20

21 **Running head:** Effect of soil qualities on competition in *Larix*

22

1 **Abstract** Forest management has potential to detrimentally impact long-term
2 plantation productivity. Establishment of mixed plantations and fertilization are two
3 important management approaches when trying to maintain soil qualities and
4 productivity. In this study, two types of experiments were conducted to investigate the
5 influence of soil qualities on intra- and interspecific competition dynamics in two
6 larch species. Experiment 1: We transplanted two deciduous larch species, *Larix*
7 *kaempferi* and *L. olgensis*, to study intra- and interspecific competition dynamics in
8 two different types of soil: one from a c. twenty years old *L. kaempferi* plantation
9 (named larch soil) and another from a secondary natural forest (named mixed-forest
10 soil). Experiment 2: Effects of N fertilization on the competition dynamics of the two
11 larch species were tested in the larch soil. In the experiment 1, we hypothesized that
12 the growth of *L. kaempferi* in the larch soil under no fertilization is inhibited when
13 competing with *L. olgensis*, and their competition relationships may be different in the
14 mixed-forest soil. In both species, the starch and TNC (total non-structural
15 carbohydrate) concentrations of roots and shoots were significantly higher in the
16 mixed-forest soil when compared to the concentrations in the larch soil without N
17 fertilization (N-). The relative competition intensity (RCI) was affected by the soil
18 type. RCI of *L. olgensis* was higher than that of *L. kaempferi* in the larch soil N-
19 condition, and RCI of *L. kaempferi* was higher than that of *L. olgensis* in the
20 mixed-forest soil in 2015. However, the RCI values did not show significant
21 differences in 2014. In the experiment 2, *L. kaempferi* showed superior
22 competitiveness in the larch soil N+ condition, with the highest RCI value in 2014,

1 but the RCI value of *L. kaempferi* declined while the RCI value of *L. olgensis*
2 increased from 2014 to 2015. Both experiments indicated that the benefiting species
3 had higher element (C, N and P) and non-structural carbohydrate (starch and soluble
4 sugar) content accumulation ratios from 2014 to 2015. We found that competition
5 relationships changed between years and depending on conditions. We suggest that
6 mixed plantations and N fertilization together could effectively promote the
7 productivity of *Larix*.

1 **1. Introduction**

2

3 Although the total area of forests is declining globally, different types of forest
4 plantations are increasing. Forest plantations provide wood products to meet the social
5 and economic demands and help to restore degraded land (Paul et al., 2010; Gong et
6 al., 2013). Yet, forest management has the potential to detrimentally impact long-term
7 plantation productivity. The paper by Keeves (1966) drew attention to potential
8 productivity declines in successive rotations of *Pinus radiata* and, thereafter, many
9 other studies have revealed similar results in different types of plantations around the
10 world (reviewed by, e.g., Fox, 2000; O’Hehir and Nambiar, 2010). Several methods
11 are available to solve such forest management problems. The establishment of mixed
12 plantations and the use of fertilization are two important management approaches to
13 maintain soil qualities and plantation productivity (Fox, 2000; O’Hehir and Nambiar,
14 2010; Richards et al., 2010).

15

16 The benefits of mixed-forest plantations are probably due to interactions between
17 species or interactions with soils that are not present in monoculture plantations
18 (Richards et al., 2010; Guo et al., 2016). Types of plant-plant competition (positive,
19 negative or neutral) frequently shift or change in response to different environmental
20 factors. As previously shown, spatial and temporal environmental heterogeneity can
21 alter competitive relationships (Sthultz et al., 2007; Maestre et al., 2009; Soliveres et
22 al., 2010; Liu et al., 2013; Biswas and Wagner, 2014). Species can distinguish

1 conspecific and heterospecific individuals, and this may lead to substantial changes in
2 interactions (Schmid and Kazda, 2002; Miller et al., 2007; Duan et al., 2014).
3 Competitive responses are dynamic processes and they have been examined by many
4 modelers (e.g., Damgaard et al., 2002; Crone, 2016). Several experiments have
5 confirmed temporal changes in competition by measuring simultaneous changes in
6 resource capture and biomass production (e.g. Trinder et al., 2012a, b). Typical
7 one-time biomass measurements cannot provide unambiguous insights into the
8 competition dynamics of plants.

9
10 After several successive rotations, forest plantations typically show declined soil
11 qualities, for example, lowered N availability to plants (Fox, 2000; O’Hehir and
12 Nambiar, 2010). Thus, fertilization is an important way to ameliorate plantation soil
13 qualities and promote productivity. Soil nutrient availability limits ecosystem
14 productivity, either on their own or in combination with other mineral nutrients
15 (Wassen et al., 2005). Plants have been shown to display different root distributions
16 between conspecific and heterospecific species for resource capture (Schmid and
17 Kazda, 2002). Many experiments have confirmed that plants’ competitive interactions
18 vary along with the availability and form of N or P (Maestre et al., 2005; Trinder et al.,
19 2012b; Ahmad-Ramli et al., 2013; Wilberts et al., 2014), and negative competition
20 reduces species richness (Hautier et al., 2009). Also, effects of forest plantations on
21 soil microbial community structures could be an important reason that affects soil
22 qualities and productivity. He et al. (2014) have shown that after the replacement of a

1 natural broadleaf forest, bacteria with a close phylogenetic relationship to *Pedobacter*
2 *cryoconitis* disappear, but those with a close phylogenetic relationship to
3 *Xanthomonas spp.* and *Rhodanobacter spp.* begin to appear in the soil of a
4 *Cunninghamia lanceolata* plantation.

5

6 The accumulation of N pools affects the performance and growth of plants (Jordan et
7 al., 2012, 2014). Non-structural carbohydrates, the sum of soluble sugars and starch,
8 play a key role in physiological processes, such as serving as signaling molecules,
9 providing basic C energy to growth and respiration (Koch, 2004; Secchi and
10 Zwieniecki, 2011) and maintaining cell turgor and osmoregulation (Muller et al.,
11 2011). It has been shown that non-structural carbohydrate storage can enhance plants'
12 ability to resist stress conditions (Myers and Kitajima, 2007; Wiley et al., 2013;
13 O'Brien et al., 2014). Non-structural carbon pools positively correlate with survival,
14 especially when seedlings experience shade and defoliation (Myers and Kitajima,
15 2007). Species differ in the ways they produce, use, store and allocate non-structural
16 carbohydrates, and this may determine their competitive ability. A few studies have
17 found that intra- and interspecific competition modulates the concentration or
18 accumulation of starch or soluble sugars (Liu et al., 2004; Duan et al., 2014; Guo et
19 al., 2016). Differences in sizes of carbon pools are important functional traits that may
20 reflect plants' competitive ability.

21

22 In this study, we conducted experiments to investigate intra- and interspecific

1 competition dynamics in two deciduous tree species *Larix kaempferi* (Lamb.) Carr
2 and *L. olgensis* A. Henry under two different soil types and under N fertilization.
3 These two species are closely similar in life history traits and morphological traits,
4 which make them difficult to be distinguished from each other, especially at the
5 juvenile stage. However, they show differences in the growth rate, photosynthetic rate
6 and N-use efficiency (Li et al., 2016). In the Experiment 1, we used one kind of soil
7 from the *L. kaempferi* plantation and another type of soil from a natural secondary
8 forest. We aimed to reveal the effects of the two soil types on competition dynamics.
9 We hypothesized that the growth of *L. kaempferi* in the *L. kaempferi* soil under no
10 fertilization is inhibited when competing with *L. olgensis*, and their competition
11 relationships may be different in the soil sampled from the natural secondary forest.
12 There is previous knowledge that a particular species may decline its growth in its
13 own soil, while the growth of another species may not be negatively affected (Bever
14 et al., 2012; Hendriks et al., 2015). In the Experiment 2, we studied the effects of N
15 fertilization on the competition dynamics of the two larch species in the larch soil.
16 Previously, Li et al. (2016) have shown that N fertilization promotes the growth of *L.*
17 *kaempferi* in the *L. kaempferi* soil. We wanted to know, whether N fertilization would
18 affect the competitive performance of the two larch species grown in the *L. kaempferi*
19 soil. Finally, we wanted to know how the plants' nutrition and non-structural
20 carbohydrate accumulation are affected by competition.

2. Methods and materials

2.1. Study site and experimental design

Our study was conducted at the Qingyuan Experimental Station of the Forest Ecology, Institute of Applied Ecology, Chinese Academy of Sciences, located in a mountainous region in the eastern Liaoning Province, Northeast China (41°51'N, 124°54'E). Larch forests are the dominant forest plantation type through northeastern Asia to central Siberia (Liang et al., 2004). The studied species, *L. kaempferi* and *L. olgensis*, are the major plantation tree species in cold and medium temperate zones of China. Two different soil types were used and they originated from a *c.* twenty years old planted forest community of *L. kaempferi* and from a natural secondary forest community. *Quercus mongolica* and *Juglans mandshurica* are the dominant tree species in the natural secondary forest. Hereafter, we call the two types of soil larch soil and mixed-forest soil, respectively. The sampled soil was homogenized before planting. The two types of soil were different in their physical and chemical properties. The former type of soil (pH 5.65, C 18.61 g kg⁻¹, N 1.82 g kg⁻¹, P 4.38 g kg⁻¹) is light brown and the percentage of gravel (> 2 mm) averages 7.28%, while the latter type of soil (pH 6.24, C 42.78 g kg⁻¹, N 3.89 g kg⁻¹, P 6.01 g kg⁻¹) is dark and the percentage

1 of gravel averages 21.37%.

2

3 2.2. *Experiment 1: two soil types*

4

5 The intra- and interspecific competition treatments were designed as follows:

6 monoculture plantations reflecting intraspecific, competition *L. kaempferi* + *L.*

7 *kaempferi* and *L. olgensis* + *L. olgensis*; mixed cultures representing interspecific

8 competition, *L. kaempferi* + *L. olgensis*. This experiment aimed to reveal the soil

9 effect on the competition dynamics of the two species. Three competition treatments

10 and two soil types (larch and mixed-forest soil) were set up.

11

12 2.3. *Experiment 2: N supplied to the larch soil*

13

14 Effects of N fertilization were tested only in the larch soil. Urea (46.3% N) was used

15 for N fertilization (as in Zhu et al. 2011) in the monocultures and mixed plantations of

16 both species using larch soil. We added urea twice a year, in May and June (5.1 g each

17 time) during years 2014 and 2015. The urea was homogeneously applied to each pot,

18 which were immediately watered. Three competition treatments and two N conditions

19 (with and without N fertilization) were set up. Thus, in the larch soil, there were three

20 treatments without N fertilization: two monoculture plantations (Mo), one for each

21 species, and one mixed culture (M), and three additional treatments with N

22 fertilization: two monoculture plantations, one for each species (PN) and one mixed

1 plantation (MN). Competition treatments were the same as in experiment 1. The three
2 treatments without N fertilization in experiment 2 were the same as the three
3 treatments in the larch soil in experiment 1.

4

5 One-year old seedlings with approximately the same crown size and height (no
6 significant statistical differences) were selected from a local nursery garden. In late
7 October, 2013, two seedlings were planted in each plastic pot (external diameter and
8 height 56 cm and 33 cm, respectively) to set up intra- and interspecific competition
9 treatments for both species using two different types of soil (*c.* 70 kg soil per pot).
10 Sixteen replicates per treatment were included in the study. Additionally, three
11 individuals of each species were grown singly (S) in each type of soils and in the N
12 fertilized larch soil (SN).

13

14 *2.4. Harvesting and measurements*

15

16 We harvested plants twice, on the 29th of August, 2014 and 4th of September, 2015. In
17 2014, four pots from each treatment were randomly harvested and all individuals were
18 divided into leaves, shoots and roots. In 2015, four or five pots from each treatment
19 were selected and the harvested individuals were divided into leaves, branches, stems,
20 coarse roots (diameter > 2 mm) and fine roots (diameter < 2 mm). All harvested plants
21 were dried at 70 °C for 72 h. Three replicates from single plantation patterns (S and
22 SN) were harvested only in 2015. All dried materials were ground into a powder for

1 further measurements.

2

3 We measured the concentrations of C, N, P, starch and soluble sugars in each part of
4 the harvested materials. The C, N and P concentrations were determined by the rapid
5 dichromate oxidation technique (Nelson and Sommers, 1982), the semi-micro
6 Kjeldahl method (Mitchell, 1998) and the vanadate-molybdate yellow colorimetric
7 method (Yang et al., 2011) after minor modifications. Methodological details of the
8 measurements of starch and soluble sugars were described by Guo et al. (2016).

9

10 *2.5. Data analysis*

11

12 Firstly, we calculated the relative competitive intensity (RCI) of both species when
13 exposed to different competition treatments, N fertilization or soil types in 2014 and
14 2015, according to the formula described by Grace (1995) as follows:

$$15 \text{ RCI} = B_c - B_s / B_s$$

16 Where B_c represents the total biomass of an individual from interspecific competition
17 and B_s represents the average total biomass of corresponding plants from intraspecific
18 competition. Positive RCI value stands for a better growth with a heterospecific
19 species than with a conspecific one.

20

21 Secondly, we calculated the concentration dynamics of C, N, P and non-structural
22 carbohydrates (starch, soluble sugars and total non-structural carbohydrates TNC) of

1 each plant organ during both years. TNC of each organ was the sum of its starch and
2 soluble sugars. The formula was as follows:

$$3 \text{ Concentration variation} = [\text{Concentration}_{2015} - \text{Concentration}_{2014}] / \text{Concentration}_{2014},$$

4 where $\text{Concentration}_{2015}$ and $\text{Concentration}_{2014}$ represented the concentrations of C, N,
5 P and non-structural carbohydrates in 2015 and 2014, respectively. In 2015, we
6 defined the shoot as the sum of branches and stems. Concentrations of shoots were
7 calculated as follows:

$$8 \text{ Concentration} = [\text{Bio}_{\text{Branch}} \times \text{Concentration}_{\text{Branch}} + \text{Bio}_{\text{Stem}} \times \text{Concentration}_{\text{Stem}}] /$$
$$9 [\text{Bio}_{\text{Branch}} + \text{Bio}_{\text{Stem}}], \text{ where } \text{Bio}_{\text{Branch}} \text{ and } \text{Bio}_{\text{Stem}} \text{ represent branch and stem biomasses,}$$

10 respectively.

11 Similarly, concentrations of roots were computed as follows:

$$12 \text{ Concentration} = [\text{Bio}_{\text{Coarse}} \times \text{Concentration}_{\text{Coarse}} + \text{Bio}_{\text{Fine}} \times \text{Concentration}_{\text{Fine}}] /$$
$$13 [\text{Bio}_{\text{Coarse}} + \text{Bio}_{\text{Fine}}], \text{ where } \text{Bio}_{\text{Coarse}} \text{ and } \text{Bio}_{\text{Fine}} \text{ represent biomasses of coarse and fine}$$

14 roots, respectively.

15

16 Changes in the contents of C, N, P and non-structural carbohydrates (starch, soluble
17 sugars and TNC) were calculated as follows: $\text{Content accumulation} = [\text{Content}_{2015} -$
18 $\text{Content}_{2014}] / \text{Content}_{2014}$, where Content_{2015} and Content_{2014} represent the contents
19 of C, N, P and non-structural carbohydrates in 2015 and 2014, respectively. The
20 content of each plant part, for instance, the leaf N content of an individual was
21 obtained by multiplying the leaf N concentration by leaf biomass. In 2015, the
22 contents of shoots were the sum of branch and stem contents.

Data were checked for normality and the homogeneity of variances. Parameters were log-transformed when needed. Tukey's *b* tests were carried out for each species to detect their RCI differences among treatments. Three-way analyses of variance (ANOVA) were performed for individuals grown in the larch soil to detect the effects of species, competition treatment and N fertilization. When significant interactions were observed, Tukey's *b* tests were conducted as post hoc tests to discover significant differences among treatments. Similarly, two-way analyses of variance were performed for individuals grown in the mixed-forest soil to discover the effects of species and competition patterns. If a significant factor interaction between species and competition was found, Tukey's *b* tests were conducted as well. In order to discover the effects of soil type, an Independent-Samples T test was conducted for the same species in the same competition treatment but grown in two types of soil. All data were analyzed with the software Statistical Package for the Social Science (SPSS) version 20.0.

1

2

3

4 **3. Results**

5

6 *3.1. Relative competitive intensity*

7

8 The results showed that the relative competitive intensity (RCI) of the two species
9 was influenced by the competition treatment, N fertilization or soil type. More
10 importantly, RCI showed considerable temporal changes from 2014 to 2015 (Fig. 1).
11 In 2014, the RCI value of *L. kaempferi* was significantly higher when grown with *L.*
12 *olgensis* in the N-fertilized larch soil than in other treatments, while no other
13 treatment differences were detected. Thus, the growth of *L. kaempferi* was facilitated
14 by *L. olgensis* under N fertilization (Fig. 1a). In 2015, the RCI value of *L. olgensis*
15 was higher than that of *L. kaempferi* in the larch soil N-, whereas the RCI of *L.*
16 *kaempferi* was higher than that of *L. olgensis* in the mixed-forest soil (Fig. 1b).
17 During the second year, after N fertilization in the larch soil, the RCI of *L. kaempferi*
18 was still higher compared to that of *L. kaempferi* in the larch soil N-. However, the
19 RCI of *L. olgensis* was higher compared to that of *L. olgensis* in the mixed-forest soil
20 (Fig. 1b).

21

22 When compared with individuals grown alone without any competition, intra- and

1 interspecific competition declined the biomass of both studied species (Table 1). In
2 the larch soil N⁺ condition, the growth of *L. kaempferi* was much greater under MN
3 (mixed culture with N fertilization) and it exhibited significantly higher biomasses of
4 coarse roots, fine roots, total roots and whole individuals when compared with PN
5 (monoculture with N fertilization). A positive growth response was found also in the
6 mixed culture (M) in *L. olgensis*, whose biomasses (e.g. branches and leaves) were
7 significantly higher than those of plants grown in the monoculture (Mo) in the larch
8 soil N⁻ condition. However, the relationship shifted between the two species in the
9 mixed-forest soil. Specifically, the growth of *L. kaempferi* greatly benefited from the
10 presence of *L. olgensis*, as a greater total biomass difference between M and Mo was
11 detected (Table 1).

12

13 3.2. Concentration variation

14

15 Single factors (competition, species or N fertilization) or their interactions caused
16 temporal variation in C, N and P concentrations, except for the concentration of leaf C
17 and shoot C in different soil types (see Table S1 in Supplementary materials). In the
18 larch soil N⁻ condition, the root C concentration of both species was significantly
19 greater in mixed cultures (M) compared to monocultures (Mo), and this difference
20 disappeared in the larch soil N⁺ condition (Fig. 2a). The leaf N concentration of *L.*
21 *kaempferi* from the monoculture (Mo) was significantly higher than that of
22 individuals grown under interspecific competition (M) in the larch N⁻ soil (Fig. 2b).

1 In the mixed-forest soil, both leaf and shoot N concentrations of *L. olgensis* from
2 mixed culture (M) were significantly lower compared with *L. olgensis* grown in
3 monocultures (Mo) (Fig. 2b). The shoot P concentration of *L. kaempferi* from MN
4 was significantly lower compared with the same species from PN in the larch soil N+
5 condition (Fig. 2c). N and P concentration variation between the two soil types were
6 also observed, for example, leaf N and leaf P concentrations of *L. kaempferi* from the
7 mixed culture (M) in the mixed-forest soil were significantly higher than those of *L.*
8 *kaempferi* from the mixed culture (M) in the larch soil N- condition (Fig. 2b, c).

9

10 In larch soil N- condition, concentrations of shoot starch, soluble sugars and TNC as
11 well as of leaf starch and TNC of *L. kaempferi* from mixed culture (M) increased
12 more than those of individuals from *L. kaempferi* monoculture (Mo); by contrast,
13 concentrations of root soluble sugars and root TNC of *L. kaempferi* were significantly
14 higher in Mo (Fig. 2d, e, f). In *L. olgensis*, a significant concentration change was
15 found only in root starch, which was higher in M than in Mo in the larch soil N-
16 condition (Fig. 2d). In the mixed-forest soil, significant interactions of competition
17 and species concerning the starch concentration of shoots and roots were observed
18 (Table S1). Concentrations of root starch, root soluble sugar and root TNC of *L.*
19 *kaempferi* from the mixed culture were significantly higher in the mixed-forest soil
20 compared with those of *L. kaempferi* in the larch soil N- condition (Fig. 2d, e, f).

21

22 *3.3. N and P pool sizes and accumulation dynamics*

1

2 Different factors (competition, N fertilization and species) alone or their interactive
3 effects influenced C, N and P contents of plant organs, as well as those of whole
4 plants in different soils (Tables S2, S3 and S4 in Supplementary materials). We
5 discovered that the growth of *L. kaempferi* greatly benefited from the presence of *L.*
6 *olgensis* in the mixed-forest soil and it tended to have a significantly higher C
7 accumulation or N pool size in leaves and shoots and in the whole individual (Tables
8 S2 and S3).

9

10 In the larch soil N- condition, C, N and P content accumulation ratios of roots and
11 shoots of *L. olgensis* were significantly higher in the mixed culture (M) when
12 compared with monoculture (Mo), while *L. kaempferi* in the mixed-forest soil
13 exhibited similar values in the mixed culture and monoculture (Fig. 3a, c, e).
14 Corresponding results were observed at the whole plant level (Fig. 3b, d, f). In the
15 larch soil N+ condition, the accumulation ratios of root C, shoot C, leaf N, shoot P
16 and root P as well as the accumulation ratios of C, N and P of whole individuals of *L.*
17 *olgensis* were significantly higher in the mixed culture (MN) compared with the
18 monoculture (PN), while the whole plant P accumulation ratio of *L. kaempferi* tended
19 to decrease more in the mixed culture (MN) (Fig. 3). There were tendencies that C, N
20 and P accumulation ratios were higher in the mixed-forest soil (Fig. 3).

21

22 *3.4. Non-structural carbohydrate pool sizes and accumulation dynamics*

1

2 Different factors (competition, N fertilization and species) alone as well as their
3 interactive effects influenced starch, soluble sugar and TNC contents of plant organs
4 as well as those of whole plants (Tables S3, S5 and S6 in Appendix). The species
5 benefiting from the presence of another species when growing in different types of
6 soil tended to have higher non-structural carbohydrate contents (Tables S3 and S5).

7

8 In the larch soil N- condition, the contents of starch (roots and shoots), root soluble
9 sugars and TNC (roots and shoots), as well as those of whole plants of *L. olgensis*
10 became significantly higher in the mixed culture (M) compared with the monoculture
11 (Mo) (Fig. 4). Under N fertilization in the larch soil, contents of starch (roots, shoots
12 and whole plant), soluble sugars (leaves and whole plant) and TNC (shoots, leaves
13 and whole plant) of *L. kaempferi* were negatively affected by the presence of *L.*
14 *olgensis* (Fig. 4). In the mixed-forest soil, starch (shoots, whole plant) and both
15 soluble sugars and TNC (roots, shoots, leaves and whole plant) of *L. kaempferi*
16 increased under the presence of *L. olgensis*, while the contents of root soluble sugars
17 in *L. olgensis* decreased under the presence of *L. kaempferi* (Fig. 4). There were also
18 tendencies that the starch, soluble sugars and TNC accumulation ratios were higher in
19 the mixed-forest soil (Fig. 4).

20

21

22

1 **4. Discussion**

2

3 Ecologists have suggested that both negative and positive competition play important
4 roles in the structuring of populations and communities in the nature (Bertness and
5 Callaway, 1994; Trinder et al., 2013; Biswas and Wagner, 2014). Through different
6 experiments in diverse environments, researchers try to find explanations for how and
7 to what extent neighboring organisms influence competition dynamics. In our study,
8 we discovered that the soil type has an important role in determining competition
9 relationships.

10

11 *4.1. Competition dynamics responding to N fertilization*

12

13 Tilman's theory (1987) suggests that competition for soil nutrients is stronger at low
14 nutrient levels compared with high nutrient levels, while the stress gradient hypothesis
15 (Bertness and Callaway, 1994) proposes that individuals of different species may
16 negatively compete for resources or space in a productive environment but they may
17 positively compete (facilitate) in a severe environment, and there is a possibility for
18 intraspecific competition for the same resources or space (Miller, 1996; Goldenheim
19 et al., 2008; Maestre et al., 2009; Fajardo and McIntire, 2011; Liu et al., 2013). In the
20 productive soil (larch soil N+), *L. kaempferi* showed strong positive inter-specific
21 competition and some negative effects on the growth of *L. olgensis* in 2014 (Fig. 1a),
22 which partly supported the stress gradient hypothesis. Also previously, *L. kaempferi*

1 has been shown to exhibit early superiority that is greatly facilitated by the presence
2 of *L. olgensis* in the larch soil N+ (total biomasses: *L. kaempferi* 74.80 g vs. *L.*
3 *olgensis* 29.22 g, $P < 0.05$; Guo et al., 2016). In 2015, RCI of *L. olgensis* greatly
4 increased and RCI of *L. kaempferi* was still higher, although slightly lower compared
5 to the value in 2014 in the larch soil N+ (Fig. 1b). The growth of *L. olgensis* was no
6 longer inhibited by the presence *L. kaempferi* and its biomass was significantly higher
7 than that in monoculture in the larch soil N+ condition (Table 1), which then partly
8 supported the Tilman's theory (1987). Therefore, our results did not fully support
9 either of the two contrasting competition theories.

10

11 4.2. Competition dynamics responding to soil type

12

13 Our results provided evidence that the competitive performance of the two *Larix*
14 species was different in the larch soil N- condition and in the mixed-forest soil. Many
15 studies have proposed that the effects of the plant-soil feedback are plant
16 species-specific and negative (Kulmatiski et al., 2008; van der Putten et al., 2013;
17 Hendriks et al., 2015). Successive plantation cycles reduce productivity due to
18 negative effects on soil qualities (Fox, 2000; O'Hehir and Nambiar, 2010). Starch and
19 TNC concentrations of shoots and roots in *L. kaempferi* from monoculture in larch
20 soil N- condition were significantly lower than those in *L. kaempferi* from
21 monoculture in mixed-forest soil (Fig. 2d, f). Furthermore, the starch and TNC
22 contents and accumulation ratios also showed similar patterns (Table S5; Fig. 4).

1 Therefore, the negative effects of larch soil on *L. kaempferi* were probably the reason
2 that determined its negative performance in interspecific competition with *L. olgensis*
3 in the larch soil N- condition at 2015 (Fig. 1b).

4
5 When a plant is confronted with foreign soil, root growth may be accelerated
6 (Hendriks et al., 2015). Resource exploration has long been considered as a major
7 mechanism determining the success of several invasive species (Levine et al., 2003).
8 The root (including fine and coarse root) growth of *L. olgensis* was markedly
9 inhibited by *L. kaempferi* when compared with *L. olgensis* monoculture grown in the
10 mixed-forest soil in 2015 (Table 1). This indicated that *L. kaempferi* was a strong
11 competitor to capture and store nutrition relative to *L. olgensis*, when they interacted
12 in foreign soil (Fig. 2, 3), which probably increased its C fixation and simultaneously
13 accelerated both growth and carbon storage (Fig. 4).

14 15 4.3. Temporal changes in competition

16
17 Crone (2016) stated that the effects of among-site variation and among-year variation
18 (environmental stochasticity) are important for the population dynamics of *Pulsatilla*
19 *patens*, as revealed by a 10-year demographic monitoring study. Intraspecific
20 competition of *Alliaria petiolata* was found to show seasonal variation in both
21 experimental and field conditions; specifically, statistically significant negative
22 density-dependent survival during the productive summer period and positive

1 density-dependent survival over the severe winter period were observed (Biswas and
2 Wagner, 2014). The temporal determinants of responses of forest tree species to
3 climatic changes are important for forest dynamics. For example, Linares et al. (2010)
4 suggested that the growth decline and death of *Abies pinsapo* occurred as a result of
5 interacting effects of both competition and climate stressors acting at long- and
6 short-term time scales. In our study, although we regularly watered the plants to meet
7 their specific water demand, variation in climate conditions, such as the amount of
8 rainfall, was not measured during the experiments. However, we did find temporal
9 changes, as there were interacting effects of competition and soil qualities. Temporal
10 variation in the competition dynamics was also detected between the larch soil N-
11 condition and the mixed-forest soil from 2014 to 2015. Total biomasses of the two
12 species grown together were not significantly different in 2014 (*L. kaempferi* 31.09 vs
13 *L. olgensis* 21.00, $P > 0.05$, larch soil, Guo et al. 2016; *L. kaempferi* 21.17 vs *L.*
14 *olgensis* 29.64, $P > 0.05$, mixed-forest soil, data unpublished) and their RCIs showed
15 no differences (Fig. 1a). However, *L. olgensis* benefited from the presence of *L.*
16 *kaempferi* in the larch soil N- condition, while *L. kaempferi* benefited from the
17 presence of *L. olgensis* in the mixed-forest soil in 2015 (Figs. 1b and 5; Table 1). We
18 concluded that soil type effects on competition show temporal variation and species
19 may need a relatively long time to provide proof of their competitive ability.

20

21 Through our experiments, we revealed that the resource accumulation dynamics is
22 tightly coupled with the temporal dynamics of species competition. As shown

1 previously, N accumulation by *Plantago lanceolata* exceeded that of *Dactylis*
2 *glomerata* during the first 62 days, but, thereafter, *D. glomerata* accumulated more N,
3 which indicated temporal variation in competitive interactions (Trinder et al., 2012a).
4 Neighbors may affect non-structural carbohydrate concentrations, which then
5 influence competition performance under different environmental conditions
6 (Anderson et al., 2001; Liu et al., 2004; Duan et al., 2014). Apparently, in our study,
7 there was temporal variation in the concentration dynamics of non-structural
8 carbohydrates (Fig. 2). Resource (N and P) resorption making plants less dependent
9 on the availability of nutrients is a critical strategy in nutrient conservation, especially
10 in deciduous species. Resource resorption is affected by nutrient addition (Lü et al.,
11 2013; Mayor et al., 2014), and nutrient residence times or resorption efficiency are
12 different in interspecific and intraspecific competition (reviewed by Richards et al.,
13 2010). Non-structural carbohydrates can be reallocated from foliar to other plant parts.
14 The process of resorption may also show temporal variation and may affect
15 competition dynamics, although we did not explore it in this study.

16

17 *4.4. Storage and competition*

18

19 Plants can potentially buffer environmental changes or stochasticity by using stored
20 resources. Many reports have depicted the role of non-structural carbohydrates in
21 determining tolerance to severe stress, like shade and drought (Myers and Kitajima,
22 2007; Adams et al., 2013; O'Brien et al., 2014). Stored nutrients affect plant growth

1 and performance (Pellicer et al., 2000; Uhde-Stone et al., 2003; Jordan et al., 2012,
2 2014). Pellicer et al. (2000) suggested that the rooting of leafy cuttings of *Larix* ×
3 *eurolepis* was limited by the initial amount of N reserves. In our study, the benefiting
4 species possessed a higher amount of nutrients and non-structural carbohydrates, as
5 well as a stronger C accumulation compared to its neighbors. Probably our results
6 partly answered, why some mixed cultures were more resistant to disturbances than
7 monocultures.

8

9 Plant species are thought to have a high year-round content of non-structural
10 carbohydrates regardless of seasonal fluctuations, habitat and climate (Hoch et al.,
11 2003; Körner, 2003; Würth et al., 2005). Carbohydrate pools stored in aboveground
12 parts of mature deciduous trees are estimated to be sufficient to replace the entire leaf
13 canopy four times in the absence of photosynthesis (Hoch et al., 2003). However, a
14 considerable fraction of the starch pool stored in the xylem becomes sequestered
15 (Millard et al., 2007) and fails to be used (Sala et al., 2010). Although *L. kaempferi*
16 exhibited the highest contents of starch and soluble sugar when planted with *L.*
17 *olgensis* in the larch soil N+ condition in 2014, we observed that the RCI of *L.*
18 *kaempferi* declined along with the increasing RCI of *L. olgensis* in 2015 when
19 growing in the larch soil N+ condition (Fig. 1b). Consequently, the element (C, N and
20 P) and non-structural carbohydrate accumulation ratios of *L. kaempferi* were
21 significantly influenced by competition with *L. olgensis* in the larch soil N+ condition
22 (Figs. 3 and 4).

1

2 4.5. Competition and temporal niche

3

4 Competition interactions are always regulated by resource partitioning, such as
5 preferences for different nutrient forms in soil (McKane et al., 2002; Turner, 2008;
6 Ahmad-Ramli et al., 2013). The preference for P forms regulates the competitive
7 outcomes between *Vaccinium vitis-idaea* and *Deschampsia cespitosa* (Ahmad-Ramli
8 et al., 2013). As shown previously, the two studied *Larix* species have different
9 growth traits; for example, the net photosynthesis rate and content of non-structural
10 carbohydrates of *L. kaempferi* are significantly higher than those of *L. olgensis* in
11 normal conditions (Li et al., 2016). Differences in carbohydrate storage can explain
12 species coexistence (Myers and Kitajima, 2007). Temporal changes in plant traits,
13 such as root biomass and starch content of *L. olgensis* from 2014 to 2015 in two types
14 of soil led to changes in resource competition. Resource competition is dependent on
15 the spatial and temporal distribution of resources between species (Alpert et al., 2000).
16 Soil reduces establishment and growth for some species, while other plant species are
17 less harmed. Species are probably different in their demands, and there may be
18 temporal niche differentiation. In *Larix*, competition dynamics is evidently regulated
19 by the combined effects of species, soil type and temporal variation, which contribute
20 to the coexistence of species and to the dynamics of their communities.

21

22 5. Conclusions

1

2 Our study revealed the effects of soil type on the competition dynamics of the two
3 *Larix* species. N fertilization was found to be an effective method for promoting the
4 productivity of *Larix* plantations. The results indicated that N fertilization alleviated
5 the negative effects of *L. kaempferi* soil on the growth of *L. kaempferi* and promoted
6 the growth of both species when they were grown in a mixed culture.

2

3 **Figure 1.** Relative competitive intensities (RCIs) of *L. kaempferi* and *L. olgensis* in
4 2014 and at 2015. (a) RCI of the two species in 2014. (b) RCI of the two species in
5 2015. Larch soil N- indicates *L. kaempferi* without N fertilization; larch soil N+
6 indicates *L. kaempferi* soil with N fertilization; mixed-forest soil indicates soil from a
7 secondary forest. Different lowercase letters indicate significant differences between
8 treatments according to Tukey's *b* test at $P < 0.05$. The black and white bars denote *L.*
9 *kaempferi* and *L. olgensis*, respectively. For RCI calculation, please see the Methods
10 and materials section.

11

12 **Figure 2.** Variation in element and nonstructural carbohydrate concentrations of *L.*
13 *kaempferi* and *L. olgensis* under different treatments from 2014 to 2015. (a), (b) and
14 (c) represent C, N and P concentration changes, respectively; (d), (e) and (f) represent
15 starch, soluble sugar and TNC (total non-structural carbohydrates) concentration
16 changes. Mo, intraspecific competition; M, interspecific competition; PN,
17 intraspecific competition under N fertilization; MN, interspecific competition under N
18 fertilization. Different lowercase letters indicate significant differences between *L.*
19 *kaempferi* and *L. olgensis* in the larch soil according to Tukey's *b* test at $P < 0.05$.
20 Different capital letters indicate significant differences between *L. kaempferi* and *L.*
21 *olgensis* in the mixed-forest soil according to Tukey's *b* test at $P < 0.05$. The red
22 dotted frame indicates treatments in the mixed-forest soil. *** $P \leq 0.000$, ** $0.000 < P$

1 ≤ 0.01 , * $0.01 < P \leq 0.05$, ^{ns} $P > 0.05$, Independent-Samples T test between the two
2 types of soil. The bars with and without oblique lines denote *L. kaempferi* and *L.*
3 *olgensis*, respectively. The white, grey and black portions denote roots, shoots and
4 leaves, respectively.

5

6 **Figure 3.** C, N and P content accumulation ratios in leaves, shoots and roots as well
7 as in the whole plant in *L. kaempferi* and *L. olgensis* under different treatments from
8 2014 to 2015. (a), (c) and (e) represent C, N and P content accumulation ratios in
9 leaves, shoots and roots, respectively; (b), (d) and (f) represent C, N and P content
10 accumulation ratios in the whole plant, respectively. Mo, intraspecific competition; M,
11 interspecific competition; PN, intraspecific competition under N fertilization; MN,
12 interspecific competition under N fertilization. Different lowercase letters indicate
13 significant differences between *L. kaempferi* and *L. olgensis* in the larch soil
14 according to Tukey's *b* test at $P < 0.05$. Different capital letters indicate significant
15 differences between *L. kaempferi* and *L. olgensis* in the mixed-forest soil according to
16 Tukey's *b* test at $P < 0.05$. The red dotted frame indicates treatments in the
17 mixed-forest soil. *** $P \leq 0.000$, ** $0.000 < P \leq 0.01$, * $0.01 < P \leq 0.05$, ^{ns} $P > 0.05$,
18 Independent-Samples T test between the two types of soil. The bars with and without
19 oblique lines denote *L. kaempferi* and *L. olgensis*, respectively. The white, grey and
20 black portions denote roots, shoots and leaves, respectively.

21

22 **Figure 4.** Non-structural carbohydrate content accumulation ratios in leaves, shoots

1 and roots as well as in the whole plant in *L. kaempferi* and *L. olgensis* under different
2 treatments from 2014 to 2015. (a), (c) and (e) represent starch, soluble sugar and TNC
3 (total non-structural carbohydrates) content accumulation ratios of leaves, shoots and
4 roots, respectively; (b), (d) and (f) represent starch, soluble sugar and TNC content
5 accumulation ratios of the whole plant, respectively. Mo, intraspecific competition; M,
6 interspecific competition; PN, intraspecific competition under N fertilization; MN,
7 interspecific competition under N fertilization. Different lowercase letters indicate
8 significant differences between *L. kaempferi* and *L. olgensis* in the larch soil
9 according to Tukey's *b* test at $P < 0.05$. Different capital letters indicate significant
10 differences between *L. kaempferi* and *L. olgensis* in the mixed-forest soil according to
11 Tukey's *b* test at $P < 0.05$. The red dotted frame indicates treatments in the
12 mixed-forest soil. *** $P \leq 0.000$, ** $0.000 < P \leq 0.01$, * $0.01 < P \leq 0.05$, ^{ns} $P > 0.05$,
