Abstract

Objectives: The aim of this study was to determine the effects of escalation of respiratory support and prolonged postoperative invasive ventilation on patient–centered outcomes, and identify perioperative factors associated with these two respiratory complications.

Design**:** A retrospective cohort analysis of cardiac surgical patients admitted to cardiothoracic intensive care unit (ICU) between August 2015 and January 2018. Escalation of respiratory support was defined as 'unplanned continuous positive airway pressure', 'non-invasive ventilation' or 'reintubation' following surgery; prolonged invasive ventilation was defined as 'invasive ventilation beyond the first 12 hours following surgery'. The primary endpoint was the composite of escalation of respiratory support and prolonged ventilation.

Setting: Tertiary cardiothoracic ICU.

Participants: A total of 2,098 patients were included and analyzed.

Interventions: None.

Measurements and Main Results: The composite of escalation of support or prolonged ventilation occurred in 509 patients (24.3%). Patients who met the composite had higher mortality (2.9% vs 0.1%; P<0.001) and longer median [interquartile range] length of ICU (2.1 [1.0–4.9] vs 0.9 [0.8–1.0] days; P<0.0001) and hospital (10.6 [8.0–16.0] vs 7.2 [6.2–10.0] days; P<0.0001) stay. Hypoxemia and anemia on admission to ICU were the only two factors independently associated with need for escalation of respiratory support or prolonged invasive ventilation.

Conclusions**:** Escalation of respiratory support or prolonged invasive ventilation are frequently seen in cardiac surgery patients, and are highly associated with increased mortality and morbidity. Hypoxemia and anemia on admission to ICU are potentially

modifiable factors associated with escalation of respiratory support or prolonged invasive ventilation.

Key Words**:** cardiac surgery; postoperative pulmonary complications; pulmonary morbidity; invasive ventilation

Introduction

A new consensus definition of 'postoperative pulmonary complications' has been recently proposed by the 'Standardized Endpoints for Perioperative Medicine' (StEP) Collaboration.[1] This consensus definition consists of four rather subjective pulmonary outcome measures, namely atelectasis, pneumonia, aspiration, and the acute respiratory distress syndrome.[1,2] The StEP Collaboration also introduced a concept of 'severity' of pulmonary complications after surgery, which may reduce the subjectivity of the definition.[1,2] In their consensus, severity is classified as 'severe' when a patient needs escalation of respiratory support, defined as 'unplanned continuous positive airway pressure' (CPAP), 'unplanned non-invasive ventilation' (NIV), or 'reintubation and invasive ventilation'.[1]

As with other major surgeries, cardiac surgery is associated with postoperative pulmonary morbidity associated with adverse clinical outcomes such as increased mortality and prolonged hospital stay, and also increased healthcare utilization costs.[3,4] Postoperative pulmonary complications in the context of cardiac surgery have been poorly defined and cardiac surgery–specific factors such as the use of cardiopulmonary bypass and apnea during cardiopulmonary bypass, intraoperative manipulation of the lungs and thoracic cage, and midline sternotomy appear to increase the risk for pulmonary complications after surgery.[5, 6]

The StEP Collaboration approach has not yet been explored in a cardiac surgical population.[3,4] The current study aimed to quantify the rate of escalation of respiratory support (as defined by StEP Collaboration for 'severe' pulmonary complications) or

prolonged postoperative invasive ventilation (not used by the StEP Collaboration, but yet another frequent and unwanted respiratory complication after cardiac surgery), and determine their relation with mortality and morbidity. In addition, perioperative factors predictive of escalation of respiratory support or prolonged invasive ventilation were identified. Establishing the severity of respiratory complications after cardiac surgery, and potentially modifiable risk factors associated with their development, will eventually allow development and evaluation of mitigation strategies. Our null hypothesis was therefore that StEP-defined severe postoperative pulmonary complications and prolonged postoperative invasive ventilation are not associated with adverse outcomes of mortality and ICU length of stay.

Methods

We retrospectively examined a cohort of adult cardiac surgical patients who underwent elective cardiac surgery with cardiopulmonary bypass (first–time coronary artery bypass grafting, valve surgery or combined coronary artery bypass with valve surgery) and were admitted to Royal Papworth Hospital National Health Service (NHS) Trust cardiothoracic intensive care unit (a leading heart and lung center in Cambridgeshire, UK and one of the largest specialist cardiothoracic hospitals in Europe), between August 2015 and January 2018. The study period was selected based on the fact that were no changes to standard patient management procedures during this period, minimizing a potentially significant source of bias. Patients who underwent redo–sternotomy, post–cardiotomy cardiac or respiratory extracorporeal membrane oxygenation or other procedures ('off pump' surgery, aortic root surgery, heart or lung transplantation, septal defect surgery, and vascular reconstruction) were excluded.

The analysis and reporting adhered to the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) statement.[7] The project proposal was reviewed and approved by the Royal Papworth Hospital NHS Foundation Trust Research and Development board (S02402, correspondence 14/03/2018), it was deemed to have no material ethical issues and written informed consent was not a requirement. All data were depersonalized and anonymized.

Data was collected via the perioperative surgical and intensive care unit (ICU) electronic clinical information systems and the local clinical audit and research data system.

Escalation of respiratory support was defined as described by the StEP Collaboration[1], as follows:

1. need for unplanned postoperative use of CPAP, or

2. need for unplanned postoperative NIV, or

3. need for reintubation and invasive ventilation

Prolonged invasive ventilation was defined as need for invasive ventilation beyond 12 hours after surgery.[8-1]

Intensive care unit and hospital mortality were defined as death during the time they were in the ICU or in the hospital. Length of stay in ICU was defined as time between point of entry to the ICU to discharge back to the cardiac surgery ward, or time of mortality in ICU if this occurred. Hospital length of stay refers to the day of surgery to last day in hospital alive.

The local intraoperative and postoperative strategies during the study period were not rigid, but comprised strong advice to use tidal volumes of 6–8 ml/kg^{-1} predicted body weight; positive end–expiratory pressure (PEEP) level of 5 cm H_2O without routine use of alveolar recruitment maneuvers; and cessation of mechanical ventilation and zero PEEP during cardiopulmonary bypass.[11] The intraoperative red cell transfusion threshold was 70 g/L. Postoperative management in the ICU consisted of cardiac monitoring, and optimization of hemodynamics. Weaning of ventilatory support, transition from assist ventilation to spontaneous ventilation, and extubation were conducted when patients met appropriate criteria namely normothermia, absence of bleeding, established regular spontaneous respiratory

pattern, hemodynamic stability, and no residual neuromuscular blockade or abnormal neurological findings.

Decisions to escalate respiratory support or to continue invasive mechanical ventilation was at the discretion of the attending intensivist. High–flow nasal oxygen therapy was only seldomly used at the time of this study.

Baseline patient characteristics including gender, age, weight, height, body mass index, type of cardiac surgery, logistic and additive European System for Cardiac Operative Risk Evaluation (EuroSCORE)[12] were extracted from the electronic clinical information system and the local clinical audit and research data system. Perioperative data (cardiopulmonary bypass time, cross-clamp time, and duration of invasive ventilation) were derived from the local clinical audit and research data system. Hemoglobin levels and ratio of arterial partial pressure of oxygen to inspired fraction of oxygen on admission to ICU were extracted from the electronic clinical information system. Escalation of respiratory support in the first five postoperative days, survival, and length of stay data were derived from the local electronic clinical information, clinical audit and research data systems.

The primary endpoint of the study was the composite of ‘need for escalation of respiratory support’ and ‘prolonged invasive ventilation’. The composite of postoperative escalation of respiratory support, as defined by StEP collaboration and prolonged invasive ventilation was chosen as the primary endpoint as it integrates both intraoperative (e.g., ventilator–induced lung injury, transfusion associated lung

injury, and transfusion associated circulatory overload) and postoperative complications (e.g., atelectasis); our composite outcome is therefore a 'non–mortality' outcome reflecting quality of perioperative care which makes it more meaningful to patients, healthcare providers and the public than specific physiological pulmonary outcomes or individual postoperative pulmonary complications.[1,2,13]

Secondary outcomes were the risk of mortality and length of stay in ICU and hospital. Other outcomes were mediating perioperative factors contributing to the primary outcome.

Statistical Analysis

Where appropriate, continuous data between groups were compared using either the student t–test (mean comparison) or Wilcoxon Rank Sum (median comparison) and categorical data were compared using chi-squared tests. Where dependent variables were continuous, an adjusted generalized linear regression model was used to assess the impact of a unit of change per dependent variable described as a regression coefficient. Alternatively, where dependent variables were binary an adjusted logistic regression was conducted to assess the unit of change as an odds ratio (OR). The composite outcome consisting of patients who required escalation of respiratory support or prolonged invasive ventilation was described using the frequency of patients rather than treated as separate events to prevent multiple counting of the same individual (e.g. to prevent individuals who were intubated for over 12 hours and required post–extubation CPAP being counted twice).

Time dependent data such as 'time to extubation', and lengths ICU and hospital stay were presented using Kaplan–Meier analyses comparing patients who required

escalation of respiratory support or prolonged invasive mechanical ventilation against those who did not require these interventions.

Risk factors were identified contributing to the development of either a requirement for escalation of respiratory support or a prolonged invasive ventilation. The models identifying risk factors were developed in accordance with transparent reporting of a multivariable prediction model for individual prognosis or diagnosis (TRIPOD) guidelines.[14] Potential risk factors based on demographic and physiological data were prespecified based on a review of the literature and data availability. An unadjusted association between potential risk factors and need for escalation of respiratory support or prolonged invasive ventilation was assessed using univariate logistic regression. A liberal P–value threshold of < 0.15 was set as the cut–off point following univariate regression to select variables for inclusion in the multiparametric model. Statistical significance in the multivariate model was set at a P–value < 0.05. Where missing data were present in variables of interest a complete-case analysis was conducted when developing the regression model, as very few cases had any missing data (n=9).

Following development of a regression model, the multivariate model was internally assessed using bootstrap methods. Each model created was validated on 100 replications using the bootstrap method. These results were then visually compared to the main analysis to assess for any differences in performance.

All analyses were performed using Stata version 14.2 (StataCorp. 2015. Stata Statistical Software: Release 14. College Station, TX: StataCorp LLC) software. A P–value < 0.05 was considered statistical significance.

Results

Study Population

Of 4,732 patients admitted, 2,098 patients met the inclusion criteria (Figure 1). Baseline characteristics and outcomes are presented in Tables 1 and 2. The majority of patients were male and underwent coronary artery bypass graft surgery. The median [interquartile range (IQR)] time to extubation was 6.1 [4.0–11.0] hours.

Escalation of Respiratory Support or Prolonged Invasive Ventilation

Rate of escalation of respiratory support in the first five postoperative days was 7.3% and rate of prolonged invasive ventilation was 22.8% (Table 2). The rate of the composite of escalation of respiratory support or prolonged invasive ventilation was 24.3%.

Patients who met the composite had a longer median time to extubation (23 [14–61] vs 5 [3–7] hours; P<0.0001), longer median ICU (2.1 [1.0–4.9] vs 0.9 [0.8–1.0] days; P<0.0001) and hospital (10.6 [8.0–16.0] vs 7.2 [6.2–10.0] days]; P<0.0001) stay (Table 3, Figure 2). A subgroup analysis is presented in supplementary material section (Figure 3) where the composite group is broken down into patients who required escalation of respiratory support and patients who received prolonged invasive ventilation. ‘Time to extubation’, ‘time to discharge from ICU’ and ‘time to discharge from hospital’ were longer in patients with either complication.

After adjusting for possible confounding factors, including EuroSCORE, cardiopulmonary bypass time, age, gender, body mass index, cross–clamp time, ICU admission hemoglobin level, admission arterial partial pressure of oxygen to inspired

fraction of oxygen ratio, and type of surgery, there was a significant between–group difference in length of ICU stay [regression coefficient 3.0 (95% CI, 1.3–4.8)], hospital length of stay [regression coefficient 10.0 (95% CI, 5.8–14.3)], and in–hospital mortality (2.9% vs 0.1 %; P< 0.001).

Risk Factors for Escalation of Respiratory Support or Prolonged Invasive Ventilation

The results of the unadjusted univariate logistic regression are summarized in Tables 4 and 5. Additional data on levels of oxygenation and internal validation using bootstrap replication are shown in supplementary material (Appendix A, e-Tables 1-3).[15] Multivariable adjustment showed that the hemoglobin level (OR 0.98 [0.97–0.99]; P=0.002) and the arterial partial pressure of oxygen to inspired fraction of oxygen ratio (OR 0.92 [0.90–0.94]; P<0.001) directly after surgery were significant risk factors for subsequent escalation of respiratory support. These factors remained congruent following bootstrap validation.

Discussion

Escalation of respiratory support or invasive ventilation beyond 12 hours after cardiac surgery was associated with adverse clinical outcomes of increased mortality and prolonged ICU and hospital length of stay, which are outcomes of interest to patients and relatives as well as clinicians and healthcare organizations. This was demonstrated in an unselected patient population, which suggests that the StEP collaboration criteria combined with prolonged ventilation are useful for routine surveillance, and may form the metric for quality improvement work in this area. Unsurprisingly, within this cohort, patients undergoing more complex surgery (as defined by longer cardiopulmonary bypass time) and more comorbid patients (higher EuroSCORE) were at higher risk of need for escalation of respiratory support or prolonged invasive ventilation, a finding that adds clinical plausibility to the measure.

It is likely that occurrence of escalation of respiratory support reflects one or more severe postoperative pulmonary complications leading to severe respiratory insufficiency. The StEP Collaboration criteria for severity of respiratory complications after surgery are objective measures which are not susceptible to criteria based on a clinical diagnosis. Indeed, diagnosing pneumonia can be complex, and simple factors such as not using chest radiography routinely or changes in microbiological sampling techniques can alter the reported rates of diagnosis.[16]

One retrospective study of 1,225 cardiac surgical patients found that the rate of unplanned NIV use was 5.1%, which is in line with our findings (6.0%). However, that study had a smaller sample size and reported reintubation rates in the context of NIV failure only.[17]

We demonstrated that hypoxemia and anemia on admission to ICU are associated with escalation of respiratory support or prolonged invasive ventilation. The arterial partial pressure of oxygen to inspired fraction of oxygen ratio has been shown to predict mortality in the cardiac surgical setting.[18] Its usefulness as a predictor of escalation of respiratory support or prolonged invasive ventilation has not been described before. Perioperative anemia, defined as hemoglobin < 100 g/L, leads to a 3–fold increase in risk for postoperative pulmonary complications, independent of type of surgery.[19, 20] Anemia in the context of cardiac surgery is associated with adverse postoperative outcomes although in moderate to high risk cardiac surgical patients a restrictive transfusion strategies (hemoglobin < 75g/L) are non-inferior to liberal transfusion thresholds.[21-23]The causal link between postoperative anemia and respiratory complications after surgery is yet uncertain. However, one might hypothesize that need for escalation of respiratory support or prolonged invasive ventilation can be explained by higher blood transfusion requirements in anemic patients potentially resulting in transfusion–related lung injury or circulatory overload.[24, 25] Of note, it was impossible to include intraoperative ventilatory variables like PEEP or other parameters of pulmonary mechanics such as driving pressure or mechanical power since these data were not available. Future studies should aim to obtain such data as they may be significant predictors of respiratory complications after surgery, and if so whether they are modifiable.

Several authors have reported outcomes related to prolonged invasive ventilation after cardiac surgery and developed prediction models mainly using 24–, 36– or 48–hour thresholds for prolonged invasive ventilation.[26-33] The standard definition of prolonged invasive ventilation according the Society of Thoracic Surgeons (STS) is a

duration exceeding 24 hours.[13] It has been shown that 'time to extubation' after cardiac surgery longer than 16 hours predicts poor clinical outcomes (morbidity, mortality and reintubation) and that liberation from the ventilator within the first nine hours is a predictor of better postoperative outcomes.[34-36] Recent evidence suggests that extubation after 12–hours is associated with poor outcomes and that major morbidity, operative mortality, and prolonged length of stay after cardiac surgery do not significantly increase until 'time to extubation' exceeds 12 hours.[8-10] On this basis, here the 12–hour benchmark was incorporated as an indicator of prolonged invasive ventilation into the composite.

In addition to prolonged cardiopulmonary bypass time and aortic cross–clamp time (known risk factors for prolonged invasive mechanical ventilation beyond 24 hours), anemia and hypoxemia on admission to ICU were identified as risk factors for prolonged invasive ventilation.[37-40] As an observational study we cannot determine the mechanisms which lead to the associations found, however from the literature we can hypothesize that long cardiopulmonary bypass time can lead to pulmonary dysfunction and need for prolonged invasive ventilation through the following mechanism: systemic inflammatory response and activation of proinflammatory cytokines leading to endothelial damage, increased pulmonary capillary permeability and extravascular lung water affecting lung compliance and gas exchange.[41] Similarly, the association between prolonged aortic cross–clamp time and delayed extubation could reflect pulmonary microvascular dysfunction, although the mechanistic link between ischemia-reperfusion and lung injury is not well understood. It is assumed that it is related to an increase in pulmonary vascular resistance and capillary permeability caused by prostaglandins, free radicals and complement

activation.[42] The association between postoperative anemia and prolonged ventilation may reflect postoperative bleeding and as a result maintenance of sedation and invasive ventilation in case reoperation is needed. Hypoxemia may be due to one or more postoperative pulmonary complications (e.g., atelectasis, ventilator–induced lung injury). Hypoxemia would ordinarily delay tracheal extubation until lung tissue is re–recruited and oxygenation is considered adequate.

The strengths of our study lie in using a large dataset with high level of completeness, the fact that there was no change in practice during the study period, the robust outcome measures with minimal scope for subjectivity, and the excellent follow-up rates. In addition, we were able to conduct internal validation of our predictive model using bootstrapping demonstrating internal reliability of our findings.

Certain limitations to our study should be acknowledged. First, its retrospective design renders the study susceptible to selection bias and only data which is recorded routinely was available, limiting our ability to analyze factors such as intra-operative ventilation or report on individual postoperative pulmonary complications (atelectasis,

pneumonia, acute respiratory distress syndrome, pulmonary aspiration).[1, 2] In addition, due to the observational nature of the study it was not possible to control for clinical decision making; however, agreed standards and protocol–driven care minimize variations in individual practice within the institution where our study took place. In our modelling examining the length of stay, we were unable to account for early mortality in both groups. Although, the number of patients who died during the study period was low (n=16), this may introduce a possible censoring bias which

should be considered in studies. Second, the study was undertaken at a large volume cardiothoracic center and the risk factor analysis was not externally validated on other data sets; therefore, our results are not necessarily generalizable nor transportable to other settings or geographical areas. Third, it was not possible to include fluid balance, volumes and types of transfused blood products, hemodynamic variables or vasoactive drug data which could potentially be related to risk factors causing planned or unplanned prolonged invasive ventilation (e.g., delayed extubation due to significant hemodynamic instability, hemorrhage and/or high vasoactive drug requirements or volume overload affecting gas exchange) and escalation of respiratory support (in cases of low cardiac output state and cardiac failure). Finally, other confounding factors such as peri-operative respiratory tract infections, heavy smoking history, pre-existing lung disease,[43] acute onset atrial fibrillation, slow recovery from anesthesia or acute neurological deficit, could potentially have a hidden effect on our collapsed composite outcome.

Having validated the StEP criteria for severity of postoperative pulmonary complications in a cardiac surgical population, we propose a number of possible uses for this approach. The key question is whether pulmonary complications after surgery are preventable, and if so whether their prevention improves patient–focused outcomes. Potential interventions to test include: early extubation thresholds (e.g., 6– or 12–hours) as recent data suggested no detrimental effect of extubation by 6 hours [8, 10], perioperative oxygenation targets, effect of perioperative transfusion strategies and intraoperative ventilatory strategies, including PEEP and alveolar recruitment maneuvers. If our risk–adjustment is validated in subsequent studies, it may offer a method for producing risk–adjusted postoperative pulmonary complications rates

allowing effective prospective comparison within and between units, facilitating the use of postoperative pulmonary complications rates as a quality measure.

Conclusion

In a low to medium risk patient population undergoing routine cardiac surgery, escalation of respiratory support or prolonged invasive ventilation are associated with adverse outcomes. Hypoxemia and anemia after cardiac surgery are potentially modifiable risk factors for pulmonary complications, which need to be better addressed in future studies.

Figure Legends

Figure 1. Flow diagram of study population.

Figure 2. Time to event curves for patients with and without the composite outcome (Panels A-C)

Panel A - time alive whilst receiving invasive mechanical ventilation

Panel B - time alive and remaining in intensive care unit

Panel C - time alive and remaining in hospital

Escalation of respiratory support (StEP criteria) was defined as unplanned continuous positive airway pressure, non–invasive ventilation or reintubation and invasive ventilation. Prolonged ventilation was defined as invasive mechanical ventilation for more than 12 hours after exit from operation room.

StEP, Standardized Endpoints for Perioperative Medicine

Figure 3. Time to event curves for patients with and without StEP-defined pulmonary complications (Panels A-C) and for patients receiving immediate postoperative invasive mechanical ventilation for >12 and <12 hours (Panels D-F)

Panel A and D -time alive whilst receiving mechanical ventilation

Panel B and E- time alive and remaining in intensive care unit

Panel C and F- time alive and remaining in hospital

Escalation of respiratory support (StEP criteria) was defined as unplanned continuous positive airway pressure, non–invasive ventilation or reintubation and invasive ventilation. Prolonged ventilation was defined as invasive mechanical ventilation for more than 12 hours after exit from operation room.

StEP, Standardized Endpoints for Perioperative Medicine

Appendix A. Supplementary Data

e-Table 1. Table showing initial postoperative arterial partial pressure of oxygen to inspired fraction of oxygen ratios on admission to intensive care unit.

e-Table 2. Table showing internal validation using bootstrap replication for escalation of respiratory support multivariate model.

e-Table 3. Table showing internal validation using bootstrap replication for the prolonged invasive ventilation multivariate model.

Table 1. Patient characteristics.

Patient characteristics	**Study cohort (*n*= 2,098)**
Age (years)	69.8 (10.7)
Sex	
Male	1498 (71.4%)
Height (meters)	1.70 (0.10)
Weight (kg)	82 [71 to 93]
BMI (kg/m^2)	28.5 (5.2)
Hemoglobin (g l^{-1})	103.4 (15.9)
Logistic EuroSCORE	4.0 [2.1 to 7.5]
Additive EuroSCORE	5 [3 to 7]
Time to extubation (hours)	6.14 [4.04 to 11.02]
Surgical characteristics	
Type of surgery	
CABG	919 (43.8%)
Valve surgery	786 (37.5%)
CABG and valve surgery	393 (18.7%)
Cardiopulmonary bypass time (minutes)	85 [68 to 105]
Cross clamp time (minutes)	57 [44 to 72]

Data are mean (SD), number (%) or median [interquartile range].

Abbreviations: BMI, body mass index; CABG, coronary artery bypass graft; EuroSCORE, European System for Cardiac Operative Risk Evaluation; n, number; SD, standard deviation

Table 2. The occurrence of escalation of respiratory support and prolonged invasive ventilation within the first 5 postoperative days

Outcome	**Frequency of event (*n*=2098)**	**Percentage (%)**
CPAP/NIV	126	6.0
Reintubation	40	1.9
Prolonged invasive ventilation (> 12 hours)	478	23
Composite outcome groups		
Escalation of respiratory support (requiring CPAP/NIV or reintubation and invasive ventilation- StEP defined severe pulmonary complications)	154	7.3
Escalation of respiratory support (requiring CPAP/NIV or reintubation and invasive ventilation) and/or prolonged invasive ventilation (> 12 hours)	510	24.3

Data are frequencies of patients experiencing the outcomes and percentages (the composite outcome consisting of patients who required escalation of respiratory support or prolonged invasive ventilation was described using the frequency of patients rather than treated as separate events to prevent multiple counting of the

same individual (e.g. to prevent individuals who were intubated for over 12 hours and required post–extubation CPAP being counted twice)

Abbreviations: CPAP, continuous positive airway pressure; NIV, non-invasive ventilation; StEP, Standardized Endpoints for Perioperative Medicine

Table 3. Characteristics of patients requiring escalation of respiratory support or invasive mechanical ventilation for more than 12 hours after exit from operation room (Escalation of respiratory support$_{12}$ group) *vs.* the rest of the cohort (No escalation of respiratory support group).

Variable	**Escalation of Respiratory Support$_{12}$ (*n*=510)**	**No escalation of respiratory support (*n*=1588)**	***P* value**
Surgical characteristics			
Type of surgery			
CABG	211 (41%)	708 (45%)	
Valve surgery	159 (31%)	627 (40%)	
CABG and valve surgery	140 (28%)	253 (16%)	<0.001
Cardiopulmonary bypass time (minutes)	92.5 [73 to 120]	84 [66 to 101.5]	<0.0001
Cross clamp time (minutes)	61 [47 to 82]	56 [44 to 70]	<0.0001
Patient characteristics			
Age (years)	71.5 (10.4)	69.2 (10.8)	<0.0001
Sex			
Male	357 (70%)	1588 (72%)	
Height (metres)	1.69 (0.10)	1.70 (0.10)	0.0989
Weight (kg)	83 [71 to 97]	81 [71 to 92]	0.0247

BMI (kg/m^2)	29.4 (6.0)	28.2 (4.9)	<0.0001
Hemoglobin ($g\ l^{-1}$) mean (SD)	99.8 (17.2)	104.6 (15.2)	<0.0001
Logistic EuroSCORE	5.1 [2.5 to 9.2]	3.7 [2.1 to 6.7]	<0.0001
Additive EuroSCORE	6 [4 to 8]	5 [3 to 7]	<0.0001
P_aO_2:FiO_2 ratio	30.5 [22.1-39.0]	35.3 [28.4-42.7]	<0.0001
Outcomes			
ICU length of stay (days)	2.1 [1.0 to 4.9]	0.9 [0.80 to 1.0]	<0.0001
Hospital length of stay (days)	10.6 [8.0 to 16.0]	7.2 [6.2 to 10.0]	<0.0001
Time to extubation (hours)	23 [14 to 61]	5 [3 to 7]	<0.0001
In-hospital mortality	15 (2.9%)	1 (0.1%)	<0.001

Data are mean (SD), number (%) or median [interquartile range]. The reported *P* values were derived from t-test (means), Wilcoxon rank sum test (medians), and chi-squared test (categorical data).

Abbreviations: BMI, body mass index; CABG, coronary artery bypass graft; EuroSCORE, European System for Cardiac Operative Risk Evaluation; ICU, intensive care unit; n, number; SD, standard deviation; P_aO_2:F_iO_2 ratio, *ratio* of arterial *partial pressure of oxygen* to inspired fraction of *oxygen*

Table 4. Table showing univariable and multivariable regression of risk factors for postoperative escalation of respiratory support (StEP criteria).

Variable of Interest	**Univariate analysis**	**P value**	**Included in multivariate model (*P* value<0.15)**	**Multivariate Analysis**	***P* value**
