Quenching of metastable states of antiprotonic helium atoms by collisions with H_2 molecules

BERNHARD KETZER¹ FOR THE PS205 COLLABORATION AT CERN/LEAR ¹Physik-Department, Technische Universität München, D-85748 Garching, Germany

Antiprotonic helium atoms are formed by Coulomb capture of antiprotons stopped in a helium target. In a series of laser spectroscopy experiments we have shown that the unusual longevity of some 3% of these exotic atoms occurs due to the formation of metastable states of the \overline{p} -e⁻-He²⁺ system [1,2]. The experimental technique used until now, however, was restricted to laser-induced transitions between metastable states (n, l), n being the principal quantum number and l the angular momentum quantum number, and adjacent nonmetastable ones (n - 1, l - 1) at the end of each cascade with vibrational quantum number v = n - l - 1 = const.

Recently, we have overcome this restriction by taking advantage of state dependent quenching effects observed when H₂ is added to the helium at ppm levels. By selectively shortening the lifetimes of states with higher n, six "inverse" resonant transitions $(n, l) \rightarrow (n+1, l+1)$ between normally metastable states of antiprotonic helium atoms were observed [3]. The partial level scheme of \overline{p}^4 He⁺ shown in Fig. 1 summarizes the six "H₂-assisted inverse resonances" (HAIR) (bold arrows) and the two "conventional" transitions from a metastable (bold horizontal lines) to a short-lived level (zigzag lines) at the end of the cascades v = 2 and v = 3.

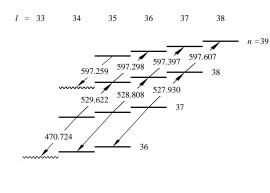

Fig. 1 Partial level scheme of the $\overline{p}He^+$ system, summarizing the six HAIR transitions between normally metastable states (bold arrows) and the two "conventional" transitions from a metastable to a short-lived state at the end of the v = 2 and v = 3 cascades (thin arrows). The experimental vacuum wavelengths for these transitions are given in units of nm.

We have employed the HAIR method to determine the decay rates of the states (n, l) = (39, l), l = 36, 37, 38 and (38, l), l = 35, 36, 37 of $\overline{p}He^+$ as a function of the H₂ admixture [4]. The quenching cross sections deduced for the states with n = 39 were found to be of the order of the geometrical cross section for $\overline{p}He^+$ -H₂ collisions $(2 \cdot 10^{-15} \text{ cm}^2)$, with a moderate decrease of the sensitivity to H₂ with increasing l. Within a given cascade v = n - l - 1 = const, the quenching cross sections for states with n = 38 are smaller by a factor of four to six than those for states with n = 39. The physico-chemical interactions leading to these strongly state dependent quenching effects are not yet understood.
