composition, lithium was expected to replace magnesium by $2LiF \rightarrow 2Li'_{Mg} + 4Al^x_{Al} + 7O^x_O + V_{O}^{\bullet\bullet} + MgF_2 + MgO$, rather than by forming conductivity-enhancing V''_{Mg} .²¹⁵ Although the defect chemistry is speculative, possible lower lithium concentration at boundaries suggested by nano-SIMS could either increase conductivity at boundaries due to higher magnesium content or decrease conductivity if lithium occupies magnesium vacancies. The counteraction of absorption by LiF also indicated a lower charge-carrier concentration. As for the sample without LiF, decades lower *specific* conductivity *across* grain-boundaries than for the bulk was attributed to poor ionic transport across the core. Based on EIS between 750°C and 850°C, where arcs were well-resolved, activation energies for bulk and field-perpendicular grain-

boundary conductivity using the series model for the sulfate-powder sample with 1 wt% LiF were estimated at 1.07 eV and 1.04 eV, respectively, but a higher value had been expected for the boundaries.

If conductivity is predominantly ionic in spinel, decreased bulk and grain-boundary conductivity (perpendicular and parallel) with LiF addition does not necessarily contradict the enhanced densification observed with LiF addition attributed to increased bulk or interface diffusion. This is because O^{2-} is the rate limiting species for densification and its diffusivity and ionic conductivity are decades lower than for the cations, and it is likely cation conductivities (and hence diffusivities) are also affected by LiF. In addition, most densification studies with LiF have been conducted with pressure-assisted sintering, which provides an additional driving force for transport from surfaces and grain boundaries to voids, subjecting ion diffusion to different driving forces than conductivity.

Higher total conductivity than for comparable single crystals for the alkoxide-powder sample was also primarily attributed to field-parallel grain-boundary conductance. Although impurity concentration was low, grain-boundary charge-carriers were still expected. The presence of isolated MgO nodules was not expected to contribute significantly to impedance. Lower total conductivity compared to sulfate-powder samples was attributed to MgO-rich stoichiometry and cleaner grain boundaries, and also demonstrated that greater grain-boundary area alone does not necessarily increase conductivity and that carbon contamination likely has less effect than stoichiometry and impurities, as this sample was subjected to identical hot-pressing conditions.

Determining the effective grain-boundary width for calculating specific conductivities was problematic. The effective width of 1 nm deemed to contribute to impedance across grain-boundaries was an approximation of assumed mechanisms near the core. When the effective width was calculated using $d \approx D(C_{\text{bulk}}/C_{\text{gb}})$ and capacitance values from the series model,²⁹⁹ a value of 135 nm was obtained for the sample with LiF (where distinct grain-boundary arcs were observed). However, this assumed equal bulk and grain-boundary permittivities, which is unlikely due to grain-boundary stoichiometry, impurity, and additive gradients. Although, the value of $\epsilon_{\text{bulk}} = 9.0$, calculated from $\epsilon_{\text{gb}\perp} = C_{\text{gb}\perp}(d/D)(A/L)(1/\epsilon_0)$ using a grain-boundary width of 135 nm compared favorably with $\epsilon_{\text{spinel}} = 8-9.2$.² The effective width contributing to enhanced conduction along grain-boundaries of 20 nm was also an approximation, as stoichiometry and

impurity gradients differ between samples. For the sample with LiF, the lack of detection of Mg-depleted grain-boundary zones with STEM (at least over the ~50 nm widths examined) may indicate stoichiometry gradients were shallower and wider than for samples without LiF rather than absent. This was suggested by observable grain-boundary scatter by optical microscopy (in the absence of grain-boundary phases), in which case using an effective grain-boundary width of 20 nm overestimated parallel conductivity (consistent with lithium incorporation decreasing conductivity).

Although high conductivity along grain-boundaries due to stoichiometry gradients and impurities was suggested, their respective contributions and the specific impurities and point-defects responsible could not be unequivocally determined. Analysis was complicated as conduction mechanisms and transference numbers as a function of stoichiometry and temperature in spinel are not known with certainty. EIS studies varying grain size, stoichiometry, and grain-boundary impurities while keeping other variables fixed, and using blocking and non-blocking electrodes, combined with measurement of grain-boundary conductivities with microelectrodes would help determine respective conductivity contributions. Decoration with cathodoluminescence combined with SEM and TEM to identify and quantify resistive features such as secondary-phases at triple junctions and grain boundaries would also be valuable.

CHAPTER 5 GENERAL DISCUSSION

This chapter provides a general discussion of the results. Section 5.1 summarizes the results of powder and bulk compact characterization, Sections 5.2, 5.3, and 5.4 discuss the effects of stoichiometry, impurities, and LiF on interfaces and on mechanical, optical, and electronic properties, and Section 5.5 discusses combined effects on interfaces, mainly relating to electronic properties.

5.1 Interfaces and Starting Powders

The interfaces of spinel compacts made from powders with different stoichiometries, impurity contents, and LiF additions were probed by optical and electron microscopy, atomic-force microscopy, and various diffraction and spectroscopic methods. In order to relate interface properties to processing and properties, starting powders and bulk properties were also characterized. Although starting powders had similar crystallite, particle, and agglomerate size characteristics, sulfate-derived powders were slightly alumina-rich ($x \sim 1.05$) and had more impurities (>1000 ppm, mainly sulfur), whereas alkoxide powders were slightly MgO-rich ($x \sim 0.995$) and had less impurities (<100 ppm). These small differences in stoichiometry and impurity content, as well as small changes in LiF additions, were found to affect the free energy, diffusion, lattice parameter, stress state, and mechanical, optical, and electronic properties of interfaces, which in turn affected sintering, densification, microstructure evolution and bulk properties. Although hydroxide-derived powders were not directly compared to sulfate and alkoxide-derived powder compacts, small, deliberately induced differences in stoichiometry in these compacts had similar effects on interfaces and properties.

5.2 Interfaces, Stoichiometry, and Microstructure Evolution

Effect of MgO-rich stoichiometry on densification

Compacts made with Al_2O_3 -rich hydroxide-derived powders ($x = 1.5$) were found to have the lowest grain-boundary to surface energy ratio ($\gamma_{gb}/\gamma_s = 0.38$), followed by MgO-rich hydroxide-powder compacts ($x = 0.95$, $\gamma_{gb}/\gamma_s = 0.52$) and stoichiometric hydroxide-powder compacts ($x = 1.0$, $\gamma_{gb}/\gamma_s = 0.77$). The low γ_{gb}/γ_s for MgO-rich compacts, combined with reported grain-boundary drag from intrinsic defects and higher bulk conductivity due to oxygen vacancies, was expected to favor densification over coarsening, consistent with dilatometry results and reported enhanced densification for MgO-rich spinel. However, due to precipitation and local depletion of MgO, interfaces in these compacts were expected to be closer to stoichiometric than the bulk, suggesting interface energy may be sensitive to even smaller stoichiometry differences. Grain-boundary MgO-depletion was suggested by a smaller lattice parameter than grain interiors by convergent-beam electron diffraction (CBED). Unfortunately, chemical gradients associated with stoichiometry gradients were not observed by electron-energy loss spectroscopy (EELS), possibly because they were too shallow to be detected.

Effect of Al₂O₃-rich stoichiometry on coarsening and densification

The low γ_{gb}/γ_s ratio for Al₂O₃-rich spinel compacts appeared inconsistent with reports indicating delayed sintering for these compositions and with dilatometry results, with the explanation lying in the densification mechanism. Compared to stoichiometric, Al₂O₃-rich spinel reportedly exhibits higher bulk, grain-boundary, and likely surface diffusion, the latter favoring coarsening, which is typically observed. Thus, although interface energies favor densification for Al₂O₃-rich spinel, it is opposed by coarsening due to higher surface transport. However, during pressure-assisted sintering, pressure directs mass transport from areas of higher stress at interparticle contacts to areas of lower stress at intervening pores, allowing surface transport to contribute to densification. Under these conditions, Al₂O₃-rich compositions are expected to enhance densification.

Effect of non-stoichiometry on compact surface stress state

Astoichiometry also affected compact surfaces, which were Al₂O₃-rich compared to the bulk due to MgO evaporation during sintering. Al₂O₃-rich spinel has a smaller lattice parameter, a slightly lower thermal expansion, and is associated with a volume reduction compared to stoichiometric spinel. However, it is unclear how these affected the stress state at surfaces. Differential sintering of compact surfaces and the slightly lower thermal expansion of Al₂O₃-rich spinel were expected to result in surface compression. However, polarized-light microscopy indicated low single-digit MPa surface tension, possibly because the volume reduction associated with the stoichiometry change offset the thermal expansion difference.

Effect of stoichiometry on properties

Al₂O₃-rich compositions exhibited larger grain sizes due to increased interface transport and associated coarsening. Although not conclusively demonstrated, stoichiometry gradients at internal interfaces such as grain boundaries were expected to affect fracture, optical, and electronic properties. Grain-boundary MgO-depletion was expected to (i) result in residual stress due to thermal-expansion mismatch and/or volume change compared to grain interiors, (ii) to cause optical scatter due to refractive index variation, and (iii) to affect electronic conductivity (Sections 5.4 and 5.5).

5.3 Interfaces, Impurities, and Microstructure Evolution

Effect of impurities on densification and microstructure evolution

Impurities (~1000 ppm) in sulfate-derived powder compacts segregated at grain boundaries, especially within aggregates of submicrometer-sized grains, which were interspersed between larger micron-sized matrix grains. The only features that corresponded to the well-dispersed nature of the aggregates were crystallite-size variation and agglomeration. These were expected to result in inhomogeneous green bodies and associated grain-size variations, and assumed to have contributed to the formation of the aggregates.

Segregated impurities in sulfate-powder compacts formed a eutectic melt with spinel at processing temperatures and upon cooling solidified into glassy C, S, Si, and K-rich phases at triple junctions within submicrometer-grain aggregates and along interfaces between the aggregates and matrix grains. The morphology of the glassy phase, its location along the interface between matrix grains and submicrometer-grain aggregates, and the planarity of this interface, suggested the phase wet this interface at processing temperatures and de-wet upon cooling. The phase was expected to have an associated vapor at processing temperatures, which was expected to fill or partially-fill triple junctions. Impurities and the glassy phase were expected to restrict grain-growth by solute drag and Zener pinning, respectively, while the associated vapor was expected to oppose both grain growth and densification, explaining the small grain size within the submicrometer grain aggregates. While the glassy phase restricted grain-growth in the aggregates, it stabilized the interface between the aggregates and larger matrix grains, allowing the latter to grow at the expense of the former. Submicrometer grain boundaries intersected larger adjoining matrix boundaries at high angles, indicating a high relative surface energy for the matrix grains, which in turn is a driving force for coarsening. The uniform grain-size observed in compacts hot-pressed with higher-purity alkoxide-derived powders (which also exhibited agglomeration) was attributed to a lack of impurities and demonstrated that agglomeration alone does not necessarily cause bi-modal grain-size distributions.

Effect of impurities on fracture properties

Bi-modal grain-size distributions caused by a combination of agglomeration and impurities in sulfate-derived powder compacts were associated with large grains, which serve as fracture origins and lower strength. Matrix grains in these compacts fractured trans-granularly, whereas grains within submicrometer grain aggregates fractured inter-granularly due to the presence of impurities and glassy phases.

Effect of impurities on optical properties

Absorption over the entire visible spectrum, due to carbon contamination in the starting powders and from the graphitic furnace, was the main source of reduced light transmission in sulfate and alkoxide powder compacts. In sulfate-powder compacts, the additional scatter from glassy phases caused by less than ~1000 ppm impurities contributed to opacity. Glassy phases at triple-junctions scattered wavelengths on the order of their sizes, grain-boundary phases perpendicular to the incident light scattered shorter wavelengths, and those near-parallel to the incident light were expected to scatter longer wavelengths, especially phases with a larger areal extent, like the interfaces between matrix grains and submicrometer grain aggregates. The size-range and large extent of the glassy phases (submicrometer grains constituted the majority of the grain-boundary area) resulted in scatter from the near-UV to the visible and lower transmittance in the infrared. Impurities were also deemed to increase grain-boundary conductivity, as discussed in Section 5.5.

5.4 Interfaces, LiF, and Microstructure Evolution

LiF was found to have a complex and profound effect on the free-energy, diffusion, fracture, optical and electronic properties of interfaces, thereby affecting sintering, densification, microstructure and final properties. LiF addition (i) caused spinel crystallites to coarsen during the initial stages of sintering, (ii) shifted stoichiometry towards Al_2O_3 -rich composition, (iii) lowered the impurity content, (iv) lowered the densification temperature, (v) increased grain size and homogeneity, (vi) increased transparency, and (vii) decreased conductivity, but it also (viii) embrittled grain boundaries and (ix) caused scatter at grain-boundaries at shorter visible wavelengths.

Reaction of LiF with spinel to form MgO

The coarsening of loose spinel crystallites during thermal treatment, observed only with LiF addition, indicated vapor-phase transport, which in turn required the formation of volatile magnesium and aluminium-containing species. Thermodynamic simulations indicated that LiF reacted with spinel to form MgF_2 , LiAlO_2 and AlF_3 , with MgF_2 indicated as the prevalent volatile reaction species. Thus, and also partly because of the formation of the LiF: MgF_2 eutectic (at $\sim 740^\circ\text{C}$), MgF_2 was expected to evaporate more prevalently than volatile aluminium species during processing. Chemical analysis confirmed compacts processed with LiF were magnesium-deficient, especially at surfaces, shifting stoichiometry from $x \sim 1.05$ to $x \sim 1.15$ in sulfate powder compacts. Although pure LiF melts at $\sim 850^\circ\text{C}$, STA-MS, dilatometry, and thermodynamic simulations indicated it reacted with spinel at as low as $\sim 650^\circ\text{C}$. This partially explained the lower sintering onset of 800°C with LiF, 200°C below that observed without LiF. With added pressure, some densification occurred at 600°C , up to 400°C lower than without LiF, with only 200°C of this attributable to the nominal 3 MPa applied below 1200°C during hot-pressing.

Reaction of LiF with impurities

In addition to lowering magnesium content, chemical analysis indicated lower impurity (C, Ca, S, Si, Fe) content in compacts hot-pressed with LiF, especially at surfaces and by orders of magnitude for some impurities. STA-MS of sulfate-derived spinel powders with LiF showed LiF catalyzed the decomposition of remnant magnesium and aluminum sulfates to volatile SO_x species at $\sim 1075^\circ\text{C}$ in argon, air, or vacuum. Thermodynamic simulations indicated fluorine and MgF_2 reacted with calcium, iron, and likely other impurities, to form volatile fluorides. In turn, SO_x species and impurity fluorides could be removed during hot pressing by applying pressure at a temperature above that at which these species outgassed. Whereas, applying pressure at lower temperatures forced densification to lower temperatures, trapping volatiles within compacts.

Incorporation of LiF in the lattice

While LiF reduced impurity content, approximately half of the original lithium ($\sim 15,000$ ppm for 1 wt% addition) remained in the compacts. Whereas fluorine from LiF reacted to form fluorides, secondary-ion mass spectroscopy (SIMS) showed lithium was uniformly distributed within spinel grains. The increased inversion parameter indicated by Raman spectroscopy suggested lithium incorporated via a lattice replacement. Moreover, fluorescence observed by

Raman spectroscopy and under ultraviolet laser irradiation suggested lithium incorporation was associated with the formation of point-defects. Lithium likely replaced Mg^{2+} since the ionic radius is similar and the charge difference is smaller than for Al^{3+} , with charge likely compensated by oxygen vacancies and/or Al^{3+} on Mg^{2+} sites and the replaced magnesium and free oxygen forming MgO . The latter was indicated by magnesium depletion in sulfate powders and MgO nodule formation in (MgO -rich) alkoxide powders hot-pressed with LiF . Hence, in addition to magnesium depletion from MgF_2 formation, lithium likely contributed to magnesium depletion by MgO formation, some of which likely evaporated during processing due to its higher vapor pressure.

Effect of LiF on interface energies

Atomically-smooth surfaces observed by atomic-force microscopy (AFM) in thermally-etched polished compacts hot-pressed with LiF , as opposed to atomically-rough surfaces in those without LiF , indicated LiF increased surface transport and/or energy. Increased surface transport due to LiF was indicated by faceted growth in loose crystallites and increased densification with applied pressure. Lower lithium content at grain boundaries suggested by nano-SIMS could not be confirmed with other methods. However, it would be consistent with magnesium-deficient grain boundaries indicated by CBED, as these would have fewer sites for lithium to replace magnesium, in which case, $\text{Al}_{\text{Mg}}\cdot$ rather than Li_{Mg}' would charge-compensate V_{Mg}'' .

Effect of LiF on densification

Increased surface and vapor transport and the shifting of stoichiometry towards Al_2O_3 -rich composition, which exhibits higher diffusion and causes coarsening, precluded densification of spinel powders with added LiF without pressure, as confirmed by dilatometry. However, as explained above, increased surface and vapor transport enhanced densification and lowered its onset temperature during pressure-assisted sintering, as demonstrated by hot-press displacement curves for compacts processed with LiF . Since densification is controlled by the slowest species along the fastest path, which reports suggest is grain-boundary oxygen-ion diffusion, the uniform distribution of lithium and the associated point defects were expected to increase densification, especially if at least some of the defects were present at interfaces. Moreover, the lower yield stress associated with Al_2O_3 -rich stoichiometry likely also contributed to densification.

Effect of LiF on microstructure evolution

LiF-induced coarsening and the removal of eutectic-forming impurities prevented the formation of submicrometer-grain aggregates and resulted in a larger and more uniform grain size. The formation of spherical MgO nodules in alkoxide powders hot-pressed with LiF suggested a high interface energy and the nodules likely restricted grain size by pinning boundaries. However, depending on the amount of LiF added, excess MgF₂, and likely LiF, accumulated at triple junctions and pinned grain boundaries, as demonstrated by the gradient in impurity and lithium concentration from compact geometric center to exterior surface that was concomitant with increased grain-size and transmittance.

Effect of LiF on fracture

Compacts processed with LiF exhibited intergranular fracture, as opposed to transgranular fracture without it. However, the cause of intergranular fracture could not be determined with certainty. The shifting of stoichiometry towards Al₂O₃-rich composition by LiF was expected to be greater at boundaries due to higher evaporation and outward diffusion of MgO in the late stages of sintering. However, this should have been at least partially counter-balanced by MgO diffusion from grain interiors to boundaries. If present, Al₂O₃-rich boundaries would be expected to result in residual tensile stress due to the lower thermal expansion compared to stoichiometric or near-stoichiometric grain interiors (as grain interiors with higher shrinkage would exert an inward traction on the boundaries).

Grain-boundary embrittlement by LiF

CBED possibly suggested a smaller lattice parameter at boundaries and the reversing contrast of lattice-fringe patterns observed by de-focus transmission electron microscopy (TEM) indicated a chemical or lattice variation at boundaries, both more prominently in compacts with LiF addition. However, apart from possibly lower lithium content at boundaries suggested by nano-SIMS, significant chemical gradients were not observed by STEM-EDS or STEM-EELS. It is possible that species contributing to chemical gradients were below the resolution of the instrument or that chemical gradients were too wide and shallow for the small length scales examined (<50 nm). Strain contours observed by TEM in compacts hot-pressed with LiF suggested the presence of stress, but it could not be determined whether it was tensile or compressive. The low grain-boundary to surface-energy ratio indicated for Al₂O₃-rich

compositions by AFM would be expected to result in stronger, rather than weaker boundaries. However, these results were for compacts processed without LiF; the results for compacts with LiF were ambiguous.

STEM-EDS confirmed grain boundaries in samples processed with LiF had higher impurity contents and this was attributed to impurity concentration with decreasing grain-boundary area associated with coarsening. However, embrittlement was also observed in high-purity (<100 ppm total) alkoxide-derived flame-spray pyrolysis powder compacts hot-pressed with as little as 0.25 wt% LiF. Quenching experiments indicated a transition from intergranular to transgranular fracture after quenching, suggesting solute species or point-defects at boundaries were re-dissolved in the bulk during thermal treatment. It is possible that a combination of defect chemistry variation, residual tensile stress, and a lower work of fracture caused the embrittlement observed in compacts processed with LiF.

Effect of LiF on optical properties

LiF addition enabled transparency by removing impurities. However, when added in higher concentration (>1 wt% for the typical hot-pressing regime) or if densification was forced to occur below the vaporization range (1000°C – 1200°C) of LiF or its by-products by pressure application or by using spinel powders with higher sintering activity, then LiF and/or its by-products (MgF_2) accumulated at triple junctions and became the main source of optical scatter. However, even for lower concentrations (1 wt%), chemical analysis indicated half of the added lithium remained, and this concentration was higher than all of the other impurities combined. Despite high remnant lithium in compacts with 1 wt% LiF addition, only scarce triple-junctions with MgF_2 and/or LiF were observed, confirming SIMS results indicating lithium incorporated within the spinel lattice. However, optical scatter made grain boundaries within the thickness of these compacts visible by optical microscopy. Even though this required scattering features on the order of the scattered light (500 – 750 nm), no such scattering features were identified. Similar to the preceding discussion on embrittlement, it is likely that strain or shallow stoichiometry or point-defect gradients were responsible.

Hot-press experiments, electron microscopy, and spectrophotometry indicated scatter at short wavelengths in MgO-rich alkoxide-derived powder compacts with added LiF was caused by

the refractive index variation associated with MgO nodules ($n = 1.735$ versus 1.710 for spinel) and their surrounding strain fields, while absorption was caused by carbon contamination. Indeed, absorption was completely eliminated by shielding compacts with molybdenum foil and using alumina dies. Moreover, absorption correlated with Al_2O_3 -rich stoichiometry and thermodynamic simulations indicated aluminum oxy-carbides as a source. The specific light-absorbing impurity or point-defect removed by lithium fluoride was not determined with certainty. However, it was most likely carbon, as this was identified as the source of absorption in compacts hot-pressed without LiF and its concentration was lower with LiF addition. Doping experiments with Li_2O and AlF_3 suggested lithium, rather than fluorine, was responsible for counteracting absorption, although the specific mechanism was not identified. It is possible lithium reacted with carbon to form volatile lithium-carbon compounds or that the presence of lithium altered the behavior or light-absorbing defects or impurities. Although impurities concentrated at boundaries in compacts with LiF, electrochemical impedance spectroscopy indicated the larger grain-size resulted in a lower volume-fraction of conductive boundaries (Section 5.5).

5.5 Interfaces and Combined Effects

Stoichiometry, impurities, and LiF had combined effects on internal and external interfaces and sintering, densification, microstructure evolution, and bulk properties, especially optical and electronic properties. LiF reduced impurities and shifted stoichiometry towards Al_2O_3 -rich compositions and entrained gradients in these quantities and in properties they affected. Moreover, the effects of LiF were compounded by its entrapment within compacts under certain conditions, for example when using MgO-rich powders which sintered more readily or when applying pressure at lower temperatures during hot-pressing. For MgO-rich powders, LiF-precipitation of MgO nodules affected microstructure evolution and optical properties. The effect of LiF was more dramatic when more impurities were present in starting powders.

Conductivity was also affected by the interaction of stoichiometry, impurities, and LiF with interfaces. Compact conductivities were found to be more than one decade higher than reported values for single-crystals of similar stoichiometry and the activation energies for conductivity were lower. Higher conductivity was attributed to conductance and current-line detouring along magnesium-depleted, impurity-rich, field-parallel grain-boundaries with specific conductivities

decades higher than the bulk. Whereas, specific conductivity across boundaries was decades lower than the bulk, attributed to poor transport across the core. However, the presence of parallel conductivity precluded determining specific bulk and grain-boundary dielectric properties with certainty. Carbon contamination from the starting powders and the graphitic furnace, and magnesium loss due to reduction likely contributed to increased bulk and especially grain-boundary conductivities. LiF addition decreased bulk and grain-boundary conductivities and increased the activation energies for conductivity, attributed to larger grain size caused by LiF-induced coarsening, less grain-boundary area and current-line detouring, lower total impurity and charge-carrier concentration, and lithium replacing magnesium (the main charge carrier) in the lattice. Conductivity of low-impurity, fine grain-size, MgO-rich (alkoxide powder) compacts was one decade or lower than higher-impurity, larger grain-size, Al₂O₃-rich (sulfate powder) compacts, attributed to MgO-rich stoichiometry and cleaner grain boundaries. The results suggest conductivity in polycrystalline spinel is a highly sensitive function of stoichiometry, stoichiometry gradients, impurities, carbon contamination, defect chemistry and gradients, and grain-boundary area.

CHAPTER 6 SUMMARY

This chapter provides a condensed summary of the experiments, results, the main findings, and also guidance for future work.

The interfaces of transparent polycrystalline magnesium aluminate spinel compacts made by a variety of methods and using powders with different stoichiometries, impurities and LiF sintering additive contents were characterized using a variety of analytical methods, with emphasis placed on how they affected densification, microstructure evolution and electro-optical properties. Small variations in starting powder stoichiometry, parts-per-million impurities, and minor additions of LiF were found to significantly affect the free energy, diffusion, lattice parameter, stress state, and mechanical, optical, and electronic properties of grain boundaries and surfaces, in turn affecting densification, microstructure evolution, and bulk properties.

For the first time, by using atomic-force microscopy, the ratio of grain-boundary to surface energy as a function of stoichiometry for spinel was determined. Astoichiometric compositions exhibited a lower grain-boundary to surface energy ratio, favoring densification. However, increased interface transport for Al_2O_3 -rich compositions favored coarsening, precluding densification without pressure. Preferential MgO evaporation resulted in compact-scale and grain-boundary stoichiometry gradients, which affected fracture behavior, caused optical scatter, and affected conductivity, with Al_2O_3 -rich compositions exhibiting higher conductivity, attributed to increased magnesium vacancies.

The specific mechanisms by which impurities modified interfaces to yield observed microstructures and the specific causes of optical scatter and absorption were determined. Starting powder impurities segregated at grain boundaries, restricting grain-growth by solute drag. Where present in higher concentration, they formed a eutectic melt with spinel at processing temperatures that wet grain boundaries, stabilizing interfaces between abnormal and adjacent smaller grains and contributing to bi-modal grain-size. When present at triple-junctions, the eutectic phase pinned grain boundaries, while its associated vapor opposed grain growth and densification. Combined with starting powder particle-size variation and agglomeration, the net effect was the formation of micron-sized grains interspersed with aggregates of sub-micrometer grains.

The impurity phase de-wet boundaries upon cooling and solidified into a glassy phase, especially at triple-junctions, resulting in intergranular fracture, optical scatter over the entire visible spectrum and into the infrared, and increased conductivity. Impurity-related scatter

combined with absorption caused by carbon contamination from the graphitic hot-press fixtures resulted in opacity.

The multi-faceted effects and mechanisms associated with LiF were described for the first time. The mechanism by which LiF enhances pressure-assisted sintering was explained, and the mechanism by which fluorine reacts with impurities and magnesium was confirmed by simultaneous thermal analysis combined with mass spectroscopy, chemical analysis, and thermodynamic simulations. The incorporation of lithium into the lattice was conclusively demonstrated by secondary-ion mass spectroscopy, and the formation of stoichiometry and impurity gradients and associated embrittlement and optical scatter were explained. For the first time, the variation of lattice parameter at grain boundaries due to LiF-induced stoichiometry gradients was characterized using convergent-beam electron diffraction. Moreover, a new characterization tool; secondary-ion mass spectroscopy combined with transmission electron microscopy (PIES) was validated.

LiF reacted with spinel, increasing surface energy and/or transport, and forming volatile species that contributed to vapor-phase transport and coarsening. LiF also reacted to form volatile MgF_2 and MgO, which evaporated preferentially and shifted stoichiometry to Al_2O_3 -rich, especially at interfaces. For MgO-rich compositions, increased MgO formation resulted in precipitation of MgO nodules, which restricted grain growth and caused optical scatter. While lithium incorporated into the lattice, fluorine reacted with impurities to form volatile fluorides, which could be removed by evaporation with careful processing. The net effect of LiF was to enhance densification, reduce its onset temperature, and result in coarsening, which with added pressure resulted in fully-dense compacts. Reduced impurity content combined with enhanced densification due to increased surface and grain-boundary transport during pressure-assisted sintering resulted in transparency. However, stoichiometry and point-defect gradients embrittled grain boundaries, caused optical scatter, and reduced electronic conductivity. Moreover, when present in higher concentration, LiF and its by-products were the main sources of optical scatter.

For the first time, the dielectric properties of fully-dense transparent polycrystalline compacts and their grain boundaries were quantified. Higher conductivity compared to single crystals was attributed to conductance along impurity-rich, magnesium-depleted grain

boundaries. LiF was found to decrease conductivity by reducing grain-boundary area due to coarsening, reducing total impurity content, and by forming conductivity-reducing defects by replacing magnesium in the lattice.

The work highlighted the importance and complexity of interfaces. From a practical standpoint, the key variables (particle-size characteristics, stoichiometry, and impurities and additives) involved in the processing of transparent spinel were identified and guidance given as how to improve transmittance. The work demonstrated that fabrication of highly-transparent spinel, and likely transparent ceramics in general, requires a holistic approach that considers all variables and their interactions over length scales ranging from the atomic- to the compact-scale and occurring throughout the entirety of processing, but especially during sintering. However, although many of the questions asked at the outset were answered, the specific cause of grain-boundary embrittlement, grain-boundary optical scatter, and the specific point-defects caused by lithium incorporation were not conclusively determined.

Although significant advances have been made in the understanding and technological development of transparent polycrystalline spinel in the last fifty years, work still remains. Stoichiometry is a potentially powerful tool to modify densification, microstructure, and nearly all bulk properties. Yet there remains a lack of understanding of stoichiometry and of ability to manipulate it, especially stoichiometry gradients. Moreover, the ion diffusivities of stoichiometric compositions at grain boundaries, the effect of grain-boundary and surface stoichiometry gradients on properties, the role of point defects and grain-boundary space-charge, and the transference numbers as a function of stoichiometry are either not fully-understood or not known. Much progress also remains with respect to manufacturing, especially up-scaling fine grain-size technologies, strengthening grain boundaries, and lowering costs. However, the outlook for transparent spinel, and for transparent ceramics in general, remains bright. This is in part due to the unique properties that allow applications no other materials can fulfill, and in part due to the accumulation of sufficient scientific and technical know-how to produce high-quality components.

PERSONAL INFORMATION

Curriculum Vitae

Personal

Name Marc Rubat du Merac
Born 03.08.1968 in Montreal, Quebec, Canada
Status Married

Education

1994-1999 B.Sc. Mechanical Engineering, University of Calgary, Calgary, AB, Canada
2000-2005 M.Sc. Materials Science, University of Calgary, Calgary, AB, Canada
2012-2014 Ph.D. Materials Science, Technische Universität Darmstadt, Darmstadt, Germany

Vocational

1994-2005 Private/Commercial Pilot Training, Southern Aero and Westpoint Aviation, Springbank/Calgary, AB, Canada

Work Experience

2000-2005 Teacher's assistant, University of Calgary, Calgary, AB, Canada
2006-2008 Materials engineer (failure analysis, manufacturing support, materials consulting), Acuren Inc./Rubat du Merac Engineering Inc., Calgary, AB, Canada
2008-2012 Research assistant (transparent ceramic research), Colorado School of Mines, Golden, CO, USA
2012-2014 Research assistant (transparent ceramic research), Technische Universität Darmstadt, Darmstadt, Germany
2015-2016 Research scientist (transparent yttria-zirconia laminates), Forschungszentrum Jülich, Jülich, Germany
2016-2018 Scientist (ceramics, transparent ceramics), CeramTec GmbH, Plochingen, Germany

Publications

M. Rubat du Merac, I. E. Reimanis, C. Smith, H.-J. Kleebe, M. M. Müller, 'Effect of Impurities and LiF Additive in Hot-Pressed Transparent Magnesium Aluminate Spinel', *Int. J. App. Ceram. Tech.*, 10 [1] 33-48 (2013).

M. Rubat du Merac, H.-J. Kleebe, M. M. Müller, I. E. Reimanis, '50 Years of Research and Development Coming to Fruition; Unraveling the Complex Interactions during Processing of Transparent Magnesium Aluminate (MgAl_2O_4) Spinel', *J. Am. Ceram. Soc.*, 96 [11] 3341-3365 (2013).

M. Rubat du Merac, I. E. Reimanis, H.-J. Kleebe, 'Electrochemical Impedance Spectroscopy of Transparent Polycrystalline MgAl_2O_4 Spinel Hot-Pressed with and without LiF', *J. Am. Ceram. Soc.*, 98 [7] 2130-2138 (2015).

J. A. Miller, I. E. Reimanis, M. Rubat du Merac, 'Enhanced Fracture Toughness in Non-stoichiometric Magnesium Aluminate Spinel through Controlled dissolution of Second Phase Alumina', *J. Am. Ceram. Soc.*, 101 [2] 812-820 (2017).

M. Rubat du Merac, I. E. Reimanis, J. A. Miller and H.-J. Kleebe, 'Interface Energies in Non-stoichiometric Transparent MgAl_2O_4 Spinel Determined by Thermal Grain-Boundary Grooving', to be submitted to the Journal of the European Ceramic Society, August, 2018.

Conferences

M. Rubat du Merac, I. E. Reimanis, H.-J. Kleebe, C. Smith, "Effect of Impurities in Hot-Pressed Transparent MgAl_2O_4 ", 34th International Conference and Exposition on Advanced Ceramics and Composites, Daytona Beach, FL, USA, January 27, 2010 (Presentation).

M. Rubat du Merac, I. E. Reimanis, C. Smith, H.-J. Kleebe, "The Role of LiF and the Effect of Impurities in Hot-Pressed Transparent MgAl_2O_4 ", Gordon Conference on Solid State Studies in Ceramics, New London, NH, USA, August 15-20, 2010 (Poster).

M. Rubat du Merac, I. E. Reimanis, H.-J. Kleebe, "Role of LiF & Effect of Impurities in Hot-Pressed Transparent MgAl_2O_4 ", 35th International Conference and Expo on Advanced Ceramics and Composites, Daytona Beach, FL, USA, January 26, 2011 (Presentation).

M. Rubat du Merac, I. E. Reimanis, H.-J. Kleebe, C. S. Smith, "The Role of Chemical Interactions and Point-Defects on the Sintering and Optical Properties of Hot-Pressed Transparent MgAl_2O_4 ", 36th International Conference and Exposition on Advanced Ceramics and Composites, Daytona Beach, FL, USA, January 26, 2012 (Presentation).

M. Rubat du Merac, I. E. Reimanis, "Sintering, Theory, Practice, and Applications. Case Study: Transparent MgAl_2O_4 ", Netzsch Symposium Ceramic Nuclear Focused Workshop, Albuquerque, NM, USA, May 9, 2012 (Invited Presentation).

M. Rubat du Merac, I. E. Reimanis, "Grain-Boundary Embrittlement in Transparent MgAl_2O_4 Hot-Pressed with LiF", Gordon Conference on Solid State Studies in Ceramics, South Hadley, MA, USA, August 12-17, 2012 (Poster).

M. Rubat du Merac, M. Müller, H.-J. Kleebe, I. E. Reimanis, "The Role of Point-Defects in the Sintering of Transparent Polycrystalline MgAl_2O_4 ", 37th International Conference and Exposition on Advanced Ceramics and Composites, Daytona Beach, FL, USA, January 30, 2013 (Presentation).

M. Rubat du Merac, H.-J. Kleebe, I. E. Reimanis, "Electrochemical Impedance Spectroscopy of Transparent Polycrystalline MgAl_2O_4 ", Gordon Conference on Solid State Studies in Ceramics, South Hadley, MA, USA, July 20-25, 2014 (Poster).
