## Abstract

Five rate constant expressions for combustion relevant bimolecular reactions of NCN, HNO and HCO have been measured directly behind shock waves. NCN and HNO are known as short-lived flame intermediates that are involved in the formation of nitrogen oxide (NO<sub>x</sub>) pollutants. HCO is a key radical on the main oxidation pathway of hydrocarbons yielding CO. Accurate knowledge of the rate constants of all involved reactions in the ensuing complex reaction mechanisms makes it possible to develop strategies to (at least) reduce the problem of pollutant formation in combustion processes.

Concentration-time profiles of NCN radicals have been detected via UV laser absorption spectroscopy to measure the rate constants of the reactions NCN + H, NCN + H<sub>2</sub>, and NCN + O<sub>2</sub>. The thermal decomposition of cyanogen azide (NCN<sub>3</sub>) was used as quantitative NCN source behind shock waves. The extremely toxic and highly explosive NCN<sub>3</sub> had to be directly synthesized from the reaction of NaN<sub>3</sub> with BrCN since it could not be purified. The thermal decomposition of ethyl iodide (C<sub>2</sub>H<sub>5</sub>I) has been used as high temperature H atom source. The rate constant of the reaction NCN + H, which critically determines the formation of HCN along the prompt-NO formation pathway, has been directly measured for the first time. From the measured rate constant data, conclusions could be drawn for the product channel branching ratios and the disputed value of the enthalpy of formation of NCN. The reaction NCN + H<sub>2</sub>, which has so far always been neglected for NCN modeling in flames, turned out to be comparatively fast and hence gains some importance under H<sub>2</sub> rich flame conditions. From the consideration of possible reaction product sets, the abstraction reaction NCN + H<sub>2</sub> → HNCN + H turned out to be the most reasonable reaction channel.

Using the sensitive absorption based frequency modulation spectroscopy, HNO has been detected for the first time behind shock waves. A reaction mechanism for the simulation of HNO formation from the 193 nm photolysis of glyoxal/NO mixtures was compiled from available literature data and has been validated experimentally. HNO detection was performed at three different absorption lines of the ( $\tilde{A}^1A'' \leftarrow \tilde{X}^1A'$ )(100 ← 000) transition. HNO and HCO concentration-time profiles have been measured at similar reaction conditions at room temperature and behind shock waves. From the consistent modeling of the two species profiles, the HNO absorption cross section has been obtained for the transition at  $\tilde{\nu} = 16173.86 \text{ cm}^{-1}$ . Based on these analyses high temperature rate constant values for the reaction HNO + O<sub>2</sub> → NO + HO<sub>2</sub> were obtained for the first time. The resulting rate expression is up to five orders of magnitude higher than frequently used  $k_{\text{HNO}+\text{O}_2}$  expressions in existing combustion mechanisms.

HCO formation from the thermal decomposition of glyoxal has been observed by frequency modulation spectroscopy. By adding oxygen to the reaction mixtures, the rate constant of the reaction HCO + O<sub>2</sub> → HO<sub>2</sub> + CO could be directly measured. These experiments significantly extend the range of available rate constant data towards higher temperatures of 1285 - 1760 K and were also used to test the capability of an extensive glyoxal oxidation mechanism for intermediate and high temperatures.

## Zusammenfassung

Die Geschwindigkeitskonstanten von fünf verbrennungsrelevanten bimolekularen Reaktionen von NCN, HNO und HCO wurden hinter Stoßwellen direkt gemessen. Bei NCN und HNO handelt es sich um kurzlebige Zwischenprodukte in Flammen, die an der Stickoxid- ( $\text{NO}_x$ -) Bildung beteiligt sind. Das HCO-Radikal ist ein zentrales Intermediat während der Oxidation von Kohlenwasserstoffen, die zur CO-Bildung führt. Komplexe Reaktionsmechanismen sind nötig, um die Schadstoffbildung in Verbrennungsprozessen zu beschreiben. Durch genaue Kenntnis der Geschwindigkeitskonstanten aller beteiligten Reaktionen, können Strategien entwickelt werden, um diese Schadstoffbildung zu verringern.

Konzentrations-Zeit-Profile von NCN-Radikalen wurden mittels UV Laser-Absorptions-Spektroskopie aufgenommen. Auf diese Weise gelang es, die Geschwindigkeitskonstanten der Reaktionen  $\text{NCN} + \text{H}$ ,  $\text{NCN} + \text{H}_2$  und  $\text{NCN} + \text{O}_2$  erstmals bei hohen Temperaturen direkt zu messen. Als quantitative Quelle für NCN-Radikal hinter Stoßwellen wurde der thermische Zerfall von Cyanazid ( $\text{NCN}_3$ ) verwendet. Das sehr giftige und hochexplosive  $\text{NCN}_3$  wurde aus  $\text{NaN}_3$  und  $\text{BrCN}$  direkt synthetisiert, da es nicht aufgereinigt werden konnte. Als Quelle für H-Atome diente der Zerfall von Ethyliodid ( $\text{C}_2\text{H}_5\text{I}$ ). Die Geschwindigkeitskonstante der Reaktion  $\text{NCN} + \text{H}$ , die entscheidend für die HCN-Bildung und damit für die prompt-NO-Bildung ist, wurde zum ersten Mal direkt experimentell bestimmt. Aus den gemessenen Geschwindigkeitskonstanten für  $\text{NCN} + \text{H}$  konnten Rückschlüsse auf die Produktverteilung der Reaktion und die nach wie vor umstrittene Bildungsenthalpie des NCN-Radikals gezogen werden. Zusätzlich wurde die Reaktion  $\text{NCN} + \text{H}_2$ , die bisher für die Simulation von Flammen vernachlässigt wurde, hinsichtlich ihrer Reaktionsprodukte betrachtet. Als wahrscheinlichster Reaktionskanal wurde der Abstraktionskanal  $\text{NCN} + \text{H}_2 \rightarrow \text{HNCN} + \text{H}$  ermittelt.

Mittels der sehr empfindlichen Frequenz-Modulations-Spektroskopie ist es erstmals gelungen HNO hinter Stoßwellen nachzuweisen. Zunächst wurde ein Reaktionsmechanismus zur Simulation der HNO Bildung aus der 193 nm Photolyse von Glyoxal/NO-Mischungen aus Literaturdaten zusammengestellt und danach experimentell überprüft. Für die HNO-Detektion wurden drei verschiedene Linien des  $(\tilde{A}^1A'' \leftarrow \tilde{X}^1A')(100 \leftarrow 000)$  Übergangs ausgewählt. Durch Kombination von HNO- und HCO-Experimenten bei ähnlichen Reaktionsbedingungen hinter Stoßwellen und bei Zimmertemperatur konnte der HNO Absorptionsquerschnitt bei  $\tilde{\nu} = 16173.86 \text{ cm}^{-1}$  bestimmt werden. Basierend auf diesen Ergebnissen wurden erstmals Geschwindigkeitskonstanten für die Reaktion  $\text{HNO} + \text{O}_2 \rightarrow \text{NO} + \text{HO}_2$  bei hohen Temperaturen gemessen. Die ermittelten Ergebnisse liegen bis zu fünf Größenordnungen über den bisher in Verbrennungsmechanismen enthaltenen Ausdrücken für  $k_{\text{HNO}+\text{O}_2}$ .

Weiterhin wurde die HCO-Bildung aus dem thermischen Zerfall von Glyoxal mittels FM-Spektroskopie beobachtet. Durch den Zusatz von Sauerstoff zu den Reaktionsmischungen wurde zusätzlich die Geschwindigkeitskonstante der Reaktion  $\text{HCO} + \text{O}_2 \rightarrow \text{HO}_2 + \text{CO}$  direkt gemessen. Diese Messungen haben den zugänglichen Temperaturbereich der Geschwindigkeitskonstante auf 1285 bis 1760 K erweitert. Außerdem wurde mit den Messungen ein umfangreicher Mechanismus zur Oxidation von Glyoxal bei mittleren und hohen Temperaturen validiert.

# 1 Introduction

The global requirement for energy, heat, and electricity is continually growing since the industrial revolution. Even though the effort of making regenerative energy sources accessible is considerable, the combustion of fossil fuels like coal, oil, and gas is still required to cover the high energy demand of all industrial nations. Fig. 1.1a summarizes the mix of primary energy supply. The graph shows that about 82% of the world's energy requirement is currently (status 2012) covered by fossil materials and only 13% by renewable sources. In addition, parts of renewable sources, namely bio-fuels and waste, are also based on combustion. As pointed out in Fig. 1.1b, Global Future scenarios assume that combustion will still play the leading role in energy supply in the conceivable future.<sup>[1]</sup>

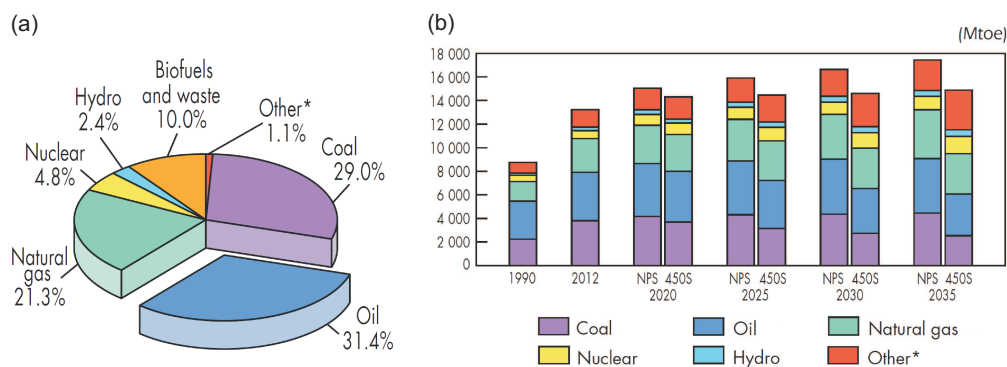

Figure 1.1: a) Fuel share of the world total primary energy supply in 2012 in mega tonnes of oil equivalents (Mtoe). b) Outlook on world total primary energy supply based on New policies Scenario (NPS) and on a post-2012 climate-policy framework (450S). Adopted from Ref. 1. \*: geothermal, solar, wind, heat, etc.

Alternative energy sources to fossil fuels are required because there are several problems connected with their use. Not only are they slowly running out and are expected to become more and more expensive on the long run, also toxic substances are released into the environment by burning of the fuels. The most prominent pollutant gas is carbon dioxide ( $\text{CO}_2$ ), which is known as a major green house gas causing global warming. And in fact the traceable impact of anthropogenic  $\text{CO}_2$  on the environment is constantly growing.<sup>[2,3]</sup> Furthermore, sulfates ( $\text{SO}_2$ , responsible for acid rain), nitrogen oxides ( $\text{NO}_x$ , see section 1.1), polycyclic aromatic hydrocarbons (PAH), and soot particles are formed during combustion.<sup>[4]</sup>

Since combustion will remain crucial for our energy supply, extensive studies are required to promote effective use of fossil fuels and to optimize the combustion processes in general. For a full characterization of combustion processes, a combination of chemical and physical quantities need to be considered. Within flames, mixing (fuel-fuel or fuel-air), transportation, and streaming processes take place that affect the distribution of the reacting species. Also the heat transport and the heat distribution are important factors. Furthermore, myriads of elementary chemical reactions proceed simultaneously in flames and they are strongly coupled to these physical factors.<sup>[5]</sup> A proper reaction mechanism for the combustion of only one combustible easily includes several hundreds of elementary reactions and their temperature and pressure dependencies have to be known. Especially the kinetics of very reactive, mostly radical-like intermediates are important. Different reactive species are formed under different conditions affecting the amount of harmful substances that are produced. A detailed knowledge of the elementary reactions and their rate constants provides the background for the construction of more effective combustors and thereby lower pollutant emissions.

### 1.1 Formation mechanisms and environmental impact of nitrogen oxides (NO<sub>x</sub>)

Subject to combustion conditions different amounts of environmentally harmful nitrogen oxides such as NO, NO<sub>2</sub>, and N<sub>2</sub>O (NO<sub>x</sub>) are generated from the burning of fossil fuels. Released into the atmosphere all nitrogen oxides have diverse, dangerous impacts on the environment over a variety of mostly radical reactions. Which kind of reactions take place is dependent on the particular conditions like temperature, solar radiation, humidity and concentration as well as the nature of the surrounding reactants.<sup>[6,7,8]</sup>

For example, through the photochemical process (1), NO<sub>2</sub> provides atomic oxygen that contributes to the (undesired) formation of the so called “urban ozone” in the troposphere (first layer of the atmosphere, ~ 10 km height).<sup>[7]</sup>

In contrast, in the stratosphere (between 10 - 50 km above the ground) overall ozone concentrations are higher and NO<sub>x</sub> is responsible for the destruction of the ozone layer over a catalytic cycle:

At high humidity levels, NO<sub>x</sub> species will be washed out of the atmosphere and lead to generation of nitric acid according to reaction (6). This elution of nitrogen oxides from the atmosphere contributes

to the formation of acid rain.<sup>[8]</sup>

Depending on the combustion conditions, for example the fuel air ratio  $\phi$ , and the type of fuel, four main pathways of  $\text{NO}_x$  formation can occur.<sup>[5,9,10]</sup>

Figure 1.2: Reaction path diagram abstracting fuel-, thermal-, and prompt-NO formation pathways, according to Glarborg.<sup>[11]</sup>

(i) Fossil fuels like coal naturally contain a certain amount of nitrogen that can be oxidized to NO over several reaction steps (see Fig. 1.2). This so-called fuel-N-conversion especially takes place under fuel-air equivalent ratios below  $\phi < 1.3$ .

(ii) Even if the fuel itself does not contain any nitrogen,  $\text{NO}_x$  formation takes place due to the oxidation of atmospheric nitrogen, called *thermal-NO*. For this pathway, the combustion temperature needs to be very high such that O atoms from the atmospheric oxygen can oxidize the very stable  $\text{N}\equiv\text{N}$  triple bond according to the following mechanism.

This is the so-called Zeldovich mechanism.<sup>[12]</sup>

(iii) Another way to form NO, especially under leaner combustion conditions and at lower temperatures, proceeds through  $\text{N}_2\text{O}$ . According to Wolfrum,<sup>[13]</sup>  $\text{N}_2\text{O}$  can be formed by the recombination reaction (10).

Due to the need for a collision partner M, this mechanism is favored at high pressures.

(iv) The fourth way of  $\text{NO}_x$  formation, the *prompt-NO*, was supposed to proceed according to the Feni-more mechanism for a long time. This mechanism describes the reaction of small hydrocarbon radicals with nitrogen molecules stemming from the combustion air over the spin-forbidden reaction:<sup>[14]</sup>

Although there has not been any experimental evidence of this elementary reaction step, it has been widely accepted for a very long time. The required intersystem crossing (ISC) probability from the doublet to the quartet potential energy surface is actually very low, causing a huge deviation between experimental flame modeling work<sup>[15,16]</sup> and theoretically<sup>[17]</sup> determined rate constants. The measured rate constant data for the reaction  $\text{CH} + \text{N}_2$  are about two orders of magnitude higher than the theoretical estimates for the rate constant of reaction channel (12a).<sup>[18,19]</sup> A solution for this dilemma was found by Moskaleva and Lin in 2000.<sup>[20,21,22]</sup> They introduced a new prompt-NO initiation pathway over the spin-allowed formation of NCN radicals:

Based on quantum chemical methods, Lin and coworkers<sup>[20,23]</sup>, Berman et al.<sup>[24]</sup>, and Harding et al.<sup>[25]</sup> calculated the potential energy surface (PES) diagram for the reaction  $\text{CH} + \text{N}_2$  shown in Fig. 1.3. It can be seen that the formation of  $\text{NCN} + \text{H}$  is thermodynamically unfavorable compared to  $\text{HCN} + \text{H}$  formation, but does not require an ISC process. As the overall energy thresholds for both reaction pathways (12a) and (12b) are similar and, additionally, the first reaction step forming NCN is a simple bond fission process compared to the activation-controlled HCN formation, the spin-allowed reaction channel is dominating the overall reaction. However for the reverse reaction  $\text{NCN} + \text{H}$ , the ISC point is energetically lower than the energy of the educts such that it is likely to produce  $\text{HCN} + \text{N}$ .<sup>[23,26]</sup> The rate constant of the reaction  $\text{NCN} + \text{H}$  has been directly measured in this work for the first time. The accessible reaction channels and the product branching ratios are discussed in chapter 4.

Figure 1.3: Potential energy surface for the reaction  $\text{CH} + \text{N}_2$ , according to Lin and coworkers,<sup>[20,21,23]</sup> Berman et al.,<sup>[24]</sup> and Harding et al.<sup>[25]</sup>

In the meantime, the formation of NCN and its correlation with CH and NO concentrations in flames has been experimentally proven by several laser-induced fluorescence (LIF) studies.<sup>[27,28,29]</sup> Moreover, a shock tube study by Vasudevan et al.<sup>[26]</sup> finally verified that NCN is the main product (> 70%) of the reaction  $\text{CH} + \text{N}_2$ . Consequently, NCN high-temperature kinetics has been implemented into prompt-NO mechanism for flame simulations. Prominent examples are the detailed mechanisms by Konnov (Konnov 0.6 mechanism)<sup>[30]</sup> and Lamoureux et al. (GDFkin3.0\_NCN mechanism)<sup>[31,32]</sup>. Until now, however, due to the lack of experimental data, NCN reaction rates are mostly taken from theoretical predictions and estimations provided by the M. C. Lin group. It was a main objective of this work to make accurate high-temperature bimolecular rate constants available that should improve NCN flame modeling mechanisms.

## 1.2 High temperature cyanonitrene (NCN) kinetics

After Moskaleva and Lin<sup>[20]</sup> proposed NCN to be the main product of the initial prompt-NO reaction  $\text{CH} + \text{N}_2$ , several studies have been performed to detect NCN formation in flames and to provide first high-temperature NCN rate constant data. In 2006 El Bakali et al.<sup>[33]</sup> embedded the prompt-NO pathway and NCN chemistry in the GDF-Kin 3.0 mechanism. Rate constant expressions were adopted from the early estimates of Glarborg et al.<sup>[34]</sup> Already by using these roughly estimated rate constant data they obtained much better agreements between simulated and measured CH and NO concentration profiles for low-pressure methane, ethane, and propane flames than for the mechanism without NCN chemistry, especially under fuel rich conditions. Gersen et al.<sup>[35]</sup> implemented the new prompt-NO reaction (12b) into the combustion mechanism GRI-Mech 3.0<sup>[36]</sup> and could also show significant improvements simulating HCN profiles under fuel rich conditions for a methane-air flame. As expected, the rate constant for reaction (12b) turned out to be crucial and the value from the calculations by Moskaleva and Lin had to be adjusted to improve the simulation results.

Vasudevan et al.<sup>[26]</sup> studied the reaction  $\text{CH} + \text{N}_2$  behind shock waves using NCN and CH laser absorption. They determined the total rate constant for the overall reaction (12) and branching ratios  $\phi = k_{12b}/(k_{12a} + k_{12b})$  at temperatures between 1943 and 3543 K. Their obtained rate constant for the NCN formation is in very good agreement with the results of multi-reference quantum chemical calculations performed by Harding et al. for temperatures between 1000 K and 3000 K.<sup>[25]</sup> Their ab initio calculations also revealed that an accurate value of the enthalpy of formation of NCN is crucial for the resulting rate constant. A work by Goos et al.<sup>[37]</sup> highlighted this issue and reviewed experimental and calculated values for  $\Delta_f H_{298\text{ K}}^\circ(\text{NCN})$ . Values in-between 445 and 501 kJ/mol have been reported in the literature. Most recent studies favor a theoretical value of about 459 kJ/mol,<sup>[23,25]</sup> whereas experiments differ between 452 kJ/mol<sup>[38]</sup> and 467 kJ/mol.<sup>[39]</sup>

A set of rate constants for NCN consumption reactions including  $\text{NCN} + \text{H}$ ,  $\text{NCN} + \text{N}$ ,  $\text{NCN} + \text{C}$  and  $\text{NCN} + \text{CN}$ , calculated using ab initio data and Rice-Ramsperger-Kassel-Marcus (RRKM) theory, was published by Lin and coworkers already in the year 2000.<sup>[20,21]</sup> Later, Lin and coworkers expanded their NCN submechanism by NCN decomposition<sup>[40]</sup> and the reactions  $\text{NCN} + \text{O}_2$ ,<sup>[41]</sup>  $\text{NCN} + \text{NO}$ <sup>[42]</sup> and  $\text{NO}_2$ ,<sup>[43]</sup>  $\text{NCN} + \text{O}$ ,<sup>[44]</sup> and  $\text{NCN} + \text{OH}$ .<sup>[45]</sup> Very recently, they updated their predictions for

the reaction  $\text{NCN} + \text{H}$ .<sup>[23]</sup> In 2008 Sutton et al.<sup>[28,46]</sup> modeled NO and NCN profiles measured by laser-induced fluorescence (LIF) in low-pressure rich, stoichiometric, and lean methane flames. Their simulations of the experimental data could be improved using the NCN rate constant data published by Lin et al. instead of the estimated data from Glarborg et al.<sup>[34]</sup> In a similar study, Konnov<sup>[30]</sup> also adopted the NCN data from Lin and coworkers to work out a mechanism for NCN/NO modeling in lean and rich flames of  $\text{CH}_4$ ,  $\text{C}_2\text{H}_4$ ,  $\text{C}_2\text{H}_6$  and  $\text{C}_3\text{H}_8$ .

Figure 1.4: Reaction scheme for prompt-NO formation in a rich  $\text{CH}_4\text{-O}_2\text{-N}_2$  flame, according to Lamoureux et al.<sup>[31]</sup>

Lamoureux et al.<sup>[31]</sup> combined LIF and cavity ring-down spectroscopy (CRDS) to measure absolute concentration profiles of CH, NCN and NO in methane and ethylene flames. By simulating the measured profiles with the GDFkin 3.0 mechanism, again extended by NCN chemistry taken from Lin and coworkers, the new prompt-NO reaction mechanism was established. The reaction scheme is illustrated in Fig. 1.4. It reveals that the reactions  $\text{NCN} + \text{H}$ ,  $\text{NCN} + \text{OH}$ ,  $\text{NCN} + \text{O}$  and  $\text{NCN} + \text{O}_2$  are the most important NCN reactions along the prompt-NO pathway. It also highlights the fact that the reactions  $\text{NCN} + \text{H}$  and  $\text{NCN} + \text{OH}$  generate HCN, which is the product initially assumed for reaction (12),  $\text{CH} + \text{N}_2$ , in the *traditional* Fenimore mechanism. HCN is further oxidized to NO. Overall, complemented by the intermediate NCN formation, this reaction sequence resembles a straightforward *extended* Fenimore pathway. This finding explains why the *traditional* Fenimore mechanism, despite the wrongly assumed initial products, was actually quite suitable to model experimental findings. However, due to the direct oxidation of NCN by O atoms and  $\text{O}_2$ , CN and NCO are formed, respectively. The most favored reaction process always depends on the combustion conditions and hence the implementation of NCN chemistry is essential.

Other flame modeling groups came to the conclusion that even with the new NCN reaction pathway NO concentrations in flames are still underestimated. Therefore, Konnov<sup>[30]</sup> and Williams and Fleming<sup>[47]</sup> proposed another NCN forming reaction,  $\text{C}_2\text{O} + \text{N}_2 \rightarrow \text{NCN} + \text{CO}$ , to account for the missing NO. At this point, it remains unclear if the persisting discrepancies are real or only reflect uncertainties in the used NCN submechanism. Direct measurements of NCN rate constants are therefore needed to update and validate the proposed NCN mechanisms.

So far, experimental work on NCN high temperature kinetics is scarce and has been accomplished mainly in the Kiel shock tube lab. Dammeier et al. developed the  $\text{NCN}_3$  decomposition behind shock waves in combination with narrow-bandwidth UV laser absorption to generate and detect NCN radicals.<sup>[48,49]</sup> Following a thorough characterization of  $\text{NCN}_3$  thermal decomposition as a source

of NCN radicals,<sup>[48]</sup> in 2011 Dammeier and Friedrichs published direct shock tube studies for the reactions  $\text{NCN} + \text{NO}$  and  $\text{NCN} + \text{NO}_2$ , which are important for the combustion of nitrogen containing fuels.<sup>[50]</sup> Moreover the unimolecular decomposition  $\text{NCN} + \text{M}$ , and the reactions  $\text{NCN} + \text{NCN}$  and  $\text{NCN} + \text{O}$  have been investigated.<sup>[51]</sup> Besides our work, only two other shock tube studies on the reaction  $\text{NCN} + \text{H}$  by Vasudevan et al.<sup>[26]</sup> and  $\text{NCN} + \text{M}$  by Busch et al.<sup>[52,53]</sup> have been performed. In the Arrhenius plot in Fig. 1.5, previous rate constant determinations for NCN reactions (excluding results of this work) are summarized.

Figure 1.5: Summary of Arrhenius expressions for NCN reactions previously studied by Vasudevan et al.,<sup>[26]</sup> Busch et al.,<sup>[53]</sup> and in our working group at the Kiel shock tube lab.<sup>[50,51]</sup>

### 1.3 High temperature nitrosyl hydride (HNO) kinetics

HNO (nitrosyl hydride also called azanone or nitroxyl) is a combustion intermediate that can directly be oxidized to NO and is therefore closely linked to the total  $\text{NO}_x$  concentration (see Fig. 1.4 as well). Most important for combustion modeling are the bimolecular reactions with highly reactive combustion intermediates like H, OH and O, the reaction with  $\text{O}_2$  stemming from the combustion air and the unimolecular decomposition  $\text{HNO} (+ \text{M}) \rightleftharpoons \text{H} + \text{NO} (+ \text{M})$ . NO is one of the main product of all this reactions. Very early (1964 - 1972) experimental rate constant data from measurements in flames are available for the two NO forming hydrogen abstraction reactions

at temperatures between  $1600 \text{ K} < T < 2100 \text{ K}$ .<sup>[54,55,56]</sup> The results of these studies differ by a factor of about 2.6 for reaction (13) and 8.3 for reaction (14). All three analyses show that the reaction with OH radicals is faster than the reaction with H atoms. Rate constant ratios  $k_{14}/k_{13}$  are between 5 and 15, which is consistent with the general trend that OH radicals are more reactive than H atoms for abstracting hydrogen from hydrocarbon molecules. In contrast, more recent theoretical studies

by Soto et al.<sup>[57,58]</sup> and Nguyen et al.<sup>[59]</sup> predicted opposite  $k_{14}/k_{13}$  ratios. The ab initio calculations provide HNO + OH rate constant data close to the experimental data, but significantly higher reaction rates for HNO + H. Clearly, further experimental investigations of this two fundamental NO forming reactions at high temperatures are required.

In 2004, the first study for HNO + O reaction rates at combustion relevant temperatures have been published by Du et al.<sup>[60]</sup> They performed B3LYP density functional calculations for temperatures between 500 and 2500 K and revealed three possible reaction channels with OH + NO being the most favored reaction products. Since no experimental high temperature rate constant data for HNO + O are available, combustion mechanisms often rely on the rate expression from Inomata and Washida measured at temperatures below 473 K.<sup>[61]</sup> For the reaction

there is also only one experimental expression available in the literature, which has been measured at temperatures between 296 K - 421 K.<sup>[62]</sup> Even though this reaction is a major NO source under reducing combustion conditions, only estimated rate expressions are included in most flame modeling mechanisms.<sup>[36,63,64]</sup> The equilibrium between HNO and NO is also an important factor for overall NO concentrations in flames. Especially under oxy-fuel conditions (e.g., under O<sub>2</sub>/CO<sub>2</sub> atmosphere) the reaction  $\text{HNO} (+ \text{M}) \rightleftharpoons \text{H} + \text{NO} (+ \text{M})$  plays a key role for the removal of NO, which is exploited in reburning processes.<sup>[65]</sup> Three recent experimental studies on this reaction, which are in reasonable agreement, have been performed up to temperatures of  $T = 1170$  K.<sup>[66,67,68]</sup> For the combustion of nitrogen containing fuels, existing mechanisms were expanded by the reactions  $\text{HNO} + \text{NO}$ ,<sup>[69]</sup>  $\text{NO}_2$ ,<sup>[70]</sup> and  $\text{NH}_2$ .<sup>[71]</sup> The used rate expressions have been estimated mostly. Overall the existing HNO high temperature kinetic data are not very consistent. Moreover, there is only one study reporting on HNO detection in flames, published by Lozovsky et al.<sup>[72,73]</sup> in 2000. They applied the sensitive intracavity laser absorption spectroscopy (ICLAS) to monitor HNO spectra in low-pressure hydrocarbon flames. So far, HNO has not been detected in shock tube experiments due to low absorption coefficients (see section 2.3.2.). It was the aim of this work to establish a high temperature HNO source, an HNO detection system as well as to directly measure HNO rate constants at high temperatures for the first time.

#### 1.4 High temperature kinetics of the formyl radical (HCO)

The formyl radical (HCO) is a key intermediate along the direct CH<sub>4</sub> oxidation pathway of hydrocarbon (see Fig. 1.6). The bimolecular reactions of HCO with the most important oxygen species O, OH, and O<sub>2</sub>, the HCO thermal decomposition, and the reaction  $\text{HCO} + \text{H}$ <sup>[74]</sup> result in the direct formation of CO. Measured rate constant data for these reactions, crucial for accurate modeling of the overall oxidation process in flames, are mostly stemming from low temperature studies. For example, the reaction  $\text{HCO} + \text{O} \rightarrow \text{CO} + \text{OH}$  has only been measured up to temperatures of  $T = 425$  K.<sup>[75]</sup> For the reaction  $\text{HCO} + \text{OH} \rightarrow \text{CO} + \text{H}_2\text{O}$  only temperature independent, estimated rate constant values are

available.<sup>[76]</sup> A few studies have been performed on the reaction

providing barely consistent results for the activation energy and overall rate constant.<sup>[36,77,78,79]</sup> A recent direct measurement on the rate constant of reaction (16) was performed behind shock waves by Colberg and Friedrichs.<sup>[80]</sup> Their study was carried out at temperatures between  $769 \text{ K} < T < 1108 \text{ K}$ , so below average flame temperatures. A pronounced positive temperature dependence was found indicating a dominating direct abstraction channel. This is in contrast to theoretical work of Hsu et al.<sup>[79]</sup> who predicted an indirect abstraction channel, which is initiated by HCO-O<sub>2</sub> complex formation with a slightly negative temperature dependence, to dominate up to temperatures of 1000 K. Rate constant measurements at temperatures above 1100 K are needed to finally clarify the role of the indirect versus the direct abstraction channel for flame modeling. More direct measurements on rate constants of bimolecular HCO reactions at combustion relevant temperatures would be highly desirable.

Figure 1.6: Reaction scheme of a methane oxidation pathway, according to Najm et al.<sup>[81]</sup>

## 1.5 Aim and structure of this work

To model the overall formation of atmospheric pollutants stemming from combustion processes, high temperature kinetics of many species have to be considered. The experimental studies of this work focus on bimolecular reactions of the two nitrogen containing species NCN and HNO and the key reaction  $\text{HCO} + \text{O}_2$  of the flame intermediate HCO under combustion relevant conditions. These compounds are important intermediates for nitrogen oxide formation and to properly model the overall hydrocarbon oxidation process.

The shock tube method is well established for experimental studies on high temperature rate constants. Combustion relevant experimental conditions are easily accessible behind shock waves and in combination with sensitive absorption measurements, time-resolved concentration profiles of reactive intermediates can be detected. Building on previous studies in our working group, especially of the PhD thesis of J. Dammeier,<sup>[82]</sup> the reactions  $\text{NCN} + \text{H}$ ,  $\text{NCN} + \text{H}_2$  and  $\text{NCN} + \text{O}_2$  should be

measured for the first time. Preliminary measurements of the rate constants of  $\text{NCN} + \text{H}$  and  $\text{NCN} + \text{H}_2$ , performed in the Diploma thesis of the author,<sup>[83]</sup> had to be considerably extended to allow for a thorough analysis including product branching ratios and the unsettled value of the enthalpy of formation of  $\text{NCN}$ . In addition to the experimental work, first flame modeling work was performed in collaboration with N. Lamoureux and P. Desgroux (Université Lille 1, France).

First detection of  $\text{HNO}$  behind shock waves has been achieved by applying the sensitive frequency modulation (FM) spectroscopy. The 193 nm photolysis of glyoxal/ $\text{NO}$  mixtures served as  $\text{HNO}$  source. Detecting the also formed  $\text{HCO}$  as a reference substance, quantitative  $\text{HNO}$  detection was possible. Further the rate constants of the reaction  $\text{HNO} + \text{O}_2$  and  $\text{HCO} + \text{O}_2$  should be directly measured. Updated rate constant data were implemented into a detailed glyoxal oxidation mechanism in collaboration with P. Glarborg (Technical University of Denmark) and P. Marshall (University of North Texas).

This thesis is structured as follows: The basic theoretical background and experimental details of the performed shock tube measurements, applied spectroscopic methods and sample preparation are outlined in chapter 2 and 3. Five papers reporting on the experimental results and their implications follow in separate chapters. For  $\text{NCN}$ , concentration-time profiles have been measured at  $\tilde{\nu} = 30383.11 \text{ cm}^{-1}$  ( $\lambda = 329.1302 \text{ nm}$ ) by difference laser absorption spectroscopy. Rate constants for the reactions  $\text{NCN} + \text{H}$  (chapter 4),  $\text{NCN} + \text{H}_2$  (chapter 5), and  $\text{NCN} + \text{O}_2$  (chapter 6) could be obtained for temperatures of about 1000 K to 2500 K.  $\text{HNO}$  and  $\text{HCO}$  have been detected by FM spectroscopy at wavelengths of about  $\lambda = 618.28 \text{ nm}$  and  $\lambda = 614.76 \text{ nm}$ , respectively. The formation of  $\text{HNO}$  from the photolysis of glyoxal/ $\text{NO}$  mixtures as well as the  $\text{HNO}$  absorption cross section and the rate constant of the reaction  $\text{HNO} + \text{O}_2$  are investigated in chapter 7. Finally, in chapter 8 the results of rate constant measurements on the reaction  $\text{HCO} + \text{O}_2$  are presented.

## 2 Theoretical background

### 2.1 The shock tube method

In 1808 Poisson<sup>[1]</sup> published first theoretical considerations on shock waves in ideal gases. The first apparatus for shock wave generation was built in 1899 by Paul Vieille.<sup>[2]</sup> A schematic picture of a shock tube is shown in Fig. 2.1. In principle the design of this first shock tube, consisting of a high and a low pressure section divided by a membrane, is still common.<sup>[2,3]</sup> At the beginning, shock tubes were applied to study shock wave propagation and reflection behavior.<sup>[4,5]</sup> Later they were also used for experimental studies on high temperature chemical kinetics.<sup>[6]</sup> Today the generation of shock waves is a very well established method to investigate fast gas phase reactions at combustion relevant temperatures. Temperatures between 500 and 15000 K and pressures of  $0.1 \text{ bar} \leq p \leq 1000 \text{ bar}$  are accessible. The over-adiabatic compression and, therefore, the heating of the test gas takes place in less than  $1 \mu\text{s}$ . The reaction conditions can be accurately predicted, provided that the shock wave velocity and the initial conditions of the test gas are known. But they are only stable for a few milliseconds, depending on the shock tube design. Due to spontaneous burst of the membrane and the non-ideal flow behavior of the gas, two experiments will never result in exactly the same reaction conditions. Hence, averaging of several single-shot experiments is not easily possible.<sup>[7]</sup>

#### 2.1.1 Shock wave theory

Shock waves are generated in a closed tube shown schematically in Fig. 2.1. The tube consists of a high pressure (driver) and a low pressure (driven) section divided by a diaphragm (aluminum foil). The low pressure section is filled with the test gas. To generate a shock wave, the high pressure section is filled with an inert driver gas (hydrogen or mixtures of hydrogen and nitrogen) until the diaphragm bursts due to the pressure difference between both sections. Due to the spontaneous rupture of the membrane compression waves are formed which propagate through the test gas section with sonic speed  $a$ .

$$a = \sqrt{\frac{\gamma RT}{M}} \quad (2.1)$$

## 2. Theoretical background

Where  $\gamma = c_p/c_v$  is the adiabatic coefficient and  $M$  is the average molecular mass of the gas,  $T$  is the absolute temperature and  $R$  the gas constant. Due to the adiabatic compression the test gas heats up by a succession of compression waves. Therefore later compression waves travel with higher velocities than the early waves. In addition, the gas starts to flow in the same direction as the compression wave propagation. As a result, the compression waves form a single shock front propagating through the test gas with supersonic speed (about three times the velocity of sound) with respect to the resting, pre-shock gas. The shock wave causes a sudden increase in temperature, pressure and density due to over-adiabatic compression.

Figure 2.1: Schematics of shock wave propagation.

Fig. 2.1 illustrates the wave propagation through a shock tube after the burst of the membrane in a  $t$ - $x$ -diagram. The initial conditions are labeled with the index 1 and the test gas conditions behind the incident shock with index 2. For measurements behind incident shock waves it must be taken into account that the test gas is in motion. When the shock front is reflected at the end plate of the shock tube, the shock wave proceeds through the already compressed (and pre-heated) test gas, brings the test gas to a rest and results in a second temperature and pressure jump. Typically, the temperature  $T$  and pressure  $p$  behind the reflected shock are about two times higher than behind the incident shock. The reaction conditions after the reflected shock wave are labeled with the index 5. Fig. 2.1 also shows the  $t$ - $x$ -traces of the rarefaction waves spreading through the driver section and the contact surface between the driver gas and the test gas following the shock front. If one of these waves reach the measurement point, the measurement conditions are no longer constant and the experiment is over (point 3 in Fig. 2.1).

The measurement point is located close to the end of the low pressure section. The typical pressure (and temperature) profile at this point is shown in a  $p/T$ - $t$  diagram in the right plot of Fig. 2.1. Constant measurement conditions are only achieved for a certain time. Incident shock wave conditions (stable for about 0.5 ms) are limited by the arrival of the reflected shock wave. Temperature and pressure

behind the reflected wave are stable for about 2 ms (for this work).

The temperatures and pressures during shock tube experiments cannot be easily measured directly because they rise abruptly and are constant on short timescales only. So the conditions (temperature  $T$ , pressure  $p$ , and density  $\rho$ ) behind the incident and reflected shock waves have to be calculated. By assuming an ideal flow behavior of the test gas (ideal shock wave), this can be readily accomplished based on the conservation equations of mass, momentum and energy:

$$\text{Mass flow: } \Phi_m = \rho_1 u_1 = \rho_2 u_2 \quad (2.2)$$

$$\text{Momentum flow: } \Phi_i = p_1 + \rho_1 u_1^2 = p_2 + \rho_2 u_2^2 \quad (2.3)$$

$$\text{Energy flow: } \frac{\Phi_e}{\Phi_m} = H_1 + \frac{1}{2} u_1^2 = H_2 + \frac{1}{2} u_2^2. \quad (2.4)$$

Here,  $H$  is the specific enthalpy of the gas and  $u$  is the flow velocity. To determine the shock wave velocity, four fast piezoelectronic pressure transducers are mounted flush into the tube wall in the low pressure section at defined distances. The pre-shock wave conditions (index 1) are also needed, but can be easily measured before every experiment.

The so called *Rankine-Hugoniot*-equations 2.5 - 2.7 for calculation of incident shock wave conditions can be derived from the conservation equations 2.2 - 2.4 by assuming ideal gas behavior. In the case of argon for example the temperature dependence of the enthalpy can be characterized by the caloric equation of states ( $H_2 - H_1 = c_p \times (T_2 - T_1)$ ) and the state variables are connected by the ideal gas law ( $p = \rho RT$ ).

$$\frac{p_2}{p_1} = \frac{2\gamma M_1^2 - (\gamma - 1)}{\gamma + 1} \quad (2.5)$$

$$\frac{\rho_2}{\rho_1} = \frac{(\gamma + 1) \times M_1^2}{(\gamma - 1) \times M_1^2 + 2} \quad (2.6)$$

$$\frac{T_2}{T_1} = \frac{\left(\gamma M_1^2 - \frac{\gamma-1}{2}\right) \times \left(\frac{\gamma-1}{2} M_1^2 + 1\right)}{\left(\frac{\gamma+1}{2}\right)^2 M_1^2} \quad (2.7)$$

Resulting temperatures, pressures, and densities behind the reflected shock waves can then be calculated based on the conditions behind the incident shock waves.<sup>[8,9]</sup>

$$\frac{p_5}{p_2} = \frac{\frac{\gamma+1}{\gamma-1} + 2 - \frac{p_1}{p_2}}{1 + \frac{\gamma+1}{\gamma-1} \times \frac{p_1}{p_2}} \quad (2.8)$$

$$\frac{T_5}{T_2} = \frac{p_5}{p_2} \times \left( \frac{\frac{\gamma+1}{\gamma-1} + \frac{p_5}{p_2}}{1 + \frac{\gamma+1}{\gamma-1} \times \frac{p_5}{p_2}} \right). \quad (2.9)$$

When using polyatomic gases in shock tube experiments, real gas effects have to be taken into account. The heat capacity  $c_p$  can no longer be treated as temperature independent and the calculated experimental conditions have to be determined by numerical procedures.<sup>[9]</sup> When rotational and vibrational

motions of the molecules are excited, the heat capacity increases and in the end the temperature is lower than for a monoatomic gas. Moreover, as the heating of the vibrational degrees of freedom is slow, at first the temperature is higher than expected for a vibrationally equilibrated system. Then, caused by vibrational relaxation, the temperature decreases exponentially and finally reaches the state of the fully equilibrated system. The resulting temperature profile can be approximately calculated by assuming that the pressure is nearly constant.<sup>[9]</sup> In order to minimize relaxation effects, the concentrations of polyatomic reactants should always be kept as low as possible. An example for the need of a significant temperature correction due to the addition of up to 17% O<sub>2</sub> is further outlined in chapter 6.

## 2.2 UV difference laser absorption spectroscopy

To detect NCN radicals in very low concentrations behind shock waves a fairly sensitive spectroscopic method had to be applied. For this work NCN was detected by difference amplification laser absorption spectroscopy at a wavelength of  $\lambda = 329.1302$  nm.

### 2.2.1 NCN spectroscopy

The pyrolysis of NCN<sub>3</sub> mainly leads to the generation of electronically excited <sup>1</sup>NCN radicals. Due to fast collision induced intersystem crossing (CIISC) NCN is subsequently converted into its electronic triplet ground state. Under incident shock wave conditions stable plateau concentrations of <sup>3</sup>NCN could be observed subsequently.

A detailed kinetic study on <sup>3</sup>NCN formation has been published by Dammeier et al.<sup>[10,11]</sup>

The first two electronic states of the linear NCN radical are the  $\tilde{X}^3\Sigma_g^-(010)$  and the  $\tilde{A}^3\Pi_u(010)$  state. In case of the (010) vibration level, the Born-Oppenheimer approximation breaks down and the <sup>3</sup>Π<sub>u</sub> state splits due to coupling of electron and vibration motion (Renner-Teller effect). Additionally, spin-orbit interactions are observed. The electronic ground state  $\tilde{X}^3\Sigma_g^-$  with quantum numbers  $\Lambda = 0$  and  $l = 1$  is converted into a vibronic Π state according to  $K = |\pm \Lambda \pm l|$ . The former Π state with  $\Lambda = 1$  and  $l = 1$  splits into three vibronic Renner-Teller components, the  ${}^3\Sigma_g^+$  and  ${}^3\Sigma_g^-$  states with  $K = 0$  and the degenerated <sup>3</sup>Δ<sub>g</sub> state ( $K = 2$ ).<sup>[12,13,14]</sup>

NCN has been detected by narrow-bandwidth laser absorption at overlapping transitions belonging to the  $Q_1$  branch of the  ${}^3\Sigma^+ - {}^3\Pi$  subband and the vibrationally hot  $\tilde{A}^3\Pi_u(010) - \tilde{X}^3\Sigma_g^-(010)$  system at  $\tilde{\nu} = 30383.11$  cm<sup>-1</sup>. The spectrum is illustrated in Fig. 2.2. The corresponding absorption cross section

$$\log\left(\frac{\sigma}{\text{cm}^2/\text{mol}}\right) = 8.9 - 8.3 \times 10^{-4} \times T/\text{K} \quad (2.10)$$

has been adopted from Dammeier and Friedrichs.<sup>[10]</sup> The stated uncertainty was  $\Delta\sigma = \pm 25\%$ . Under typical experimental conditions applied in this work ( $T = 1500$  K,  $p = 500$  mbar, electronic time-

resolution  $\Delta t \approx 1 \mu\text{s}$ ), minimum detectable NCN concentrations were about  $4 \times 10^{-12} \text{ mol/cm}^3$  (corresponding to mole fractions of a few ppm).

Figure 2.2: High resolution spectra of  $^3\text{NCN}$ . Upper graph: Measured room temperature spectrum. Lower graph: Comparison between simulated spectra at  $T = 298 \text{ K}$  and  $T = 1600 \text{ K}$ , adopted from Dammeier and Friedrichs.<sup>[10]</sup>

## 2.3 Frequency modulation (FM) spectroscopy

Frequency modulation (FM) spectroscopy is an absorption based spectroscopic method, which was used for HNO and HCO detection in this work. Bjorklund<sup>[15]</sup> developed this measurement technique and demonstrated its capability of highly sensitive detection of absorption and dispersion of narrow spectral features. Since then FM spectroscopy has been applied and described in many publications.<sup>[16,17,18,19,20,21,22]</sup> In comparison with conventional absorption methods, FM spectroscopy is more sensitive and can therefore be used for time-resolved detection of small radicals and highly reactive atoms behind shock waves as firstly demonstrated by Friedrichs.<sup>[23,24]</sup>

### 2.3.1 Theory of FM spectroscopy

To perform frequency modulation spectroscopy the light of a narrow bandwidth cw-laser beam has to be phase modulated by an electrooptical modulator (EOM). The principle of FM spectroscopy is illustrated in Fig. 2.3, adopted from Friedrichs.<sup>[21]</sup> The phase modulation at frequency  $\omega_m$  induces first

## 2. Theoretical background

order (and higher order) sidebands, which are  $1 \times \omega_m$  ( $n \times \omega_m$ ) apart from the center frequency  $\omega_0$  of the laser. The modulated signal is monitored by a scanning etalon, which is necessary to properly set the modulation strength and to determine the modulation index  $M = \Delta\omega/\omega_m$ , with  $\Delta\omega$  corresponding to the maximum frequency shift induced by the modulation. By using stronger modulation fields and therefore higher modulation indexes more energy is transferred to the sidebands leading to the generation of higher order sidebands that are displaced by higher integer multiples of  $\omega_m$  from the center frequency  $\omega_0$ . Meanwhile the intensity at center frequency gets lower and disappears at a modulation index of  $M \approx 2.4$ .

In a purely phase (or frequency) modulated beam, the upper and lower sidebands are exactly out-of-phase (phase shift of  $180^\circ$ ). Detecting the light by a photodetector will result in a constant DC signal (null signal), which is proportional to the square of the total light intensity. However, if the two sidebands in Fig. 2.3 are attenuated to a different extent by an absorbing sample, the balance of upper and lower sideband is broken. As a result an amplitude modulated beam with a modulation frequency of  $\omega_m = 2\pi\nu_m$  is observed, which can be detected with a fast photodetector. The amplitude of the corresponding AC signal is proportional to the absorption and hence to the concentration of the absorbing species.

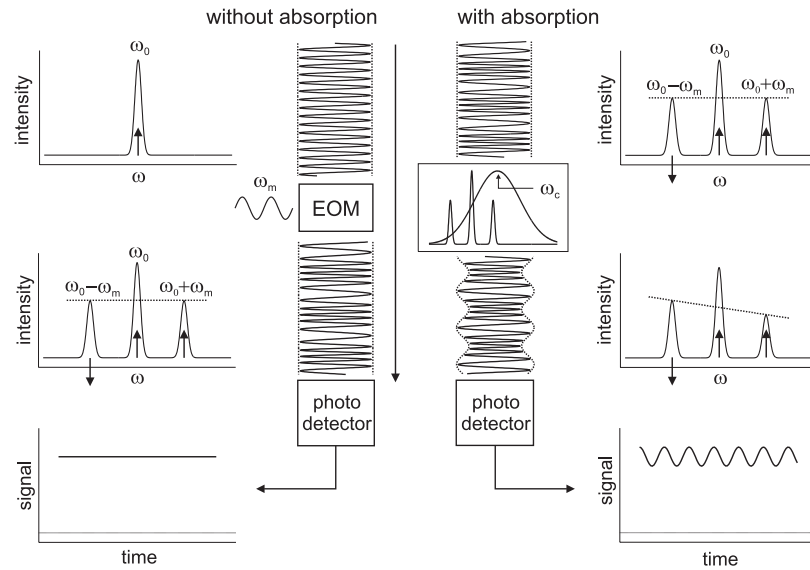

Figure 2.3: Scheme of FM spectroscopy, according to Friedrichs.<sup>[21]</sup>

For quantitative detection of an absorbing species, the relation between the AC FM signal intensity and the concentration of the species has to be known. Sinusoidal phase modulation with the modulation frequency  $\omega_m$ , the center frequency  $\omega_0$ , and the modulation index  $M = \Delta\omega/\omega_m$  yields an electric field of the modulated laser beam, which can be expressed as:<sup>[18]</sup>

$$E(t) = E_0 \exp[i(\omega_0 t + M \sin \omega_m t)] \quad (2.11)$$

$$= E_0 \exp(i\omega_0 t) \sum_{n=-\infty}^{+\infty} J_n(M) \exp(in\omega_m t) \quad (2.12)$$

If the FM light passes through a gas sample, the absorption and dispersion experienced by the center frequency and the side bands can be described by a transmission function  $T(\omega_n)$  resulting in the transmission field:

$$E_T(t) = E_0 \exp(i\omega_0 t) \sum_{n=-\infty}^{+\infty} T(\omega_n) J_n(M) \exp(in\omega_m t) \quad (2.13)$$

The intensity  $I_T(t)$ , detectable by a photodetector, is proportional to  $|E_T(t)|^2$ . Considering only the components with a frequency of  $\omega_m$ , and assuming a weak absorption, the measured FM signal intensity  $I_{\text{FM}}$  can be related to the concentration of the absorbing species by the equation:

$$I_{\text{FM}} = \frac{I_0}{2} \times \Delta f \times \sigma c l \times G \quad (2.14)$$

with the total light intensity  $I_0$ , the narrow-bandwidth absorption cross section at line center  $\sigma$ , the absorption path length  $l$ , the gain factor  $G$  and the FM factor  $\Delta f$ . The factor  $G$  subsumes the total electronic gain factor of the used FM spectrometer (see section 3.2.2.2). The FM factor  $\Delta f$  accounts for the summation over the contributions of all frequency components contained in the frequency spectrum of the modulated light and can be calculated with the knowledge of the line shape data of the probed absorption feature, the modulation frequency  $\omega_m$  and modulation index  $M$  as well as the demodulation phase angle.<sup>[21]</sup>

### 2.3.2 HNO spectroscopy

The 193 nm photolysis of glyoxal/NO mixtures has been used as a source for HNO molecules according to the reaction sequence:<sup>[25]</sup>

HNO is a bent molecule with a bond angle of about  $\sim 120^\circ$ . Its electronic ground state is a singlet (closed shell configuration), which makes HNO a more stable flame species compared to radical-like intermediates. The  $(\tilde{A}^1A'' \leftarrow \tilde{X}^1A')(100 \leftarrow 000)$  transition of HNO has been very well characterized in previous absorption measurements.<sup>[26,27,28,29]</sup> The only detection of HNO at high temperatures has been reported by Lozovsky et al.,<sup>[29]</sup> who measured HNO spectra by ICLAS in flames and compared the absorption intensities of the  $(100 \leftarrow 000)$  transition, around 618 nm, and the  $(011 \leftarrow 000)$  transition, around 643 nm. Although it turned out that the spectra in the  $(011 \leftarrow 000)$  transition range are more intense than in the  $(100 \leftarrow 000)$  range, we used the  $(100 \leftarrow 000)$  transition because its wavelength region is closer to the HCO  $(\tilde{A}^2A'' \leftarrow \tilde{X}^2A')(09^00 \leftarrow 00^10)$  transition at  $\sim 615$  nm. HNO and corresponding HCO measurements have been performed to determine the HNO absorption cross section. In order to find the most suitable absorption line for HNO detection three selected lines of the  $(100 \leftarrow 000)$  transition have been characterized (see chapter 7). The measurements of this work represent the first detection of HNO behind shock waves. The minimum detectable HNO concentrations under typical

## 2. Theoretical background

experimental conditions of  $T = 1000$  K and  $p = 1000$  mbar were about  $1 \times 10^{-10}$  mol/cm<sup>3</sup> (corresponding to a mole fraction of 50 ppm).

### 2.3.3 HCO spectroscopy

HCO radicals were generated from the 193 nm glyoxal photolysis<sup>[30]</sup> or from the thermal decomposition of glyoxal<sup>[31]</sup> and were detected by means of FM spectroscopy. HCO detection behind shock waves has been thoroughly described by Colberg and Friedrichs.<sup>[30]</sup> In accordance with this work, HCO detection was performed at the Q(6)P(1) absorption line of the ( $\tilde{A}^2A'' \leftarrow \tilde{X}^2A'$ )(09<sup>0</sup>0  $\leftarrow$  00<sup>1</sup>0) transition at  $\tilde{\nu} = 16266.61$  cm<sup>-1</sup> (corresponding to the maximum of the FM signal).

For quantitative HCO detection the narrow-bandwidth absorption cross section

$$\ln\left(\frac{\sigma}{\text{cm}^2/\text{mol}}\right) = 6.57 - 1.39 \times 10^{-3}(T/\text{K}) + 3.16 \times 10^{-7}(T/\text{K})^2 - 4.08 \times 10^{-11}(T/\text{K})^3 \quad (2.15)$$

has been adopted from Friedrichs et al.<sup>[32]</sup> The stated uncertainty of  $\sigma$  is about  $\pm 30\%$ . The adopted absorption cross section has been determined for the Q(9)P(2) transition (see Fig. 2.4). With respect to the slightly different absorption features of the actually used Q(6)P(1) line, the absorption cross section from Friedrichs et al. was increased by a factor of  $\sim 1.18$ .<sup>[33]</sup> Under typical experimental conditions of this work ( $T = 1500$  K,  $p = 1300$  mbar), minimum detectable HCO concentrations were about  $5 \times 10^{-10}$  mol/cm<sup>3</sup> (corresponding to a mole fraction of 50 ppm).

Figure 2.4: a) Simulated absorption spectrum of the ( $\tilde{A}^2A'' \leftarrow \tilde{X}^2A'$ )(09<sup>0</sup>0  $\leftarrow$  00<sup>1</sup>0) transition of HCO at room temperature. b) Comparison of measured and simulated HCO FM spectra, adopted from Ref. 33.

## 3 Experimental

Several experimental methods have been applied to study the high temperature kinetics of NCN, HNO, and HCO. The shock tube method was used to heat up the test gases in  $t < 1 \mu\text{s}$  and to achieve stable reaction conditions for about 1 ms. Pressure and temperature values due to shock compression were calculated reliably based on a 1-dimensional shock tube code. NCN, HNO, and HCO have been generated in-situ from precursor molecules which had to be synthesized before the experiments. As the concentrations of the precursors and of all molecules that have been added as reactants have to be known for quantitative measurements, a mixing system with calibrated mass flow controllers was used to prepare reaction gas mixtures. A difference laser absorption setup and an FM spectrometer were used to detect time-resolved concentration profiles of different species in the gas phase. Rate constants were obtained from the experiments by fitting numerical simulations to the measured concentration-time profiles. Under the applied reaction conditions, the respective target reaction was always the most important one for the simulations.

The different experimental setups and numerical methods for the investigation of NCN, HNO, and HCO reactions in the gas phase are described in this chapter.

### 3.1 Shock tube setup

All high temperature measurements have been carried out in an overall 8.35 m long stainless steel shock tube with an inner diameter of 81 mm and a 10 mm thick wall. The 3.65 m long driver (high pressure) section was slightly shorter than the 4.05 m long, electro-polished test (low pressure) section. By a combination of an oil-free turbomolecular (Pfeiffer Vacuum, TMU261) and a membrane pump (Pfeiffer Vacuum, MVP055-3) the test section could be evacuated down to a pressure of  $p \approx 10^{-7}$  mbar. A cold-cathode ionization gauge (Pfeiffer Vacuum, IKR 261) was used for pressure measurements in the test section. The pressure of the test gas in the low pressure section before shock compression could be measured by a second pressure gauge (MKS 622AX12MBE). The leak rate of the metal sealed test section was  $1.6 \times 10^{-6}$  mbar L/s.

The high pressure section was mounted on wheels such that the aluminum foil dividing the high pressure section from the test section (low pressure section) could be easily exchanged. The driver section was filled with a driver gas until the foil burst spontaneously. Either 30, 80 or 100  $\mu\text{m}$  thick aluminum foils were used. In combination with the used driver gases hydrogen (Air Liquide,  $\geq$

### 3. Experimental

---

99,999%), helium (Air Liquide,  $\geq 99,999\%$ ), or different mixtures of hydrogen and nitrogen (Air Liquide,  $\geq 99,99\%$ ) temperatures between 700 and 2500 K after incident shock waves were accessible. Also a wide pressure range of  $0.2 \text{ bar} \leq p \leq 2.1 \text{ bar}$  was within reach. The mixing of two different driver gases was accomplished by two magnetic valves (Danfoss, BA024A), which could be separately opened for particular times between 25 and 475  $\mu\text{s}$  by an electronic controller. After an experiment the shock tube could be flushed with nitrogen to remove remaining pieces of aluminum foil. The test gas was passed into the test section by a tubing system that connected the shock tube head with the gas mixing system. Before an experiment the test gas mixture was flushed through the test section for about 3 min to minimize possible effects due to adsorption effects on the shock tube wall.

To determine the shock wave velocities needed for the calculations of experimental pressures and temperatures, four fast pressure transducers (PCB Piezotronics M 113A21) were embedded flush to the shock tube walls of the test section at defined positions. They were connected to a fast count unit. For spectroscopic measurements the laser beam was coupled into the shock tube head through two quartz windows. The observation time behind the incident wave was determined by the distance between the observation plane and the end plate of the shock tube head. This distance could be varied between 19 mm and 60 mm by installing an additional tube part, resulting in observation times of approximately  $200 \mu\text{s} \leq t \leq 600 \mu\text{s}$  behind the incident shock wave.

#### 3.1.1 Flow cell

FM measurements of HNO and HCO at room temperature were carried out in a 45 cm long glass flow cell that could be integrated into the shock tube setup. The two quartz windows at both ends of the cell were mounted in Brewster angle. To avoid depositions of reaction products, the windows could be flushed with nitrogen during the experiments. During the FM measurements the detection laser beam and the photolysis beam, with a much larger diameter, were collinearly coupled into the cell from opposite sides. The large diameter of the photolysis laser guaranteed that diffusional processes could be neglected. Two pressure gauges (5 mbar and 100 mbar) were attached to the cell to adjust the test gas flow during the experiments.

#### 3.1.2 Gas mixing system

For the preparation of well defined gas mixtures the gas mixing system shown schematically in Fig. 3.1 was used. The prepared gas mixtures were stored in different tanks and passed into the test section of the shock tube through a valve in the shock tube head. Since the test section was evacuated near the membrane (end of test section) the test gas could be flushed through the whole section to compensate for possible wall adsorption effects. Alternatively the test gas was led to the flow cell. The mixing system mainly consisted of stainless steel tubing. For the storage and preparation of gas mixtures by the partial pressure method, gas bottles, glass flasks and tanks of stainless steel could be connected to the system. It was possible to purify gases like NO and NO<sub>2</sub> by freeze-pump-thaw cycles performed in a 5 L flask equipped with a cooling finger. The NCN<sub>3</sub> was only diluted in argon and not further

purified due to its tendency to explode in condensed phase. The prepared gas mixtures were passed through four different mass flow controllers (Aera, FC-7700CU 10, 50, 100 and 1000 sccm) for further mixing and dilution (mostly in argon) directly before entering the shock tube. A rotary vane pump with a cooling trap was used for fast evacuation of the gas mixing system and the test section of the shock tube. To avoid condensation of  $\text{NCN}_3$  in the cooling trap it could be evacuated over a bypass (see Fig. 3.1). For evacuation down to pressures of  $\sim 10^{-6}$  mbar, a turbomolecular pump (Pfeiffer Vacuum, TMH071-P) together with a diaphragm pump (Pfeiffer Vacuum, MVP 015-2) was used. Three different pressure gauges (MKS 722AMCE2FA, MKS 622AX12MBE, Pfeiffer Vakuum PKR 251) allowed to measure the pressure in the range of  $5 \text{ bar} \geq p \geq 10^{-7}$  mbar.

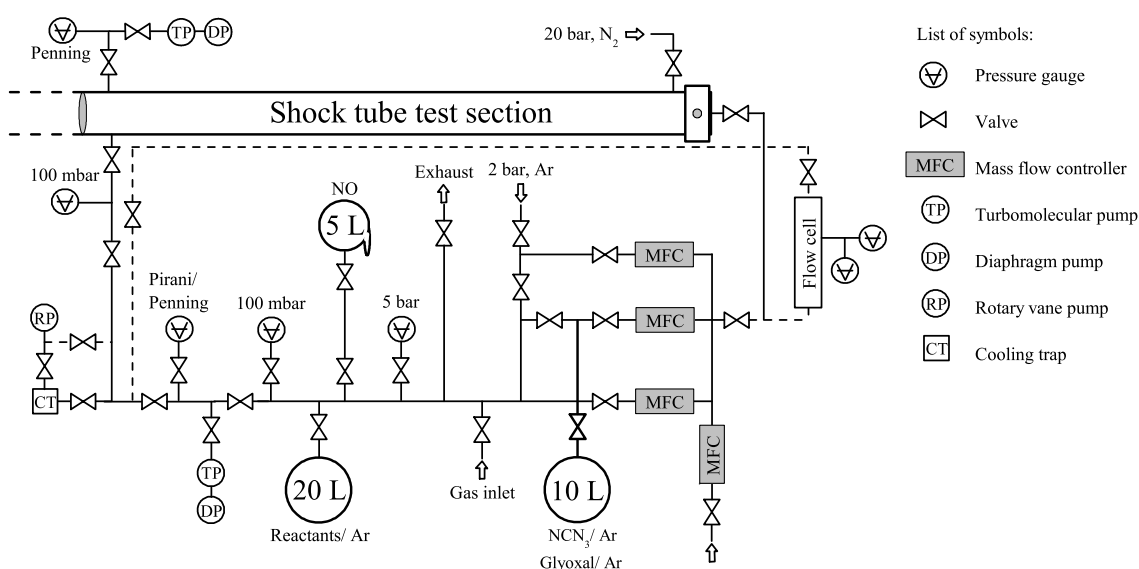

Figure 3.1: Scheme of the gas mixing system, which could either be connected to the shock tube head or a flow cell.

## 3.2 Absorption spectrometer

UV/VIS spectroscopy was used for the detection of  $\text{HNO}$ ,  $\text{HCO}$ , and  $\text{NCN}$  radicals. By absorption based measurements of selected electronic transitions the different species could be directly observed. Assuming that the particular absorption cross sections are known it was possible to determine the concentrations of the species in the reaction mixture. In the visible spectral region, frequency modulation (FM) spectroscopy was used for highly sensitive detection of  $\text{HNO}$  and  $\text{HCO}$  ( $(\alpha cl)_{\min} = 5 \times 10^{-5}$ ). Since FM spectroscopy cannot be used in the UV region,  $\text{NCN}$  was detected by narrow-bandwidth difference laser absorption (DLA) spectroscopy ( $(\alpha cl)_{\min} = 5 \times 10^{-4}$ ) instead.

### 3.2.1 UV difference absorption spectrometer

Fig. 3.2 illustrates the schematic setup for the UV absorption experiment. The UV light ( $\lambda \approx 330 \text{ nm}$ ) was generated by intra-cavity frequency doubling of a continuous-wave ring-dye laser (Coherent 899

### 3. Experimental

series), which was optically pumped by a solid state Nd:YVO<sub>4</sub> laser (Coherent Verdi V10). A LiIO<sub>4</sub> crystal, which was constantly flushed with boil-off nitrogen, was inserted in the laser cavity to achieve the frequency doubling. Typically, at 10 W pumping power, 1.5 mW UV light were generated. About 2 mW of the laser fundamental were coupled out of the cavity through a highly reflective mirror for wavelength measurements by an interferometric wavemeter (MetroLux WL200) referenced to a HeNe laser. By this means, taking into account a small wavemeter offset of  $\Delta\tilde{\nu} = 0.02 \text{ cm}^{-1}$ , the wavelength could be determined with an accuracy of about  $5 \times 10^{-7}$  ( $\Delta\tilde{\nu} = 0.015 \text{ cm}^{-1}$ ). Using DCM-Spezial (4-Dicyanomethylen-2-methyl-6-p-dimethyl-aminostyryl-4H-pyran, Radiant Dyes) as a laser dye the wavelength of the fundamental could be set to  $\tilde{\nu} = 15191.56 \text{ cm}^{-1}$ , hence the frequency-doubled laser beam was centered at  $\tilde{\nu} = 30383.11 \text{ cm}^{-1}$  to observe the  $^3\Sigma^+(010) - ^3\Pi(010)$   $^3\text{NCN}$  transition.

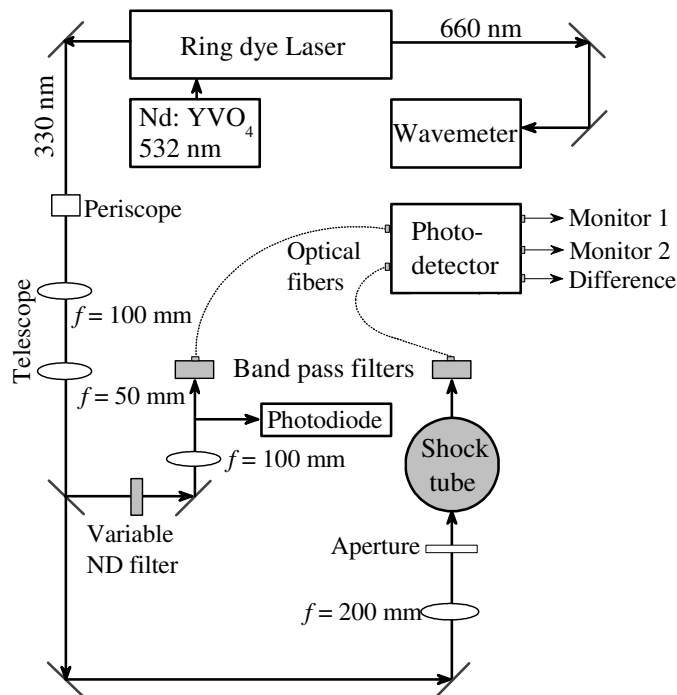

Figure 3.2: Scheme of the difference laser absorption spectroscopy setup.

The generated UV laser beam was deflected by a periscope to adjust the height of the laser beam to the height of the shock tube and collimated to a diameter of about 2 mm by a telescope. A 50:50 beam splitter plate was used to split the laser beam into a probe and a reference beam. The detection beam was focused by a quartz lens ( $f = 200 \text{ mm}$ ) and passed through the shock tube windows. After passing the shock tube the beam was band-pass filtered (Andover, 326FS25-12.5) and coupled into a quartz optical fiber (Thorlabs BF H22-550) connected to a balanced photodetector and difference amplifier (Thorlabs PDB 150A-EC). The reference beam was passed through a circular variable neutral density filter to match the intensity of the reference beam with the intensity of the probe beam. The intensities of the two separated beams (Monitor 1 and 2 in Fig. 3.2) were monitored on a digital oscilloscope (Hameg, HM 507, 50 MHz, 8 Bit). As the monitor exhibit a low time response, in order to check the stability of the laser beam, about 10% of the reference beam were split off the main beam by a quartz plate and were focused on a fast Si photodiode (Hamamatsu S5973-2). The finally resulting amplified

difference signal from the balanced photodetector was low-pass-filtered (1.4 MHz), further amplified (Ortec Fast Preamp 9305, 18 dB) and stored by an analog input board (Measurement Computing, PCI-DAS4020/12, 20 MHz, 12 bit).

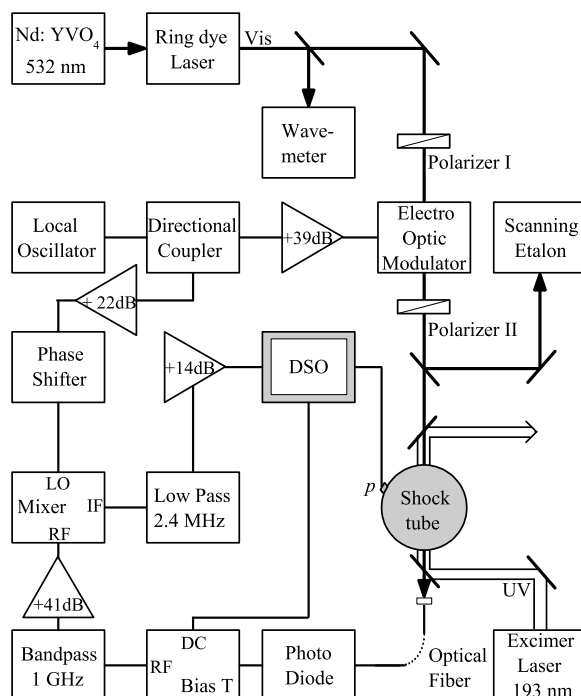

Figure 3.3: Block diagram of the used FM setup.

### 3.2.2 FM spectrometer

The basic FM setup for the HNO and HCO detection is schematically shown in Fig. 3.3. The ring-dye laser (Coherent 899 series) was operated with the dye Kiton Red (Sulforhodamine B, Radiant Dyes), thereby wavelength between 600 and 650 nm were accessible. The narrow-bandwidth laser beam was focused by a telescope, passed through a first polarizer (New Focus Inc., 5524), was phase-modulated by an external electro-optical modulator (EOM, New Focus Inc., 4421) and then passed a second polarizer. The two polarizer setup was necessary to properly set the input polarization with respect to the EOM crystal axis and to conveniently set the demodulation phase angle (see Section 1.2.2.1).

The EOM was driven by a part of the power of a local oscillator (Hewlett Packard, 8657B) providing the modulation frequency of 1000 MHz. The initial output power of the oscillator was divided by a bidirectional coupler (Mini Circuits ZFDC-10-5). The power for the EOM was amplified by 39.4 dB (Hughes 10 W Series) and could be varied by additional attenuators (between  $-1$  dB and  $-3$  dB) to obtain different modulation indices up to  $M = 1.7$ . To monitor the exact modulation index, a small part of the laser beam was split off and analyzed by a scanning etalon (Coherent, Typ SM 240-1).

The frequency modulated detection beam was focused ( $f = 300$  mm) before passing the shock tube head and was then coupled into an optical fiber right after the shock tube window. The fiber output was strongly refocused ( $f = 25$  mm) onto a fast Si photodiode (Hamamatsu, S5973) with a photo active

diameter of 0.4 mm. The signal collected by the photodiode was divided into its AC and DC component by a Bias Tee (Mini Circuits, ZFBT-4R2G). The DC component was directly monitored with a digital oscilloscope (Lecroy, Wavesurfer 454) without further amplification. The AC component, on the other hand, was filtered by a tunable bandpass filter (Trilithic) at 1 GHz, amplified by 41 dB (Mini Circuits, ZHL 0812 HLN) and fed into the signal input of a double balanced frequency mixer (Mini Circuits, 5542-ZFM-2000) for demodulation. The reference signal input for the frequency mixer came from the coupled line of the bidirectional coupler, which was connected to the local oscillator (Hewlett Packard, 8657B). The phase and thereby the demodulation angle of the resulting demodulated signal was adjusted by a variable phase shifter (Knick, J45). The demodulated signal was low pass filtered (2.5 MHz, Mini Circuits, SLP-2.5), amplified by 14 dB (Stanford Research System, SR445A) and stored in the digital oscilloscope (Lecroy, Wavesurfer 454).

**3.2.2.1 Setting of the demodulation angle** For a strong FM signal reflecting the pure absorption of the sample, the demodulation phase angle  $\theta$  had to be set to  $0^\circ$  or  $180^\circ$  degrees. This setting could be accomplished by the two-polarizer setup as described by Friedrichs and Wagner.<sup>[1]</sup> For normal operation the polarization of the two polarizers in front and behind the EOM was set vertically to the axis of the modulation crystal. By rotating one of the polarizers by a few degrees a small amplitude modulation was induced in addition to the phase or frequency modulation. This amplitude modulation is out-of-phase with respect to an absorption signal and causes an offset of the FM baseline. Rotating the second polarizer back and forth resulted in a strong positive and negative FM baseline shift if the phase angle was far from pure absorption ( $0^\circ$  or  $180^\circ$ ). Then, by changing the demodulation phase angle, by the voltage controlled phase shifter (Knick, J45) until the observed baseline shifts virtually disappeared, it was possible to set the demodulation electronics to a phase angle, which is close to the pure absorption case ( $\pm 2^\circ$ ). Finally, the polarizers were rotated back to normal operation.

**3.2.2.2 Gain factor determination** For quantitative FM measurements the FM factor  $\Delta f$  and the gain factor  $G$  of the particular experimental setup had to be known. On the one hand, the gain factor as a value for the overall electronic amplification of the used FM spectrometer needed to be determined experimentally prior to the actual measurements.<sup>[1]</sup> On the other hand, the FM factor could be calculated based on the value of the modulation index and the line shape data for the absorbing species. In this work the gain factor  $G$  has been determined according to the scanning etalon method resulting in  $G = 184 \pm 14$ . This value was in good agreement with the gain factor estimated from the used electronic components and quantitative measurements of HCO radical concentrations.

**Scanning etalon method:** A scanning etalon in reflective mode was integrated into the beam path of the usual FM setup.<sup>[2,3]</sup> In this mode, the etalon acted like a narrow-bandwidth absorber resulting in a measurable FM spectrum. As an example, a typically measured FM spectrum and the corresponding absorption spectrum (measured by monitoring the attenuation of the total light intensity using the DC output of the Bias Tee) are depicted in Fig. 3.4. From these spectra the  $G$  factor could be directly

calculated using the equation

$$G = \frac{2 \times I_{\text{FM}}}{A \times I_0 \times \Delta f}. \quad (3.1)$$

Here,  $A$  is the absorption measured at the center of the peaks corresponding to the first upper and lower sidebands, and  $I_0$  is the intensity of the DC output of the Bias Tee.

Figure 3.4: a) Measured FM signal and b) corresponding absorption signal from the scanning etalon used as narrow-bandwidth absorber.

**FM electronic setup:** In principle, it is possible to calculate the gain factor from the amplifications (attenuations) of all the used electronic components and the characteristics of the photodiode. Instead of using the data specified by the manufactures, the actual amplification and attenuation values have been determined experimentally. For it, a first frequency generator (Hewlett Packard, 8657B) was used to provide a signal with a frequency of  $\nu = 1.000$  GHz and a defined amplitude. This signal and a second signal with a frequency of  $\nu = 1.001$  GHz from a second frequency generator (Marconi Instruments, 2023) were connected to the inputs of the frequency mixer and its output has been displayed with an oscilloscope. From the amplitude of the resulting 1 MHz sinusoidal signal and the amplitude of the 1.00 GHz signal the attenuation of the frequency mixer was determined. Next, the other electronic devices were integrated in-between the first frequency generator and the frequency mixer. The resulting signal amplitudes measured with the oscilloscope with and without the integrated device directly reflected the attenuation or amplification resulting from this specific device. Tab. 3.1 shows the results for the electronic devices of the used FM setup. The only thing that could not be quantified for the determination of the gain factor was the exact frequency-dependence of the responsivity of the used photodiode. This value had to be estimated from technical data. The sum of all specific amplifications, taking a small loss due to the cables and connections into account, resulted in a maximum gain factor of  $G_{\text{max}} = 238$ . Together with  $G_{\text{Diode}} = 0.8$  estimated for the used photodiode an overall gain factor of  $G = 190$  could be determined. Taking into account the uncertainties, this estimate was in very good agreement with the result from the scanning etalon method.

Table 3.1: Measured amplification of FM electronic components.

**HCO absorption measurements:** Concentration-time profiles of HCO, a species with a known absorption cross section<sup>[4,5]</sup> which has been previously measured with an accuracy of  $\pm 30\%$ , have been detected to test the determined gain factor. HCO was generated from the thermal decomposition of glyoxal, which has been studied extensively in previous work.<sup>[6]</sup> Shock tube experiments with well known mole fractions of glyoxal (about 1% in argon) were performed at temperatures between 1299 and 1757 K (see chapter 8). The measured HCO profiles and maximum intermediate HCO concentrations could be very well reproduced by simulations using the adopted HCO cross section and glyoxal mechanism from Friedrichs et al.<sup>[6]</sup> together with the determined gain factor of  $G = 184$ . In fact, the HCO concentration maxima could be reproduced with an accuracy of about 10%. This is well within the uncertainty of the method and indicates an accurate gain factor.

### 3.3 Numerical Methods

#### 3.3.1 Data analysis

Extensive reaction mechanisms containing a huge number of elementary reaction steps are necessary to describe combustion processes. Although the number of reactants in shock tube experiments is comparably small numerical procedures are required to simulate the measured concentration-time profiles.

The fitting procedures for all the experimental data of this work have been performed by the Chemkin-II program package.<sup>[7]</sup> The program performs the numerical integration of a high number of reactions with rate constants given in terms of the extended Arrhenius expression:

$$k_i = A_i T^{n_i} \exp[-E_{a,i}/RT]. \quad (3.2)$$

The core mechanism as well as a feasible set of rate constants were adopted from previous results of the working group Friedrichs and recent literature data. An additional background mechanism was

added to the core mechanism to take possibly important secondary chemistry into account. The core reaction mechanisms for NCN, HNO and HCO simulations are presented in chapters 4 - 8, respectively. Either the GRI-Mech 3.0<sup>[8]</sup> or the GDFkin3.0\_NCN<sup>[9,10]</sup> have been used as background mechanisms. For the simulation of HCO concentration-time profiles measured during the thermal decomposition of glyoxal, a new glyoxal oxidation mechanism has been developed in collaboration with P. Glarborg, Technical University of Denmark, and P. Marshall, University of North Texas, (see chapter 8). To run the Chemkin-II program and to calculate the reverse rate constants the thermodynamic data for all involved species had to be included in form of NASA-polynomials. Thermodynamic data have been adopted from the databases of Goos et al.<sup>[11]</sup> and Konnov.<sup>[12]</sup> Additionally, the initial reaction conditions had to be specified. For the determination of a rate constant  $k_x$ , its value has been changed during the fitting procedure until the simulated and the measured profile were in good agreement. By using the Senkin routine sensitivity analyses have been performed.<sup>[7]</sup> Sensitivity coefficients  $\sigma$  provide informations about how much the resulting simulation was influenced by the rate constant of a certain reaction. Sensitivity analyses allows one to design the experiments in a way that they are most sensitive to the rate constant under study. In a sensitivity analysis the rate constants of all reactions are individually varied by a factor  $a_i$  (starting with  $a_i = 1$ )

$$k_{i, \text{ varied}} = a_i \times A_i T^{n_i} \exp[-E_{a,i}/RT] \quad (3.3)$$

To get comparable values of sensitivity coefficients  $\sigma(i, j, t)$ , they were normalized as follows

$$\sigma(i, j, t) = \frac{\partial c(i, j, t)}{\partial a_i} \quad (3.4)$$

$$\sigma_{\text{max}}^{\circ}(i, j, t) = \sigma(i, j, t) \times \frac{a_i}{c_{\text{max}}(j)}. \quad (3.5)$$

Home-written Gnuplot<sup>[13]</sup> routines were used for further processing of the experimental and simulated data. Fitting of analytical functions was performed with the program Origin.<sup>[14]</sup>

### 3.3.2 Quantum chemical calculations

Quantum chemical calculations on the reaction  $\text{NCN} + \text{H}_2 \rightarrow \text{HNCN} + \text{H}$  were carried out using the Gaussian 09 suite of programs.<sup>[15]</sup> Formation enthalpies were calculated on the G4 level of theory and the transition state of the reaction was located and verified by using a synchronous transit-guided quasi-Newton method (QST3 option) and intrinsic reaction coordinate following.

## 3.4 Synthesis of precursor molecules

HNO, HCO, and NCN are short-lived species and had to be generated directly during the experiments by photolysis and/or pyrolysis of precursor molecules. The used precursors are not stable, not commercially available and therefore they were synthesized in the following manner.

3.4.1 Cyanogen azide (NCN<sub>3</sub>) synthesis

Figure 3.5: Schematic setup of the equipment for the NCN<sub>3</sub> synthesis. DP: Diffusion pump, CT: Cooling trap, OP: Oil pump, P: Pressure gauge, V: Valve.

The NCN radicals were generated from the 193 nm pyrolysis of NCN<sub>3</sub> molecules behind shock waves according to the reaction sequence:

The initial thermal decomposition of NCN<sub>3</sub> yields NCN in its first electronically excited singlet state, it is converted into the triplet ground state by a collision induced inter system crossing (CIISC) process.<sup>[16,17]</sup> According to studies of Bock and Dammel<sup>[18]</sup> as well as Benard et al,<sup>[19]</sup> cyanogen azide (NCN<sub>3</sub>) pyrolysis quantitatively yields <sup>3</sup>NCN. Since cyanogen azide is known to be a toxic and, especially in condensed phase, a highly explosive substance, it was synthesized in the gas phase by a variation of a method from Milligan et al.<sup>[20]</sup> For safety reasons, no attempt was made to purify NCN<sub>3</sub> after synthesis. Instead, the reactants were applied in very high purity. In the glass apparatus illustrated in Fig. 3.5, gaseous cyanogen bromide was passed into a 1000 mL flask containing a huge excess of solid sodium azide.

About 10 g (150 mmol) of very finely pestled sodium azide were degassed *i. vac.* at  $2 \times 10^{-4}$  mbar overnight to remove impurities of H<sub>2</sub>O and CO<sub>2</sub>. Directly before the start of the reaction, 0.25 g (2.4 mmol, mass before purification) BrCN were also degassed *i. vac.* ( $2 \times 10^{-4}$  mbar) at  $T = -78^\circ \text{C}$  for about 10 min and were passed through a molecular sieve (3 Å) to remove H<sub>2</sub>O. This procedure was repeated after BrCN was re-sublimated in a second flask. The purified BrCN was then evaporated into the sodium azide containing flask and the flask was closed vacuum tight. The reaction mixture was allowed to stand for 8 h and was carefully shaken every 30 min to guarantee a complete mixing of the reactants, which is important for a high yield of NCN<sub>3</sub>. The amount of the initially applied BrCN

was chosen in a way that the resulting partial pressure of  $\text{NCN}_3$  never exceeded 50 mbar (the reported approximate vapor pressure of  $\text{NCN}_3$  at room temperature). Hence, care was taken that the highly explosive compound would never condense in the reaction flask. Immediately after the end of the reaction time, the gaseous reaction product was analyzed by FT-IR spectroscopy to control the purity. The described synthesis procedure typically yields  $\text{NCN}_3$  in purities of  $> 97\%$ .  $\text{NCN}_3$  decomposes due to bimolecular reactions slowly forming dimers and polymers. It was directly diluted with Argon ( $x(\text{NCN}_3) \leq 0.1\%$ ) in a 10 L glass flask and was used within 3 days. The  $\text{NCN}_3$  loss in the mixture was about 10% per day.

### 3.4.2 FT-IR spectra of $\text{NCN}_3$

The yield of the synthesized  $\text{NCN}_3$  was always checked by FT-IR analysis to detect possible impurities of  $\text{H}_2\text{O}$ ,  $\text{CO}_2$  and to determine the fraction of unreacted  $\text{BrCN}$ . The used spectrometer (Bruker, IFS 66V, resolution:  $0.25 \text{ cm}^{-1}$ ) has been calibrated using different  $\text{BrCN}$  concentrations beforehand.<sup>[21]</sup>  $\text{BrCN}$  absorption at  $\tilde{\nu} = 2530 \text{ cm}^{-1}$  served as an indicator for the quantification of  $\text{BrCN}$  impurity when the total pressure in the probe cell was known.

Figure 3.6: IR spectrum of the reaction products of a typical  $\text{NCN}_3$  synthesis with a yield of  $x(\text{NCN}_3) \approx 99\%$  measured at  $p = 2.5 \text{ mbar}$  and  $T = 298 \text{ K}$  in a 10 cm long measuring cell.

Fig. 3.6 shows a typical IR spectrum of a  $\text{NCN}_3$  sample. Three fundamental vibration bands of  $\text{NCN}_3$  occur in the observed wavelength region, assignment of the  $\text{NCN}_3$  transitions is listed in Tab. 3.2 and was taken from Bak et al.<sup>[22]</sup> The spectrum also shows a very weak  $\text{CO}_2$  peak (mole fraction  $< 0.2\%$ ) but almost no visible signs of  $\text{H}_2\text{O}$ . The wavelength region around  $\tilde{\nu} = 2530 \text{ cm}^{-1}$  where a  $\text{BrCN}$  signal would be expected to be visible in the spectrum is magnified in the inset. Almost no signal is detectable corresponding to  $\text{BrCN}$  impurities well below 1%.

### 3. Experimental

Table 3.2: Band position for  $\text{NCN}_3$  and impurities of the reaction product obtained from synthesis.

$\text{NCN}_3$	This work/ $\text{cm}^{-1}$	Literature data/ $\text{cm}^{-1}$
$-\text{N}_3$ (sym. str.)	1232-1262	1246 <sup>[22]</sup>
$-\text{N}_3$ (asym str.)	2079-2155	2198 <sup>[22]</sup>
$-\text{C}\equiv\text{N}$ (str.)	2181-2261	2248 <sup>[22]</sup>
Impurities		
$\text{H}_2\text{O}$ (sym + asym. str.)	3564-3925	3570-3760 <sup>[23]</sup>
$\text{H}_2\text{O}$ (bending)	1400-1770	1600-1630 <sup>[23]</sup>
$\text{BrCN}$ (combination band)	2520-2535	2495-2565 <sup>[24]</sup>
$\text{CO}_2$ (asym. str.)	2313-2367	2349 <sup>[25]</sup>

For comparison, a second IR spectrum is shown in Fig. 3.7. Here, a large amount of  $\text{H}_2\text{O}$  and  $\text{CO}_2$  is present most likely due to a leakage in the synthesis apparatus. Additionally the clearly visible  $\text{BrCN}$  peak, corresponding to a mole fraction of  $\sim 50\%$ , indicates that too much  $\text{BrCN}$  was used or that the reaction time was too short. Such a poor result of the synthesis was an exception. For the kinetic measurements only mixtures with an  $\text{NCN}_3$  yield of at least 97% have been used.

Figure 3.7: IR spectrum of an  $\text{NCN}_3$  synthesis with significant amounts of impurities measured at  $p = 2.3$  mbar and  $T = 298$  K in a 10 cm long measuring cell.

#### 3.4.3 Glyoxal synthesis

The glyoxal monomer  $((\text{CHO})_2)$  has been prepared by dehydration of the trimer hydrate  $((\text{CHO})_2)_3 \times 2\text{H}_2\text{O}$  according to reaction (4).

FT-IR analysis showed that this procedure yielded glyoxal monomers without the impurities of H<sub>2</sub>O and CO<sub>2</sub>.<sup>[5]</sup> One eq. of the trimer was mixed with 3 eq. of phosphoric anhydride (P<sub>2</sub>O<sub>5</sub>) and some silica sand. The mixture was slowly heated to a temperature of  $T = 155^\circ\text{C}$  *i. vac.* ( $2 \times 10^{-2}$  mbar). A slight pressure rise indicated the formation of the gaseous reaction products, which were passed through a first cooling trap ( $T = 0^\circ\text{C}$ ) to remove impurities, for example water. The yellow (CHO)<sub>2</sub> crystals were re-sublimated in a second cooling trap ( $T = -78^\circ\text{C}$ ). The solid glyoxal crystals could be stored in liquid nitrogen over a longer time period. When preparing the mixtures of  $\sim 1 - 2\%$  glyoxal in argon, the first few mbar of sublimating (CHO)<sub>2</sub> were always pumped off. The glyoxal/argon mixtures were used within a few days because glyoxal tend to form polymeres that deposit on the walls of the storage tank.

Own contributions:

Prior to dissertation:

- Shock tube experiments.
- Preliminary data analysis.

During the dissertation:

- Complete re-Analysis of the experimental data considering multiple product channels for the reaction  $\text{NCN} + \text{H}$  and new data for  $\text{C}_2\text{H}_5\text{I}$  decomposition
- Discussion on product branching ratio and  $\text{NCN}$  enthalpy of formation.
- Writing of paper draft.

## Abstract

The overall rate constant of the reaction (2),  $\text{NCN} + \text{H}$ , which plays a key role in prompt-NO formation in flames, has been directly measured at temperatures  $962 \text{ K} < T < 2425 \text{ K}$  behind shock waves.  $\text{NCN}$  radicals and  $\text{H}$  atoms were generated by the thermal decomposition of  $\text{NCN}_3$  and  $\text{C}_2\text{H}_5\text{I}$ , respectively.  $\text{NCN}$  concentration-time profiles were measured by sensitive narrow-line-width laser absorption at a wavelength of  $\lambda = 329.1302 \text{ nm}$ . The obtained rate constants are best represented by the combination of two Arrhenius expressions,  $k_2/(\text{cm}^3\text{mol}^{-1}\text{s}^{-1}) = 3.49 \times 10^{14} \exp(-33.3 \text{ kJ mol}^{-1}/RT) + 1.07 \times 10^{13} \exp(+10.0 \text{ kJ mol}^{-1}/RT)$ , with a small uncertainty of  $\pm 20\%$  at  $T = 1600 \text{ K}$  and  $\pm 30\%$  at the upper and lower experimental temperature limits. The two Arrhenius terms basically can be attributed to the contributions of reaction channel (2a) yielding  $\text{CH} + \text{N}_2$  and channel (2b) yielding  $\text{HCN} + \text{N}$  as the products. A more refined analysis taking into account experimental and theoretical literature data provided a consistent rate constant set for  $k_{2a}$ , its reverse reaction  $k_{1a}$  ( $\text{CH} + \text{N}_2 \rightarrow \text{NCN} + \text{H}$ ),  $k_{2b}$  as well as a value for the controversial enthalpy of formation of  $\text{NCN}$ ,  $\Delta_f H_{298\text{K}}^\circ = 450 \text{ kJ/mol}$ . The analysis verifies the expected strong temperature dependence of the branching fraction  $\phi = k_{2b}/k_2$  with reaction channel (2b) dominating at the experimental high-temperature limit. In contrast, reaction (2a) dominates at the low-temperature limit with a possible minor contribution of the  $\text{HNCN}$  forming recombination channel (2d) at  $T < 1150 \text{ K}$ .

## 4.1 Introduction

Nitrogen oxides,  $\text{NO}$  and  $\text{NO}_2$  ( $\text{NO}_x$ ), are major atmospheric pollutants formed by different reaction mechanisms in combustion processes. Especially under fuel rich combustion conditions, the so-called prompt-NO formation pathway becomes significant. According to Fenimore,<sup>[1]</sup> prompt-NO formation is initiated by the reaction of small hydrocarbon radicals with molecular nitrogen from the combustion air. Although it has been proven both theoretically<sup>[2,3,4]</sup> and experimentally<sup>[5,6]</sup> that the key initiation reaction  $\text{CH} + \text{N}_2$  yields the spin-allowed products  $\text{H} + \text{NCN}$ ,

instead of the previously assumed spin-forbidden products  $\text{N} + \text{HCN}$ ,

so far  $\text{NCN}$  chemistry has only been implemented in two detailed kinetic mechanisms for combustion modeling, namely `konnov0-6` and `GDFkin3.0_NCN`.<sup>[7,8]</sup> Adopted  $\text{NCN}$  reaction rate constant parameters are largely based on the theoretical work of the M. C. Lin group who reported rate constant values for the most important bimolecular  $\text{NCN}$  consumption reactions  $\text{NCN} + \text{H}$ ,<sup>[2,4]</sup>  $\text{O}$ ,<sup>[9]</sup>  $\text{OH}$ ,<sup>[10]</sup> and others.<sup>[11,12,13]</sup> Experimental high-temperature data for  $\text{NCN}$  reactions are scarce. Next to the early shock

tube detection of  $\text{NCN}$  and indirect rate constant measurements of the reaction  $\text{NCN} + \text{H}$  performed by Vasudevan et al.,<sup>[6]</sup> Busch and Olzmann investigated the thermal decomposition of  $\text{NCN}$  by means of C-ARAS detection behind shock waves.<sup>[14,15]</sup> All other direct high-temperature measurements are based on work performed in the Kiel shock tube laboratory operated by us. We use the thermal decomposition of cyanogen azide ( $\text{NCN}_3$ ) as a quantitative source of  $\text{NCN}$  radicals.<sup>[16]</sup> So far, we were able to report rate constant data for the bimolecular  $\text{NCN}$  reactions with  $\text{O}$ ,  $\text{NCN}$ ,  $\text{NO}$ ,  $\text{NO}_2$ , and its unimolecular decomposition  $\text{NCN} + \text{M} \rightarrow \text{C} + \text{N}_2 + \text{M}$ .<sup>[17,18]</sup> The purpose of this paper is to provide the first direct high-temperature measurements of the total rate constant of the reaction  $\text{NCN} + \text{H}$ . At combustion temperatures, the reaction exhibits two main reaction channels:

Depending on the reaction conditions, two additional minor reaction channels forming  $\text{HNC} + \text{N}$  and  $\text{HNCN}$  are accessible (see discussion section 4.4). The rate of reaction (2) and its exact branching ratio turned out to be crucial factors for modeling the fate of  $\text{NCN}$  in hydrocarbon flames.<sup>[7,8,19]</sup> On the one hand reaction (2a) constitutes the reverse of the prompt- $\text{NO}$  initiation reaction (1a) and can be calculated from  $k_{1a}$  via the thermochemical equilibrium constant  $K(\text{CH} + \text{N}_2 \rightleftharpoons \text{NCN} + \text{H}) = k_{1a}/k_{2a}$ . On the other hand the products of reaction (2b) are the same as the products of the formerly assumed spin-forbidden reaction (1b), which brings the new  $\text{NCN}$  chemistry back to the old Fenimore  $\text{NO}_x$  formation route.

Reported rate constant values for reaction  $\text{NCN} + \text{H}$  have been included in the Arrhenius diagram shown in Fig. 4.1. An early rate constant estimate of Glarborg et al.<sup>[20]</sup> assumed reaction (2b) to proceed with a temperature independent rate constant close to the collisional rate,  $k_{2b} = 1 \times 10^{14} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  (upper solid line). Shortly after, the reaction  $\text{NCN} + \text{H}$  has been theoretically analyzed by Moskaleva and Lin.<sup>[2]</sup> As a side note in their paper on the overall rate constant of the reaction  $\text{CH} + \text{N}_2 \rightarrow \text{NCN} + \text{H}$ , but unfortunately without giving much details on the underlying theoretical model, they reported a pressure independent rate constant expression of  $k_{2b} = 1.89 \times 10^{14} \times \exp(-35.3 \text{ kJ/mol}/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  revealing that the reaction takes place over a sizable barrier (lower dash-dotted line). Hence, with  $k_{2b} = 1.1 \times 10^{13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  at  $T = 1500 \text{ K}$ , the reaction is one order of magnitude slower than the initial estimate. Experimentally, Vasudevan et al.<sup>[6]</sup> indirectly determined the rate constant of reaction (2b) in the temperature range of  $2378 \text{ K} < T < 2492 \text{ K}$  by measuring absorption-time profiles of  $\text{NCN}$  in ethane/ $\text{N}_2$  mixtures behind shock waves (triangles with error bars). Following fast  $\text{NCN}$  generation by reaction (1a), the observed slow decays of the  $\text{NCN}$  radical concentration profiles were found to be consistent with  $k_{2b}$  values close to the ones reported by Moskaleva and Lin.

In an indirect experimental and numerical study of the role of  $\text{NCN}$  formation in low pressure flames, Lamoureux et al.<sup>[8]</sup> reported the value  $k_{2b} = 2.5 \times 10^{13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  (dotted line), which was also adopted for the GDFkin3.0\_ $\text{NCN}$  mechanism. Essentially, this value had been chosen to match the experimentally measured  $\text{NCN}$  and  $\text{NO}$  concentration profiles in methane and acetylene flames with peak

flame temperatures of  $T = 1600 \text{ K} - 1835 \text{ K}$ . Therefore, this reported value is highly dependent on the value of the assumed absorption cross section for NCN, which is subject to ongoing discussion.<sup>[21]</sup> Furthermore, the assumed enthalpy of formation of NCN, here  $\Delta_f H_{298\text{K}}^\circ = 452 \text{ kJ/mol}$ , is a critical quantity as  $k_{2a}$  is calculated from  $k_{1a}$  via thermochemical equilibrium in their simulations. The crucial role of NCN thermochemistry for modeling prompt-NO formation in flames has been recently highlighted in a paper by Goos et al.<sup>[22]</sup> They nicely demonstrated that the modeled branching ratio of the overall reaction (2) heavily depends on the assumed enthalpy of formation value for NCN. For example, by switching the enthalpy of formation from the low value  $\Delta_f H_{298\text{K}}^\circ = 444.5 \text{ kJ/mol}$  (representative for theoretical estimates based on single-reference computations)<sup>[16,23]</sup> to the high value  $466.5 \text{ kJ/mol}$  (experimental result based on photodissociation experiments)<sup>[24]</sup> both the simulated NCN peak mole fraction and final NO yield varied by a factor of about 3 for a fuel rich low-pressure  $\text{CH}_4\text{-O}_2\text{-N}_2$  flame. In view of this large variation it becomes clear that also the indirect  $k_{2b}$  value of Lamoureux et al. is uncertain.

Figure 4.1: Experimental and theoretical literature rate constant data for the reaction  $\text{NCN} + \text{H}$  in comparison with the results of this work. Estimate of Glarborg et al.<sup>[20]</sup>, shock tube data of Vasudevan et al.<sup>[6]</sup>, flame data of Lamoureux et al.,<sup>[8]</sup> and theoretical predictions of Teng et al.<sup>[4]</sup> and Moskaleva and Lin<sup>[2]</sup> are illustrated as outlined in the legend. The squares depict the experimental data of this work; the shaded area and the thick solid curve correspond to the range of uncertainty and a fit of the experimental data, respectively.

Very recently the M.C. Lin group<sup>[4]</sup> updated their theoretical prediction of the rate constants of the reactions  $\text{CH} + \text{N}_2$  and  $\text{NCN} + \text{H}$  based on (i) high-level *ab initio* calculation (CCSD(T) with complete basis set limit) of the underlying quartet and doublet potential energy surfaces and (ii) by correct-

ing a previous coding error in a program used in their original paper<sup>[2]</sup> from the year 2000. Teng et al.<sup>[4]</sup> clearly showed that reaction (2b) is a spin-allowed process predominantly taking place on a quartet surface, in contrast to reaction (2a) taking place only on a doublet surface. In comparison with their previous work, they now recommend the rate expression  $k_{2b} = 4.96 \times 10^{12} \times T^{0.41} \times \exp(-22.8 \text{ kJ/mol}/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  yielding 20% to 40% higher  $k_{2b}$  values at temperatures from 1500 K to 2000 K (upper dash-dotted line in Fig. 4.1). Another important finding was that an alternative reaction channel yielding  $\text{HNC} + \text{N}$  is minor and that the recombination reaction yielding  $\text{HNCN}$ , which dominates at room temperature, contributes to less than 5% at combustion relevant temperatures of  $T > 1000 \text{ K}$  at 1 bar total pressure. Remarkably high total rate constant values with a shallow minimum of  $k_2 \approx 1.3 \times 10^{14} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  at  $T = 3180 \text{ K}$  have been reported in their work as well (long-dashed curve), which we consider unfeasible. As it turns out in this work, the recommendation of Teng et al. for reaction channel (2a) alone is already up to 6 times higher (short-dashed curve) than our experimentally determined total rate constant  $k_2$  (see also Discussion Section 4.4).

From this short overview of existing literature data we conclude that a reliable modeling of  $\text{NCN}$  chemistry in flames is not possible so far. Clearly, experimental data on the rate constant of the reaction  $\text{NCN} + \text{H}$  are needed to constrain the rate constant uncertainties and to advance current prompt-NO formation models.

## 4.2 Experimental

### 4.2.1 Shock tube apparatus

All experiments were carried out in an electropolished stainless steel shock tube with inner diameter of 81 mm. A more detailed description can be found elsewhere.<sup>[25]</sup> Briefly, hydrogen or mixtures of hydrogen and nitrogen were used as driver gas; diaphragms were made from 80 or 100  $\mu\text{m}$  thick aluminum foil. The experimental conditions behind the incident and reflected shock waves were calculated from pre-shock conditions and the shock wave velocity, which was measured by four fast piezo-electric sensors (PCB Piezotronics M113A21). A frozen-chemistry code was applied taking into account real gas effects and the measured shock wave damping, which was on the order of 1% per meter. Storage gas mixtures of 500-750 ppm  $\text{NCN}_3$  and 1000 ppm  $\text{C}_2\text{H}_5\text{I}$  in argon were prepared using the partial pressure method and were further diluted with argon using calibrated mass flow controllers (Aera, FC-7700CU). The low pressure section of the shock tube was flushed for about 5 min at  $p \approx 30 \text{ mbar}$  to reduce possible adsorption effects on the shock tube wall.

### 4.2.2 $\text{NCN}$ precursor

The thermal decomposition of cyanogen azide ( $\text{NCN}_3$ )

has been used as a quantitative source of  $\text{NCN}$  radicals.<sup>[26,27]</sup> It was shown in previous publications<sup>[16,28]</sup> that the thermal decomposition initially yields  $\text{NCN}$  in its first electronically excited singlet state. Under the experimental conditions applied in this work with total densities  $\rho > 2 \times 10^{-6} \text{ mol/cm}^3$  and temperatures  $T > 962 \text{ K}$ , the subsequent collision induced intersystem crossing (CIISC) is rate limiting for triplet  $\text{NCN}$  formation according to

The CIISC efficiency is strongly dependent on the nature of the collider, reveals a non-linear pressure dependence due to a pressure saturation effect, and increases with increasing temperature.<sup>[18,28]</sup> In order to accurately model the initial formation rate of  ${}^3\text{NCN}$  (denoted  $\text{NCN}$  in the following), the CIISC rate constant has been allowed to vary within the error limit reported by Dammeier et al.<sup>[28]</sup>

The highly toxic and explosive precursor molecule  $\text{NCN}_3$  has been directly synthesized using a procedure described previously.<sup>[29,30]</sup> Briefly, a small amount of gaseous cyanogen bromide ( $\text{BrCN}$ ,  $\sim 20 \text{ mbar}$ ) was passed into an evacuated 1 L glass flask containing a huge excess of solid sodium azide ( $\text{NaN}_3$ ). After a 8 - 10 h reaction time, the gaseous products were analyzed by FTIR spectroscopy. Almost no water and carbon dioxide ( $\sim 0.01\%$ ), which serves as an indicator for a potential gas leak, were present in the reaction samples and the impurities of remaining cyanogen bromide were well below 4%, in some cases  $< 0.1\%$ . A slow decomposition of about 10%  $\text{NCN}_3$  per day took place in the storage flask, therefore mixtures were used up within 3 days. Accurate initial  $\text{NCN}_3$  mole fraction in the actual reaction mixtures were determined by modeling the maximum  $\text{NCN}$  yield in the experiments and were found to be consistent with the expected  $\text{NCN}_3$  content in the storage gas mixtures in all cases.

### 4.2.3 H precursor

Hydrogen atoms were generated by the thermal unimolecular decomposition of ethyl iodide ( $\text{C}_2\text{H}_5\text{I}$ ). Under typical experimental conditions behind shock waves, the reaction can be assumed to take place close to the high pressure limit<sup>[31]</sup> and exhibits two main reaction channels:

H atom formation proceeds through the fast subsequent decomposition of the ethyl radical,

Although ethyl iodide has been widely used as an H atom precursor, until recently the assumed absolute values and temperature dependences of the H atom yield were uncertain and often represented the most significant source of error in such studies. Selected values of reported branching ratios  $\phi = k_{5a}/(k_{5a} + k_{5b})$  are collected in Fig. 4.2. The most frequently used value of  $\phi = 0.87 \pm 0.11$  is based

on direct H and I atom resonance absorption spectroscopic (ARAS) measurements performed by Kumaran et al.<sup>[32]</sup> at temperatures of  $946 \text{ K} < T < 1303 \text{ K}$ . Also based on ARAS experiments, Herzler and Roth<sup>[33]</sup> reported a coinciding value, Yamamori et al.<sup>[34]</sup> used lower values of  $\phi < 0.78$  at overall higher temperatures, Miyoshi et al.<sup>[35]</sup> determined a higher value of  $\phi = (0.92 \pm 0.06)$ , and Giri et al.<sup>[36]</sup> assumed  $\phi = 1$  by considering the hydrogen forming pathway only. Recently, Weber et al.,<sup>[37]</sup> Yang and Tranter,<sup>[38]</sup> and Bentz et al.<sup>[39]</sup> revisited the ethyl iodide pyrolysis. Whereas Yang and Tranter found excellent agreement with their laser-schlieren densitometry shock tube measurements by assuming  $\phi = 0.87$ , Weber et al. report a significantly lower value of  $\phi = (0.7 \pm 0.1)$  from a mass spectrometric investigation of the flash pyrolysis of ethyl iodide. However, Bentz et al. could show by a combination of H- and I-ARAS measurements and statistical rate calculations that the abstraction reaction  $\text{H} + \text{C}_2\text{H}_5\text{I} \rightarrow \text{C}_2\text{H}_5 + \text{HI}$ , which had been neglected in former studies, needs to be taken into account for an accurate analysis of the branching ratio. Their experimental data, together with other available literature data, have been very recently reanalyzed by Varga et al.<sup>[31]</sup> in a follow-up publication using a new global optimization method developed by Turányi.<sup>[40]</sup> The simultaneous optimization of the rate constant expressions of all relevant reactions yielded a considerably temperature dependent branching ratio decreasing from  $\phi(T = 962 \text{ K}) = 0.96$  to  $\phi(T = 2450 \text{ K}) = 0.71$  over the temperature range of this study. A very low  $3\sigma$  uncertainty level of  $\pm 0.035$  has been specified by Varga et al. at a temperature of  $T = 1200 \text{ K}$ . As can be seen in Fig. 4.2 the recommended branching ratios are consistent with most of the previous literature data. We consider these results to be most reliable and therefore adopted the ethyl iodide decomposition mechanism as reported by Varga et al. It is included in the list of reactions in Table 4.1.

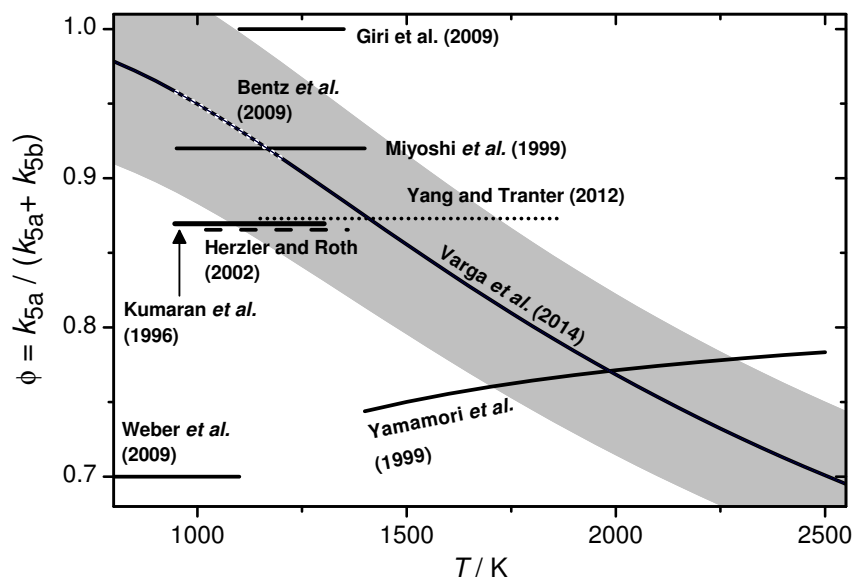

Figure 4.2: Selected literature values for the branching ratio  $\phi$  of the thermal decomposition of ethyl iodide yielding  $\text{C}_2\text{H}_5 + \text{I}$  (channel 5a) and  $\text{C}_2\text{H}_4 + \text{HI}$  (channel 5b), respectively. H and/or I atom resonance absorption measurements: Kumaran et al.,<sup>[32]</sup> Yamamori et al.,<sup>[34]</sup> Miyoshi et al.,<sup>[35]</sup> Herzler and Roth,<sup>[33]</sup> Giri et al.,<sup>[36]</sup> and Bentz et al.;<sup>[39]</sup> laser schlieren technique: Yang and Tranter;<sup>[38]</sup> mass spectrometry: Weber et al.;<sup>[37]</sup> global optimization: Varga et al.<sup>[31]</sup> The gray area represents the assumed uncertainty range of  $\pm 7\%$ .

We have recommended the use of a different expression with opposite temperature dependence of  $\phi$  in a previous paper dating back to the year 2002.<sup>[41]</sup> That recommendation was based on a theoretical treatment of the unimolecular decomposition of ethyl iodide with barrier heights taken from the paper of Kumaran et al. Then, the energy barrier  $E_0$  of the I atom forming C-I bond fission channel (5a) was assumed to be about 15 kJ/mol higher than of the HI elimination channel (5b). However, the recent accurate CCSD(T) ab initio data of Bentz et al.<sup>[39]</sup> showed that both barriers are more or less energetically equal, which is more consistent with the reported decrease of  $\phi$  with increasing temperature. For a more detailed treatment of the unimolecular decomposition reactions of alkyl iodides in the framework of statistical rate theories we refer to the work of Kumaran et al., Miyoshi et al., and Bentz et al.<sup>[32,35,39]</sup>

Table 4.1: Rate constant parameters for important NCN reactions and the ethyl iodide submechanism. Rate constants are given in terms of  $k = AT^n \exp(-E_a/RT)$  in units of  $\text{cm}^3, \text{mol}^{-1}, \text{s}^{-1}$  and kJ. The listed rate constants for NCN (representing  $^3\text{NCN}$ ) reactions have been duplicated for  $^1\text{NCN}$  to approximately take into account  $^1\text{NCN}$  secondary chemistry. In addition to the reactions listed here, the GRI-Mech 3.0 has been used as base mechanism<sup>[42]</sup> supplemented by iodine chemistry adopted from our previous work.<sup>[41]</sup>

#### 4.2.4 NCN detection

Triplet NCN radicals were detected by time-resolved difference amplification laser absorption spectroscopy at  $\tilde{\nu} = 30383.11 \text{ cm}^{-1}$  ( $\lambda = 329.1302 \text{ nm}$ ). The absorption feature at this wavelength mainly

4. Direct Measurements of the total rate constant of the reaction  $\text{NCN} + \text{H}$

stems from a superposition of the  ${}^3\Pi_1$  sub band of the  $\tilde{A}{}^3\Pi_u(000) - \tilde{X}{}^3\Sigma_g(000)$  and the  $Q_1$  band head of the  ${}^3\Sigma^+(010) - {}^3\Pi(010)$  transition.<sup>[21]</sup> About 1 mW UV laser radiation was generated by intra-cavity frequency doubling of a continuous-wave ring-dye laser (Coherent, 899) with DCM-Special as dye pumped with a solid state Nd:YVO<sub>4</sub> laser using 8 W at  $\lambda = 532$  nm (Coherent Verdi V10). The wavelength of the laser fundamental was measured interferometrically by a wavemeter (MetroLux) with an accuracy of  $\Delta\tilde{\nu} \approx \pm 0.015$  cm<sup>-1</sup>. The UV laser beam was split into a detection and a reference beam by a (50:50) beam splitter plate. The detection beam was passed through the shock tube and coupled into an optical fiber (Thorlabs BF H22-550) connected to a balanced photodetector and amplifier (Thorlabs PDB 150A-EC). The intensity of the reference laser beam was fine-tuned by a variable neutral density filter to match the intensity of the detection beam. The resulting difference signals were low-pass-filtered (1.4 MHz), amplified (Ortec Fast Preamp 9305, 18 dB), and stored by an analog input board (Measurement Computing, PCI-DAS4020/12, 20 MHz, 12 bit). The NCN concentration-time profiles were calculated from the detected absorption profiles based on NCN absorption cross sections  $\log(\sigma(\text{base e})/(\text{cm}^2\text{mol}^{-1})) = 8.9 - 8.3 \times 10^{-4} \times T/\text{K}$  previously measured with an accuracy of  $\pm 25\%$  using the same apparatus at similar temperatures and pressures.<sup>[16]</sup>

### 4.3 Results

The reaction of NCN radicals with hydrogen atoms has been investigated behind incident and reflected shock waves in the temperature and pressure ranges  $962 \text{ K} < T < 2425 \text{ K}$  and  $290 \text{ mbar} < p < 2130 \text{ mbar}$ , respectively, at three different total densities of  $\rho \approx 3.5 \times 10^{-6}$ ,  $7.4 \times 10^{-6}$ , and  $1.5 \times 10^{-5} \text{ mol/cm}^3$ . Reaction gas mixtures contained 72-363 ppm ethyl iodide and 3-31 ppm  $\text{NCN}_3$  in argon. In most cases, a large excess of ethyl iodide with  $[\text{C}_2\text{H}_5\text{I}]_0/[\text{NCN}_3]_0$  ratios up to 60 was applied, hence the hydrogen atom was used as the excess species. Experimental conditions are listed in Table 4.2.

Figure 4.3: (a) Experimental NCN profile in comparison with numerical simulations.  $T = 1720 \text{ K}$ ,  $\rho = 3.43 \times 10^{-6} \text{ mol/cm}^3$ ,  $p = 490 \text{ mbar}$ ,  $x(\text{NCN}_3) = 21 \text{ ppm}$ ,  $x(\text{C}_2\text{H}_5\text{I}) = 72 \text{ ppm}$ ,  $k_2 = 5.5 \times 10^{13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . (b) Sensitivity analysis.

Fig. 4.3a illustrates a typical experiment behind the incident shock wave at a temperature  $T = 1720 \text{ K}$  and a total density  $\rho = 3.43 \times 10^{-6} \text{ mol/cm}^3$  with initial mole fractions of  $x(\text{NCN}_3) = 21 \text{ ppm}$  and  $x(\text{C}_2\text{H}_5\text{I}) = 72 \text{ ppm}$ . After the arrival of the incident shock wave, the NCN signal increases within  $20 \mu\text{s}$ . Obviously, both the thermal decomposition of  $\text{NCN}_3$  and the singlet-triplet relaxation of NCN are fast. The subsequent NCN decay is well resolved and is more or less complete at the end of the experimental time window set by the Schlieren signal of the reflected shock wave at  $t = 460 \mu\text{s}$ .

In order to extract rate constants for reaction (2),  $\text{NCN} + \text{H} \rightarrow \text{products}$ , the NCN profiles were numerically simulated using the CHEMKIN-II package.<sup>[46]</sup> The GRI-Mech 3.0 was used as a base mechanism<sup>[42]</sup> supplemented by an iodine submechanism adopted from our previous work<sup>[41]</sup> and the reactions outlined in Table 4.1. The mechanism for NCN secondary chemistry was assembled from

literature data, in particular from our previous measurements that have been validated to reproduce NCN concentration-time profiles of pure  $\text{NCN}_3/\text{argon}$  mixtures over a wide range of experimental conditions. The ethyl iodide decomposition has been modeled by including the recently optimized submechanism reported by Varga et al.<sup>[31]</sup> (vide supra). In order to identify potential contributions of  $^1\text{NCN}$  secondary chemistry, all triplet NCN reactions have been duplicated for singlet NCN. Although this treatment neglects the presumably different  $^1\text{NCN}$  reactivity, it can be safely assumed that  $^1\text{NCN}$  secondary chemistry is dominated by its relaxation reaction forming triplet NCN within the first few  $\mu\text{s}$  of the experiments. Thermodynamic data were taken from Burcat’s thermodynamic database<sup>[47]</sup> with updated NASA polynomial parameters for NCN from Goos et al.<sup>[22]</sup> Note that the assumed value for the enthalpy of formation of NCN, although of utmost importance for the discussion of the branching ratio of reaction (2) (vide infra), is not important for the determination of the total rate constant from the experimental profiles.

The solid curve in Fig. 4.3a reflects the best fit of the data using  $k_2$  as an adjustable parameter. Two additional simulations using  $k_2$  varied by a factor of two (dashed curves) are shown as well. They deviate strongly from the experimental profile demonstrating the high sensitivity of reaction (2). Assuming either the products of reaction channel (2a),  $\text{CH} + \text{N}_2$ , or reaction channel (2b),  $\text{HCN} + \text{N}$ , did not change the extracted  $k_2$  value within error limits. The high sensitivity of reaction (2) is further outlined in the sensitivity analysis shown in Fig. 4.3b. Here, the sensitivity coefficient  $\sigma(i, t)$  for reaction  $i$  at time  $t$  was normalized with respect to the maximum concentration  $[\text{NCN}]_{\text{max}}$  over the time history,  $\sigma(i, t) = 1/[\text{NCN}]_{\text{max}} \times (\partial[\text{NCN}]/\partial \ln k_i)$ . For the analysis, a branching ratio of  $\phi = k_{2b}/k_2 = 0.5$  has been assumed. Following the initial increase of the signal, which is determined by the NCN relaxation reaction (4), reaction (2) dominates the NCN decay. The relatively high sensitivity coefficients for reactions (5a) and (5b) directly reflect the influence of the branching ratio of reaction (5) and hence the assumed H atom yield from ethyl iodide pyrolysis. Presuming that this branching ratio is accurate, the sensitivity analysis reveals that the rate constant of reaction (2) could be directly measured under nearly pseudo first-order conditions.

Whereas the highest feasible experimental temperature was limited by the increasingly fast thermal decomposition of NCN, towards lower temperatures non-NCN secondary chemistry becomes significant as well. This is illustrated by the  $T = 1150 \text{ K}$  experiment and sensitivity analysis shown in Fig. 4.4. Both reaction (14),  $\text{H} + \text{C}_2\text{H}_5\text{I}$ , and the assumed products of reaction (2) become important. Assuming the products of channel (2a),  $\text{HCN} + \text{N}$ , at longer reaction times the reaction  $\text{N} + \text{NCN}$  significantly consumes NCN. Similarly, assuming the products of channel (2b),  $\text{CH} + \text{N}_2$ , the reaction  $\text{C} + \text{NCN}$  gains importance. Here, C atoms are efficiently generated by the reaction  $\text{CH} + \text{H} \rightarrow \text{C} + \text{H}_2$ . Consistent with the expected diminishing role of the activation controlled channel (2b), somewhat better agreement with the experiment is obtained by assuming channel (2a). However, as the remaining differences between simulation and experiment could not be clearly attributed to a specific secondary reaction, no attempt was made to further improve the simulation at longer reaction times. Instead, the rate of reaction (2) was extracted from the NCN decay by fitting the transient at short reaction times where secondary chemistry did not yet exert a significant influence.

All measured rate constants  $k_2$  are listed in Table 4.2 and are shown in Arrhenius form in Fig. 4.5.

#### 4. Direct Measurements of the total rate constant of the reaction $\text{NCN} + \text{H}$

Figure 4.4: (a) Experimental NCN profile in comparison with numerical simulations.  $T = 1150 \text{ K}$ ,  $\rho = 7.48 \times 10^{-6} \text{ mol/cm}^3$ ,  $p = 720 \text{ mbar}$ ,  $x(\text{NCN}_3) = 6.5 \text{ ppm}$ ,  $x(\text{C}_2\text{H}_5\text{I}) = 138 \text{ ppm}$ ,  $k_2 = 4.8 \times 10^{13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . (b) Sensitivity analysis.

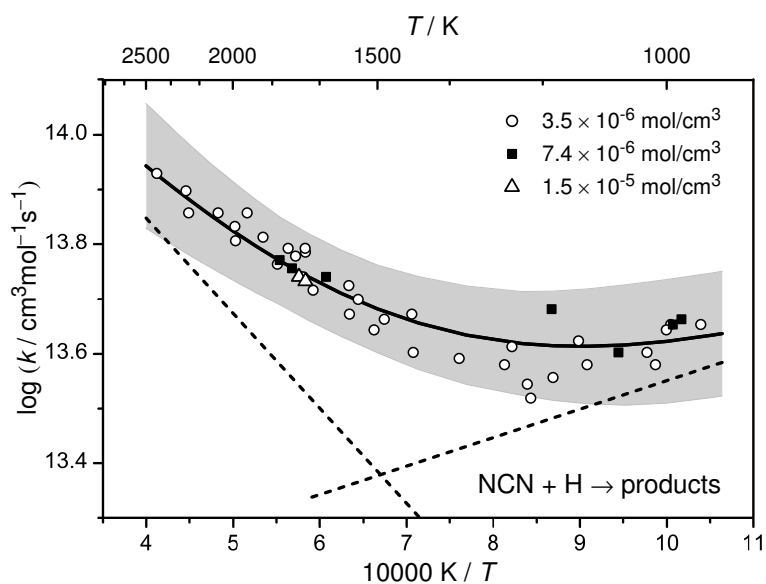

Figure 4.5: Arrhenius plot for  $k_2$  measured at three different total densities. The solid curve corresponds to a fit of the data using a sum of two Arrhenius expressions (dashed lines). The gray area represents the uncertainty range based on a comprehensive error analysis.

Overall, the rate constants follow the same trend independent of total density (varied by a factor of 4) and mixture composition (varied within  $1.7 < [\text{C}_2\text{H}_5\text{I}]_0/[\text{NCN}_3]_0 < 60$ ). The data reveal a shallow minimum at temperatures around 1050-1200 K indicating that at least two reaction channels are active, presumably channels (2a) and (2b) with (2b) becoming more important towards higher temperatures. Accordingly, in the temperature range  $962 \text{ K} < T < 2425 \text{ K}$  the total rate constant can be best represented by the sum of two Arrhenius expressions,

$$\begin{aligned} k_2/(\text{cm}^3\text{mol}^{-1}\text{s}^{-1}) = & \\ & 3.49 \times 10^{14} \exp(-33.3 \text{ kJ mol}^{-1}/RT) + \\ & 1.07 \times 10^{13} \exp(+10.0 \text{ kJ mol}^{-1}/RT), \end{aligned} \quad (\text{I})$$

depicted as the solid curve in Fig. 4.5. The two single Arrhenius terms are also shown as dashed lines and can be roughly interpreted to represent the contributions of channel (2b) (first term) and channel (2a) (second term). A more refined analysis of the overall rate constant will be presented below.

An error analysis has to take into account uncertainties resulting from the scatter of the data ( $\pm 6\%$ ), the mixture composition (in particular the initial ethyl iodide mole fraction,  $\pm 3\%$ ), the channel branching ratio of the ethyl iodide decomposition (estimated from Fig. 4.2 to be  $\pm 7\%$ ), the NCN absorption cross section ( $\pm 25\%$ , resulting in a 3% uncertainty in  $k_2$ ), and the secondary chemistry. In the middle of the investigated temperature range ( $T \approx 1600 \text{ K}$ ), a direct pseudo first-order evaluation was possible and hence errors from secondary chemistry are minor. Nevertheless, we allow for a 10% error due to a possibly large uncertainty of the rate constant of the reaction (10),  $\text{NCN} + \text{N}$ , which has not been directly measured so far. Increasing its rate constant from  $1 \times 10^{13} \text{ cm}^3\text{mol}^{-1} \text{ s}^{-1}$  to  $1 \times 10^{14} \text{ cm}^3\text{mol}^{-1} \text{ s}^{-1}$  would make this reaction sensitive because N atoms are formed in reaction (2b) and hence slightly too high  $k_2$  values would have been determined by our analysis. Taking into account partial error compensation, we estimate the overall uncertainty of  $k_2$  to be  $\pm 20\%$  at  $T = 1600 \text{ K}$ , increasing to  $\pm 30\%$  due to higher uncertainties resulting from secondary chemistry and the employed ethyl iodide branching ratio at the high and low temperature limit of the experiments. A corresponding uncertainty range is indicated by the gray shaded area in Fig. 4.5.

## 4.4 Discussion

The obtained total rate constant expression for  $k_2$  is compared with selected literature values and further analyzed in order to derive a consistent set of rate constants for the two main high-temperature reaction channels (2a) and (2b) as well as the NCN enthalpy of formation  $\Delta_f H_{298 \text{ K}}^\circ$  ( $\Delta H$  in the following) in Fig. 4.6. As it was shown by the high level *ab initio* calculations of Teng et al.,<sup>[4]</sup> from the four feasible reaction channels

Figure 4.6: Analysis of total rate constant data in terms of  $\Delta_f H_{298\text{ K}}^\circ(\text{NCN})$  ( $\Delta H$  in the following). The squares, the corresponding solid curves, and the shaded areas reflect the experimental data for  $k_2$  of this work and their uncertainty limits. *Upper plot a:* Analysis with respect to channel (2a). The upper dotted curve depicts the original expression for  $k_{2a}$  adopted from Teng et al.,<sup>[4]</sup> the lower dotted curve a re-evaluation of their data using  $\Delta H = 458$  kJ/mol. The dashed curves reflect  $k_{2a} = k_{1a}/K$  with  $k_{1a}$  from Harding et al.<sup>[3]</sup> derived for different  $\Delta H$  values using Eq. (II). For the lower solid curve, Eq. (II) was scaled by a factor of 0.65. *Lower plot b:* Analysis with respect to channel (2b). Triangles with error bars and the dotted line reflect the experimental and theoretical data reported by Vasudevan et al.<sup>[6]</sup> and Teng et al.,<sup>[4]</sup> respectively. The dashed curves depict  $k_{2b} = k_2 - k_{2a}$  expressions obtained from the  $k_2$  values of this work and  $k_{2a}$  derived from Harding et al.; case 1:  $k_2 \times 1.0$ ,  $k_{1a} \times 1.0$ ,  $\Delta H = 440$  kJ/mol; case 2:  $k_2 \times 1.0$ ,  $k_{1a} \times 0.65$ ,  $\Delta H = 450$  kJ/mol. The lower solid curve reflects the recommended  $k_{2b}$  expression, which is equal to the Teng et al.<sup>[4]</sup> expression scaled by a factor of 1.6. The dash-dotted curve corresponds to  $k_2 = k_{2a} + k_{2b}$  using the two recommended rate expressions.

reaction channel (2c) yielding  $\text{HNC} + \text{N}$  exhibits high activation barriers and does not play a role. The recombination channel (2d), which dominates at room temperature and very high pressures, becomes less important with increasing temperature and can be expected to be of minor importance at combustion relevant temperatures  $T > 1000$  K as well. At a typical total pressure of  $p = 0.5$  bar used in this work, the theoretical predictions of Teng et al.<sup>[4]</sup> range channel (2d) to contribute about 1.2% at 1000 K and 3.8% at  $T = 800$  K to the overall reaction. Due to the inconsistencies in that paper (vide infra) these number should be interpreted with caution, however, the order of magnitude reveals that this channel starts to play a role at the lowest experimental temperatures of this study. Nevertheless, as a good starting point, we limit our analysis of the  $k_2$  data to channels (2a) and (2b) in the following. Regarding the potential energy surface for reaction (2) from Teng et al.,<sup>[4]</sup> channel (2a) proceeds on the doublet surface over the formation of an  $\text{HNCN}$  complex and is supposed to have a slightly negative temperature dependence. In contrast, channel (2b) exhibits a small activation barrier and predominantly proceeds on a quartet surface. The kinetic calculations also reveal that both reaction channels are important at combustion temperatures.

**Analysis method a:** In Fig. 4.6a, the upper dotted curve depicts the calculated rate expression for  $k_{2a}$  from Teng et al.<sup>[4]</sup> The very high rate constant values for  $k_{2a}$  as well as the very high total rate constants  $k_2$  (dashed curve included in Fig. 4.1) are unreasonable. Compared to our experimentally determined *total* rate constant values, the expression yields up to 6 times higher rate constants for channel (2a) already. Moreover, there seems to be an inconsistency in the reported rate constants for the equilibrium  $\text{CH} + \text{N}_2 \rightleftharpoons \text{NCN} + \text{H}$  in the paper of Teng et al. Using their values for the rate constant of the forward reaction (1a) and their preferred value for the enthalpy of formation,  $\Delta H = 458$  kJ/mol, we calculate reverse rate constants  $k_{2b}$ . Thermodynamic data for  $\text{CH}$ ,  $\text{N}_2$ ,  $\text{H}$ , and  $\text{NCN}$  were taken from Burcat's database<sup>[47]</sup> with updated heat capacity data for  $\text{NCN}$  from Goos et al.,<sup>[22]</sup> where 7-term NASA polynomial parameter  $a_6$  has been scaled to adjust  $\Delta H(\text{NCN})$ . Obtained  $k_{2b}$  values are 2-3 times lower than reported by Teng et al. (lower dotted curve in Fig. 4.6a). Another indication that the reported rate constants may be flawed comes from the reported total rate constant values; for example, the recommended room temperature value  $k_2 \approx 7 \times 10^{14} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  is higher than the Lennard-Jones collision limit of  $k_{\text{LJ}} \approx (3.5 - 5.5) \times 10^{14} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ , which can be estimated based on the Lennard-Jones parameters reported in the literature (parameters for  $\text{H}$ :<sup>[48,49,50]</sup>  $\sigma = (2.00 - 3.26) \text{ \AA}$  and  $\varepsilon/k_{\text{B}} = (2.7 - 145) \text{ K}$ ; parameters for  $\text{NCN}$ :<sup>[48]</sup>  $\sigma = 3.83 \text{ \AA}$  and  $\varepsilon/k_{\text{B}} = 232 \text{ K}$ ).

To the best of our knowledge, no other experimental or theoretical values for  $k_{2a}$  have been reported explicitly in the literature yet. Therefore, we continue our analysis by calculating  $k_{2a}$  values from the

reverse reaction  $k_{1a}$ , which has been thoroughly studied both experimentally and theoretically. For an overview of available literature data we refer to the work of Harding et al.<sup>[3]</sup> who performed high-level *ab initio* and transition state theory calculations on the reaction  $\text{CH} + \text{N}_2$  using multi-reference electronic structure methods. Using their recommended value of the enthalpy of formation,  $\Delta H = 459$  kJ/mol, the theoretical prediction was found to be in quantitative agreement with the most recent shock tube data of Vasudevan et al.<sup>[6]</sup> over the temperature range  $2100 \text{ K} < T < 3350 \text{ K}$ . At these high temperatures, the predicted rate constant is less dependent on the assumed value of  $\Delta H$ . Towards lower temperatures and in the practically important temperature range of  $1000 - 2000 \text{ K}$ , however, an accurate enthalpy of formation is crucial. In an Arrhenius plot, Harding et al.<sup>[3]</sup> present their results of temperature dependent calculations of the rate constant of reaction (1a) assuming different values for the enthalpy of formation of NCN (Fig. 13 in their paper). For example, it was shown that changing  $\Delta H$  by  $\pm 8$  kJ/mol yields a factor of 1.6 higher ( $-8$  kJ/mol) or 1.9 lower ( $+8$  kJ/mol)  $k_{1a}$  value at  $T = 1000 \text{ K}$ . In order to take this pronounced thermodynamic effect into account in our analysis and to derive rate constant estimates for  $k_{2a} = k_{1a}/K$  as function of the assumed NCN enthalpy of formation, we reparameterized the original data of Harding et al. and used the expression

$$k_{1a}/(\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = e^{(274.5 - 0.556x)} \times (T/\text{K})^{(-31.24 + 0.0706x)} \times e^{(-71.2 \text{ kJ mol}^{-1}/RT)} \quad (\text{II})$$

with  $x = \Delta_f H_{298 \text{ K}}^\circ(\text{NCN})$  in kJ/mol. Eq. (II) provides a stable fit of the rate constant data of Harding et al. and yields a reasonable extrapolation to somewhat higher and lower  $\Delta_f H_{298 \text{ K}}^\circ(\text{NCN})$  values. Representative literature values of the enthalpy of formation span the range from  $444.5$  kJ/mol (single-reference computations)<sup>[16,23]</sup> to  $459$  kJ/mol (high-level basis set extrapolation or multi-reference computations)<sup>[3,4]</sup> for theoretical and from  $451.8$  kJ/mol (electron affinity of NCN)<sup>[51]</sup> to  $466.5$  kJ/mol (NCN photodissociation)<sup>[24]</sup> for experimental literature data. The resulting  $k_{2a}$  expressions are shown as dashed curves in Fig. 4.6a. They reveal a weak and negative temperature dependence of the reaction  $\text{NCN} + \text{H} \rightarrow \text{CH} + \text{N}_2$  with the absolute rate constant values basically offset by the assumed enthalpy of formation of NCN. Clearly, the higher enthalpies of formation yield unfeasible  $k_{2a}$  values that are up to a factor of 2.4 higher than the total rate constant measured in this work. Assuming that (i) the branching fraction  $k_{2a}/k_2 = 1$  around  $T = 1000 \text{ K}$ , (ii)  $k_{1a}$  from Harding et al. is correct, and (iii)  $k_2$  is at the upper limit of the uncertainty range of our experimental data (+30%), an upper limit of  $\Delta H < 454$  kJ/mol can be estimated from this analysis.

**Analysis method b:** A second analysis of our data focusing on the rate constant of channel (2b) is shown in Fig. 4.6b. The indirect experimental data of Vasudevan et al.<sup>[6]</sup> (triangles with error bars) and the most recent theoretical estimate of Teng et al.<sup>[4]</sup> (dotted curve) are shown as well. In the light of the negative temperature dependence of channel (2a) it becomes clear that the experimentally determined positive temperature dependence of  $k_2$  towards higher temperatures arises from the increasingly dominant activation controlled channel (2b). Moreover, the high temperature activation energy  $E_a = 33$  kJ/mol estimated from the two channel fit of our experimental data (see Fig. 4.5 and Eq. (I)) is in

very good agreement with the theoretically predicted activation energies of 35 kJ/mol and 28 kJ/mol reported by the M.C. Lin group<sup>[2,4]</sup> (see Figs. 4.1 and 4.6b). Hence, we consider the activation energy of reaction channel (2b) a well-constrained quantity with a preferred value of  $E_a \approx 28$  kJ/mol adopted from the most recent *ab initio* study.<sup>[4]</sup> Having the temperature dependence of  $k_{2b}$  fixed, it is possible to arrive at a consistent value for the enthalpy of formation. Here,  $\Delta H$  has been chosen in a way such that the rate constant expression for  $k_{2b} = k_2 - k_{2a}$ , with  $k_2$  values taken from Eq. (I) of this work and  $k_{2a}$  values calculated via thermodynamic equilibrium from the  $k_{1a}$  expression Eq. (II), yields a temperature dependence that is consistent with 28 kJ/mol. A matrix of appropriate enthalpy of formations with  $k_2$  and  $k_{1a}$  varied within their uncertainty limits is given in Table 4.3. Here, uncertainties of  $k_2 \pm 30\%$  as obtained in this work and  $k_{1a} \pm 35\%$  as reported for the experimental shock tube results of Vasudevan et al.<sup>[6]</sup> (which are in turn consistent with the  $k_{1a}$  expression of Harding et al.) have been assumed. Table 4.3 reveals a large range of possible enthalpy of formations,  $423 \text{ kJ/mol} < \Delta H < 456 \text{ kJ/mol}$ . Nevertheless, two conclusions can be drawn from this analysis. First, increasing  $k_{1a}$  yields unfeasible enthalpy values that are even well below the results of the single-reference computations (about 444.5 kJ/mol), which can be regarded a reasonable lower limit for  $\Delta H$ . Even with  $k_{1a}$  unchanged, the highest value of 445 kJ/mol would be close to this limit. Secondly, the upper limit of 456 kJ/mol, corresponding to a scenario with  $k_2 + 30\%$  and  $k_{1a} - 35\%$ , is in agreement with the upper limit of 454 kJ/mol inferred from analysis method a. Therefore, the high experimental value of Bise et al.<sup>[24]</sup> ( $466.5 \pm 2.9$  kJ/mol), the results of the high-level basis set extrapolation and multi-reference computations (about 459 kJ/mol),<sup>[3,4]</sup> and the most recent recommendation of the Active Thermochemical Tables as cited in Goos et al.<sup>[22]</sup> ( $457.8 \pm 2$ ) are hardly compatible with this work.

Resulting  $k_{2b}$  expressions are illustrated in Fig. 4.6b for two selected cases. Case 1, assuming that both  $k_2$  and  $k_{1a}$  exhibit values as given by Eqs. (I) and (II), yields  $\Delta H = 440$  kJ/mol. Case 2, assuming  $k_2$  from Eq. (I) and  $k_{1a}$  from Eq. (II) scaled by a factor of 0.65, yields  $\Delta H = 450$  kJ/mol. For all other cases outlined in Table 4.3, similar  $k_{2b}$  curves have been obtained, of course somewhat offset for different assumed  $k_{1a}$  values (not shown). It is obvious from Fig. 4.6b that the calculated  $k_{2b}$  expressions deviate from linearity at temperatures below 1250 K. With decreasing temperatures and hence a decreasing contribution of  $k_{2b}$  the analysis procedure gets less reliable, hence, part of this deviation may be attributed to inaccuracies of the analysis method itself. However, it may also indicate the onset of the low temperature reaction channel (2d), which has been neglected in the analysis. In this sense, the increase of  $k_{2b}$  at low temperatures would simply arise from the neglected contributions of this channel.

Table 4.3: Feasible values of  $\Delta_f H_{298 \text{ K}}^\circ(\text{NCN})$  for different combinations of  $k_{1a}$  and  $k_2$  values. The reported enthalpy values in kJ/mol yield activation energies  $E_{a,2a} \approx 28$  kJ/mol for reaction channel (2a) that are consistent with the corresponding theoretical estimate of Teng et al.<sup>[4]</sup>

$\Delta_f H_{298 \text{ K}}^\circ(\text{NCN})$	$k_2 + 30\%$	$k_2$	$k_2 - 30\%$
$k_{1a} + 35\%$	436	430	423
$k_{1a}$	445	440	432
$k_{1a} - 35\%$	456	450	443

Overall, relying on the direct  $k_2$  determination of this work, an enthalpy value of 450 kJ/mol is most

consistent with both the enthalpy limits set by the single-reference computations and our analysis,  $444.5 \text{ kJ/mol} < \Delta_f H_{298 \text{ K}}^\circ(\text{NCN}) < 454 \text{ kJ/mol}$ , the experimental and theoretical values for  $k_{1a}$  from Vasudevan et al.<sup>[6]</sup> and Harding et al.,<sup>[3]</sup> the activation energy of reaction channel (2b) reported by Teng et al.,<sup>[4]</sup> and the indirect shock tube measurements for  $k_{2b}$  from Vasudevan et al.<sup>[6]</sup> This enthalpy value is also in very good agreement with the experimental electron affinity measurements of Clifford et al.<sup>[51]</sup> ( $451.8 \pm 16.7 \text{ kJ/mol}$ ) that has been, for example, used in the GDFkin3.0\_NCN flame modeling mechanism as well.<sup>[8]</sup>

Using  $\Delta H = 450 \text{ kJ/mol}$ , the recommended rate constant expressions for  $k_{1a}$ ,  $k_{2a}$ , and  $k_{2b}$  are as follows: Compatible with the lower experimental uncertainty limit of Vasudevan et al.,  $k_{1a}$  is set to 0.65 times the values of Harding et al. (Eq. (II)):

$$k_{1a}/(\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 2.3 \times 10^{10} \times (T/\text{K})^{0.53} \times \exp(-71.2 \text{ kJ/mol}/RT)$$

Using the updated NASA polynomial parameters for NCN from Goos et al.<sup>[22]</sup> (scaled to  $\Delta H = 450 \text{ kJ/mol}$ ), this corresponds to a reverse reaction rate constant  $k_{2a}$  of

$$k_{2a}/(\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 4.2 \times 10^{15} \times (T/\text{K})^{-0.69} \times \exp(-2.0 \text{ kJ/mol}/RT)$$

Adopting the temperature dependence of Teng et al., their rate expression is recommended for  $k_{2b}$  adjusted by a factor of 1.6 to fit the case 2 data in Fig. 4.6b:

$$k_{2b}/(\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 7.94 \times 10^{12} \times (T/\text{K})^{0.41} \times \exp(-22.8 \text{ kJ/mol}/RT)$$

This expression is also compatible with the upper limit of the indirect shock tube measurements of Vasudevan et al.<sup>[6]</sup>

Finally, the sum of  $k_{2a}$  and  $k_{2b}$  is shown in Fig. 4.6b as dash-dotted curve. It is in close agreement with the  $k_2$  rate expression given by Eq. (I), except at the lowest temperatures where channel  $k_{2a}$  presumably starts to play a role. The recommended rate expression for  $k_{2b}$  corresponds to a branching ratio  $\phi = k_{2b}/k_2$  that increases from  $\phi = 0.21$  at  $T = 1000 \text{ K}$  to  $\phi = 0.74$  at  $T = 2500 \text{ K}$ . Hence, in the temperature range relevant for flame modeling, channel switching between channel (2a) dominating at low temperatures and channel (2b) dominating at high temperatures takes place.

#### 4.5 Concluding Remarks

The overall rate constant of the reaction  $\text{NCN} + \text{H}$  has been directly measured at temperatures between 962 K and 2425 K behind shock waves using the thermal decomposition of  $\text{NCN}_3$  and  $\text{C}_2\text{H}_5\text{I}$  as suitable precursors for NCN radicals and H atoms, respectively. A conservative error analysis revealed that comparatively narrow error limits of  $\pm 20\%$  at  $T = 1600 \text{ K}$ , increasing to  $\pm 30\%$  at the upper and lower temperature limits of the measurements, could be achieved. A main error arises from the possibly large uncertainty of the potentially important secondary reaction (10),  $\text{NCN} + \text{N}$ , which has not been measured yet. If the theoretical estimate of Moskaleva and Lin<sup>[2]</sup> turns out to be right,

the influence of reaction (10) would be very small and the error estimate could be further reduced. The second most important uncertainty is related to the assumed overall H atom yield from  $\text{C}_2\text{H}_5\text{I}$  decomposition. However, relying on the very recently published global analysis data on the ethyl iodide composition by Varga et al.,<sup>[31]</sup> this error contribution could be safely assumed to be not more than 7% (an error estimate of 3.5% at  $T = 1200$  K has been stated in the original paper).

The high reliability of the rate constant data enabled us to analyze the  $k_2$  data in terms of branching ratio and the crucial value of the enthalpy of formation of NCN. Taking into account experimental and theoretical literature data for the rate constant of reaction (1a) and the temperature dependence of reaction channel (2b),  $\Delta_f H_{298\text{K}}^\circ = 450$  kJ/mol was found to be most consistent. With a robust upper limit of  $\Delta_f H_{298\text{K}}^\circ < 456$  kJ/mol derived from the  $k_2$  values of this work, significantly higher literature values – about 459 kJ/mol from high-level *ab initio* calculations<sup>[3,4]</sup> and 466.5 kJ/mol from NCN photodissociation experiments<sup>[24]</sup> – are at odds with our analysis. Clearly, more work is needed to further constrain the uncertainty of the enthalpy of formation of NCN.

Modeling of  $\text{NO}_x$  formation in flames critically depends on the branching ratio of the reaction  $\text{NCN} + \text{H}$ . Whereas channel (2a) constitutes the reverse reaction of the main prompt-NO formation reaction (1a),  $\text{CH} + \text{N}_2$ , it is in particular reaction channel (2b) with the products  $\text{HCN} + \text{N}$  that brings the overall reaction forward on the prompt-NO pathway. The results of this study with branching fractions  $\phi = k_{2b}/k_2$  increasing from  $\phi(T = 1000 \text{ K}) = 0.21$  to  $\phi(T = 2500 \text{ K}) = 0.74$  verifies the expected strong temperature dependence of this quantity. However, again the actual value of the derived branching ratio strongly depends on the assumed value of the enthalpy of formation of NCN. In fact, accurate measurements of the branching ratio would be very useful to constrain the enthalpy of formation of NCN. Moreover, in conjunction with the already compiled theoretical and experimental rate constant data, accurate branching fractions would help to draw final conclusions on this reaction system including the contributions of the recombination channel (2d), which may play a role even at temperatures as high as 1000 K.

- Preliminary data analysis.

During the dissertation:

- Shock tube experiments at higher pressures to clarify the pressure dependence of the reaction.
- Discussion on the products considering the pressure independence of the reaction.
- Quantum chemical calculations for  $\text{NCN} + \text{H}_2 \rightarrow \text{HNCN} + \text{H}$ .
- Collaboration with modeling group (N. Lamoureux, Université Lille 1) to implement the reaction  $\text{NCN} + \text{H}_2$  into the GDFkin3.0\_NCN mechanism.
- Writing of paper draft.

## Abstract

Bimolecular reactions of the  $\text{NCN}$  radical play a key role for modeling prompt- $\text{NO}$  formation in hydrocarbon flames. The rate constant of the so far neglected reaction  $\text{NCN} + \text{H}_2$  has been experimentally determined behind shock waves under pseudo-first order conditions with  $\text{H}_2$  as the excess component.  $\text{NCN}_3$  thermal decomposition has been used as a quantitative high temperature source of  $\text{NCN}$  radicals, which have been sensitively detected by difference UV laser absorption spectroscopy at  $\tilde{\nu} = 30383.11 \text{ cm}^{-1}$ . The experiments were performed at two different total densities of  $\rho \approx 4.1 \times 10^{-6} \text{ mol/cm}^3$  and  $\rho \approx 7.4 \times 10^{-6} \text{ mol/cm}^3$  (corresponding to pressures between  $p = 324 \text{ mbar}$  and  $p = 1665 \text{ mbar}$ ) and revealed a pressure independent reaction. In the temperature range  $1057 \text{ K} < T < 2475 \text{ K}$ , the overall rate constant can be represented by the Arrhenius expression  $k / (\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 4.1 \times 10^{13} \exp(-101 \text{ kJ/mol}/RT)$  ( $\Delta \log k = \pm 0.11$ ). The pressure independent reaction as well as the measured activation energy is consistent with a dominating H abstracting reaction channel yielding the products  $\text{HNCN} + \text{H}$ . The reaction  $\text{NCN} + \text{H}_2$  has been implemented together with a set of reactions for subsequent  $\text{HNCN}$  and  $\text{HNC}$  chemistry into the detailed `GDFkin3.0_NCN` mechanism for  $\text{NO}_x$  flame modeling. Two fuel-rich low-pressure  $\text{CH}_4/\text{O}_2/\text{N}_2$ -flames served as examples to quantify the impact of the additional chemical pathways. Although the overall  $\text{NCN}$  consumption by  $\text{H}_2$  remains small, significant differences have been observed for  $\text{NO}$  yields with the updated mechanism. A detailed flux analysis revealed that  $\text{HNC}$ , mainly arising from  $\text{HCN}/\text{HNC}$  isomerization, plays a decisive role and enhances  $\text{NO}$  formation through a new  $\text{HNC} \rightarrow \text{HNCO} \rightarrow \text{NH}_2 \rightarrow \text{NH} \rightarrow \text{NO}$  pathway.

## 5.1 Introduction

Nitrogen oxides ( $\text{NO}_x$ ) are atmospheric pollutants formed as byproducts in combustion processes. Especially under fuel rich conditions,  $\text{NO}$  is favorably formed over the so called prompt- $\text{NO}$  pathway, which is initiated by the reaction of small hydrocarbon radicals with molecular nitrogen from the combustion air. According to the traditional Fenimore mechanism,<sup>[1]</sup> it has been assumed for a long time that prompt- $\text{NO}$  formation is mainly initiated by the reaction

Even though the formation of the products  $\text{N} + \text{HCN}$  is spin-forbidden and despite of the fact that theoretical estimates<sup>[2,3]</sup> for the rate constant  $k_{1a}$  turned out to be inconsistent with the experimentally determined high temperature rate constants for the overall  $\text{CH} + \text{N}_2$  reaction,<sup>[4,5]</sup> reaction (1a) is still used in some flame modeling studies. Already in the year 2000, based on quantum-chemical and RRKM calculations, Moskaleva et al.<sup>[6]</sup> suggested the alternative spin-conserved reaction channel

and predicted  $\text{NCN} + \text{H}$  to be the main product of the reaction. In the meantime it has been experimentally proven that  $\text{NCN}$  radicals are in fact formed in flames<sup>[7,8,9]</sup> and that  $\text{NCN}$  is the main product of the reaction  $\text{CH} + \text{N}_2$ .<sup>[10]</sup> Consequently, flame mechanisms for  $\text{NO}$  modeling have been updated with regard to  $\text{NCN}$  high temperature chemistry. Current versions of  $\text{NCN}$  submechanisms are the Konnov0.6<sup>[11]</sup> and the GDFkin3.0\_NCN<sup>[12,13]</sup> mechanism. The performance of the latter has been extensively validated and improved over the last years by quantitative measurements and modeling of  $\text{CH}$ ,  $\text{NO}$  and  $\text{NCN}$  concentration profiles in low-pressure  $\text{CH}_4/\text{O}_2/\text{N}_2$  and  $\text{C}_2\text{H}_2/\text{O}_2/\text{N}_2$  flames of various fuel/air equivalent ratios.<sup>[12,14]</sup> Recently, corresponding  $\text{NCO}$ ,  $\text{CN}$  and  $\text{HCN}$  profiles have been measured as well.<sup>[13]</sup> Whereas early versions of  $\text{NCN}$  submechanisms relied on rate constant estimates of Glarborg et al.,<sup>[15]</sup> the more recent implementations are based on extensive rate constant data from the theoretical work performed in the M.C. Lin group. They reported RRKM and TST studies for the most important bimolecular  $\text{NCN}$  reactions  $\text{NCN} + \text{O}_2$ ,<sup>[16]</sup>  $\text{O}$ ,<sup>[17]</sup>  $\text{OH}$ <sup>[18]</sup> and  $\text{H}$ <sup>[19]</sup> as well as for the  $\text{NCN}$  forming reaction  $\text{CH} + \text{N}_2$ .<sup>[6,19]</sup> From the experimental point of view, most direct rate constant measurements of  $\text{NCN}$  reactions have been accomplished over the past few years in the shock tube laboratory of the authors (N.F. and G.F.). Beside our studies on  $\text{NCN} + \text{O}$ ,  $\text{H}$ ,  $\text{M}$ ,  $\text{NCN}$ ,  $\text{NO}$ , and  $\text{NO}_2$ ,<sup>[20,21,22]</sup> only two other shock tube studies have been performed. Vasudevan et al.<sup>[10]</sup> measured  $\text{NCN}$  absorption profiles during the pyrolysis of ethane/ $\text{N}_2$  mixtures and Busch et al.<sup>[23,24]</sup> investigated the unimolecular decomposition reaction  $\text{NCN} + \text{M} \rightarrow \text{C} + \text{N}_2 + \text{M}$  by C atom resonance absorption spectroscopy (ARAS). Ongoing work of one of the authors (N.L.) is concerned with the implementation, testing, and validation of the expanding - even though not yet complete - experimental database on  $\text{NCN}$  chemistry for flame modeling. Here, in order to assess the potential influence of the reaction  $\text{NCN} + \text{H}_2$  on  $\text{NO}_x$  flame modeling, we rely on the GDFkin3.0\_NCN submechanism as a well-validated starting point.

Surprisingly, despite of rather high  $\text{H}_2$  concentrations in the flame front, the title reaction

has not yet been implemented into flame mechanisms. Seemingly it was considered to be rather slow and therefore dispensable. However, neither experimental nor theoretical studies have been performed so far to confirm or falsify this assumption. In contrast, the rather slow  $\text{NCN} + \text{O}_2$  reaction is included both in the Konnov0.6 and the GDFkin3.0\_NCN mechanisms. Starting from early and too high rate constant estimates,<sup>[15]</sup> this reaction was initially believed to be crucial for  $\text{NCN}$  modeling,<sup>[25]</sup> but later theoretical calculations of Zhu and Lin<sup>[16]</sup> clearly showed that the reaction is activation controlled, slow, and therefore plays a less important role for  $\text{NO}_x$  formation in flames. As it turns out below, the rate constant of the reaction  $\text{NCN} + \text{H}_2$  is about two orders of magnitude higher than for  $\text{NCN} + \text{O}_2$ . Therefore, an accurate rate constant determination and a thorough analysis of its impact for  $\text{NO}_x$

modeling as reported in this work is overdue.

## 5.2 Experimental

The used shock tube apparatus has been described in more detail elsewhere.<sup>[26]</sup> Briefly, the experiments have been performed in an overall 8.3 m long stainless steel shock tube with a 4.4 m long electropolished test section that could be evacuated to pressures of  $p \approx 10^{-7}$  mbar by a combination of an oil-free turbo-molecular drag and a diaphragm pump. The test section and the driver section were separated by aluminum membranes of 30, 80 or 100  $\mu\text{m}$  thickness. Hydrogen or hydrogen/nitrogen gas mixtures have been used as driver gas. The experimental conditions behind the incident and reflected shock waves were calculated from pre-shock conditions and the shock wave velocity, which was measured by four fast piezoelectronic sensors (PCB Piezotronics M113A21), by using a frozen-chemistry code.

Storage gas mixtures of 500 ppm to 1000 ppm  $\text{NCN}_3$  in argon were prepared using the partial pressure method. The reaction mixtures were prepared using calibrated mass flow controllers (Aera, FC-7700CU; 10, 50, and 1000 sccm). Pure  $\text{H}_2$  (Air Liquide,  $\geq 99.999\%$ ) and the  $\text{NCN}_3$  mixtures were further diluted with argon (Air Liquide,  $\geq 99.999\%$ ) in a flow system and were passed into the test section of the shock tube. The section was flushed with the test gas mixture for about 5 min to minimize possible gas adsorption effects on the shock tube walls. High  $\text{H}_2$  mole fractions up to 9.6% were necessary in the reaction gas mixtures to achieve a fast  $\text{NCN}$  consumption due to reaction (2). At such high mole fractions, vibrational relaxation effects may compromise a simple frozen-chemistry calculation of the experimental conditions. Equilibration of the Boltzman population of  $\text{H}_2$  in its  $v = 0$  and  $v = 1$  vibrational states may cause a noticeable, gradual decrease of the temperature behind the shock wave. However, on the one hand the vibrational relaxation time of  $\text{H}_2$  in argon is known to be rather short, about 9  $\mu\text{s}$  at  $p = 700$  bar and  $T = 1750$  K,<sup>[27]</sup> and hence close to the time resolution of the experiments. On the other hand, due to the high vibrational quanta of  $\text{H}_2$ , the fraction of  $\text{H}_2$  in the  $v = 1$  state and with it the overall temperature effect remains small. At a typical experimental temperature of  $T = 1750$  K, the ratio  $\text{H}_2(v = 1)/\text{H}_2(v = 0) = 0.03$ . Calculation of shock wave conditions assuming fully and non-relaxed  $\text{H}_2$  showed that even at the highest experimental temperatures and  $\text{H}_2$  concentrations used in this work, the maximum expected temperature effect was  $\Delta T < 5$  K. This is within the 1% uncertainty of the temperature calculation from the shock wave velocity. Consequently, due to the fast relaxation and the overall small temperature effect, it could be safely assumed that  $\text{H}_2$  relaxation did not interfere with the rate constant measurements.

### 5.2.1 $\text{NCN}$ precursor

It has been shown by Dammeier et al.<sup>[28,29]</sup> that the thermal decomposition of cyanogen azide ( $\text{NCN}_3$ ) serves as a quantitative source of  $\text{NCN}$  radicals.  $\text{NCN}_3$  thermal decomposition yields  $\text{NCN}$  in its first electronically excited singlet state, which is rapidly converted to the triplet ground state by collision induced intersystem crossing (CIISC).

Table 5.1: Arrhenius parameters for the rate constants of all included NCN reactions as used for simulating the experimental NCN profiles behind shock waves.  $k_i = AT^n \exp[-E_a/RT]$ , given in units of  $\text{cm}^3$ ,  $\text{mol}^{-1}$ ,  $\text{s}^{-1}$  and kJ. Except for reactions (3) and (4), all reactions have been duplicated for  $^1\text{NCN}$  to take  $^1\text{NCN}$  chemistry approximately into account. In addition to the listed reactions, the GDFkin3.0 mechanism<sup>[12]</sup> was used as a background mechanism.

Rate constants for reaction (3) and (4) have been adopted from previous work and are listed in Table 5.1. As it is known that the CIISC process (4) strongly depends on the collision partner and hence reaction mixture composition, its rate constant was allowed to vary within the error limits reported in Ref. 29.

The extremely explosive and toxic precursor  $\text{NCN}_3$  cannot be purified by freeze-pump cycles. It has therefore been synthesized directly in high purity in the gas phase, according to  $\text{BrCN}(\text{g}) + \text{NaN}_3(\text{s}) \rightarrow \text{NCN}_3(\text{g}) + \text{NaBr}(\text{s})$ , using a method described in detail in Ref. 22. After an 8 h reaction time the remaining BrCN impurities were usually  $< 3\%$  according to FTIR analysis. The pure  $\text{NCN}_3$  was diluted in argon and was used within three days since  $\text{NCN}_3$  tends to slowly form solid polymers. The actual initial  $\text{NCN}_3$  concentrations in the reaction gas mixtures were determined from the NCN absorption signal plateaus behind the incident shock waves (for experiments behind the reflected shock wave) or by fitting the maximum of the NCN concentration profile (for experiments behind the incident shock wave). In all cases, the determined concentration was consistent with the concentration calculated from the expected  $\text{NCN}_3$  mole fraction in the storage gas mixture.

### 5.2.2 NCN detection scheme

The narrow-bandwidth laser absorption setup for time-resolved radical detection behind shock waves has been described in detail elsewhere.<sup>[22]</sup> Briefly, about 1 mW of UV radiation was generated by

intra-cavity frequency doubling of a frequency-stabilized continuous-wave ring-dye laser (Coherent 899) operated with DCM-Special as dye and pumped using 8 W at  $\lambda = 532$  nm from a Nd:YVO<sub>4</sub> solid state laser (Coherent Verdi V10). The UV laser beam was split into a detection and a reference beam by a 50:50 beam splitter plate. The detection beam was focused, passed the shock tube through two quartz windows, and was coupled into an optical fiber connected to a balance photo-detector and amplifier (Thorlabs PDB 150A-EC). The reference beam intensity could be precisely adjusted by a variable neutral density filter to match the intensity of the detection beam. The resulting difference signal ( $\Delta I$ ) and the monitor signal of the detection beam ( $I_0$ ) were stored by an analog input board (Measurement Computing PCI-DAS4020/12, 12 bit, 20 MHz) for further data processing.

Triplet NCN has been detected at  $\tilde{\nu} = 30381.11$  cm<sup>-1</sup> ( $\lambda = 329.1302$  nm) on the maximum of an absorption band stemming from the superposition of the  ${}^3\Pi_1$  sub-band of the  $\tilde{A}{}^3\Pi_u(000) - \tilde{X}{}^3\Sigma_g(000)$  transition with the  $Q_1$  band head of the vibronic  ${}^3\Sigma^+(010) - {}^3\Pi(010)$  transition.<sup>[30]</sup> NCN concentration-time profiles were calculated using the previously reported temperature-dependent absorption cross section, which has been measured with an accuracy of  $\pm 25\%$  using the same apparatus at similar temperatures and pressures as used in this work.<sup>[28]</sup> As the (010) vibrational state becomes significantly populated at combustion temperatures, the absorption cross sections were comparatively high (e.g.,  $\sigma(1500$  K, base e) =  $4.5 \times 10^7$  cm<sup>2</sup>mol<sup>-1</sup>). Hence, with a detection limit of  $4 \times 10^{-12}$  cm<sup>3</sup>/mol (corresponding to  $1.5 \times 10^{-3}$  absorption at  $T = 1500$  K,  $p = 500$  mbar, and an electronic time-resolution of  $\Delta t \approx 1$   $\mu$ s), NCN could be detected with high signal-to-noise ratios even at NCN mole fractions as low as a few ppm.

### 5.2.3 Numerical methods

Numerical simulations of NCN concentration-time profiles from the shock tube experiments were performed using the Chemkin-II program package<sup>[31]</sup> in combination with the GDFkin3.0\_NCN as a detailed background mechanism. In order to be consistent with previous shock tube work, rate constants for NCN reactions have been replaced or added according to our directly measured rate constant data set.<sup>[20,21,22]</sup> The most important reactions for modeling the shock tube experiments are listed in Tab. 5.1. For sensitivity analysis, the sensitivity coefficient  $\sigma(i, t)$  for reaction  $i$  at time  $t$  was normalized with respect to the maximum concentration  $[\text{NCN}]_{\text{max}}$  over the time history,  $\sigma(i, t) = 1/[\text{NCN}]_{\text{max}} \times (\partial[\text{NCN}]/\partial \ln k_i)$ .

Flame modeling was performed with the Chemkin/Premix code<sup>[31,32]</sup> and the detailed mechanism GDFkin3.0\_NCN.<sup>[12]</sup> As will be further outlined below, the mechanism has been modified to take into account reaction (2) and subsequent chemistry of HNCN and HNC. Rate-of-production (ROP) and the N-atom flux analyses have been accomplished at the NCN peak locations using a homemade post processor that relies mostly on the Chemkin subroutines.<sup>[31]</sup> Atom flux analysis has been performed with the program Kinalc, and the reaction fluxes were plotted with the included FluxViewer visualisation tool.<sup>[33]</sup> Thermodynamic data were adopted from GDFkin3.0<sup>[12]</sup> with updated NCN thermochemistry as described in Ref. 13. Hence, in agreement with recent experimental work,<sup>[22]</sup> the controversial value of the enthalpy of formation of NCN<sup>[34]</sup> was set to  $\Delta_f H_{298\text{K}}^\circ = 450.2$  kJ/mol. For HNCN and

Figure 5.1: (a) Typical experimental NCN concentration-time profile in comparison with numerical simulations.  $T = 1582$  K,  $p = 544$  mbar,  $\rho = 4.13 \times 10^{-6}$  mol/cm<sup>3</sup>,  $[\text{H}_2] = 4.0\%$ ,  $[\text{NCN}_3] = 8.2$  ppm,  $k_{2e}(\text{NCN} + \text{H}_2 \rightarrow \text{HNCN} + \text{H}) = 1.8 \times 10^{10}$  cm<sup>3</sup>mol<sup>-1</sup>s<sup>-1</sup> (best fit, solid curve). (b) Corresponding sensitivity analysis for NCN.

HNC, thermodynamic data were extracted from the Goos/Ruscic database.<sup>[35]</sup>

Quantum chemical calculations were carried out using the Gaussian 09 suite of programs.<sup>[36]</sup> The transition state of the reaction  $\text{NCN} + \text{H}_2 \rightarrow \text{HNCN} + \text{H}$  was located and verified by using a synchronous transit-guided quasi-Newton method (QST3 option) and intrinsic reaction coordinate following.

## 5.3 Results and discussion

### 5.3.1 Shock tube experiments

The rate constant of reaction (2),  $\text{NCN} + \text{H}_2$ , has been measured behind incident and reflected shock waves with reaction gas mixtures containing 3 - 27 ppm  $\text{NCN}_3$  and 0.8 - 9.6 %  $\text{H}_2$  in argon.  $k_2$  values have been obtained in the temperature and pressure ranges  $1057 \text{ K} \leq T \leq 2475 \text{ K}$  and  $324 \text{ mbar} \leq p \leq 1665 \text{ mbar}$ , at two total densities of  $\rho \approx 4.1 \times 10^{-6}$  and  $7.4 \times 10^{-6}$  mol/cm<sup>3</sup>. Under these experimental conditions the reaction  $\text{NCN} + \text{H}_2$  was always the most important reaction for NCN consumption. Experimental temperature limits were set by the thermal decomposition of NCN, which becomes the dominant reaction above 2500 K, and by the rate of reaction (2) itself, which becomes too slow at temperatures  $T < 1000$  K to be measured with sufficient sensitivity.

Fig. 5.1a shows a typical NCN concentration-time profile behind the incident shock wave at  $T =$

1582 K and a total density of  $\rho = 4.13 \times 10^{-6} \text{ mol/cm}^3$ . The NCN profile reveals a rather slow NCN consumption with a half-life of  $t_{1/2} \approx 200 \mu\text{s}$ . Since there are no studies on the possible reaction channels of the reaction  $\text{NCN} + \text{H}_2$ , numerical simulations of the experimental NCN profiles have been performed assuming different sets of reaction products. Potential reaction products of reaction (2) include:

		$\Delta_r H_{298\text{K}}^\circ / (\text{kJmol}^{-1})$
(2a)	${}^3\text{NCN} + {}^1\text{H}_2 \rightarrow {}^1\text{H}_2\text{NCN}$	-317.2
(2b)	$\rightarrow {}^1\text{HNCNH}$	-304.2
(2c)	$\rightarrow {}^3\text{CH}_2 + {}^1\text{N}_2$	-59.0
(2d)	$\rightarrow {}^1\text{HCN} + {}^3\text{NH}$	38.4
(2e)	$\rightarrow {}^2\text{HNCN} + {}^2\text{H}$	83.6
(2f)	$\rightarrow {}^1\text{HNC} + {}^3\text{NH}$	100.5
(2g)	$\rightarrow {}^2\text{NH}_2 + {}^2\text{CN}$	174.7

The formation of the thermodynamically most favorable products  $\text{H}_2\text{NCN}$  (2a) and  $\text{HNCNH}$  (2b) is spin-forbidden and hence their formation constitutes a presumably unimportant pathway. All other, increasingly endothermic channels are spin-allowed and may become accessible at combustion temperatures. Except for reaction (2e), the assumed product sets require the formation of an unlikely collision complex on the triplet surface followed by several rearrangement steps. This is in particular the case for reaction (2c), where a feasible reaction pathway can hardly be imagined. Actually, reactions (2a) and (2g) may become important for the corresponding  ${}^1\text{NCN}$  reaction as singlet radicals are known to prefer insertion reactions. For the triplet radical, however, reaction (2e) constitutes the by far most probable reaction channel. Next to the decomposition of a  ${}^3\text{HNCNH}$  intermediate, this reaction can take place as a direct activation controlled H abstraction reaction as well. It is known that H abstraction channels often become the dominating pathway at high temperatures even if complex-forming pathways are accessible.<sup>[26,37]</sup> Therefore, the most reasonable reaction products  $\text{HNCN} + \text{H}$  have been assumed for the target reaction  $\text{NCN} + \text{H}_2$  in a first round of data evaluation. The effect of assuming different product sets will be further discussed below. The experimental NCN concentration-time profiles have been simulated based on a detailed mechanism assembled from our previous work (Table 5.1). Except for reactions (3) and (4), all reactions have been duplicated for  ${}^1\text{NCN}$  to take  ${}^1\text{NCN}$  chemistry approximately into account. Moreover, the reaction model was complemented by the extensive GDFkin3.0 mechanism.<sup>[12,13]</sup> Subsequent  $\text{HNCN}$  chemistry is only partly accounted for. Next to the reverse of reaction (2e),  $\text{H} + \text{HNCN}$ , only the thermal decomposition of  $\text{HNCN}$  has been included in the mechanism by the reverse of reaction (11). For the latter, the used rate expression for atmospheric pressure has been adopted from recent work of Teng et al.;<sup>[19]</sup> a formerly reported rate expression for the low pressure limit of the unimolecular decomposition reaction (-11) by Moskaleva and Lin,<sup>[6]</sup> which is implemented into the Konnov0.6 mechanism, turned out to yield unrealistic high rate constant values. Other rate constant data for bimolecular  $\text{HNCN}$  loss reactions such as  $\text{HNCN} + \text{C}/\text{CN}/\text{N}$  are not available in the literature, however, these reactions are not expected to play significant

roles for modeling the shock tube experiments.

In Fig. 5.1a, the solid curve represents the best numerical simulation of the NCN profile using  $k_{2e} = 1.8 \times 10^{10} \text{ cm}^3\text{mol}^{-1}\text{s}^{-1}$ . Variation of  $k_{2e}$  by a factor of two yields the two dotted curves that fail to reproduce the experiment. The sensitivity analysis in Fig. 5.1b reveals that reaction (2e) is by far the most important reaction for NCN consumption. Only at reaction times  $t > 250 \mu\text{s}$ , the reaction  $\text{NCN} + \text{H}$  gains some influence. Its high temperature rate constant and branching ratio, however, has been directly measured recently.<sup>[22]</sup> The sole other sensitive reaction, which is important to model the initial NCN formation at short reaction times, is the CIISC process (4). It has been studied in some detail by Dammeier et al.<sup>[29]</sup> and its rate constant value is dependent on the composition of the reaction gas mixture. Here,  $k_4$  has been used as an adjustable parameter and was varied within the error limits reported in Ref. 29 in order to model the initial increase of the NCN signal. Finally, an alternative rate constant determination by fitting the NCN decay assuming a simple pseudo-first order exponential decay without applying any reaction mechanism has been performed as well. As expected for negligible secondary chemistry, very similar rate constant values are obtained. For example, for the experiment shown in Fig. 5.1 a rate constant of  $k_2 = 1.9 \times 10^{10} \text{ cm}^3\text{mol}^{-1}\text{s}^{-1}$  has been obtained over the interval  $25 \mu\text{s} \leq t \leq 250 \mu\text{s}$ , which is very close to the  $k_{2e} = 1.8 \times 10^{10} \text{ cm}^3\text{mol}^{-1}\text{s}^{-1}$  value from the numerical simulation mentioned above.

In order to analyze a possible influence of the assumed products of reaction (2), the experimental NCN concentration-time profiles have been simulated using different product sets. Fig. 5.2a illustrates an experimental NCN profile at a reflected shock wave temperature of  $T = 2123 \text{ K}$ . Assuming reaction channel (2e) with the radical products  $\text{HNCN} + \text{H}$  yields a rate constant of  $k_{2e} = 1.3 \times 10^{11} \text{ cm}^3\text{mol}^{-1}\text{s}^{-1}$  (red curve). The sensitivity analysis for the chosen high temperature experiment reveals that the influence of secondary chemistry is more pronounced than for the previously discussed  $T = 1582 \text{ K}$  experiment (Fig. 5.1). For example, the thermal decomposition of NCN,  $\text{NCN} + \text{M} \rightarrow \text{C} + \text{N}_2 + \text{M}$ , starts to play a significant role. Its rate constant has been measured in two independent studies and highly consistent values have been reported.<sup>[21,24]</sup> Hence, a sensitive determination of  $k_2$  is still possible. Next, the same value for the rate constant  $k_2$  but the alternative recombination product  $\text{HNCNH}$  of channel (2b) has been used instead of the products  $\text{HNCN} + \text{H}$ . The resulting simulated curve predicts a somewhat too slow NCN decay (black curve). As no additional  $\text{HNCNH}$  chemistry has been included into the mechanism and hence  $\text{HNCNH}$  has been treated as a stable species, the difference between the two simulations reflects the impact of the secondary reactions resulting from the radical products formed in case of the channel (2e) products. Similar results are obtained when assuming reaction channel (2a). In contrast, simulations with the other potential radical forming reaction channels (2c), (2d), (2f) or (2g) yielded more or less the same  $k_2$  values as for channel (2e). In Fig. 5.2a, the blue curve represents the simulation using the products of channel (2f),  $\text{HNC} + \text{NH}$ , as an example. Within error limits it is identical to the simulation using channel (2e).

Total rate constant values for reaction (2) have been extracted from 36 shock tube experiments. The experimental conditions of all experiments are listed in Table 5.2, an Arrhenius plot of the obtained  $k_2$  values is given in Fig. 5.3. The symbols correspond to the results assuming  $\text{HNCN} + \text{H}$  as the reaction products. Within the scatter, the obtained data for the two different total densities of  $\rho \approx$

Figure 5.2: (a) Comparison of numerical simulations assuming HNCN + H (2e), HNC + NH (2f), or HNCNH (2b) as alternative products of the reaction  $\text{NCN} + \text{H}_2$ .  $T = 2123 \text{ K}$ ,  $p = 719 \text{ mbar}$ ,  $\rho = 4.08 \times 10^{-6} \text{ mol/cm}^3$ ,  $[\text{H}_2] = 1.5\%$ ,  $[\text{NCN}_3] = 25 \text{ ppm}$ .  $k_2 = 1.3 \times 10^{11} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  has been used for all three simulations. (b) Corresponding sensitivity analysis assuming the products HNCN + H.

$4.1 \times 10^{-6} \text{ mol/cm}^3$  (open squares) and  $7.4 \times 10^{-6} \text{ mol/cm}^3$  (star symbols) agree, showing that the reaction is not significantly pressure dependent. The data points can be nicely represented by a two-parameter Arrhenius expression.

$$k_2 / (\text{cm}^3 \text{ mol}^{-1} \text{ s}^{-1}) = 4.1 \times 10^{13} \exp\left(-\frac{101 \text{ kJ/mol}}{RT}\right), \Delta \log k_2 = \pm 0.11.$$

The error bars in Fig. 5.3 exemplify the cumulative uncertainty of  $k_2$  resulting from different error sources. Simulations show that a pessimistic  $\pm 25\%$  error estimate for the initial  $\text{NCN}_3$  concentration, which arises from the 25% error of the used NCN absorption cross section,<sup>[28]</sup> result in a  $\pm 6\%$  uncertainty in  $k_2$ . Varying the most important background reactions within their error limits sum up to  $\pm 8\%$ . Finally, the uncertainty of the  $\text{H}_2$  concentration was  $\pm 2\%$  and the statistical error of the Arrhenius fit of the scattered data amounts to  $\pm 8\%$  ( $2\sigma$  standard error of the mean). A reasonable total error estimate in the middle of our temperature range at  $T \approx 1750 \text{ K}$  is therefore  $\pm 24\%$ , corresponding to  $\Delta \log k_2 = \pm 0.11$ . The dashed line in Fig. 5.3 corresponds to the Arrhenius expression  $k_2 / (\text{cm}^3 \text{ mol}^{-1} \text{ s}^{-1}) = 6.5 \times 10^{13} \times \exp(-105 \text{ kJ/mol}/RT)$  that has been obtained by assuming the unlikely formation of a stable reaction product (i.e., channel (2a) or (2b)). Such an evaluation yields data (not shown) that start to deviate from the evaluation assuming radical products (i.e., channels (2c)-(g))

at temperatures  $T > 1700$  K with a maximum deviation of +30% at  $T = 2480$  K.

A comparison with a similar reaction and quantum-chemical calculations show that the obtained activation energy is roughly consistent with a reaction that is dominated by an H abstraction pathway according to channel (2e). On the one hand, a comparable H abstraction reaction of the N-centered triplet species <sup>3</sup>NH,  $\text{NH} + \text{H}_2 \rightarrow \text{NH}_2 + \text{H}$ , exhibits an activation energy, which is 33 kJ/mol higher than the corresponding reaction enthalpy of  $\Delta_r H_{298\text{K}}^\circ = 32$  kJ/mol.<sup>[38]</sup> Accordingly, an activation energy of  $E_A \approx 84$  kJ/mol + 33 kJ/mol = 117 kJ/mol would be expected for reaction (2e). On the other hand, an estimate of the activation enthalpy of channel (2e) based on quantum-chemical calculations using G4 level of theory yields a similar result. This method provides a reaction enthalpy for channel (2e) of  $\Delta_r H_{298}^0 = 86$  kJ/mol, which is close to the value of 84 kJ/mol from thermodynamic data taken from literature. The calculated energy of the H<sub>2</sub>⋯NCN transition state (H<sub>2</sub> is bonded to one of the N atoms and is oriented essentially perpendicular to the slightly bended NCN moiety) yields  $\Delta H^\ddagger(T = 1750 \text{ K}) = 101$  kJ/mol. Accordingly, taking into account the simple transition state theory expression  $E_A \approx \Delta H^\ddagger + 2RT$ , an activation energy of about 130 kJ/mol can be estimated for channel (2e) at  $T = 1750$  K. However, a more detailed comparison with theory should be based on more advanced multi-reference quantum-chemical and kinetic calculations including tunneling corrections as well as a complete RRKM/master equation analysis of the possible role of additional complex-forming reaction pathways. Given that accurate energy calculation of NCN related species turned out to be very challenging,<sup>[34]</sup> such an analysis would have been beyond the scope of this paper.

Figure 5.3: Arrhenius plot of the rate constant for the reaction  $\text{NCN} + \text{H}_2 \rightarrow \text{products}$ . Experimental data at two different total densities  $\rho \approx 4.1 \times 10^{-6} \text{ mol/cm}^3$  (open squares) and  $\rho \approx 7.4 \times 10^{-6} \text{ mol/cm}^3$  (star symbols) and corresponding Arrhenius fit (solid line) for an evaluation assuming radical products (channel (2c)-(g)) are shown. The dashed line depicts an Arrhenius fit obtained for an alternative data evaluation (corresponding data points are not shown) assuming stable reaction products (channels (2a) and (2b)).

### 5.3.2 Flame modeling

The reaction  $\text{NCN} + \text{H}_2$  turns out to be comparatively fast. With a rate constant of  $k_2 = 3.2 \times 10^{10} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  at a typical flame temperature of  $T = 1700 \text{ K}$ , it is about a factor of 300 faster than the reaction  $\text{NCN} + \text{O}_2$ . Therefore, in order to assess the potential influence of reaction (2) for  $\text{NO}_x$  formation in flames, reaction (2) as well as other  $\text{NCN}$  reactions have been implemented into the `GDFkin3.0_NC�N`<sup>[12,13]</sup> flame mechanism. Arrhenius parameters of all reactions that have been added to the original mechanism are listed in Table 5.3. Simulations have been performed with  $\text{HNCN} + \text{H}$ ,  $\text{HCN} + \text{NH}$ , and  $\text{HNC} + \text{NH}$  as the respective sole products of reaction (2).

Consideration of  $\text{HNCN} + \text{H}$  as main products implies an update of the mechanism with respect to  $\text{HNCN}$  reactions as well.  $\text{HNCN}$  species may rapidly react with  $\text{O}$  atoms (reactions (12)) generating  $\text{HNC}$  species. Consequently, two new blocks of reactions have been added to account for possible  $\text{HNCN}$  and  $\text{HNC}$  chemistry. In order to be coherent with the experimental rate constant determination, some additional  $\text{NCN}$  consumption reactions, (6) to (11), have also been considered in the detailed mechanism. In the following, this updated mechanism is named `up-GDFkin3.0_NC�N` (`up-GDF` for short) in contrast to the original mechanism `GDFkin3.0_NC�N` (`GDF` for short). Calculations were performed to simulate species profiles in selected low pressure premixed flames where the reaction  $\text{NCN} + \text{H}_2$  may play an important role in the prompt- $\text{NO}$  pathway. Two fuel rich flames of  $\text{CH}_4/\text{O}_2/\text{N}_2$  have been considered numerically. Both flames were simulated at low pressure (5.0 kPa) with the same total volumetric flow rate (300 L/h, in the standard condition of temperature and pressure)

Table 5.3: Arrhenius parameters for rate constants of NCN, HNCN and HNC reactions added to the GDFkin3.0\_NCN mechanism<sup>[13]</sup> for flame simulations. Rate constants are given as  $k_i = AT^n \exp[-E_a/RT]$  in units of  $\text{cm}^3, \text{mol}^{-1}, \text{s}^{-1}$  and kJ.

and nitrogen dilution ratio (60%), but a different richness equal to  $\phi = 1.3$  and  $\phi = 1.5$ , respectively. Imposed temperature profiles were identical for each flame. The temperature in the burned gas was limited to remain lower than 1850 K, hence thermal-NO contribution was reduced and prompt-NO formation was promoted.

Considering the original GDF mechanism, simulated temperature and species profiles of NO, NCN and  $\text{H}_2$  are reported in Fig. 5.4. In the burned gases, NO mole fractions are equal to 24.5 and 38.3 ppm for  $\phi = 1.3$  and  $\phi = 1.5$ , respectively. As shown in Fig. 5.4a, the NO mole fraction in the burned gases is hardly affected at  $\phi = 1.3$ , but is increased by 8% at  $\phi = 1.5$  when the calculations are performed with the up-GDF mechanism instead.  $\text{H}_2$  and NCN profiles are reported in Fig. 5.4b using the up-GDF mechanism. The profiles show that at the NCN peak location (height above burner, HAB ( $\phi = 1.3$ ) = 5.3 mm and HAB ( $\phi = 1.5$ ) = 6.8 mm) the mole fractions of  $\text{H}_2$  with  $x(\phi = 1.3) = 0.064$  and  $x(\phi = 1.5) = 0.091$  are high. NCN peak mole fractions are quite similar in the two flames with peak values close to 145 ppb, but the shape of the NCN profile is much thinner at  $\phi = 1.3$ .

N-atom flux analysis was performed after all the reactions have been declared in a non reversible format. In this way the atom flux reveals the flux in both directions of reversible reactions (forward and backward) separately. Some results at the NCN peak locations for both flames are presented in Table 5.4. Only NCN losses in the direction of the prompt-NO formation pathway (forward flux) are included. As expected, the reaction  $\text{NCN} + \text{H} \rightarrow \text{HCN} + \text{N}$  is the most important NCN loss reaction that dominates the NCN forward flux, followed by the reaction with O atoms (yielding  $\text{CN} + \text{NO}$ ). Nevertheless, about 1.8% of the NCN radicals are consumed through reaction (2) at  $\phi = 1.3$  and 3.5% at  $\phi = 1.5$ . The so far neglected reaction with  $\text{H}_2$  ranks third place and its contribution is even three

Figure 5.4: a) NO profiles simulated for the low pressure flames (see text) at a richness of  $\phi = 1.3$  and  $\phi = 1.5$ . Results are shown for both the GDF and up-GDF mechanisms. b) Corresponding  $\text{H}_2$  and  $\text{NCN}$  profiles simulated with the up-GDF mechanism.

orders of magnitude higher than for the reaction  $\text{NCN} + \text{O}_2$ . Note that the N-flux analysis reveals that next to reaction (2) also reaction (8),  $\text{NCN} + \text{C}$ , which was omitted in the original mechanism as well, becomes more important than other, already implemented bimolecular reactions such as  $\text{NCN} + \text{OH}/\text{HO}_2/\text{NO}/\text{M}$  that are negligible under the assumed flame conditions.

Although it turned out that the implementation of reaction (2) is important, its rather low contribution to the forward flux is in seemingly contrast to the mentioned significant change of the overall NO yield. Obviously, other reactions added to the updated mechanism must be responsible for this prominent effect. A complete reaction pathway diagram for the  $\phi = 1.5$  flame using the up-GDF mechanism is shown in Fig. 5.5. New reaction pathways that are absent in the corresponding diagram using the original GDF mechanism (not shown) are highlighted in red color. These pathways include the formation and loss reactions of the newly included species  $\text{HNCN}$  and  $\text{HNC}$ . Once formed,  $\text{HNCN}$  reacts quickly with O-atoms through reaction (12). According to theoretical calculations, the products

Table 5.4: N-atom flux analysis for the two  $\text{CH}_4/\text{O}_2/\text{N}_2$  model flames. The Table lists the forward fluxes associated with several  $\text{NCN} + \text{X}$  reactions on the prompt-NO formation pathway.

Forward flux %	H <sup>a</sup>	O	H <sub>2</sub>	C	H <sub>2</sub> O	OH	HO <sub>2</sub>	O <sub>2</sub>	NO	M
$\phi = 1.3$	69.21	25.68	1.76	1.36	1.33	0.44	0.21	< 0.01	< 0.01	< 0.01
$\phi = 1.5$	79.33	12.54	3.52	2.17	1.96	0.33	0.13	< 0.01	< 0.01	0.03

<sup>a</sup> for  $\text{NCN} + \text{H}$  (yielding either  $\text{CH} + \text{N}_2$  or  $\text{HCN} + \text{N}$ , with a relative ratio of 77/23) only the  $\text{HCN} + \text{N}$  forming channel contributes to the forward flux along the prompt-NO formation pathway

Figure 5.5: N-atom flux analysis at the NCN peak location in the  $\phi = 1.5$   $\text{CH}_4/\text{O}_2/\text{N}_2$  flame using the up-GDF mechanism. The pathways highlighted in red color are absent in a corresponding flux analysis using the original GDF mechanism.<sup>[13]</sup>

of the reaction  $\text{HNCN} + \text{O}$  are mostly  $\text{HNC} + \text{NO}$ .<sup>[39]</sup> HNC then reacts with OH radicals yielding  $\text{HNCO} + \text{H}$ , and  $\text{HNCO}$  reacts with H atoms yielding  $\text{NH}_2 + \text{CO}$ . However, it becomes clear from the flux diagram that HNC radicals are formed primarily from HCN and only secondly from HNCN. In fact, the HCN/HNC isomerization according to reactions (15), which is close to its low-pressure limit, and the H atom initiated isomerization reaction (-16),  $\text{HNC} + \text{H} \rightarrow \text{HCN} + \text{H}$ , represent 12% and 20% of the HCN consumption at  $\phi = 1.3$  and  $\phi = 1.5$ , respectively. This finding is also reflected in the HCN profiles shown in Fig. 5.6 for the  $\phi = 1.5$  flame. HCN mole fraction peak values obtained with the updated mechanism decrease by 20%. According to the ROP, HCN is mainly consumed through the reaction  $\text{HCN} + \text{O} \rightleftharpoons \text{NCO} + \text{H}$  and the reaction (-16), both being three times more important than the reactions  $\text{HCN} + \text{OH} \rightleftharpoons \text{HOCN} + \text{H}$  and  $\text{HNC} (+\text{M}) \rightleftharpoons \text{HCN} (+\text{M})$ . The combined effect of HNC formation from the reactions (-16) and (12a) results in a substantial increase of HNCO by a factor of two (Fig. 5.6). This increase is followed by a comparable increase of the peak values of  $\text{NH}_2$  as well.

To sum up, although the implementation of the reaction (2) has indeed a significant impact on NO formation through a new  $\text{HNC} \rightarrow \text{HNCO} \rightarrow \text{NH}_2 \rightarrow \text{NH} \rightarrow \text{NO}$  pathway, it is in fact the HCN/HNC isomerization and not the reaction  $\text{NCN} + \text{H}_2$  that is mainly responsible for the distinct changes obtained with the up-GDF mechanism. Note that the rate constant of the H initiated isomerization reaction (16),  $\text{H} + \text{HNC} \rightarrow \text{HCN} + \text{H}$ , is based on a theoretical QRRK estimate<sup>[42]</sup> and, to the best of our knowledge, has not been experimentally confirmed yet. Therefore, our interesting preliminary finding calls for a more detailed analysis to better constrain and verify the role of the HNC initiated

Figure 5.6: Comparison of HCN, HNCO, and  $\text{NH}_2$  profiles of the  $\phi = 1.5$  flame calculated with the original GDF (dashed curves) and the up-GDF (solid curves) mechanisms.

pathway for NO formation in flames.

The possible influence of the assumed products of the reaction (2) for the NO formation in flames has also been analyzed. Whatever channel (d, e, f) of reaction (2) was assumed, simulated NO profiles are identical to each other. However, considering the channel (2d), implementation of the reactions (12-19) could be removed since HCN and NH species are already declared in GDF.<sup>[13]</sup> In that case, simulated NO profiles would be identical to those obtained with the original GDF mechanism. Again, this clearly highlights the potential importance of the HCN/ HNC isomerization pathway through reactions (15) and (-16).

## 5.4 Conclusion

The rate constant of the reaction (2),  $\text{NCN} + \text{H}_2 \rightarrow \text{products}$ , has been measured for the first time. Shock wave experiments with time-resolved NCN radical detection by narrow-bandwidth laser UV absorption were carried out under nearly pseudo-first order reaction conditions with  $\text{H}_2$  as the excess component. The total rate constant has been measured at temperatures  $1057 \text{ K} \leq T \leq 2475 \text{ K}$  and can be represented by the Arrhenius expression

$$k_2 / (\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 4.1 \times 10^{13} \exp\left(-\frac{101 \text{ kJ/mol}}{RT}\right), \Delta \log k_2 = \pm 0.11.$$

No pressure dependence could be observed between  $p = 324 \text{ mbar}$  and  $p = 1665 \text{ mbar}$ . Quantum-chemical calculations show that the activation energy is roughly consistent with the formation of the products  $\text{HNCN} + \text{H}$ , hence the most likely direct abstraction pathway. Still, detailed quantum-

chemical calculations in combination with RRKM/TST/ME modeling are desirable to further assess the role of complex-forming reaction pathways.

The detailed reaction mechanism GDFkin3.0\_NCN has been updated to assess the potential influence of the so far neglected reaction (2) on prompt-NO formation in flames. Next to reaction (2), HNC and HNCN submechanisms have been implemented as well to describe the subsequent chemistry of the reaction products. Two fuel-rich low-pressure methane flames served as a model case and it was shown that the contribution of reaction (2) on the overall NCN loss in the direction of prompt-NO is on the order of a few percent. Of course, the reaction may become even more important for other flame conditions and, therefore, needs to be included in detailed flame mechanisms. The flame simulation also highlights the fact that the reaction  $\text{NCN} + \text{C} \rightleftharpoons \text{CN} + \text{CN}$ , which was also omitted in the original GDFkin3.0\_NCN mechanism should be considered in the future as well. As yet the rate constant for  $\text{NCN} + \text{C}$  has only been roughly determined experimentally, improved direct measurements are required. Moreover, as a pronounced impact of HCN/ HNC isomerization on NO formation has been found in this study, a critically assessment and experimental verification of the role of this new  $\text{HNC} \rightarrow \text{HNCO} \rightarrow \text{NH}_2 \rightarrow \text{NH} \rightarrow \text{NO}$  prompt-NO formation pathway is important. A thorough validation of the updated mechanism going along with the implementation of other new experimental rate constant data that recently have become available for several bimolecular reactions of NCN is currently underway.

## Acknowledgment

Financial support by the German Science Foundation (DFG-FR 1529/4) and by the University Lille1 through a BQR International 2014 sponsorship is gratefully acknowledged. We also thank Johannes Dammeier for help and support with the shock tube experiments and Pascale Desgroux for fruitful discussions.

**Abstract**

The rate constant of the comparably slow bimolecular NCN radical reaction  $\text{NCN} + \text{O}_2$  has been measured for the first time under combustion relevant conditions using the shock tube method. The thermal decomposition of cyanogen azide ( $\text{NCN}_3$ ) served as a clean high-temperature source of NCN radicals. NCN concentration-time profiles have been detected by narrow-bandwidth laser absorption at  $\tilde{\nu} = 30383.11 \text{ cm}^{-1}$ . The experiments behind incident shock waves have been performed with up to 17%  $\text{O}_2$  in the reaction gas mixture. At such high  $\text{O}_2$  mole fractions it was necessary to take  $\text{O}_2$  relaxation into account that caused a gradual decrease of the temperature during the experiment. Moreover, following fast decomposition of  $\text{NCN}_3$  and collision-induced intersystem crossing of the initially formed singlet NCN to its triplet ground state, an unexpected and slow additional formation of triplet NCN has been observed on a 100  $\mu\text{s}$  timescale. This delayed NCN formation was attributed to a fast recombination of  $^1\text{NCN}$  with  $\text{O}_2$  forming a  $^3\text{NCNOO}$  adduct acting as a reservoir species for NCN. Rate constant data for the reaction  $\text{NCN} + \text{O}_2$  have been measured at temperatures between 1674 K and 2308 K. They are best represented by the Arrhenius expression  $k_2 / (\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 1.3 \times 10^{12} \exp\left(-\frac{97 \text{ kJ/mol}}{RT}\right)$ , ( $\pm 57\%$ ). No pressure dependence has been observed at pressures between 216 mbar and 706 mbar.

**6.1 Introduction**

Nitrogen oxides, such as NO and  $\text{NO}_2$  ( $\text{NO}_x$ ), are harmful atmospheric pollutants from fossil fuel combustion. Under fuel rich combustion conditions  $\text{NO}_x$  is mainly formed over the so-called prompt-NO pathway, which is initiated by the reactions of small hydrocarbon radicals with molecular nitrogen stemming from the combustion air according to the Fenimore mechanism.<sup>[1]</sup> Based on quantum chemical calculations<sup>[2]</sup> and verified by shock tube measurement<sup>[3]</sup> it has been shown that the initiation reaction  $\text{CH} + \text{N}_2$  yields the spin-allowed products  $\text{H} + \text{NCN}$ .

In recent years, using  $\text{NCN}_3$  thermal decomposition as a quantitative source of NCN radicals and sensitive time-resolved UV absorption spectroscopy to detect NCN concentration-time profiles, we have performed several direct shock tube measurements of bimolecular NCN rate constants at high temperatures. These studies include the reactions  $\text{NCN} + \text{NO}$ ,  $\text{NO}_2$ ,<sup>[4]</sup>  $\text{NCN} + \text{NCN}$ , O, and M<sup>[5]</sup> as well as  $\text{NCN} + \text{H}$ <sup>[6]</sup> and  $\text{NCN} + \text{H}_2$ .<sup>[7]</sup> The only other direct study reported in the literature, which is in excellent agreement with our work, was concerned with the unimolecular decomposition of NCN using the C-ARAS technique.<sup>[8,9]</sup> So far, no experimental high temperature rate constant measurements have been performed for the reaction with molecular oxygen,

This reaction has been discussed to play an important role for  $\text{NO}_x$  formation in flames.<sup>[11,12]</sup> Baren

Figure 6.1: Simplified potential energy diagram (G2M(CC1) level of theory) for the reaction  $\text{NCN} + \text{O}_2$ , according to Zhu and Lin.<sup>[10]</sup>

and Hershberger performed kinetic measurements of NCN radical reactions at low temperatures and pressures by detecting NCN concentration-time profiles following 193 nm photolysis of  $\text{CH}_2\text{N}_2/\text{C}_2\text{N}_2$  mixtures using laser-induced fluorescence. They could not observe significant changes in the NCN profiles by adding  $\text{O}_2$  to their reaction mixtures and therefore estimated an upper limit of  $k_2 < 6.0 \times 10^9 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  for temperatures between 298 K and 573 K.<sup>[13]</sup> In a first attempt to compile a high temperature NCN mechanism for  $\text{NO}_x$  formation, Glarborg et al. estimated a value of  $k_2 = 1.0 \times 10^{13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ .<sup>[14]</sup> Such a high value, which has been adopted by El Bakali et al.<sup>[11]</sup> in their NCN submechanism for flame modeling, would make the reaction  $\text{NCN} + \text{O}_2$ , together with  $\text{NCN} + \text{H}$ , one of the most important reactions for modeling the fate of NCN in flames. According to ab initio and transition state theory calculations by Zhu and Lin,<sup>[10]</sup> the following two main reaction channels are accessible at high temperatures:

In Fig. 6.1 these two energetically most favorable reaction pathways are illustrated in a potential energy diagram. As discussed by Zhu and Lin, the possible formation of  $\text{NCNO} + \text{O}({}^3\text{P})$  and  $\text{NCNO} + \text{O}({}^1\text{D})$  is not important under combustion conditions and, for the sake of clarity, is omitted in Fig. 6.1. The *cis*- and *trans*-NCNOO intermediates refer to the two possible NC-NO-O isomers of the initially formed NCN- $\text{O}_2$  adduct. Relying on the G2M (CC1) level of theory results,<sup>[10]</sup> both product sets are formed from the *cis*-isomer with high transition state barriers of 117 kJ/mol (86 kJ/mol) for channel (2a) and 120 kJ/mol (89 kJ/mol) for channel (2b) relative to the energy of the *cis*-intermediate (of the educts). *cis-trans* isomerisation, with a calculated barrier height of 165 kJ/mol, does not take place. Reaction channel (2a), the formation of NCO and NO, turned out to be the most important channel with a branching ratio of about 85% in the temperature range 1000 K to 3000 K. The calculations for the total rate constant resulted in the rate expression

$k_2 / (\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 4.4 \times 10^9 \times (T/\text{K})^{0.51} \exp\left(-\frac{103 \text{kJ/mol}}{RT}\right)$ .<sup>[10]</sup> At  $T = 1500 \text{ K}$ , this rate constant is five orders of magnitude lower than the estimated rate constant value of Glarborg et al.<sup>[14]</sup> Of course, such a low value implies a reduced influence of the reaction  $\text{NCN} + \text{O}_2$  on the modeled NCN concentrations in flames than initially anticipated. For sure, the outcome of the theoretical study of Zhu and Lin supports an overall slow reaction. However, taking into account the difficulties in calculating reliable NCN energies and transition state barrier heights,<sup>[15,16,17]</sup> and facing the lack of experimental studies, the absolute value of the rate constant awaits experimental validation. This paper now reports the first direct measurements of the rate constant of the reaction  $\text{NCN} + \text{O}_2$ . Compared to our previous NCN studies, the data analysis was less straightforward. Vibrational relaxation of  $\text{O}_2$  as well as the apparent intermediate formation of an NCN reservoir species had to be properly taken into account. Nevertheless, it was possible to extract reliable rate constant values, which turned out to be about a factor of five higher than the transition state theory estimate.

## 6.2 Experimental

### 6.2.1 Shock tube setup

Similar to our previous NCN measurements the experiments have been performed in an about 8 m long stainless steel shock tube with an electro-polished test section with an inner diameter of 81 mm. The whole apparatus is described in more detail elsewhere.<sup>[18]</sup> Experimental temperatures and pressures behind the shock waves were calculated from the shock wave velocity, taking into account shock wave damping of  $\sim 1\%$  per meter, and the pre-shock conditions using a one dimensional frozen-chemistry code with real gas correction. Reported times behind the incident shock wave correspond to the actual reaction times taking into account the gas flow,  $t_{\text{reaction}} = t_{\text{laboratory}} \times \rho_2 / \rho_1$ . Reaction gas mixtures of 14 - 56 ppm  $\text{NCN}_3$  in Ar were prepared in a stainless steel gas mixing system equipped with several glass flasks and storage tanks.  $\text{NCN}_3$  synthesis as well as the procedures for gas mixture preparation have been described elsewhere.<sup>[4,19]</sup> Very high  $\text{O}_2$  mole fractions of 5.5 to 17% had to be used to achieve a measurable effect of the reaction  $\text{NCN} + \text{O}_2$  on the NCN profiles. At such high  $\text{O}_2$  concentrations, due to the relatively slow vibrational relaxation of  $\text{O}_2$ , the temperature (and density) behind shock waves cannot be assumed as constant. While the translational and rotational degrees of freedom are heated within  $1 \mu\text{s}$ , the vibrational relaxation of oxygen is much slower, about  $166 \mu\text{s}$  at  $T = 1500 \text{ K}$  and  $p = 1 \text{ bar}$  for 2.5%  $\text{O}_2$  in Ar.<sup>[20]</sup> Due to this slow equilibration, the actual temperatures decrease during the experiments. In fact, the initial temperatures are higher than the calculated temperatures using the standard shock tube code, which assumes instantaneous and complete relaxation of  $\text{O}_2$ . Therefore, starting temperatures have been calculated using a modified NASA polynomial for oxygen taking only translational and rotational degrees of freedom into account. This oxygen species will be referred to as  $\text{O}_2(\text{cold})$  in the following. In this way, the change of the temperature (and density) behind the incident shock wave could be taken into account in a straightforward manner by implementing the relaxation process  $\text{O}_2(\text{cold}) \rightarrow \text{O}_2$  into the reaction mechanism and by performing numerical simulations assuming isobaric reaction conditions. As outlined by Oertel,<sup>[21]</sup> assuming that the specific enthalpy of the heated gas mixture as well as the vibrational relaxation time  $\tau$  is approximately constant over the

whole relaxation process, the temperature change can be described by a mono-exponential law:

$$\frac{T(t) - T_\infty}{T_2 - T_\infty} = \exp\left(-\frac{c_p}{c_{p,2}} \times \frac{t}{\tau}\right)$$

Here,  $T(t)$  is the actual temperature,  $T_2$  the initial temperature behind the incident shock wave, and  $T_\infty$  the equilibrated temperature after relaxation.  $c_p$  and  $c_{p,2}$  are the specific heat capacities of the reaction mixture with and without vibrational excitation of  $\text{O}_2$ , respectively. The ratio  $c_p/c_{p,2}$  is very close to one. Under these assumptions, the experimental pressure behind the incident shock wave remains constant and  $T \times \rho = \text{const.}$  holds as well.

### 6.2.2 NCN source

As shown by Dammeier et al.,<sup>[19,22]</sup> the thermal decomposition of  $\text{NCN}_3$

serves as a clean and quantitative source for NCN with a yield of unity. The fast unimolecular decomposition of  $\text{NCN}_3$  generates NCN in its singlet excited electronic state, which undergoes a collision induced intersystem crossing (CIISC) process to the triplet ground state ( ${}^3\text{NCN}$  stated in the following as NCN). Our previous work showed that the CIISC process is the rate-limiting process for NCN formation at temperatures above 700 K, but is still fast compared to the reaction  $\text{NCN} + \text{O}_2$  measured here.<sup>[22]</sup>

### 6.2.3 NCN detection

NCN has been detected by time-resolved narrow-bandwidth laser absorption spectroscopy at a wavelength of  $\lambda = 329.1302 \text{ nm}$  ( $\tilde{\nu} = 30383.11 \text{ cm}^{-1}$ ). Details on the employed difference UV absorption setup, which was operated with about 1 mW output power of a frequency-doubled continuous-wave ring dye laser, have been described elsewhere.<sup>[19]</sup> The observed absorption band of the triplet NCN ground state is a superposition of the  ${}^3\Pi_1$  sub-band of the  $\tilde{A}{}^3\Pi_u(000) - \tilde{X}{}^3\Sigma_g(000)$  transition and the  $Q_1$  band head of the vibrationally excited Renner-Teller split  ${}^3\Sigma^+(010) - {}^3\Pi(010)$  transition.<sup>[23]</sup> The corresponding strongly temperature dependent but nearly pressure independent absorption cross section,  $\log(\sigma(\text{base e})/(\text{cm}^2\text{mol}^{-1})) = 8.9 - 8.3 \times 10^{-4} \times T/\text{K}$ , has been adopted from previous work.<sup>[19]</sup> Note that this value was recently put into question by Lamoureux et al.<sup>[24]</sup> who reported a 2.6 higher value based on elaborated theoretical spectroscopic calculations referenced to the electronic transition moment obtained from zero pressure fluorescence lifetime measurements by Smith et al.<sup>[25]</sup> A possible explanation for this discrepancy could be that the  ${}^1\text{NCN}$  yield from  $\text{NCN}_3$  thermal decomposition is well below unity. However, no indication was found in this and in our previous studies that the assumption of a quantitative  ${}^1\text{NCN}$  formation is invalid. Moreover, in a very recent study of Busch et al.,<sup>[9]</sup> who also used  $\text{NCN}_3$  as a source of NCN radicals, a C atom yield

from NCN thermal decomposition,  $\text{NCN} \rightarrow \text{N}_2 + \text{C}$ , was reported that is consistent with a quantitative NCN formation from  $\text{NCN}_3$  as well. We therefore rely on our previously reported absorption cross section value, which has been measured with an accuracy of  $\pm 25\%$ <sup>[19]</sup> using the same apparatus at similar temperatures and pressures as used in this work. Numerical simulations of concentration-time profiles were performed by the Chemkin-II program package, using the Senkin routine for sensitivity analyses.<sup>[26]</sup> An NCN mechanism for the simulations was assembled from our previous work<sup>[4,5,19]</sup> and available literature data. The most important reactions are listed in Tab. 6.1. Additionally, the GRI-Mech 3.0<sup>[27]</sup> has been used as a background mechanism to make sure that potentially important secondary reactions are considered in the simulations as well. Thermodynamic data were taken from Goos' and Burcat's thermodynamic database<sup>[28]</sup> with updated NASA polynomial parameters for NCN from Goos et al.<sup>[16]</sup> In agreement with previous work,<sup>[6]</sup> the enthalpy of formation of NCN was set to 450 kJ/mol.

## 6.3 Results

### 6.3.1 $\text{O}_2$ relaxation and NCNOO formation

Experiments have been performed behind incident shock waves at temperatures between 918 K and 2308 K and pressures of  $164 \text{ mbar} < p < 706 \text{ mbar}$ , corresponding to total densities of about  $\rho = 2.2 \times 10^{-6} \text{ mol/cm}^3$  and  $\rho = 3.6 \times 10^{-6} \text{ mol/cm}^3$ . The reaction mixtures contained 14 - 56 ppm of  $\text{NCN}_3$  and 5.5 - 17% of  $\text{O}_2$ .

Fig. 6.2 shows a typical experiment at a temperature of 1573 K. The two large Schlieren signals at  $t = 0 \mu\text{s}$  and  $t = 570 \mu\text{s}$  indicate the arrival of the incident and reflected shock wave at the observation point, respectively. Simulations using the compiled NCN mechanism revealed that, following a fast formation of NCN within a few  $\mu\text{s}$ , a slow decrease of the NCN concentration at longer reaction times would be expected mainly due to the reaction  $\text{NCN} + \text{NCN}$ . Additional loss due to the reaction  $\text{NCN} + \text{O}_2$  should further enhance the decay rate. Surprisingly, the measured NCN profile (red noisy curve) did not show the expected shape (dotted curve) but a pronounced increase during the first 300  $\mu\text{s}$ . Only at longer reaction times, the observed decay was similar to the one expected from the reaction  $\text{NCN} + \text{NCN}$  alone. A first explanation for this increase could be the slow  $\text{O}_2$  relaxation resulting in a temperature decrease during the experiment. With decreasing temperature, the NCN absorption cross section strongly increases such that the observed (apparent) NCN increase would simply reflect the temperature change due to the vibrational relaxation process. Therefore, the temperature (and density) change during the experiment has been explicitly taken into account as described in Section 6.2. The rate constants  $1/\tau$  for the relaxation process have been calculated for each reaction mixture using the relaxation times measured for Ar and  $\text{O}_2$  by White and Millikan<sup>[29]</sup> and Rao and Skinner<sup>[20]</sup> assuming a linear mixture rule. For the experiment shown in Fig. 6.2, the calculated temperature profile (blue curve) and an accordingly corrected NCN profile (black noisy curve) have been included. Two conclusions can be drawn: i) The black and red colored NCN profiles nearly overlap, hence the overall temperature (and density) effect,  $\Delta T = -9 \text{ K}$  and  $\Delta\rho = +1 \times 10^{-8} \text{ mol/cm}^3$ , is way too low to be responsible for the observed NCN increase. In fact an unfeasible temperature change of  $\Delta T = -90 \text{ K}$

Table 6.1: Selected reaction rate constant data for the numerical simulations of the experiments. Rate constants are given as  $k_i = A \times \exp[-E_a/RT]$  in units of  $\text{cm}^3, \text{mol}^{-1}, \text{s}^{-1}$  and kJ. The listed rate constants for NCN reactions have been duplicated for triplet and singlet NCN to take  $^1\text{NCN}$  chemistry approximately into account. Similarly, all reactions containing  $\text{O}_2$  have been duplicated to account for both  $\text{O}_2$  and  $\text{O}_2(\text{cold})$  reactivity. In addition to the reactions shown in the Table, the GRI-Mech 3.0 was used as background mechanism.

would have been needed to fully account for the experimentally observed NCN signal increase. ii) The timescale of the vibrational relaxation process (which is not yet complete after  $570 \mu\text{s}$  in Fig. 6.2) is significantly longer than the observed characteristic timescale of the NCN increase, hence vibrational relaxation of  $\text{O}_2$  cannot be responsible for the observed signal shape. To confirm this conclusion, additional experiments with He added to the reaction gas mixtures have been performed. Helium is known to promote  $\text{O}_2$  relaxation, however, He addition did not have any effect on the initial slope of the NCN signals.

Having shown that the effect of  $\text{O}_2$  relaxation is minor, the increase of the NCN profile must be assigned to an actual concentration increase. As it is not conceivable that  $\text{O}_2$  triggers an additional NCN formation reaction sequence that may account for the extra NCN at longer reaction times, we rather assume that the slow NCN formation indicates the formation of an NCN reservoir species that must have been formed right at the beginning of the reaction. In accordance with the initial NCN-OO adduct found by Zhu and Lin on the singlet potential energy surface,<sup>[10]</sup> it is likely that a similar adduct exists on the triplet surface as well. To serve as an explanation, the formation of this adduct must be fast in order to be able to compete against the likewise fast CIISC process (5),  $^1\text{NCN} \rightarrow \text{NCN}$ . To test the reasonability of the postulated formation of a reservoir species, the reactions

Figure 6.2: Shock tube experiment behind an incident shock wave. Red noisy curve: Experimental NCN profile assuming constant temperature and density. Black noisy curve: Calculated NCN profile allowing for temperature and density change caused by  $\text{O}_2$  vibrational relaxation. Dotted curve: Simulated NCN profile with constant temperature and without the formation of an NCN reservoir species. Solid curve: Best fit obtained with  $k_7$  and  $\phi = k_6/(k_6 + k_5)$  as adjustable parameters and  $k_8 = 1.0 \times 10^{12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . Dashed curve: Simulated NCN profile using the same  $k_7$  and  $\phi$  value but with  $k_8$  set to a high value of  $3.7 \times 10^{12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . Blue curve: Simulated temperature profile.

have been implemented into the reaction mechanism.

Actually, by adjusting the rate constants  $k_6$  and  $k_7$ , the experimental NCN profiles could be well captured in all cases; the simulated solid thick curve in Fig. 6.2 serves as an example. Reaction (7) determines the slope of the delayed NCN formation, whereas the ratio  $\phi = k_6/(k_6 + k_5)$  determines the amount of  $^1\text{NCN}$  captured by  $\text{O}_2$  and hence the overall NCN plateau. By fitting the measured NCN profiles,  $k_7$  and  $\phi$  could be reliably determined at temperatures between  $918 \text{ K} \leq T \leq 1595 \text{ K}$ . At these temperatures, the reaction  $\text{NCN} + \text{O}_2$  was too slow to contribute significantly to the overall NCN profiles and the gradual decrease of NCN at longer reaction times could be fully attributed to the reaction  $\text{NCN} + \text{NCN}$  (8). Its rate constant was inferred from Ref. 5, however, instead of adopting the recommended value of  $3.7 \times 10^{12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  that was obtained for higher total densities, we used the reported lower limit for  $k_8$  with a value of  $1.0 \times 10^{12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . According to Fig. 2 in Ref. 5, this value corresponds better to the densities used in this work. Note that the dashed curve in Fig. 6.2, which represents a simulation with  $k_8$  set to  $3.7 \times 10^{12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ , clearly shows that such a high rate constant value overestimates the observed NCN loss at longer reaction times.

The rate constant  $k_5$  of the  $^1\text{NCN}$  CIISC process has been determined by Dammeier et al. for  $\text{NCN}_3/\text{argon}$  mixtures.<sup>[22]</sup> Compared to their work, our experiments showed a much faster rise time of the  $^3\text{NCN}$  profiles revealing that oxygen is a more efficient collision partner than argon and that the CIISC process is dominated by collisions with  $\text{O}_2$ . Even for the experiment at the lowest temperature of this work, the initial increase of the NCN profile was already close to the time resolution of the experimental setup (about  $3 \mu\text{s}$ ). Therefore, it was not possible to accurately determine  $k_5$  values and

Figure 6.3: a) Determined rate constants  $k_7$  for the NCNOO decomposition and b) semilogarithmic plot of the branching ratio  $\phi = k_6/(k_6 + k_5)$ . Red symbols: experiments with about 3% He in the reaction mixture; black symbols: experiments without He; filled symbols:  $\rho \approx 2.0 \times 10^{-6} \text{ mol/cm}^3$ ; open symbols:  $\rho \approx 3.8 \times 10^{-6} \text{ mol/cm}^3$ .

hence,  $k_5$  was simply increased to a lower limit of  $1.6 \times 10^6 \text{ s}^{-1}$  to make sure that the CIISC process was modeled fast enough. Consequently, also the absolute value of  $k_6$  could not be determined but only its value relative to  $k_5$ . Experimental conditions and fitting results for  $k_7$  and  $\phi = k_6/(k_6 + k_5)$  are listed in Tab. 6.2 and plotted in Fig. 6.3a and b.

$\phi$  increases from a value of 0.08 at  $T = 920 \text{ K}$  to 0.29 at  $T = 1600 \text{ K}$ . By attributing this temperature dependence to reaction (6) alone, a lower limit of the activation energy  $E_a > 32 \text{ kJ/mol}$  for the formation of the NCNOO adduct can be inferred. In contrast to the branching ratio  $\phi$ , the rate constant  $k_7$  of the NCNOO decomposition was found to be almost temperature independent. It can be represented by the Arrhenius expression

$$k_7 / (\text{cm}^3 \text{ mol}^{-1} \text{ s}^{-1}) = 6.9 \times 10^3 \exp\left(-\frac{2.6 \text{ kJ/mol}}{RT}\right)$$

with  $E_a = (2.6 \pm 1.9) \text{ kJ/mol}$  ( $2 \sigma$  error). Within the scatter of the data, no dependence neither from the used  $\text{O}_2$  mole fractions (different symbols in Fig. 6.3a and b) nor from the density ( $\rho \approx 2.0 \times 10^{-6} \text{ mol/cm}^3$  for the filled and  $\rho \approx 3.8 \times 10^{-6} \text{ mol/cm}^3$  for the open symbols in Fig. 6.3) was found.

Table 6.2: Experimental conditions for the measurements of the rate constant of the  $\text{NCNOO}$  decomposition (7) and the  $k_6/(k_6 + k_5)$  branching ratio  $\phi$ .

$T / \text{K}$	$p / \text{mbar}$	$\text{NCN}_3 / \text{ppm}$	$\text{O}_2 / \%$	$k_7 / 10^3 \text{ s}^{-1}$	$\phi$

1584	276	33	7.3	5.4	0.37
experiments with about 3% He					
918	140	14	13	5.0	0.08
1008	156	14	11	5.5	0.07
1176	196	21	17	5.5	0.15
1331	230	22	17	5.5	0.16
1483	263	24	17	5.5	0.29
1595	276	15	6.3	6.2	0.14

Also the addition of He (red symbols in Fig. 6.3) had no influence on the extracted data for  $k_7$  and  $\phi$ .

### 6.3.2 $\text{NCN} + \text{O}_2$

The rate constant of the reaction  $\text{NCN} + \text{O}_2$  has been determined at temperatures  $1674 \text{ K} \leq T \leq 2308 \text{ K}$  and pressures between 216 and 634 mbar, corresponding to total densities of  $\rho = 1.48 \times 10^{-6}$  and  $\rho = 3.76 \times 10^{-6} \text{ mol/cm}^3$ . The upper accessible temperature limit was determined by the onset of  $\text{NCN}$  thermal decomposition,  $\text{NCN} + \text{M}$ ; the lower temperature limit was set by the reaction  $\text{NCN} + \text{NCN}$ , which becomes dominant at temperatures below 1700 K. For modeling purposes,  $\text{NCO} + \text{NO}$  have been assumed as the sole products of reaction (2), hence small contributions from the minor  $\text{CNO} + \text{NO}$  channel are included in  $k_7$

An example for a typical  $\text{NCN}$  concentration-time profile at initial reaction conditions of  $T = 2036 \text{ K}$  and  $p = 264 \text{ mbar}$  ( $\rho = 1.62 \times 10^{-6} \text{ mol/cm}^3$ ) is presented in Fig. 6.4a. Again, the experimental  $\text{NCN}$  profile calculated with constant reaction conditions (red noisy curve) is shown in comparison with the  $\text{NCN}$  profile (black noisy curve) accounting for an  $\text{O}_2$  relaxation induced temperature ( $\Delta T = -38 \text{ K}$ ) and density change ( $\Delta \rho = +6.6 \times 10^{-8} \text{ mol/cm}^3$ ). The correction is more distinct than for the profile shown in Fig. 6.2 because with 17%  $\text{O}_2$  in the reaction mixture the overall effect was stronger and at higher temperatures the  $\text{O}_2$  relaxation is faster. As can be seen from the resulting temperature profile (blue curve) the timescale of the  $\text{O}_2$  relaxation was about  $50 \mu\text{s}$ . The solid black curve represents

Figure 6.4: Determination of the rate constant  $k_2$  ( $\text{NCN} + \text{O}_2$ ). a) Experimental NCN concentration-time profiles assuming constant temperature (red noisy curve) and changing temperature (black noisy curve) resulting from  $\text{O}_2$  relaxation. The blue curve corresponds to the assumed temperature profile. The thick black curve represents the best fit using  $k_2 = 5.0 \times 10^9 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ , the other curves correspond to simulations using varied  $k_2$  values. b) Corresponding sensitivity analysis of the best fit simulation.

the best simulation using  $k_2 = 5.0 \times 10^9 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . The two dotted curves and the dashed curve, which do not fit the measured signal, correspond to simulations using a two times higher or lower  $k_2$  value and a simulation with  $k_2$  set to zero. The strong influence of the reaction  $\text{NCN} + \text{O}_2$  on the observed NCN profile is further outlined by the sensitivity analysis shown in Fig. 6.4b. At  $t > 100 \mu\text{s}$  the target reaction becomes the most sensitive reaction and hence dominates the experimentally observed NCN decay. During the first  $100 \mu\text{s}$ , however, the assumed branching ratio  $\phi$  as well as the NCNOO decomposition are most important. In order to improve the quality of the fit, these values have been allowed to vary within their error limits but were found to be essentially consistent with the high-temperature extrapolations of the data in Fig. 6.3a and b. The used values of  $\phi$  and  $k_7$  were important to reproduce the overall shape of the NCN profile at the beginning of the experiment but have only a minor influence on the NCN consumption at longer reaction times and the extracted  $k_2$  values. Interestingly, the reaction  $\text{NCN} + \text{O}$  (9) gains some importance towards the end of the observation time because O atoms are formed through the secondary reactions  $\text{CN} + \text{O}_2$  and  $\text{C} + \text{O}_2$ . The rate constant  $k_9$  has been precisely measured in previous work.<sup>[5]</sup> Since the rate constant  $k_2$  is now much faster, in contrast to the experiment in Fig. 6.2, the experiment at  $T = 2036 \text{ K}$  in Fig. 6.4 does not show a distinct influence of the reaction  $\text{NCN} + \text{NCN}$ .

As becomes clear from the discussion above, despite the interfering  $\text{O}_2$  relaxation and  $\text{NCN}$  reformation, the rate constant of the reaction  $\text{NCN} + \text{O}_2$  could be reliably extracted. Experimental conditions for 18 experiments are given in Tab. 6.3 and the extracted  $k_2$  values are plotted in Arrhenius form in Fig. 6.5. Open symbols correspond to measurements at higher total densities of  $\rho \approx 3.52 \times 10^{-6} \text{ mol/cm}^3$ , filled symbols to measurements at  $\rho \approx 1.75 \times 10^{-6} \text{ mol/cm}^3$ . Furthermore, the square symbols indicate experiments with 1% He added to the reaction mixture, circles are experiments without He. Within the scatter of the data neither the total density nor the addition of He influenced the outcome for  $k_2$ . Also experiments with varied  $\text{O}_2$  mole fractions yielded consistent results. Overall, the data points reveal a strong temperature dependence,  $E_a = (97 \pm 11) \text{ kJ/mol}$ , and are best represented by the Arrhenius expression (solid line)

2117	269	56	17	1.2	$4.2 \times 10^9$
2232	286	55	17	1.2	$1.0 \times 10^{10}$
2257	706	18	11	0	$1.1 \times 10^{10}$
2263	290	43	17	1.2	$6.0 \times 10^9$
2308	445	54	17	1.2	$9.0 \times 10^9$

$$k_2 / (\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 1.3 \times 10^{12} \exp\left(-\frac{97 \text{ kJ/mol}}{RT}\right), (\pm 57\%).$$

Allowing for partial error compensation, the error of the stated rate expression has been estimated to be  $\pm 57\%$ . Corresponding error bars for selected data points are shown in Fig. 6.5. The error arises from the statistical fit ( $\pm 25\%$ ), the uncertainties of the absolute  $\text{NCN}_3$  and  $\text{O}_2$  concentrations ( $\pm 5\%$ ) and of the rate constants assumed for the background mechanism. The two most important reactions for  $\text{NCN}$  consumption are  $\text{NCN} + \text{NCN}$  (8) and  $\text{NCN} + \text{O}$  (9). Varying  $k_8$  in the range of  $0 \leq k_8 \leq 2 \times 10^{12} \text{ cm}^3 \text{mol}^{-1} \text{s}^{-1}$  and  $k_9$  within error limits ( $k_9 \pm 40\%$ ) add a  $\pm 25\%$  uncertainty. For the less important secondary chemistry, the cumulated overall uncertainty for  $k_2$  was found to be  $\pm 7\%$ . Note that the uncertainties arising from the formation (represented by  $\phi$ ) and slow decomposition

Figure 6.5: Arrhenius plot of  $k_2$  ( $\text{NCN} + \text{O}_2$ ) data obtained in this work (symbols) in comparison with the theoretical prediction of Zhu and Lin<sup>[10]</sup> (dashed curve) and the low temperature upper estimate of Baren and Hershberger (2002).<sup>[13]</sup> Open symbols:  $\rho \approx 3.52 \times 10^{-6} \text{ mol/cm}^3$ ; filled symbols:  $\rho \approx 1.75 \times 10^{-6} \text{ mol/cm}^3$ ; squares: experiments with 1.2% He added; circles: experiments without helium; solid line: Arrhenius fit.

( $k_7$ ) of the NCNOO complex are comparably minor because these processes do not have a strong influence on the NCN decay at longer reaction times. However, as already mentioned above,  $k_7$  and  $\phi$  are important to reproduce the overall shape of the NCN profile, hence we allow for an additional uncertainty of  $k_2$  on the order of  $\pm 5\%$ .

## 6.4 Discussion

Fig. 6.5 compares  $k_2$  ( $\text{NCN} + \text{O}_2$ ) data of this work with the transition state theory prediction of Zhu and Lin (dashed curve).<sup>[10]</sup> The outdated, several orders of magnitude higher rate constant estimate from Glarborg et al.<sup>[14]</sup> is not shown. The reported upper limit by Baren and Hershberger (dotted curve),<sup>[13]</sup> which was based on low temperature (298 K to 573 K) and low pressure ( $\sim 3$  Torr) experiments is not directly comparable with our data but does not contradict our results. The overall agreement with the transition state calculations is rather satisfying. The measured Arrhenius activation energy of  $E_A = 97 \text{ kJ/mol}$  is in very good agreement with the theoretical estimate, but the absolute experimental values are about a factor of five higher. As the overall temperature dependence is dominated by the transition state barrier connecting the *cis*-NCN-OO isomer with the products (see Fig. 6.1), we tentatively assume that the remaining discrepancy stems from uncertainties of the relative heights of the entrance barriers either forming the *cis*- or *trans*-isomer, respectively. Already Zhu and Lin noted in their paper that, due to the lack of experimental data, it would be hard to quantitatively assess the reliability of their calculated energies, which were obtained by the G2M(CC1) level of theory.

The alternative CNO forming channel of reaction (2) has been neglected for the simulations of the NCN profiles. Not only that this channel has been published to be minor ( $< 15\%$ , according to Ref. 10), also the assumed products of the reaction turned out to be unimportant. Subsequent chemistry of NCO, which is included in the background mechanism (GRI-Mech 3.0), did not play any discernible role. Hence, no information on the product branching ratio of reaction (2) could be inferred from the experiments presented in this work.

Although the actual kinetic treatment of the NCN re-formation process turns out to be less important for the rate constant determination of  $k_2$ , it deserves a closer look. In fact  $^1\text{NCN}$  relaxation by CIISC, which is dominated by collisions with  $\text{O}_2$ , and the formation of the NCNOO adduct according to  $^1\text{NCN} + ^3\text{O}_2 \rightarrow ^3\text{NCNOO}$  represent two directly competing processes. Therefore, in agreement with the experimental findings (see Fig. 6.3b), the branching ratio  $\phi = k_6/(k_6 + k_5)$  is not expected to change significantly with the amount of oxygen present in the reaction mixture. Interestingly, the pronounced increase of the branching ratio with temperature reveals that NCNOO formation is an activation controlled process. As already mentioned above, a rough estimation of the corresponding activation energy yields a lower limit of  $E_a = 32$  kJ/mol. Here, the CIISC process (5) was assumed to be temperature independent; allowing for a positive temperature dependence would yield an even higher  $E_a$  value for  $k_6$ . Apparently, the formation of the  $^3\text{NCNOO}$  adduct exhibits a pronounced entrance barrier, hence similar to the  $^3\text{NCN} + ^3\text{O}_2 \rightarrow ^1\text{NCNOO}$  reaction. In contrast to  $\phi$ , the rate constant  $k_7$  for the assumed re-formation of NCN has been found to be nearly temperature independent. It is therefore unfeasible that NCN is formed through the simple reverse of reaction (6), which should be temperature dependent as well. Hence, it can be speculated that NCN re-formation takes actually place through a reaction sequence according to  $^3\text{NCNOO} \rightarrow ^1\text{NCNOO} \rightarrow ^3\text{NCN} + \text{O}_2$  involving an intersystem crossing (ISC) process. To confirm this hypothesis, ab initio calculations of the triplet potential energy surface including accurate ISC probabilities to the singlet surface are needed. Such calculations would have been beyond the scope of this paper.

## 6.5 Conclusion

Using  $\text{NCN}_3$  pyrolysis behind shock waves as a quantitative NCN radical source, the total rate constant of the reaction  $\text{NCN} + \text{O}_2$  has been directly measured for the first time. Between  $1674 \text{ K} \leq T \leq 2308 \text{ K}$ , the experimental data are best represented by the Arrhenius expression  $k_2 / (\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 1.3 \times 10^{12} \exp\left(-\frac{97 \text{ kJ/mol}}{RT}\right)$ , no pressure dependence was observed. The high activation energy of 97 kJ/mol is in very good agreement with the transition state theory prediction of Zhu and Lin,<sup>[10]</sup> but the absolute experimental rate constant values are about a factor of 5 above the theoretical estimate. Compared to other bimolecular NCN reactions, such as  $\text{NCN} + \text{H/O/OH/H}_2$ , the reaction is still slow. Hence the results of this work confirm recent findings that the reaction  $\text{NCN} + \text{O}_2$  is less important for NCN modeling in hydrocarbon flames.

The determination of  $k_2$  turned out to be difficult, which is reflected in the rather high stated uncertainty for  $k_2$  of about  $\pm 57\%$ . High  $\text{O}_2$  mole fractions up to 17% had to be used for sensitive rate constant extraction. At such high  $\text{O}_2$  concentrations, the  $\text{O}_2$  vibrational relaxation and the resulting temperature

change during the experiments had to be included for the evaluation of the NCN concentration-time profiles. Unexpectedly, the shape of the NCN profiles indicated the fast formation of an NCN reservoir species, presumably NCNOO from the reaction of  $^1\text{NCN}$  with  $\text{O}_2$ . The slow decomposition of this complex results in a re-formation of NCN at longer reaction times. While the formation of the NCNOO complex seems to be an activation controlled process, the delayed NCN formation was found to be temperature independent. This can be taken as an indication that a  $^3\text{NCNOO} \rightarrow ^1\text{NCNOO}$  intersystem crossing process is involved.

## Acknowledgments

We would like to thank the German Science Foundation (FR 1529/4) for financial support and the working group of M.C. Lin for providing many valuable theoretical NCN rate constant data that stimulated this work.

**Abstract**

Using the very sensitive absorption based frequency modulation (FM) spectroscopy, concentration-time profiles of HNO have been measured behind shock waves for the first time. The UV photolysis of glyoxal/NO mixtures at  $\lambda = 193$  nm served as a HNO source via the fast initial formation of HCO followed by the reaction  $\text{HCO} + \text{NO} \rightarrow \text{CO} + \text{HNO}$ . High temperature and room temperature FM spectra of three selected lines of the  $\tilde{A}^1A'' - \tilde{X}^1A'$  transition of HNO have been recorded at wavelengths around 618 and 625 nm. By analyzing HNO and HCO concentration-time profiles under similar reaction conditions it was possible to determine the HNO absorption cross section. A temperature dependent value of  $\log \frac{\sigma_{\text{HNO}}}{\text{cm}^2 \text{mol}^{-1}} = 5.14 - 6.0 \times 10^{-4} \times (T/\text{K})$  was determined at temperatures between 700 K and 1150 K. Experiments with 0.4% - 1% O<sub>2</sub> in the reaction gas mixture were performed to measure the rate constant of the reaction  $\text{HNO} + \text{O}_2 \rightarrow \text{NO} + \text{HO}_2$ . Between 750 K and 1275 K the experimental data are best represented by the Arrhenius expression  $k_1 / (\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 6.1 \times 10^{12} \exp\left(-\frac{21 \text{ kJ/mol}}{RT}\right)$ . The experiments have been performed at total densities of  $7.3 \times 10^{-6} \text{ mol/cm}^3 \leq \rho \leq 16.6 \times 10^{-6} \text{ mol/cm}^3$ . No pressure dependence was discernible. The determined rate constant data are up to four orders of magnitude higher than frequently used literature data.

**7.1 Introduction**

Nitrogen oxides (NO<sub>x</sub>) are atmospheric pollutants formed during combustion processes. Nitroxyl (HNO) is an important flame intermediate closely linked to NO<sub>x</sub>. Most HNO reactions with other flame intermediates like H, OH, O and O<sub>2</sub> and the HNO thermal decomposition directly form NO. Depending on the combustion conditions, most of these reactions can also proceed in the opposite direction and in this case decrease the amount of NO formed in flames. For example the Reaction  $\text{H} + \text{NO} + \text{M} \rightleftharpoons \text{HNO} + \text{M}$  contributes significantly to NO reduction using CO/H<sub>2</sub> mixtures as reducing agents during combustion (NO reburning).<sup>[1,2]</sup> To model the most favorable reaction conditions for overall NO reduction detailed mechanisms including accurate high temperature rate constant data for HNO are necessary. Yet most HNO reactions are poorly investigated experimentally, because intermediate concentrations of HNO in flames are low and the high temperature cross section is presumably small. HNO measurements at high temperatures are only reported by Lozovsky et al.<sup>[3,4]</sup> They used the sensitive intracavity laser absorption spectroscopy (ICLAS) to monitor HNO spectra in low-pressure CH<sub>4</sub> flames. So far, rate expressions for most HNO reactions implemented into combustion mechanisms rely on experiments at low temperatures or theoretical studies.

Also the title reaction

has only been measured between 296 K and 421 K by Bryokov et al.<sup>[5,6]</sup> In the only high temperature study, Miller and Bowman indirectly determined the  $k$  value for this reaction by adjusting its rate constant as part of a high temperature mechanism assembled for the reaction of isocyanic acid with nitric oxide.<sup>[7]</sup> They recommended a fairly low rate constant expression  $k_1 / (\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 1.0 \times 10^{13} \exp[-105 \text{ kJ/mol}/(RT)]$ . In the widely used mechanism GRI-Mech 3.0<sup>[8]</sup> for methane

combustion the Arrhenius activation energy of this expression has been reduced to 54 kJ/mol by comparison with the analogous reaction  $\text{RH} + \text{O}_2$ , which is not supposed to have a large barrier height. At temperatures around 1500 K, this provides about three orders of magnitude higher  $k_1$  values than reported by Miller and Bowman. An even higher overall rate expression has been assumed by Klaus and Warnatz as part of an  $\text{NO}_x$  formation/reduction mechanism.<sup>[9,10]</sup> However, the basis of their expression has not been explicated in these studies. The influence of the reaction  $\text{HNO} + \text{O}_2$  on the NO formation is strongly dependent on the reaction conditions. In a study by Wang et al. on the combustion of pyridine, reaction (1) turned out to be the main source for NO under reducing atmosphere.<sup>[11]</sup> The strong discrepancy of the few available literature data and their implementation in detailed combustion mechanisms clearly points out the need for a reliable experimental high temperature rate constant value for the reaction  $\text{HNO} + \text{O}_2$ .

## 7.2 Experimental

### 7.2.1 Shock tube and slow flow cell

All high temperature measurements were carried out in an overall 8 m long electropolished, stainless steel shock tube, which has been described in detail elsewhere.<sup>[12]</sup> Briefly, the 4.5 m long test section with an inner diameter of 81 mm could be pumped down to pressures of  $p = 10^{-7}$  mbar by a combination of turbomolecular and diaphragm pumps. The shock tube was operated with hydrogen or mixtures of hydrogen and nitrogen as driver gas, 30  $\mu\text{m}$  thick aluminum foils have been used as diaphragms. The experimental conditions were calculated from the pre-shock conditions together with the shock wave velocity, measured by four fast piezo-electric sensors mounted flush in the shock tube wall. A frozen-chemistry code taking into account real gas effects and shock wave damping has been applied. In principle the slow  $\text{O}_2$  vibrational relaxation process may compromise a simple frozen-chemistry calculation of the experimental conditions. However, the used  $\text{O}_2$  mole fractions were always below 1%, which results in a very small effect on the experimental conditions that turned out to be negligible for our analyses.

Room temperature experiments were performed in a 45 cm long slow flow cell equipped with quartz windows. The detection and the photolysis laser beams were overlapped in the cell and propagated in opposite directions.

An ArF excimer laser (Radiant Dyes Exc 200) was used for the UV photolysis of glyoxal at  $\lambda = 193$  nm. Two dichroic mirrors in front and behind the shock tube or the flow cell were used to collinearly overlap the detection and the UV laser beams. Additionally, a UV filter was placed in front of the detector to block residual intensity of the photolysis laser. For the shock tube experiments, the photolysis beam was slightly focused by a 1000 mm lens (effective diameter was about 4 mm in the shock tube), for the room temperature measurements the area of the UV beam was reduced by a telescope to about 1  $\text{cm}^2$ . In both cases the excimer laser beam diameter was larger than the diameter of the detection laser to minimize the effects of diffusional processes on the measured HNO concentration-time profiles.

### 7.2.2 Gas mixture preparation

Storage gas mixtures of about 2% glyoxal and 3% NO in Ar were prepared in a gas mixing system using the partial pressure method. The mixing system could be evacuated to pressures of  $p < 1 \times 10^{-5}$  mbar and was equipped with several 5 - 20 L glass flasks. A flask with a cooling finger was used for purification of NO by several freeze-pump-thaw cycles. The storage gas mixtures were mixed and further diluted by a flow system with mass flow controllers. The freshly prepared reaction gas mixtures slowly flushed the test section for a few minutes prior to the actual shock tube experiments to prevent possible effects from the adsorption of the reactants at the shock tube walls. Storage mixtures were used within three to four days.

Glyoxal was prepared by dehydration of the trimer dehydrate  $((\text{CHO})_2)_3 \times 2\text{H}_2\text{O}$  by 3 eq. of phosphoric anhydride ( $\text{P}_2\text{O}_5$ ). The solid reaction mixture was slowly heated up to 155°C i. vac. ( $1 \times 10^{-2}$  mbar). The gaseous product was passed through an ice water cooling trap to remove impurities. The purity of glyoxal was checked by FT-IR measurements and it was stored in a liquid nitrogen trap.

### 7.2.3 FM-spectroscopy

HNO and HCO were detected by means of frequency modulation (FM) spectroscopy which is a sensitive, absorption based detection method.<sup>[13,14,15]</sup> The used setup was similar to the one described by Friedrichs et al.<sup>[14,16]</sup> Briefly, wavelengths between 600 nm and 650 nm were generated by a cw ring dye-laser (Coherent 899 series) operated with Kiton Red as laser dye and pumped by a solid state Nd:YVO<sub>4</sub> laser (Coherent Verdi V 10). The wavelength was measured interferometrically by a wavemeter (MetroLux WL200). The laser beam was modulated at a frequency of 1 GHz by a resonant electro-optic modulator (New Focus 4421), the resulting frequency modulated spectrum was analyzed by a scanning etalon. The modulation depth was set to a modulation index of  $M \approx 1.4$ . The laser beam was focused through the shock tube windows by a 300 mm lens, coupled into an optical fiber and detected by a fast silicon photodiode (Hamamatsu, S5973). The signal was split into the AC and the DC part by a Bias Tee (Mini Circuits, ZFBT-4R2G). The DC component corresponds to  $I_0$  and was directly monitored by a digital oscilloscope, the AC component represents the FM signal. It was band-pass filtered at 1 GHz (Trilithic), demodulated by a frequency mixer (Mini Circuits, 5542-ZFM-2000), amplified and low pass filtered at 2.5 MHz resulting in the signal intensity  $I_{\text{FM}}$ . A two-polarizer setup was used to adjust a voltage controlled phase shifter (Knick, J45) to set the phase angle of demodulation to zero, resulting in pure absorption induced signal. The demodulated FM-signal is proportional to the concentration  $c$  of the absorbing species according to

$$I_{\text{FM}} = \frac{I_0}{2} \times \Delta f \times \sigma \times [c] \times l_{\text{eff}} \times G.$$

$\sigma$  is the narrow-bandwidth line center absorption cross section and  $l$  the absorption path length. The electronic gain factor  $G = 184$  of the used FM setup was determined experimentally and was in agreement with previous determinations.<sup>[12]</sup> The FM factor  $\Delta f$  was calculated from line shape data and

was about  $\Delta f = 0.8$  for HNO and  $\Delta f = 0.3$  for HCO under the experimental conditions of this work. If the absorption cross section and line shape data for one species are known, it is therefore possible to perform quantitative FM measurements. Whereas for HCO the data are well known for the Q(6)P(1) absorption line of the  $\tilde{A}^2A'' - \tilde{X}^2A'(09^00 \leftarrow 00^10)$  transition at  $\lambda = 614.752 \text{ nm}^{[12]}$ , they were determined for HNO for three selected absorption lines of the  $\tilde{A}^1A''(100) - \tilde{X}^1A'(000)$  transition in this work. To determine the initial HCO concentrations generated by glyoxal UV photolysis, HCO concentration-time profiles have been measured as a reference (see below) at similar reaction conditions and comparable photolysis energies.

#### 7.2.4 HNO source

HNO molecules were generated by  $\lambda = 193 \text{ nm}$  photolysis of glyoxal/NO mixtures in argon. The HNO formation proceeds according to the reaction sequence

To model HNO formation, additional glyoxal and HCO reactions have been adopted from our previous work<sup>[12,14,16,17,18]</sup> and the GRI-Mech 3.0<sup>[8]</sup> has been assumed as a background mechanism in order to take possible secondary chemistry into account. The initial  $[\text{H}]_0/[\text{HCO}]_0$  ratio from the glyoxal photolysis has been adopted from a previous study of Colberg and Friedrichs.<sup>[12]</sup> They showed that H atoms are formed in excess, typically ratios of about 3 at high temperatures and about 2 at room temperature were used. Over the fast reaction  $\text{HCO} + \text{NO}$  (4), which has been investigated experimentally behind shock waves by Dammeier et al.,<sup>[17]</sup> the HCO concentration is directly linked to HNO formation. Hence, both the assumed HCO mechanism as well as the overall HNO yield could be confirmed by quantitative measurements of HCO concentration-time profiles resulting from the photolysis of glyoxal and glyoxal/NO mixtures. It turned out that the HCO concentration profiles could be nicely modeled without adjusting the mechanism.

Note that the reaction

was also included in the mechanism but was found to be too slow to contribute notably to the overall HNO concentrations. Just as well, the reverse reaction  $\text{HNO} + \text{M}$  is slow and only had a minor influence on HNO removal at longer reaction times.

### 7.3 Results and Discussion

Shock tube and room temperature measurements of HNO and HCO concentration-time profiles at similar reaction conditions (temperature, pressure, mixture composition, and photolysis energy) have

Table 7.1: Important reactions for HNO formation and consumption from the photolysis of glyoxal/NO mixtures in shock tube experiments. Parameters for modified Arrhenius expression  $k = AT^n \exp(-E_a/(RT))$  are given in units of mol, cm, s and kJ.

no.	reaction	$A$	$n$	$E_a$	ref.	$T$ -range
1	HNO + O <sub>2</sub> → HO <sub>2</sub> + NO	$6.1 \times 10^{12}$		21	this work	750-1275 K
3	(CHO) <sub>2</sub> + H → H <sub>2</sub> + CO + HCO	$5.4 \times 10^{13}$		18	12	295-1107 K
4	HCO + NO → HNO + CO	$8.1 \times 10^{12}$			17	295 K
		$7.1 \times 10^{12}$			17	770-1300 K
6	HNO + H → H <sub>2</sub> + NO	$9.7 \times 10^{11}$	0.62	1.49	19	200-2500 K

		$3 \times 10^3$			this work	298 K

been performed. Different reaction mixtures with initial [NO]/[glyoxal] ratios from zero to 0.87 were used. From repeated, iterative analysis aiming on the consistent modeling of all measured HNO and HCO profiles at different experimental conditions, the HNO formation mechanism, the HNO absorption cross section, and the rate constant of the reaction HNO + O<sub>2</sub> could be determined.

### 7.3.1 HNO detection

For quantitative HNO detection and to determine the position of the maximum of the FM signal, the Doppler and pressure broadened FM spectra of three selected absorption lines of the  $\tilde{A}^1A''(100) - \tilde{X}^1A'(000)$  band at wavenumbers of 16171.99, 16173.86 and 16002.36 cm<sup>-1</sup> were investigated at different experimental conditions summarized in Tab. 7.2. The HNO absorption spectra measured by Bancroft et al. [23] and Pearson et al. [24] were used as a starting point to determine the exact positions of the HNO FM-signals. Fig. 7.1 illustrates the measured (red symbols), normalized FM spectra of the three absorption bands in comparison with the simulated absorption (dashed curves) and FM spectra (red curve).

Table 7.2: Summary of the measured pressure broadening parameters for three selected HNO absorption lines.

line	center wavelength/ cm <sup>-1</sup>	max FM signal/ cm <sup>-1</sup>	average $T$ / K	average $p$ / mbar	$\Delta\tilde{\nu}_p$ / (GHz/bar)
1	16173.86	16173.82	770	570	2.0
2	16171.99	16171.93	970	880	1.8
2	16171.99	16171.93	298	100	3.5
3	16002.36	16002.32	1250	1140	1.4

The HNO absorption spectrum has been simulated with the PGOPHER program [25] based on the spectroscopic constants taken from Pearson et al. The simulated line positions and relative intensities

have been adopted from the PGOPHER output to calculate the corresponding FM spectra with a program developed in our working group. The simulations are in good agreement with the measured data, only small line shifts on the order of  $0.02 \text{ cm}^{-1}$  were necessary. The three absorption bands have been measured at different temperatures of about 298, 970, 770 and 1250 K, respectively, and therefore yielded a set of pressure broadening parameters (see Tab. 7.2). From these data the pressure broadening coefficient was determined to be  $\Delta\nu_p \approx 3.5(T/298 \text{ K})^{-0.6} \text{ GHz/bar}$ . In agreement with our experiments the PGOPHER simulations predict similar intensities for the two  $R_3(J'')$  lines and a two times higher intensity for the  $Q_0(16)$  line at temperatures around 1000 K. Therefore, the  $Q_0(16)$  line provides better signal-to-noise ratios and was selected for all kinetic shock tube measurements of this work.

Figure 7.1: Normalized experimental FM-spectrum of HNO (red symbols) in comparison with simulated FM (red curve) and absorption spectra (dashed curve) for three lines of the (100)-(000) band of the  $\tilde{A}^1 A'' - \tilde{X}^1 A'$  HNO transition. The experimental conditions are listed in Tab. 7.2.

### 7.3.2 HNO formation mechanism and absorption cross section

For quantitative HNO measurements it is important to know the initial  $[\text{HCO}]_0$  concentrations from glyoxal photolysis. Ideally, simultaneous measurements of HCO and HNO profiles would have to be performed. However, as either HCO or HNO could be detected with our setup, all experiments have been performed at least twice under very similar reaction conditions ( $T$ ,  $p$ , mixture composition, photolysis energy) either detecting HCO or HNO. In Fig. 7.2a and 7.2b experimental and numerically modeled HNO and their corresponding HCO concentration-time profiles are displayed. As already outlined above, the HCO profile could be well simulated without any adjustment of the mechanism adopted from the literature. Only the initial  $[\text{HCO}]_0$  concentrations were varied to fit the maximum of the measured HCO profile.

HNO reactions were initially taken from GRI-Mech 3.0<sup>[8]</sup> and were varied by a factor of up to 100

to identify reactions with potentially strong impact on the simulated HNO profile. From the reactions ( $\text{HNO} + \text{H}$ ,  $\text{HNO} + \text{H}_2$ ,  $\text{HNO} + \text{CO}$ ,  $\text{HNO} + \text{NO}$ , and  $\text{HNO} + \text{M}$ ) only the reaction

turned out to be actually important for the overall HNO concentration. Available literature data for  $k_6$  at high temperatures differ by two orders of magnitude.<sup>[19,26,27]</sup> Simulations of the measured HNO concentration-time profiles both behind shock waves and at room temperature were most consistent using the most recent theoretical expression by Nguyen et al. which is valid for the entire temperature range of this work and is on the upper limit of the reported literature values.<sup>[19]</sup> Using lower rate constant values for  $\text{HNO} + \text{H}$  would result in higher simulated overall HNO concentrations and to a little to steep HNO increase at the beginning of the experiment.

Figure 7.2: a) HCO concentration-time profile measured after the photolysis of 7720 ppm glyoxal in argon in comparison with the simulation for HCO and H. b) Experimental and simulated HNO concentration-time profile at similar reaction conditions. c) Corresponding HNO sensitivity analysis.

A sensitivity analysis for an HNO profile measured behind the reflected shock wave is illustrated in Fig 7.2c and reveals the six most important reactions for HNO formation and consumption. The rate constants of the reactions (3), (4), (8) and (9) are important for HCO as well and have been validated

## 7. Shock tube measurements of the rate constant for the reaction $\text{HNO} + \text{O}_2$

by the HCO experiments. The reaction  $\text{HNO} + \text{H}$  is important because, next to HCO, H atoms are formed in high yields from the glyoxal photolysis as well. As already outlined above, its rate constant  $k_6$  is not accurately known, however its influence remains comparably small. All simulations (for reaction mixtures without  $\text{O}_2$ ) predict stable HNO concentration plateaus towards longer reaction times showing that HNO is a stable species under the reaction conditions applied in this work. In contrast, we observe a slow loss of HNO that can be attributed to diffusional loss of HNO out of the photolysis volume. HCO reacts on a much faster timescale than HNO such that no diffusion correction is needed for HCO.

Table 7.3: Experimental conditions and results for HNO absorption cross section of the  ${}^{\text{R}}\text{R}_3(4)$  transition at room temperature (295 K) and behind shock waves.

$p$ / mbar	glyoxal/ ppm	NO/ ppm	$\text{O}_2$ / ppm	$\text{HCO}_0$ / ppm	$\sigma \times 10^{-5} / \text{cm}^2 \text{mol}^{-1}$

The HNO absorption cross section for a single transition at the line center can be determined by the equation:

$$\sigma = \frac{2 \times I_{\text{FM}}}{I_0 \times \Delta f \times [\text{HNO}] \times l_{\text{eff}} \times 184}$$

The maximum [HNO] concentrations were simulated based on the mechanism in Tab. 7.1 together with the initial  $[\text{HCO}]_0$  concentrations, which were taken from the direct HCO measurements. The

$\Delta f$  values were determined using the line shape data from the measured HNO FM spectra together with the calculated experimental conditions and modulation indices  $M$ . The experimental conditions and the determined absorption cross section values for the <sup>R</sup>R<sub>3</sub>(4) line are listed in Tab. 7.3 and plotted in Fig. 7.3. Between 720 K <  $T$  < 1133 K the logarithm of the cross section can be approximated by the linearized expression:

$$\log\left(\frac{\sigma_{\text{HNO}}}{\text{cm}^2\text{mol}^{-1}}\right) = 5.14 - 6.0 \times 10^{-4} \times \left(\frac{T}{\text{K}}\right).$$

Figure 7.3: Temperature dependence of the experimentally determined HNO absorption cross section of the <sup>R</sup>R<sub>3</sub>(4) transition between 298 and 1133 K.

### 7.3.3 Room temperature measurements

FM measurements of HNO at room temperature have been performed to verify the absolute value and the temperature dependence of the HNO absorption cross section determined from the shock tube experiments. The experimental conditions of seven room temperature experiments are summarized in Tab. 7.3. Mixtures of about 1% glyoxal and 4180 to 8380 ppm NO were studied at pressures of 50 and 100 mbar. Additional O<sub>2</sub> has been added to the reaction mixtures to capture the large amounts of H atoms, formed from the glyoxal photolysis, that would cause a low HNO yield due to the fast reaction HNO + H → H<sub>2</sub> + NO. Actually, over the equilibrium

certain amounts of NO<sub>2</sub> are formed during the mixing of the reactants that rapidly react with H atoms as well. Sensitivity analyses reveal that the formed H atoms mainly react through this reaction. In Fig. 7.4a and Fig. 7.4b, a typical HNO (blue curve) and the corresponding HCO (red curve)

concentration-time profiles at room temperature and  $p = 50$  mbar are shown together with the best numerical fits. Also the simulated profiles without  $\text{O}_2$  in the reaction mixtures are shown (dashed black curves). Both HNO yield and HCO concentrations at longer reaction times would be significantly lower without the addition of  $\text{O}_2$  due to fast reaction with H atoms. This effect is more pronounced for HNO and would result in about a factor of two lower HNO concentrations at  $50 \mu\text{s}$  reaction time.

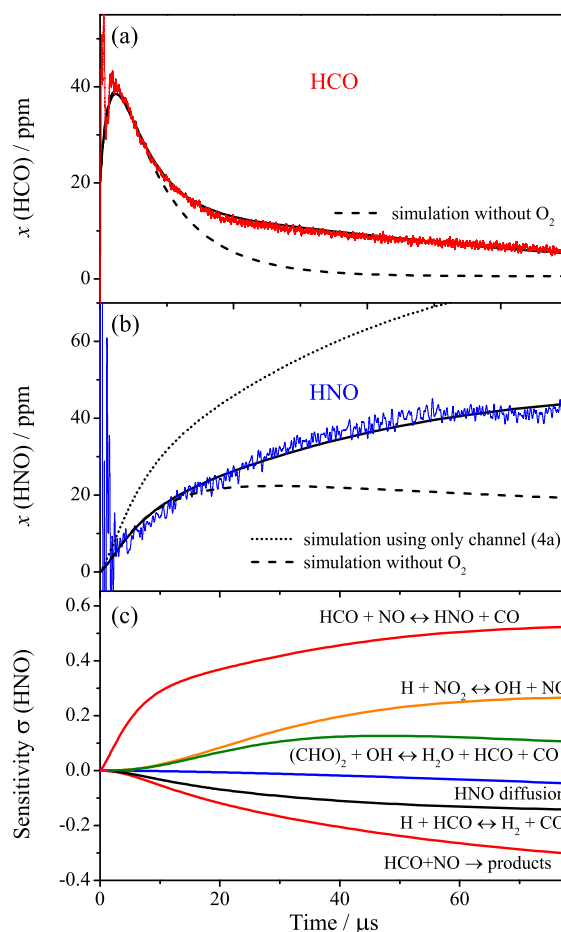

Figure 7.4: a) Experimental concentration-time profiles of HCO (red curve) and b) HNO (blue curve) under the same reaction conditions at room temperature and  $p = 50$  mbar together with the respective simulated profiles (black curves) using 1% glyoxal, 4700 ppm NO and 1500 ppm  $\text{O}_2$ . Dotted and dashed curves represent simulations using different assumptions (see text). c) Corresponding HNO sensitivity analysis.

It is known from theoretical work of Xu et al.<sup>[28]</sup> that at room temperature a second reaction channel for the HNO forming reaction  $\text{HCO} + \text{NO}$  needs to be considered.

For reaction channel (4b), the formation of a stable complex was assumed, which did not contribute further to the overall HNO formation. The actually assumed branching ratio has been fine-tuned by carefully fitting the HNO concentration rise at the beginning of the experiment. For comparison, an HNO concentration-time profile simulation only considering the HNO forming channel (4a) is also shown in Fig. 7.4b (dotted curve). This simulation does not fit the experimental profile. Also the corresponding HNO sensitivity analysis in Fig. 7.4c illustrates that the branching ratio for the two channels of reaction (4) is crucial for the overall HNO concentration. Overall, the branching ratio for the HNO forming channel (4a) was found to be about 0.70 in our experiments, which is consistent with the theoretical value of about 0.75 estimated by Xu et al. Four other reactions also appear in the HNO sensitivity analysis. The reactions H + HCO (8), H + NO<sub>2</sub> (11), and glyoxal + OH (12) are again validated by consistent modeling of HCO and HNO measurements. Also the HNO diffusion is included but its contribution is only minor due to large beam diameter of the photolysis laser (compared to the detection beam) in case of the room temperature experiments.

By analyzing experiments at different pressures and glyoxal/NO ratios an HNO absorption cross section of

$$\sigma = (1.8 \pm 0.2) \times 10^5 \text{ cm}^2/\text{mol}$$

has been found which is in very good agreement with the shock tube data. In Fig. 7.3 all experimental  $\sigma$  values (red dots) are shown together with the theoretically expected (black curve) temperature dependence of the absorption cross section. The prediction is based on the line shape parameter  $\phi(T, p)$ , the term value of the lower energy state  $E$  as well as the vibrational ( $Q_{\text{vib}}$ ) and rotational ( $Q_{\text{rot}}$ ) partition function of HNO. Overall, the experimental data points are well described by the prediction, showing that the room temperature and high temperature experiments are consistent.

### 7.3.4 Rate constant of the reaction HNO + O<sub>2</sub>

The rate constant of the reaction

has been measured behind reflected shock waves by adding between 0.43% and 1% O<sub>2</sub> to the glyoxal/NO reaction mixtures. The experimental conditions are summarized in Tab. 7.4. The HNO absorption cross section as well as the background mechanism for HNO have been adopted from the experiments without O<sub>2</sub>.

A typical HNO concentration-time profile obtained at  $T = 945$  K and  $p = 700$  mbar can be seen in Fig. 7.5a. 6900 ppm O<sub>2</sub> were added to a typical reaction mixture of 1 % glyoxal and 7600 ppm NO in argon. The two black curves in the Figure represent HNO simulations with and without oxygen present in the reaction mixture. While the rapid HNO formation directly after the photolysis is not affected by the addition of O<sub>2</sub>, the HNO concentration decreases faster in the experiment with O<sub>2</sub>. The direct comparison between the two simulations reveals that the rate constant for reaction (1) could be derived from this experiments. The corresponding sensitivity analysis is shown in Fig. 7.5b. Only the five most sensitive reactions are included in the diagram. The reaction HNO + O<sub>2</sub> is the most important reaction

to model the HNO decrease at longer reaction times, but the reactions of HCO, HNO and  $(\text{CHO})_2$  with H atoms do also contribute to the overall HNO concentration profile. However, as the mechanism has been validated by the experiments without  $\text{O}_2$  added, the perturbation of the HNO concentration-time profile can be attributed mostly to the reaction  $\text{HNO} + \text{O}_2$ .

Figure 7.5: a) Typical HNO concentration-time profile with  $\text{O}_2$  present in the reaction mixture. b) Corresponding HNO sensitivity analysis.

All experimental conditions and results for 21 experiments for the determination of  $k_1$  are summarized in Tab. 7.4 and are plotted in the Arrhenius diagram in Fig. 7.6. The data are best represented by the Arrhenius expression (solid line in Fig. 7.6):

$$k_1 / (\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 6.1 \times 10^{12} \exp\left(-\frac{21 \text{ kJ/mol}}{RT}\right), \Delta(\log k_1) = \pm 0.17$$

with a weak temperature dependence of  $21 \pm 3 \text{ kJ/mol}$ . At densities of  $\rho = 7.26 \times 10^{-6} \text{ mol/cm}^3$  to  $\rho = 1.66 \times 10^{-5} \text{ mol/cm}^3$  (corresponding to pressures of 452 - 1542 mbar) no pressure dependence was discernible. The error stated for the total rate constant expression includes several sources of uncertainty. Main errors may result from the uncertainties of the initial HCO concentrations, the HNO absorption cross section, and the secondary chemistry of HNO, HCO and glyoxal. However, both the absorption cross section and the HNO formation mechanism have been adopted from experiments without  $\text{O}_2$  and therefore it can be safely assumed that the uncertainties compensate. Overall, the associating uncertainty is about 25%. The statistical error from the fitting procedure of the experiments results in an additional  $\pm 23\%$  error ( $2\sigma$  standard error of the mean). An overall error of about  $\pm 48\%$

## 7. Shock tube measurements of the rate constant for the reaction HNO + O<sub>2</sub>

( $\Delta(\log k_1) = \pm 0.17$ ) is obtained.

### 7.3.5 Discussion

Selected literature data on the rate of the reaction HNO + O<sub>2</sub> are shown in comparison with the experimental data of this work in Fig. 7.6. A simple high temperature extrapolation of the low temperature intracavity laser absorption spectroscopic (ICLAS) measurements by Bryukov et al.<sup>[6]</sup>, which have been performed between 296 and 421 K, would yield about three order of magnitude lower rate constants at a temperature of 1000 K. However, allowing for the often found positive curvature in the Arrhenius plot, this discrepancy would be somewhat smaller. As no transition state calculations have been performed yet, a reliable extrapolation of the low temperature data is not possible. Miller and Bowman indirectly determined the rate constant of reaction (1) as part of an extensive mechanism for the gas phase reaction of isocyanic acid with nitric oxide in the presence of O<sub>2</sub>, H<sub>2</sub>O and CO.<sup>[7]</sup> They compared their calculated mole fractions of species like NO, HNCO, and O<sub>2</sub> to measured mole fractions from different experimental investigations<sup>[29]</sup>. Their estimated rate expression  $k_1 / (\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 1 \times 10^{13} \times \exp(-105 \text{ kJ/mol}/RT)$  yields a four orders of magnitude lower rate constant at  $T = 1000 \text{ K}$  and suggests a very strong temperature dependence of reaction (1) that is not consistent with our data. Already for the development of the combustion mechanism GRI Mech 3.0,<sup>[8]</sup> this unfeasible rate constant expression has been adjusted. Without further justification, by comparison with the analogous RH + O<sub>2</sub> reaction, in the GRI Mech 3.0 the pre-exponential factor has been adopted from Miller and Bowman but the Arrhenius activation energy has been decreased to 54 kJ/mol. This change increases the rate constant by a factor of 400 at  $T = 1000 \text{ K}$ , hence still a factor of 30

lower than the experimental data of this work. Finally, the expression from Klaus and Warnatz<sup>[9]</sup>  $k_1/(\text{cm}^3\text{mol}^{-1}\text{s}^{-1}) = 3.2 \times 10^{12} \times \exp(-12.5 \text{ (kJ/mol)}/RT)$ , provides the best agreement with our data. This expression stems from a detailed mechanism for  $\text{NO}_x$  formation/reduction. Unfortunately, no information about the derivation of this comparably high value has been given.

Compared to the rather uncertain and inconsistent literature data, the measurements performed in this work constitute by far the most reliable high temperature determination. Although the overall effect of  $\text{O}_2$  addition on the detected HNO profiles remained small, thanks to the perturbation approach (i.e., measurements with and without oxygen present), the rate constant could be determined with good accuracy. Note that the low rate constant estimate according to the GRI Mech 3.0 and the Miller and Bowman expressions would not have resulted in any noticeable change in the HNO profiles for experiments with and without  $\text{O}_2$ . This is in obvious disagreement with the experiments reported here.

Figure 7.6: Arrhenius plot of measured rate constants for the reaction  $\text{HNO} + \text{O}_2$  in comparison with available literature data.<sup>[6,7,8,9]</sup>

## 7.4 Conclusion

HNO has been detected behind shock waves for the first time by means of the very sensitive FM spectroscopy approach. FM spectra of three selected transitions have been recorded to determine accurate FM factors  $\Delta f$  and pressure broadening coefficients. The photolysis of glyoxal/NO mixtures was used as a source for HNO. Corresponding experiments with either HNO or HCO detection have been performed behind reflected shock waves and at room temperature to determine the HNO absorption cross section. Between 700 and 1150 K the absorption cross section of the  ${}^R\text{R}_3(4)$  transition at

16173.86 cm<sup>-1</sup> can be expressed by

$$\log\left(\frac{\sigma_{\text{HNO}}}{\text{cm}^2\text{mol}^{-1}}\right) = 5.14 - 6.0 \times 10^{-4} \times \left(\frac{T}{\text{K}}\right).$$

An HNO mechanism including the HNO formation from the reaction HCO + NO following the glyoxal photolysis as well as HNO secondary chemistry was developed and tested for various experimental conditions. Based on the determined HNO absorption cross section and this submechanism for HNO formation, which reliably describes the measured HNO profiles without O<sub>2</sub> in the reaction mixture, it was possible to measure rate constant data for the reaction HNO + O<sub>2</sub> → NO + HO<sub>2</sub>. Up to 1% O<sub>2</sub> were added to the glyoxal/NO reaction mixtures. At temperatures of 749 K ≤ T ≤ 1274 K the experimental data can be summarized by the Arrhenius expression:

$$k_1 / (\text{cm}^3\text{mol}^{-1}\text{s}^{-1}) = 6.1 \times 10^{12} \exp\left(-\frac{21 \text{ kJ/mol}}{RT}\right), \Delta(\log k_1) = \pm 0.17$$

The comparison with existing literature data reveals that the most frequently used rate constant expression of Miller and Bowman<sup>[7]</sup> and from the GRI Mech 3.0<sup>[8]</sup> yield at least one order of magnitude too low rate constant data. Clearly, future work on a detailed theoretical treatment of the reaction based on high-level quantum-chemical calculations is needed to confirm both the high temperature rate constant expression as well as the reported temperature dependence obtained in this work. Furthermore, modeling work is required to range the importance of the reaction HNO + O<sub>2</sub> for NO<sub>x</sub> formation in flames. Finally, with the experimental setup presented in this work measurements of further bimolecular HNO reactions should be possible. Such data would hold the potential to contribute to a much better and quantitative understanding of HNO for NO<sub>x</sub> modeling in flames.

New measurements and a detailed analysis of the glyoxal oxidation mechanism revealed rate constant data for the reaction  $\text{HCO} + \text{O}_2$  up to combustion-relevant high temperatures.

Own contributions:

- Shock tube experiments.
- Analysis of the experimental data.
- Interpretation and comparison of experimental data.
- Collaboration with P. Glarborg (Technical University of Denmark) and P. Marshall (University of North Texas) to assemble the glyoxal oxidation mechanism.
- Writing of manuscript draft (Experimental, Results and Discussion section and Conclusion).

**Abstract**

A detailed mechanism for the thermal decomposition and oxidation of the flame intermediate glyoxal (OCHCHO) has been assembled from available theoretical and experimental literature data. The modeling capabilities of this extensive mechanism have been tested by simulating experimental HCO profiles measured at intermediate and high temperatures in previous glyoxal photolysis and pyrolysis studies. Additionally, new experiments on glyoxal pyrolysis and oxidation have been performed with glyoxal and glyoxal/oxygen mixtures in Ar behind shock waves at temperatures of 1285 K – 1760 K at two different total density ranges. HCO concentration-time profiles have been detected by frequency modulation spectroscopy at a wavelength of  $\lambda = 614.752$  nm. The temperature range of available direct rate constant data of the high temperature key reaction  $\text{HCO} + \text{O}_2 \rightarrow \text{CO} + \text{HO}_2$  has been extended up to 1705 K and confirms a temperature dependence consistent with a dominating direct abstraction channel. Taking into account available literature data obtained at lower temperatures, the following rate constant expression is recommended over the temperature range  $295 \text{ K} < T < 1705 \text{ K}$ :

$$k_1/(\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 6.92 \times 10^6 \times T^{1.90} \times \exp(+5.73 \text{ kJ/mol}/RT)$$

At intermediate temperatures, the reaction  $\text{OCHCHO} + \text{HO}_2$  becomes more important. A detailed reanalysis of previous experimental data as well as more recent theoretical predictions favor the formation of a recombination product in contrast to the formerly assumed dominating and fast OH forming channel. Modeling results of the present study support the formation of  $\text{HOCH}(\text{OO})\text{CHO}$  and provide a two orders of magnitude lower rate constant estimate for the OH channel. Hence, low-temperature generation of chain carriers has to be attributed to secondary reactions of  $\text{HOCH}(\text{OO})\text{CHO}$ .

**8.1 Introduction**

The oxidation chemistry of glyoxal (OCHCHO) is of interest, partly because it is recognized as an intermediate in combustion of hydrocarbons and partly because glyoxal has been identified as a promising HCO high-temperature source for shock tube measurements.<sup>[1,2]</sup> Moreover, glyoxal is discussed as an important component in tropospheric chemistry.<sup>[3,4]</sup> Glyoxal can be formed from oxidation of  $\text{C}_2\text{H}_2$  at low to medium temperatures,<sup>[5,6,7,8,9]</sup> as well as in the atmosphere,<sup>[10,11,12,13,14,15,16]</sup> mostly through the chain-propagating sequence

Previous studies of OCHCHO chemistry include thermal decomposition in static reactors<sup>[17]</sup> and shock tubes<sup>[18,19]</sup> as well as low-temperature oxidation<sup>[20,21,22]</sup> and determination of explosion limits in static reactors.<sup>[23]</sup> Also data on the low temperature oxidation of glyoxal by  $\text{H}_2\text{O}_2$ <sup>[24]</sup> and  $\text{NO}_2$ <sup>[25]</sup> have been reported. More recently, Colberg and Friedrichs,<sup>[2]</sup> in a combined shock tube/photolysis study of OCHCHO/O<sub>2</sub> mixtures, obtained rate coefficients for the reaction  $\text{HCO} + \text{O}_2$  at 750-1110 K. To our knowledge, no detailed chemical kinetic modeling studies of glyoxal oxidation have previously been reported.

The objective of the present study is two-fold. We aim to develop a detailed chemical kinetic model for oxidation of OCHCHO in the intermediate to high temperature range for use in combustion studies. Furthermore, we wish to extend the measurement range for the rate constant of  $\text{HCO} + \text{O}_2$  to higher temperatures. Novel shock tube experiments are conducted for OCHCHO and OCHCHO/ $\text{O}_2$  mixtures in argon at temperatures from 1285 to 1760 K. The results from these experiments are combined with the previous data from Colberg and Friedrichs and implications for our understanding of glyoxal oxidation and for the overall rate constant of the reaction  $\text{HCO} + \text{O}_2$  are discussed.

## 8.2 Detailed Kinetic Model

A mechanism has been assembled from recent work on the chemistry of glyoxal,<sup>[2,19]</sup> formic acid,<sup>[26]</sup> formaldehyde,<sup>[27]</sup> carbon monoxide<sup>[28]</sup> and hydrogen.<sup>[29]</sup> In the present work the OCHCHO oxidation subset of the mechanism was updated. The thermodynamic properties for OCHCHO and OCHCO are shown in Table 8.1,<sup>[30,31]</sup> while Table 8.2 lists key reactions in the OCHCHO oxidation scheme.<sup>[2,19,32,34,35]</sup> The full mechanism, including pressure dependent rate coefficients for many decomposition and recombination reactions, is available as Supporting Information.

In addition to the OCHCHO subset discussed below, particular attention was paid to the reaction of HCO with  $\text{O}_2$ ,

High temperature oxidation of hydrocarbons as well as of glyoxal is very sensitive to this step. Starting from the experimentally determined rate coefficients by Colberg and Friedrichs<sup>[2]</sup> and the new experimental data presented below, we derived a rate constant expression valid over a wide range of temperatures. Hsu et al.<sup>[36]</sup> reported a theoretical study of this reaction, based on RRKM calculations for the indirect abstraction channel and VTST calculations for the direct abstraction channel. Both channels yield the products  $\text{CO} + \text{HO}_2$ . According to these calculations, at low temperatures the more or less temperature independent indirect channel dominates and the increase of the total rate constant, which is due to the direct abstraction channel, takes place not before temperatures of  $T > 1250$  K. In contrast, the Colberg and Friedrichs determination implies a distinct increase of the rate constant already at temperatures above  $T > 700$  K. For the temperature range of the present shock tube study

Table 8.1: Thermodynamic properties of selected species in the reaction mechanism. Units are kJ mol<sup>-1</sup> for  $\Delta H$ , J mol<sup>-1</sup> K<sup>-1</sup> for  $S$  and  $c_{p,T}$ , and K for temperature  $T$ .

*a*: The C-H bond dissociation enthalpy at 298 K in OCHCHO was obtained via computed CBS-QB3 energies<sup>[31]</sup> and the reaction  $\text{OCHCHO} \rightarrow \text{OCHCO} + \text{H}$ . There are isomers of OCHCO with bent C-C-O structures but the most stable isomer has an almost linear C-C-O group. The corresponding bond dissociation enthalpy is 366.2 kJ/mol, which corresponds to  $\Delta_f H_{298}^\circ(\text{OCHCO}) = -63.8$  kJ/mol. Entropies and heat capacities of OCHCO were derived using the harmonic oscillator/rigid rotor model.

(1285 - 1705 K), the extrapolated Arrhenius expression of Colberg and Friedrichs yields 2.1 - 2.5 times higher values than the theoretical prediction of Hsu et al. Hence, the new glyoxal oxidation experiments served as a critical test of both the absolute value of the rate constant and the overall temperature dependence of the reaction  $\text{HCO} + \text{O}_2$ .

Thermal dissociation of OCHCHO has been characterized experimentally behind shock waves<sup>[18,19]</sup> and theoretically.<sup>[19,37]</sup> It is a highly temperature and pressure dependent multi-channel reaction that may yield a range of products:

We have adopted the results by Friedrichs et al.<sup>[19]</sup> who detected species profiles of OCHCHO, HCO, and H behind shock waves at temperatures of 1032–2320 K. In their work, the obtained branching ratios of the thermal glyoxal decomposition were interpreted by means of RRKM/SACM/ME calculations and rate coefficients over a wide range of temperature (800 – 2500 K) and pressure (1 mbar – 100 bar) have been reported. Original data have been represented in terms of Chebyshev polynomial coefficients. We reparametrized their data and report extended Arrhenius expressions at  $p = 1$  bar in

Table 8.2 and at other total pressures in the Supporting Information. A key finding of Friedrichs et al. was that the previously neglected, energetically most unfavorable HCO channel (2d), due to its loose transition state character, becomes the dominant product channel at high temperatures and pressures. For example, at  $T = 2300$  K and  $p = 3$  bar the branching fraction of channel (2d) accounts for 48% of the total reaction rate. In contrast, the hydroxymethylene forming HCOH channel (2c), in agreement with a photochemical study of Hepburn et al.,<sup>[38]</sup> with branching fractions  $< 7\%$  at all temperatures and pressures turned out to be minor. Arguments have been put forward in ref 19 that subsequent chemistry of HCOH is not expected to serve as a significant source of additional atoms or radicals such that the overall influence of this minor channel on glyoxal chemistry remains small. With regard to a simplified description of the thermal decomposition of glyoxal, channel (2c) has therefore not been treated as a separate channel but its reported rate constant expression has been merged with reaction channel (2a), which is the main channel under the experimental conditions of this work.

Other reactions of OCHCHO include abstraction of H by radicals or O<sub>2</sub>. Only a few of these steps have been characterized experimentally. The reaction with atomic hydrogen,

has been measured at elevated temperatures (769–1107 K) by Colberg and Friedrichs<sup>[2]</sup> and their value is used in the reaction mechanism. The reaction with OH (5),

has been studied both experimentally<sup>[32,33,39]</sup> and theoretically,<sup>[40]</sup> though only at low temperatures. The experimental results are in good agreement. We have adopted the rate constant measured by Feierabend et al.<sup>[32]</sup> in the 210–390 K range.

For the reactions of OCHCHO with O (4) and O<sub>2</sub> (9),

we estimate the rate constants to be similar to the analogue reactions of CH<sub>2</sub>O.

The reaction of OCHCHO with HO<sub>2</sub> is of particular importance, since HO<sub>2</sub> is formed in significant quantities compared to the other radicals in the O/H pool at low to medium temperature conditions. The H-abstraction channel,

has not been characterized experimentally, but we assume that it has a rate constant similar to that of CH<sub>2</sub>O + HO<sub>2</sub>. The reaction would be expected to be too slow to compete at low temperatures, but may become dominating at elevated temperatures. According to the recent theoretical study of da Silva,<sup>[34]</sup>

the main product of  $\text{OCHCHO} + \text{HO}_2$  at low temperature is  $\text{HOCH}(\text{OO})\text{CHO}$ ,

However, even at low temperatures the  $\text{HOCH}(\text{OO})\text{CHO}$  radical predominantly dissociates to reform the reactants.<sup>[34]</sup> In analogy with a corresponding formaldehyde reaction,

a secondary product channel yielding OH radicals has been proposed for glyoxal oxidation by Hay and Norrish,<sup>[21]</sup>

$\text{OCHC}(\text{O})\text{OH}$  would be expected to decompose rapidly to formic acid ( $\text{HOCHO}$ ) +  $\text{CO}$ . Indeed, the existence of the OH producing channel for glyoxal +  $\text{HO}_2$  seems to be supported by the detection of formic acid<sup>[41]</sup> in glyoxal oxidation and appears to be required to explain the generation of chain carriers in glyoxal oxidation at 563-643 K.<sup>[21]</sup> From a photolysis study at 298 K, Niki et al.<sup>[41]</sup> derived a room temperature value for the OH channel of  $3 \times 10^8 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . Support for an OH-producing channel of the  $\text{OCHCHO} + \text{HO}_2$  reaction is also provided theoretically. According to da Silva,<sup>[34]</sup> the reaction forms a hydroxyperoxy radical, which decomposes to  $\text{HOCHO} + \text{CO} + \text{OH}$ ,

However, the rate constant calculated by da Silva is two orders of magnitude smaller than the value reported by Niki et al. In order to resolve this discrepancy, we have thoroughly re-interpreted the experimental results of Niki et al. (see Appendix). Our analysis indicates that the data of Niki et al. are compatible with the rate constant for (7) from da Silva,<sup>[34]</sup> provided that the association reaction (6) and the subsequent reactions of  $\text{HOCH}(\text{OO})\text{CHO}$  are taken into account. Consequently, we have adopted the rate coefficients for (6) and (7) from da Silva.

Only a few studies of the chemistry of the  $\text{OCHCO}$  radical have been reported.<sup>[33,41,42]</sup> It is expected to decompose thermally or react with  $\text{O}_2$ . The thermal dissociation,

was studied theoretically by da Silva,<sup>[35]</sup> who determined a high-pressure limit of  $k_{10,\infty} = 1.1 \times 10^{14} \times T^{0.133} \exp(-5102/T)$  between 200 and 2000 K. At the conditions of interest in the present study, this reaction is in the fall-off regime, and consequently we used extrapolations of rate constants provided by da Silva for the 150-400 K range for pressures of 0.01, 0.1, and 1 atm. The rate constant calculated by da Silva is considerably lower than the experimental value reported by Orlando and Tyndall<sup>[42]</sup> for 0.92 atm and 224-370 K. However, the latter determination was affected by the use of a too large rate constant value for  $\text{OCHCO} + \text{O}_2$ , as pointed out by da Silva.<sup>[35]</sup>

The reaction of OCHCO with O<sub>2</sub> could involve a number of product channels, i.e.,

Da Silva<sup>[35]</sup> predicts the CO + CO<sub>2</sub> + OH channel (11a) to be dominating above room temperature. In fact, in a recent kinetic study on OH formation in the Cl/OCHCHO/O<sub>2</sub> reaction system, Lockhart et al.<sup>[33]</sup> found strong evidence that the reaction (11) directly yields OH radicals with a rate constant consistent with the Da Silva estimate. The OCHCO + O<sub>2</sub> addition reaction is strongly exothermic and isomerization/decomposition of the excited peroxy radical adduct is competitive with collisional deactivation even at low temperature, leading directly to the dissociated products CO<sub>2</sub> + CO + OH. Similar to reaction (10), da Silva uses RRKM/ME theory to calculate values of  $k_{11a}$  for temperatures between 150 and 400 K and pressures of 0.01–1 bar; we extrapolate these data to the conditions of the present work. The work of da Silva indicates a small, positive activation energy (4–8 kJ mol<sup>-1</sup>). The finding that (11a) is the main product channel for OCHCO + O<sub>2</sub> is in agreement with experimental observations by Orlando and Tyndall.<sup>[42]</sup> However, they assumed the reaction to be barrierless and estimated a somewhat larger rate constant.

Addition of O<sub>2</sub> (11c) yields a ketoperoxy radical, OCHC(O)OO. This radical isomerizes with a computed barrier of 63 kJ mol<sup>-1</sup> to make OCC(O)OOH through a 1 - 4 hydrogen shift. With a low barrier of 28 kJ mol<sup>-1</sup>, the OCC(O)OOH radical would dissociate fast to form CO + CO<sub>2</sub> + OH; an overall step equivalent to (11a). Alternatively, the ketoperoxy radical could pick up an H atom at the radical oxygen resulting in OCHC(O)OOH. The new O-H bond with a bond energy of 407 kJ mol<sup>-1</sup> is reasonably strong; thus H might be abstracted from other species present including glyoxal. OCHC(O)OOH can decompose in a unimolecular step with a barrier of 87 kJ mol<sup>-1</sup> to yield HCO + CO<sub>2</sub> + OH or it can be converted to OCC(O)OOH by abstraction of H from the C-H bond. With a bond energy of 379 kJ mol<sup>-1</sup> this bond is weaker than the O-H bond. However, da Silva predicts the association rate (11c) to decrease rapidly above 300 K, and these pathways are not expected to be important under the conditions of the present study.

### 8.3 Experimental

The thermal decomposition of glyoxal has been investigated behind shock waves with and without oxygen present in the reaction gas mixtures. All experiments were carried out in an electro-polished stainless steel shock tube that is described in detail elsewhere.<sup>[2]</sup> The shock tube has been operated using hydrogen or hydrogen/nitrogen mixtures as driver gas and 30 or 80 μm thick aluminium diaphragms. Concentration-time profiles of the glyoxal decomposition product HCO were measured by means of frequency modulation (FM) spectroscopy at a detection wavelength of  $\lambda = 614.752$  nm. The experimental setup was very similar to the one used in our previous paper on the reaction HCO + O<sub>2</sub>.<sup>[2]</sup> Details on the HCO detection scheme and the implementation of FM spectroscopy for quantitative measurements of radicals behind shock waves can be found elsewhere.<sup>[43,44]</sup> According to FM

theory, the measured signal  $I_{\text{FM}}$  is related to the absolute radical concentration  $c$  by the equation

$$I_{\text{FM}} = \frac{I_0}{2} \sigma_c \times c \times l \times \Delta f \times G.$$

Here,  $I_0$  is the probe light intensity,  $\sigma_c$  the absorption cross section at line center, and  $l$  the absorption path length.  $\Delta f$ , the so-called FM factor, depends on the applied modulation frequency as well as the modulation depth and is calculated from the absorption line shape profile at the actual experimental temperature and pressure. Accurate line shape data and absorption cross sections have been adopted from Friedrichs et al.<sup>[43]</sup> The room temperature value of the absorption cross section is in excellent agreement (within 2%) with the accurate measurements of Flad et al.<sup>[45]</sup> Allowance was made for a small pressure broadening effect according to an assumed pressure broadening coefficient  $\Delta\nu = 2.0 \times (T/298 \text{ K})^{0.75} \text{ GHz bar}^{-1}$ , hence similar to the one experimentally observed for NH<sub>2</sub>.<sup>[46]</sup>  $G$  is the device-specific electronic gain factor of the FM spectrometer, which has to be determined separately. Its value has been re-measured and was found to be consistent with our previous determinations. We estimate the accuracy of the calculated HCO concentrations (including the error of the gain factor and the high temperature extrapolation of the HCO cross section) to be  $\pm 20\%$ .

Glyoxal was prepared by heating glyoxal trimeric dihydrate in the presence of P<sub>2</sub>O<sub>5</sub> and was stored in a liquid nitrogen trap. Reaction gas mixtures were prepared manometrically and contained 1% glyoxal in argon. Such high glyoxal mole fractions were necessary to ensure detectable HCO concentration levels. In about half of the experiments, mole fractions of 3185 - 9415 ppm oxygen have been added using a flow system with mass flow controllers. Experiments have been performed behind incident

(corresponding to an average total density  $\rho \approx 4.4 \times 10^{-6}$  mol cm<sup>-3</sup>) and reflected ( $\rho \approx 1.1 \times 10^{-5}$  mol cm<sup>-3</sup>) shock waves in the temperature range  $1299 \text{ K} < T < 1757 \text{ K}$ . The experimental conditions of all 28 shock tube experiments, as calculated from the measured shock wave velocity and pre-shock conditions using a standard shock tube code with real gas correction, are outlined in Table 8.3. It is known that the vibrational relaxation/equilibration of oxygen is quite slow, about  $100 \mu\text{s}$  at  $T = 1500 \text{ K}$  and  $p = 1 \text{ bar}$  in argon.<sup>[47]</sup> Therefore, in contrast to the translational and rotational degrees of freedom that are heated within  $1 \mu\text{s}$ , the vibrational degrees of freedom are not in thermal equilibrium on the typical experimental timescales of  $7 - 70 \mu\text{s}$  present in this study. This has two consequences: On the one hand, the real initial temperatures behind the shock waves were somewhat higher than calculated by the standard shock tube code. Therefore, Table 8.3 lists a corrected, up to 10 K higher initial temperature assuming that the O<sub>2</sub> vibrational degree of freedom is not heated at all. On the other hand, as the actual O<sub>2</sub>( $v = 1$ )/O<sub>2</sub>( $v = 0$ ) ratio during the experiment is lower than at thermal equilibrium (about 0.2 at  $T = 1400 \text{ K}$ ), the determined rate constant may be slightly biased by the different reactivities of O<sub>2</sub> in its  $v = 0$  and  $v = 1$  vibrational states. This non-equilibrium effect is difficult to address quantitatively and is typically neglected in the analysis of shock tube data. Within the scatter of the obtained rate constant data, and taking into account the very good agreement with our previous shock tube measurements (which were not affected due to a sufficiently long delay behind the shock wave arrival and glyoxal photolysis), we assume that the possible, presumably negative bias is not significant.

## 8.4 Results and Discussion

### 8.4.1 Branching ratio of glyoxal decomposition

Table 8.4: Previously reported channel branching ratios and total rate constants of the multi-channel thermal decomposition of glyoxal for typical experimental conditions behind the incident ( $\rho = 4.43 \times 10^{-6}$  mol cm<sup>-3</sup>) and reflected ( $\rho = 1.05 \times 10^{-5}$  mol cm<sup>-3</sup>) shock waves, according to Friedrichs et al.<sup>[19]</sup>.

OCHCHO → products $\rho / (\text{mol}/\text{cm}^3)$	$T = 1300 \text{ K}$		$T = 1700 \text{ K}$	
	$1.05 \times 10^{-5}$	$4.43 \times 10^{-6}$	$1.05 \times 10^{-5}$	$4.43 \times 10^{-6}$
$\phi$ (CH <sub>2</sub> O + CO) %	48	56	38	47
$\phi$ (2 CO + H <sub>2</sub> ) %	29	28	27	29
$\phi$ (HCOH + CO) %	7	7	6	7
$\phi$ (2 HCO) %	16	9	29	17
$k_{2,\text{total}}/\text{s}^{-1}$	$1.3 \times 10^4$	$8.3 \times 10^3$	$7.1 \times 10^5$	$3.8 \times 10^5$

Experiments with glyoxal/argon mixtures without oxygen were performed to test the overall thermal glyoxal decomposition mechanism reported in the literature. According to Friedrichs et al.,<sup>[19]</sup> the channel branching of the multi-channel unimolecular decomposition of glyoxal is strongly dependent on the temperature and total density. The effect of total density and temperature on the channel branching ratio is illustrated in Table 8.4. Note the pronounced fall-off of the total rate constant  $k_{2,\text{total}}$  ( $\rho^{\text{reflected}}/\rho^{\text{incident}} = 2.5$ , but  $k_{2,\text{total}}^{\text{reflected}}/k_{2,\text{total}}^{\text{incident}} \approx 1.7$ ) and the significantly different importance of the

HCO channel (2d) at the two different temperatures ( $\phi_{1700\text{ K}}/\phi_{1300\text{ K}} \approx 1.8$ ). Hence, the experiments behind the incident and reflected shock waves at overall different total densities provide a critical test of their rate constant data and RRKM/SACM/ME predictions.

Experimental HCO concentration-time profiles behind the reflected shock wave at three different temperatures are shown in Fig. 8.1a together with simulated profiles (thick curves). Fig. 8.1b illustrates the corresponding sensitivity analysis of the  $T = 1519\text{ K}$  experiment in order to identify the most important reactions. The numerical simulations were performed using the CHEMKIN-II package<sup>[48]</sup> and the SENKIN routine<sup>[49]</sup> based on the glyoxal oxidation mechanism outline above. Overall, the observation times of the HCO profiles were rather short and the initial increase of the HCO profiles were obscured by the strong Schlieren signal attributable to the passage of the shock wave through the detection laser beam. For a better comparison of the experimental and numerically simulated profiles, the experimental time resolution has been taken into account by convoluting the numerical simulation with an appropriate time response function (Gaussian, FWHM of 2-3  $\mu\text{s}$ ). Excluding the first few  $\mu\text{s}$  that are affected by the Schlieren signal (open symbols), both the absolute concentrations and the overall shapes of the reported concentration-time profiles are very well captured by the simulations. Toward low temperatures, the experimentally accessible temperature range was limited by too low intermediate concentrations, toward high temperatures by too short HCO lifetimes. The sensitivity analysis in Fig. 8.1b highlights the influence of the five most important reactions. Both the branching ratio of the OCHCHO decomposition as well as the rate constant of several secondary reactions have to be known to accurately predict the HCO profile. In fact, we were able to reproduce all measured HCO profiles without adjusting any rate constant data, initial glyoxal concentrations, or the temperature dependent HCO absorption cross section. From this high reproducibility we conclude that both the thermal glyoxal decomposition mechanism as well as the HCO detection scheme is highly reliable.

#### 8.4.2 Rate of Reaction $\text{HCO} + \text{O}_2$

The rate constant of the reaction

has been measured between  $1285\text{ K} \leq T \leq 1705\text{ K}$  at two different total densities of  $\rho \approx 4.3 \times 10^{-6}\text{ mol/cm}^3$  behind the incident and  $\rho \approx 1.0 \times 10^{-5}\text{ mol/cm}^3$  behind the reflected shock waves. The experimental conditions and the results for  $k_1$  are summarized in Table 8.3. Next to 1% glyoxal, serving as a source of HCO radicals from reaction (2d), the reaction mixtures contained 3185–9415 ppm  $\text{O}_2$ . Fig. 8.2a illustrates two typical experimental HCO concentration-time profiles measured behind reflected shock waves at a temperature of 1339 K and 1558 K, respectively. Both experiments were carried out at similar densities ( $\rho = 1.16$  and  $0.96 \times 10^{-6}\text{ mol/cm}^3$ ) and initial glyoxal (1.02% and 1.05%) and  $\text{O}_2$  mole fractions (4880 ppm and 5045 ppm). The observed peak HCO concentration is about four times lower at the lower temperature. For the 1558 K experiment, the total HCO observation time is only about 40  $\mu\text{s}$ , whereas HCO could be observed for  $> 200\text{ }\mu\text{s}$  at 1339 K. This behavior is well captured by the two simulated profiles (thick curves) using our glyoxal oxidation mechanism. Fig. 8.2b illustrates the results of the sensitivity analysis of the  $T = 1339\text{ K}$  experiment. It reveals

Figure 8.1: a: Three experimental HCO profiles at different temperatures behind reflected shock waves in comparison with numerically simulated profiles. Open circles mark the interfering Schlieren signals and do not contain information on HCO concentration. b: Corresponding HCO sensitivity analysis for  $T = 1519 \text{ K}$ . The sensitivity coefficients are normalized with respect to the maximum HCO concentration over the time history,  $\sigma(\text{HCO}) = 1/[\text{HCO}]_{\text{max}} \times \partial[\text{HCO}](t)/\partial \ln k$ .

that the simulated absolute concentration levels are mainly determined by the branching ratio of the thermal decomposition of glyoxal, in particular the rate constants of the reaction (2b), and by the assumed rate constant for the target reaction (1). Other consecutive reactions of HCO and glyoxal are also important, but their rates have been validated together with the branching ratio by the shock tube measurements for mixtures without  $\text{O}_2$  as outlined above. Hence it was possible to obtain a best-fit value for the rate constant of the reaction  $\text{HCO} + \text{O}_2$  by adjusting exclusively  $k_1$ . The two dashed curves in Fig. 8.2a, corresponding to numerical simulations with  $k_1$  set to  $k_1 \times 2$  and  $k_1 \div 2$ , demonstrate the sensitivity of this procedure. Especially with respect to the HCO peak concentration, the effect of changing  $k_1$  is very pronounced. Nevertheless, due to the moderate signal-to-noise ratio of the experiments, we estimate that the uncertainty of each individual  $k_1$  value with  $\pm 75\%$  is rather large.

The obtained  $k_1$  values are depicted as red symbols in comparison with selected literature data in the Arrhenius plot shown in Fig. 8.3. The included red error bar corresponds to the  $\pm 75\%$  uncertainty of a single data point; the  $2\sigma$  standard deviation of the data with respect to the final Arrhenius fit (red curve) is about  $\pm 40\%$ . For a more complete comparison of available literature data and a critical

Figure 8.2: a: Two typical experimental HCO concentration-time profiles in comparison with simulations (thick curves). The simulated profiles have been convoluted with an appropriate response function in order to allow for a direct comparison of the experiment and simulation at short reaction times. Open circles mark the interfering Schlieren signals, which were excluded from the fit. b: Corresponding HCO sensitivity analysis for the experiment at  $T = 1339 \text{ K}$ . Only the five most sensitive reactions are shown.

assessment of available room temperature data we refer to our previous publication<sup>[2]</sup> and the paper of De Sain et al.<sup>[50]</sup> Within the scatter of the data, the experiments behind the incident (open circles) and reflected shock waves (star symbols) are consistent, hence no dependence of the rate constant on the total density could be identified. In contrast, a weak positive temperature dependence is evident. Both the temperature dependence and the absolute rate constant values are in quantitative agreement with the high temperature extrapolation (blue dashed line) of our previous determination:<sup>[2]</sup>

$$k_1 / (\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 3.7 \times 10^{13} \times \exp(-13 \text{ kJ/mol}/RT)$$

The original data and error bars of the latter study are included as blue plus symbols. They had been determined using the 193 nm photolysis of glyoxal as a source of HCO radicals and their uncertainty, unlike the uncertainty of the experiments in this work, were mainly due to the assumed initial ratio of  $[\text{H}]/[\text{HCO}]$  from glyoxal photolysis. The very good agreement of these two independent studies points out the consistent modeling capabilities of our mechanism with regard to glyoxal photolysis and pyrolysis.

The recommended value from the GRI-Mech. 3.0<sup>[51]</sup> (line marked with black filled circles) is in agreement with the new high temperature results, but the temperature dependence is quite underestimated. The RRKM/VTST calculations of Hsu et al.<sup>[36]</sup> (curve marked with down triangle) underpredict the onset of the high-temperature direct abstraction channel resulting in about two times lower absolute  $k_1$  values at temperatures around 1500 K. Other experimental data for intermediate temperatures and at room temperature<sup>[2,50,52,53]</sup> reveal a more or less temperature independent rate constant, which is consistent with the expected capture controlled process of the indirect abstraction channel with an initiating recombination step and a low-lying exit barrier to the products  $\text{CO} + \text{HO}_2$ . As a reasonable fit of the overall temperature dependence of the available data, an extended Arrhenius expression is recommended over the temperature range  $295 \text{ K} < T < 1705 \text{ K}$  (red curve):

$$k_1 / (\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}) = 6.92 \times 10^6 \times T^{1.90} \times \exp(+5.73 \text{ kJ/mol}/RT)$$

The overall rate constant is independent of pressure. Even at room temperature, the collisionally deactivated recombination product  $\text{HC(O)O}_2$  does not play a role provided that the pressure does not exceed several bar.<sup>[36]</sup>

Figure 8.3: Arrhenius plot of the measured rate constants  $k_1$  for the reaction  $\text{HCO} + \text{O}_2$  of this work (incident wave  $\circ$ , reflected wave  $\star$ ) in comparison with selected experimental data from Colberg and Friedrichs (+, blue line),<sup>[2]</sup> Veyret and Lesclaux ( $\blacktriangle$ ),<sup>[52]</sup> Timonen et al. ( $\blacklozenge$ ),<sup>[53]</sup> DeSain et al. ( $\blacksquare$ ),<sup>[50]</sup> the GRI-Mech 3.0 recommendation ( $\bullet$ ),<sup>[51]</sup> and the theoretical study of Hsu et al. ( $\blacktriangledown$ ).<sup>[36]</sup> The red curve depicts the final recommended  $k_1$  rate expression.

#### 8.4.3 Model validation against literature data

To test the capacity of our mechanism we used it for the modeling of other available experimental literature data. In particular, the batch reactor experiments of Hay and Norrish<sup>[21]</sup> were of interest. Their study, which was based on manometric detection of the reaction progress and gas chromatographic

product analysis, should provide a detailed characterization of glyoxal oxidation with varying equivalence ratio at a nominal temperature of 603 K. At this intermediate temperature,  $\text{HO}_2$  related oxidation reactions such as  $\text{OCHCHO} + \text{HO}_2$  become important. However, we were not able to reconcile the results of Hay and Norrish with our present understanding of the reaction system. Using our mechanism, we were able to reproduce qualitatively the product yields and the overall shapes of the experimental concentration-time profiles – but in fact on a more than two orders of magnitude slower time scale. As a possible explanation, the hypotheses of a much higher yield of the OH radical forming channel (6),  $\text{OCHCHO} + \text{HO}_2 \rightarrow \text{HOCHO} + \text{CO} + \text{OH}$ , was tested. As already stated above and further outlined in the Appendix, we actually recommend the low  $k_6$  value calculated by da Silva<sup>[34]</sup> in our mechanism, which is two orders of magnitude smaller than the value reported by Niki et al.<sup>[41]</sup> In fact, setting  $k_6$  to the much higher value of Niki et al. significantly reduces the mismatch of the overall reaction time scales, but the agreement with the reported product yields is seriously deteriorated. In particular, the high yield of  $\text{H}_2\text{O}_2$  reported by Hay and Norrish is considerably underestimated. Further modeling attempts led us to the conclusion that the Hay and Norrish experiments presumably were not performed under isothermal conditions and that the fast observed experimental glyoxal consumption is at least partly due to an unidentified temperature increase of the reaction gas mixture. This uncertainty, along with the issue of potential surface effects in the reactor, makes these data less suitable for kinetic interpretation.

Another test for the glyoxal oxidation mechanism was the modeling of the photolysis experiments of glyoxal/oxygen mixtures performed by Colberg and Friedrichs.<sup>[2]</sup> Fig. 8.4 shows a comparison of an original experiment at  $T = 857$  K taken from ref 2 with simulations of HCO concentration-time profiles with (solid curve) and without oxygen (dash-dotted curve) present in the reaction mixture. Oxygen addition significantly reduces the overall HCO yield and lifetime. The simulation is in perfect agreement with the experimental data. To further investigate the possibility of a significant OH forming channel of the reaction  $\text{OCHCHO} + \text{HO}_2$ , a simulation with the rate of reaction (6) increased to the Niki et al. value,  $k_6 \times 200$ , is shown as well (dotted curve). With  $k_6 \times 200$ , the influence of reaction (6) on the HCO concentration profile is negligible at short reaction times, but a factor of four higher HCO concentration is simulated at  $t = 25 \mu\text{s}$ . In this case, the simulated residual HCO concentration at long reaction times can be traced back to a steady regeneration of HCO radicals due to the combined reaction sequence (5) and (10),  $\text{OCHCHO} + \text{OH} \rightarrow \text{HCO} + \text{CO} + \text{H}_2\text{O}$ . However, none of the original experiments of Colberg and Friedrichs showed this small but significant HCO concentration plateau at longer reaction times, hence further supporting the low OH yield from the reaction  $\text{OCHCHO} + \text{HO}_2$  as predicted by da Silva and recommended by us.

## 8.5 Conclusions

A detailed glyoxal decomposition and oxidation mechanism has been compiled from literature data merging previous reports on glyoxal/oxygen photolysis at room and high temperature,<sup>[19]</sup> the branching ratios of glyoxal thermal decomposition,<sup>[2]</sup> and theoretical studies on the reaction of glyoxal +  $\text{HO}_2$ ,<sup>[34]</sup>  $\text{OCHCO} + \text{O}_2$ ,<sup>[35]</sup> and formic acid oxidation.<sup>[26]</sup>

Figure 8.4: Photolysis experiment of Colberg and Friedrichs<sup>[2]</sup> at  $T = 857$  K and  $p = 1080$  mbar with 2% OCHCHO and 3160 ppm  $\text{O}_2$  in the reaction mixture. Three different simulations are shown: without  $\text{O}_2$  (dash-dotted curve) and with  $\text{O}_2$  assuming either the rate constant for the reaction  $\text{OCHCHO} + \text{HO}_2$  as reported by Niki et al.<sup>[41]</sup> (dotted curve) or by da Silva<sup>[34]</sup> (solid curve).

All HCO profiles from glyoxal decomposition behind shock waves could be very well simulated, both in terms of absolute HCO concentrations and signal shapes, using the glyoxal decomposition mechanism adopted from Colberg and Friedrichs<sup>[2]</sup> with branching fractions taken from Friedrichs et al.<sup>[19]</sup> The established glyoxal pyrolysis mechanism was able to predict the measured HCO concentration-time profiles of this work without any modifications. Moreover, by adding oxygen to the reaction mixtures, the rate constant for the reaction  $\text{HCO} + \text{O}_2$  could be measured at temperatures  $1285 \text{ K} \leq T \leq 1705 \text{ K}$ , hence significantly extending the range of direct measurements toward higher temperatures. The results are in striking agreement with the previous shock tube/photolysis experiments of Colberg and Friedrichs.<sup>[2]</sup> The absolute values as well as the overall temperature dependence, which is stronger than predicted theoretically, could be confirmed.

A detailed reanalysis of previous experimental measurements on the reaction  $\text{OCHCHO} + \text{HO}_2$  performed by Niki et al.<sup>[41]</sup> led us to the conclusion that the reported high OH yield can be traced back to a previously unidentified formation of the recombination product  $\text{HOCH}(\text{OO})\text{CHO}$  and its secondary reaction with  $\text{HO}_2$ . The theoretically predicted, two orders of magnitude lower rate constant value for OH formation reported by da Silva<sup>[34]</sup> is also supported by a reassessment of the previous glyoxal/ $\text{O}_2$  photolysis data from Colberg and Friedrichs.<sup>[2]</sup> Using the original high rate constant value of Niki et al., our glyoxal oxidation mechanism would predict HCO concentration plateau levels at long reaction times that have not been observed in the experiment.

Unfortunately, a further critical test of the performance of our mechanism at intermediate temperatures by comparing model predictions with the outcome of the glyoxal oxidation batch reactor experiments of Hay and Norrish<sup>[21]</sup> turned out to be unfeasible. Most probably those experiments were biased by an unidentified temperature increase in the reactor. Therefore, additional measurements of glyoxal

oxidation at intermediate temperatures are desirable and would offer a possibility to critically check the predicted important role of the reaction  $\text{OCHCHO} + \text{HO}_2$  for the overall reaction progress.

Detailed glyoxal oxidation reaction mechanism and pressure dependent rate constant data in PLOG format.

## 8.6 Appendix: On the $\text{OCHCHO} + \text{HO}_2$ Reaction

As discussed above, the reaction of  $\text{OCHCHO}$  with  $\text{HO}_2$  is believed to be of importance for the generation of chain carriers in oxidation of glyoxal. Figure 8.5 compares the available rate constant data for the rate of  $\text{OCHCHO} + \text{HO}_2$ . According to the recent theoretical study by da Silva,<sup>[34]</sup> glyoxal reacts with  $\text{HO}_2$  to form a hydroxyperoxy radical. At low temperatures the major reaction product is predicted to be collisionally deactivated  $\text{HOCH}(\text{OO})\text{CHO}$  (7), but a secondary product channel yielding  $\text{HOCHO}$  and  $\text{OH}$ ,

has been proposed in earlier studies of glyoxal oxidation. The only experimental determination of the rate constant for the  $\text{OH}$  channel was reported by Niki et al.,<sup>[41]</sup> who derived a value more than two orders of magnitude larger than the theoretical estimate for  $k_7$  by da Silva.<sup>[34]</sup> Figure 8.5 compares their value (open square) with the theoretical prediction of the rate constants for the different channels of the reaction  $\text{OCHCHO} + \text{HO}_2$ .

Due to the importance of the reaction of glyoxal with  $\text{HO}_2$ , it is worthwhile to take a closer look at the experimental results from Niki et al. that form the basis of their estimation of  $k_7$ . They conducted  $\text{Cl}$ -atom initiated oxidation studies of glyoxal oxidation, photolyzing a system of  $\text{Cl}_2$  (100 ppm),  $\text{OCHCHO}$  (8-22 ppm),  $\text{O}_2$  (93.3 mbar), and  $\text{H}_2$  (840 mbar). The following sequence of reactions was intended to provide data on  $k_7$ :  $\text{Cl}_2 + h\nu \rightarrow \text{Cl} + \text{Cl}$ ,  $\text{Cl} + \text{H}_2 \rightarrow \text{HCl} + \text{H}$ ,  $\text{H} + \text{O}_2 (+\text{M}) \rightarrow \text{HO}_2 (+\text{M})$ ,  $\text{OCHCHO} + \text{HO}_2 \rightarrow \text{HOCHO} + \text{CO} + \text{OH}$  (7), along with the side reaction  $\text{HO}_2 + \text{HO}_2 \rightarrow \text{H}_2\text{O}_2 + \text{O}_2$ . Niki et al. used continuous UV light for 60 or 120 seconds to obtain sufficient photolysis of  $\text{Cl}_2$ . The results of the experiments are shown in Table 8.5. Results obtained for longer reaction times are neglected here, as Niki et al. reported a considerable loss of species by surface reactions.

Figure 8.5: Arrhenius plot for the reaction  $\text{OCHCHO} + \text{HO}_2 \rightarrow \text{products}$ . The curves denote the rate constants predicted theoretically by da Silva<sup>[34]</sup> for the total reaction at the high-pressure limit and for the recombination reaction (6) as well as the OH-producing channel (7) at 1.0 atm. The H-abstraction channel forming  $\text{OCHCO} + \text{H}_2\text{O}_2$  (8) is an estimate by analogy to the reaction  $\text{CH}_2\text{O} + \text{HO}_2$ . The square symbol denotes the experimental result for the OH-producing channel (7) by Niki et al.<sup>[41]</sup>

Niki et al. estimated the  $\text{HO}_2$  radical concentration from the equation,

$$\Delta[\text{H}_2\text{O}_2] = 2k_{\text{HO}_2+\text{HO}_2}[\text{HO}_2]^2 \times \Delta t$$

using the measured  $\text{H}_2\text{O}_2$  concentration. Then, they calculated the rate constant for (7) from

$$\Delta[\text{OCHCHO}] = k_7[\text{OCHCHO}]_{\text{average}}[\text{HO}_2] \times \Delta t$$

deriving a room temperature of  $k_7 = 3 \times 10^8 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$  (Fig. 8.5).

An up-to-date kinetic analysis of the system supports most of the assumptions made by Niki et al. Once formed by the sequence of reactions outlined by Niki et al.,  $\text{HO}_2$  reacts with glyoxal,

or with itself,

The major shortcoming of their analysis is the disregard of the formation of  $\text{HOCH(OO)CHO}$ , which according to da Silva is the dominating product of the glyoxal +  $\text{HO}_2$  reaction. Provided the  $\text{HOCH(OO)CHO}$  adduct has a sufficiently long lifetime, this adduct may react with  $\text{HO}_2$  in a secondary reaction. There are no experimental or theoretical data available for  $\text{HOCH(OO)CHO} + \text{HO}_2$ , but from analogy with other hydrocarbon peroxide radicals, the reaction is likely to have two product

channels,

Dissociation of HOCH(O)CHO to HOCHO and HCO is 59 kJ mol<sup>-1</sup> exothermic. A DFT estimate indicates a barrier to dissociation of merely +1.0 kJ mol<sup>-1</sup>, which drops to -5.0 kJ mol<sup>-1</sup> at the CBS-QB3 level of theory, so we believe that dissociation of HOCH(O)CHO is essentially instant, even at 298 K. For similar reactions of HOCH<sub>2</sub>OO, CH<sub>3</sub>C(O)OO, and CH<sub>3</sub>C(O)CH<sub>2</sub>OO with HO<sub>2</sub>, branching fractions  $k_{\text{OH}}/k_{\text{total}}$  of 40% (±25%) have been reported.<sup>[54,55,56]</sup> In the present work, we have assumed a branching fraction for HOCH(OO)CHO + HO<sub>2</sub> of 50%, together with an overall rate constant of  $k_{13+14} = 6.0 \cdot 10^{12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ , which is typical for this type of reaction.

Modeling of the experimental data from Niki et al. with the detailed reaction mechanism of the present work have been performed. Appropriate reactions of chlorine species have been added and the photolysis rate for Cl<sub>2</sub> was fitted such that the calculated concentration of HCl after 60 or 120 s matched reasonably the measured values. The results are shown (in parenthesis) in Table 8.5. Even though we employ a rate constant for  $k_7$ , which is about two orders of magnitude lower than derived by Niki et al., the agreement between measured and predicted concentrations is acceptable. In support of the present interpretation of the reaction system, Niki et al. reported the detection of a transient component, which they believed to be HOCH(OOH)CHO.

Table 8.5: Cl-atom initiated reaction in the OCHCHO/H<sub>2</sub>/O<sub>2</sub> system. Photolysis of a mixture of Cl<sub>2</sub> (100 ppm), OCHCHO (8-22 ppm), O<sub>2</sub> (70 torr), and H<sub>2</sub> (630 torr). Experimental data are from Niki et al.<sup>[41]</sup> and modeling results (shown in parenthesis) from the present work.

[OCHCHO] <sub>0</sub> (ppm)	8.5	9.0	22.4
Irradiation time (s)	60	60	120
-Δ[OCHCHO] (ppm)	0.68 (0.83)	0.71 (0.88)	2.14 (3.5)
[HCl] (ppm)	13.4 (12.6)	12.3 (12.6)	22.6 (21.4)
[HOCHO] (ppm)	0.34 (0.29)	0.40 (0.31)	1.9 (1.2)

## 8.7 Supporting Information

### CHEMKIN input file

This is the CHEMKIN input file used for modeling glyoxal thermal decomposition and oxidation at high and intermediate temperatures.

Be aware of the limited pressure and temperature validity ranges of some of the listed rate expressions. For example, the parametrization of thermal decomposition reactions of glyoxal is valid over the temperature range 800 K < T < 2500 K only; for modeling attempts at significantly lower temperatures (and hence very slow decomposition) these reactions should be commented out.

Most pressure dependent reactions are reported in terms of the PLOG formalism (commented out). Newer CHEMKIN versions automatically interpolate the appropriate rate constant values at the desired pressure, see X. Gou, J.A. Miller, W. Sun and Y. Ju (2001)

[http://engine.princeton.edu/download/PLOG-documents/PLOG-software\\_distribution.pdf](http://engine.princeton.edu/download/PLOG-documents/PLOG-software_distribution.pdf)

Activation energies are specified in cal/mol units, pressures in atm.

## 9 Summary and outlook

High-temperature rate constants of five bimolecular reactions of NCN, HNO, and HCO have been measured at high temperatures. These molecules are short-lived flame intermediates that play important roles for NO<sub>x</sub> pollutant formation (NCN and HNO) and the overall oxidation rate (HCO) in flames. Combustion-relevant experimental conditions have been generated by the shock wave method.

**NCN reactions:** Narrow-bandwidth UV laser difference absorption spectroscopy has been applied for the detection of NCN concentration-time profiles. The measurements have been performed at a transition at  $\tilde{\nu} = 30383.11 \text{ cm}^{-1}$  ( $\lambda \approx 329 \text{ nm}$ ) corresponding to a superposition of the  $^3\Pi_1$  subband of the  $\tilde{A}^3\Pi_u(000) - \tilde{X}^3\Sigma_g(000)$  transition and the Q<sub>1</sub> band head of the vibrationally hot Renner-Teller split vibronic  $^3\Sigma^+(010) - ^3\Pi(010)$  transition. At high temperatures, the (010) vibrational state is significantly populated resulting in a comparably high absorption cross section suitable for a sensitive detection scheme.

For the first time, direct rate constant measurements have been performed for the reactions NCN + H, NCN + H<sub>2</sub> and NCN + O<sub>2</sub> over a wide temperature and pressure range (see Fig. 9.1). NCN radicals were generated from the thermal decomposition of NCN<sub>3</sub> in shock tube experiments. The highly explosive and very toxic NCN<sub>3</sub> has been synthesized in high purity and storage mixtures of NCN<sub>3</sub> in argon were used within a few days since a slow decomposition/polymerization takes place. The pyrolysis of ethyl iodide (C<sub>2</sub>H<sub>5</sub>I) was used as H atom source for the investigation of the reaction NCN + H. The rate constant of this reaction has been determined between temperatures  $962 \text{ K} < T < 2425 \text{ K}$ . The obtained rate constant can be best represented by the combination of two Arrhenius expressions, corresponding to two reaction channels yielding either CH + N<sub>2</sub> or HCN + N. By a detailed analysis of the data in comparison with literature data, the temperature dependent branching ratio for the reaction NCN + H as well as a consistent value for the NCN enthalpy of formation  $\Delta_r H_{298\text{K}}^\circ = 450 \text{ kJ/mol}$  were determined.

The rate constant of the reaction NCN + H<sub>2</sub>, which has so far been neglected in detailed reaction mechanisms for NO<sub>x</sub> formation, has been measured under accurately pseudo first-order reaction conditions. From different possible product channels for this reaction, the obtained Arrhenius activation energy as well as mechanistic considerations are most consistent with a direct abstraction channel yielding the products HNCN + H. Further, in cooperation with N. Lamoureux and P. Desgroux (Université Lille 1, France), the reaction NCN + H<sub>2</sub> and additionally secondary reactions have been implemented

into the detailed GDFkin3.0\_NCN mechanism for the simulation of low pressure  $\text{CH}_4/\text{O}_2/\text{N}_2$ -flames. Significant differences have been observed for the overall NO yields with the updated mechanism at two different flame conditions.

For  $\text{NCN} + \text{O}_2$ , high-temperature rate expressions used in flame modeling mechanisms differ by five orders of magnitude (at  $T = 1500$  K). Depending on the assumed rate constant value, this reaction was reported to be either very important or dispensable for flame modeling. To resolve the role of the reaction  $\text{NCN} + \text{O}_2 \rightarrow \text{NCO} + \text{NO}$  for prompt-NO modeling in flames, the rate expression was determined experimentally at temperatures between  $1577 \text{ K} \leq T \leq 2492 \text{ K}$ . The measurements confirmed that the reaction is rather slow and hence does play a minor role for NCN modeling in flames.

The measured rate constants for bimolecular NCN reactions of this work (red curves) are displayed in the Arrhenius plot in Fig. 9.1 together with previously determined rate constant data (black curves) from the Kiel shock tube group.

Figure 9.1: Arrhenius plot of bimolecular NCN rate constants measured with the Kiel shock tube setup. Rate constants measured in this work are labeled with red color.

**HNO detection and the reaction  $\text{HNO} + \text{O}_2$ :** HNO has been measured for the first time behind shock waves using the very sensitive absorption based FM spectroscopy. HNO concentrations of about 200 ppm were generated from the 193 nm UV photolysis of glyoxal/NO mixtures, initially yielding HCO radicals followed by the reaction  $\text{HCO} + \text{NO} \rightarrow \text{HNO} + \text{CO}$ . HNO FM spectra of the  $\tilde{A}^1A'' - \tilde{X}^1A'$  transition and concentration-time profiles have been detected at three different wavelengths around 618 and 625 nm. An HNO formation mechanism has been compiled from available literature data. Further, by monitoring HCO and HNO concentration time profiles at similar reaction conditions, the temperature dependent HNO absorption cross section has been determined, allowing us to perform quantitative HNO measurements at high temperatures. Based on this results and by adding specific amounts of  $\text{O}_2$  to the reaction mixtures, the reaction  $\text{HNO} + \text{O}_2 \rightarrow \text{NO} + \text{HO}_2$  has been directly measured. The obtained rate constant data are about two to three orders of magnitude higher than

frequently used literature data.

**Glyoxal oxidation and HCO + O<sub>2</sub>:** HCO concentration-time profiles have been measured by FM spectroscopy. The pyrolysis of glyoxal was used as HCO source. The applied mechanism for the thermal decomposition was developed from former experiments in our working group. By adding O<sub>2</sub> to the glyoxal reaction mixtures, the rate constant of the reaction  $\text{HCO} + \text{O}_2 \rightarrow \text{CO} + \text{HO}_2$  could be determined. Moreover, the capability of a detailed glyoxal oxidation mechanism assembled from available literature data was tested. The outcome of the experiments of this work concerning the glyoxal decomposition and the temperature dependent  $k_{\text{HCO}+\text{O}_2}$  values were in very good agreement with former findings. Together with P. Glarborg (Technical University of Denmark) and P. Marshall (University of North Texas) an extensive glyoxal oxidation mechanism was assembled from available literature data and validated by the shock tube measurements.

**Outlook:** The established experimental setups for time-resolved measurements of NCN and HNO concentration profiles behind shock waves should be used to study other important reactions of these species. For example, experimental rate constant data for the reactions of NCN with the important flame intermediates OH, CN, C and N atoms are still missing for a complete high temperature NCN submechanism. Also detection schemes for the possible reaction products of NCN reactions should be considered. For example, in order to confirm the formation of  $\text{HNCN} + \text{H}$  from  $\text{NCN} + \text{H}_2$ , H-ARAS (at  $\lambda = 121.6$  nm) could be applied. Also the reported temperature dependent product branching ratio for  $\text{NCN} + \text{H}$  needs to be experimentally verified, for example by the detection of CH (laser absorption around  $\lambda = 430$  nm) and N atoms (N-ARAS at  $\lambda = 119.9$  nm). The reactions  $\text{NCN} + \text{O}$ ,  $\text{NCN} + \text{N}$ ,  $\text{NCN} + \text{C}$  and  $\text{NCN} + \text{NCN}$  are supposed to form CN radicals; therefore ongoing CN measurements (M.Sc. thesis of S. Hesse) by means of FM spectroscopy are important to verify these assumed reaction products.

The overall aim of this work was to contribute to the implementation of a complete NCN submechanism into existing combustion mechanisms. Such a submechanism should be based on directly measured rate constants including branching ratios as well as temperature and pressure dependences. Continued cooperation with flame modeling groups is important to test and improve the capability and reliability of such mechanisms for NO<sub>x</sub> modeling.

In the case of HNO, a lot of experimental kinetic data at combustion relevant temperatures are still missing. Even the rate constants for reactions with common flame intermediates like OH, O and H atoms are not accurately known. To observe these probably fast reactions, the HNO detection scheme, established in this work, needs further optimization in order to improve the signal-to-noise ratio. One possibility is to use an EOM capable of generating higher modulation indices  $M$ , another is to search for alternative, more direct HNO generation schemes.

## Danksagungen

Abschließend möchte ich mich bei allen bedanken, die zur Entstehung dieser Arbeit auf die eine oder andere Weise beigetragen haben:

Ein besonderer Dank gilt meinem Doktorvater Prof. Dr. Gernot Friedrichs für die Möglichkeit an sehr interessanten und herausfordernden Themen arbeiten zu dürfen. Desweiteren bedanke ich mich für die Unterstützung bei allen fachlichen Problemen, die stets vorhandene Diskussionsbereitschaft und die optimistische Grundeinstellung gegenüber der Realisierbarkeit neuer Projekte.

Ich danke allen Mitgliedern der Arbeitsgruppe Friedrichs für eine angenehme und produktive Arbeitsatmosphäre. Insbesondere gilt mein Dank Johannes Dammeier, für die Einweisung ins Stoßwellenexperiment, sowie Joscha und Inga, für ein entspanntes Büroklima.

Für freundliche Unterstützung und Hilfsbereitschaft bedanke ich mich bei den Mitarbeitern der Arbeitskreise von Prof. Temps, Prof. Grottemeyer und Prof. Hartke

Dr. J. Gripp danke ich für seine Hilfe und viele nützliche Ratschläge, ich danke außerdem allen Mitarbeitern der Institutswerkstatt, allen technischen Angestellten und unseren Sekretärinnen.

I would like to thank Nathalie Lamoureux and Pascale Desgroux (Université Lille 1, France) for ongoing cooperation and flame modeling work.

I also thank Peter Glarborg (Technical University of Denmark) and Paul Marshall (University of North Texas) for a successful collaboration concerning the glyoxal oxidation.

Weiterer Dank gilt Elke Goos (DLR, Stuttgart) und Patrik Hemberger (PSI, Schweiz) für die Zusammenarbeit an der Swiss Light Source.

Bei meiner Familie und meinen Freunden, sowie meinem Freund Philipp bedanke ich mich für die fortwährende Unterstützung und für sehr willkommene Ablenkungen vom Laboralltag.

## Selbstständigkeitserklärung

Hiermit erkläre ich, Nancy Faßheber, an Eides statt, dass ich die vorliegende Arbeit selbstständig und nur unter Verwendung der angegebenen Hilfsmittel angefertigt habe. Inhalt und Form dieser Arbeit sind, abgesehen von der Beratung durch meinen Doktorvater Prof. Dr. Gernot Friedrichs, selbstständig erarbeitet worden. Die Arbeit entstand unter Einhaltung der Regeln guter wissenschaftlicher Praxis der Deutschen Forschungsgemeinschaft. Dies ist mein erster Promotionsversuch und weder die gesamte Arbeit noch Teile davon habe ich im Rahmen eines Prüfungsverfahrens eingereicht. Sie wurde in ihrer Gesamtheit nicht veröffentlicht und auch nicht zur Veröffentlichung eingereicht. Teile dieser Arbeit wurden in fachwissenschaftlichen Zeitschriften veröffentlicht, dies bezieht sich auf die folgenden Kapitel:

– Kapitel 4:

**N. Faßheber**, J. Dammeier, and G. Friedrichs, Direct measurements of the total rate constant of the reaction  $\text{NCN} + \text{H}$  and implications for the product branching ratio and the enthalpy of formation of  $\text{NCN}$ , *Phys. Chem. Chem Phys.* **2014**, 16, 11647-11657.

– Kapitel 5:

**N. Faßheber**, N. Lamoureux, and G. Friedrichs, The rate constant of the reaction  $\text{NCN} + \text{H}_2$  and its impact on  $\text{NCN}$  and  $\text{NO}$  concentrations in low pressure  $\text{CH}_4/\text{O}_2/\text{N}_2$ -flames, *Phys. Chem. Chem Phys.* **2015**, 17, 15876-15886.

– Kapitel 6:

**N. Faßheber** and G. Friedrichs, Shock tube measurements of the rate constant of the reaction  $\text{NCN} + \text{O}_2$ , *Int. J. Chem. Kinet.* **2015**, 47, 586-595.

– Kapitel 8:

**N. Faßheber**, G. Friedrichs, P. Marshall, and P. Glarborg, Glyoxal oxidation mechanism: Implications for the reactions  $\text{HCO} + \text{O}_2$  and  $\text{OCHCHO} + \text{HO}_2$ , *J. Chem. Phys. A* **2015**, 119, 7305-7315.

# Curriculum Vitae

## Personal data

Name:	Nancy Faßheber
Nationality:	German
Date of birth:	5th of May, 1986
Place of birth:	Röbel/ Müritz
Address:	Knooper Weg 122, 24105 Kiel, Germany

## Education

July 2014: since 2011:	Measurements at the Swiss Light Source Doctoral candidate of Prof. Dr. G. Friedrichs, Shock tube lab at the Institut für Physikalische Chemie at the Christian-Albrechts-Universität zu Kiel
December 2010:	Diploma Thesis: Stoßwellenuntersuchungen zur Bestimmung der Hochtemperatur-Geschwindigkeitskonstanten der Reaktionen $\text{NCN} + \text{H}$ und $\text{NCN} + \text{H}_2$
2005 - 2010:	Chemistry studies (Diploma) at the Christian-Albrechts-Universität zu Kiel
2005:	Abitur (university-entrance diploma)
1996 - 2005:	Joliot-Curie-Gymnasium, Röbel/Müritz
1992 - 1996:	Grundschule 1, Röbel/Müritz
