Part of Special Issue “Multidisciplinary approaches in natural hazards”

Abstract. Risk assessment is mainly based on certain scenarios involving an event of a certain size which is thought to be characteristic for the considered type of hazard. However, many natural hazards extend over a wide range of event sizes, and some of them are even free of characteristic scales. An expression for the risk taking into account various event sizes is derived, and its implications on risk assessment for earthquakes, forest fires, landslides, and rockfalls are discussed. Under simple assumptions on the damage as a function of the event size, it turns out that the total risk is governed by either the small number of large events or the majority of small events. The distinction between these two classes depends on both the power-law exponent of the event size distribution and the damage function. For earthquakes, forest fires, and rockfalls, the total risk is mainly constituted by the largest events, while results are non-unique for landslides.

1 From hazard to risk assessment

Risk assessment is a straightforward extension of hazard assessment towards economic sciences. While hazard assessment concerns the probability of occurrence of a certain event, risk assessment takes into account its effects on life, civilization, and economics, too.

Although the term risk has several meanings in everyday life, there is a more or less unique definition of risk in the context of natural and man-made hazards. Let N be the expected (mean) number of events of a certain type in a certain region and time interval. Determining this number, perhaps including its spatial and temporal variation and its dependence on environmental conditions, is the main goal of hazard assessment. Let further D be the expected damage caused by an event of the considered type. The risk R is then defined by

$$R = ND. \quad (1)$$

Correspondence to: S. Hergarten
(hergarten@geo.uni-bonn.de)

According to this definition, the risk R is the expected damage caused by events of a certain type within a certain region and time interval.

Although this definition is straightforward, it suffers from the restriction to events of a certain type. This restriction does not only concern the class of phenomena under consideration, e.g. earthquakes, landslides, rockfalls, storms or forest fires, but also the magnitude of the event. Thus, we cannot use Eq. (1), e.g. to determine the risk of earthquakes at San Francisco, but only to determine the risk of earthquakes of a certain magnitude there.

In those cases where a typical event size can be assigned to the considered phenomenon, this restriction is no problem. However, event sizes vary strongly for most natural hazards, such as earthquakes, landslides, rockfalls or forest fires. In the example of earthquakes, an increase in magnitude by one unit (e.g. from magnitude 6 to magnitude 7) corresponds to an increase in released energy by a factor of about 30. Thus, an earthquake of magnitude 8 releases about 1000 times more energy than an earthquake of magnitude 6. Both are able to cause considerable damage, and the question is whether a few events of magnitude 8 cause more damage than the rather large number of magnitude 6 earthquakes or not.

The same applies to many other natural hazards, such as landslides, rockfalls, and forest fires. The largest historical rockfall in the Alps involved a rock volume of more than 9 km^3 , while other rockfalls are only a few cubic meters large. A single forest fire may destroy several thousand square kilometers of forest, while the majority of forest fires is much smaller.

As a result of the large range of event sizes in many natural hazards, Eq. (1) must be replaced with an expression that regards all possible event sizes, their frequency of occurrence, and the damage corresponding to the event size. Let $P(s)$ be the cumulative size distribution of the considered phenomenon, i.e. the probability that the size of an arbitrary event is greater than or equal to s . In this context, s may be any measure of event size, e.g. magnitude, released energy

or size of the rupture area in case of earthquakes, affected area or displaced volume in case of landslides and rockfalls or destroyed area in case of forest fires.

In order to evaluate the risk regarding events of different sizes, we first need the expected damage of one event with respect to the size distribution $P(s)$. Let $p(s)$ be the corresponding probability density according to

$$p(s) = -\frac{dP(s)}{ds}, \quad (2)$$

and $D(s)$ the expected damage induced by an event of size s . As a result of basic statistics, the expected damage is

$$\bar{D} = \int p(s) D(s) ds, \quad (3)$$

where the integration extends over all possible event sizes. From this, the total risk is immediately obtained to

$$R = N\bar{D} = N \int p(s) D(s) ds. \quad (4)$$

Thus, risk assessment regarding event sizes involves two steps:

1. Determining the total number of events in a certain region, time span, and environment, N , and the size distribution of the events, $P(s)$. The result is often expressed directly in terms of the product of both, which is called the frequency-magnitude relation.
2. Assessing the damage of an event as a function of its size.

The first step is the goal of hazard assessment, which has taken a major place in research on natural hazards in the last decades. Size distributions of some natural hazards are reviewed in the following section. In contrast, the second step is the transition from hazard to risk. It may be much more complicated than hazard assessment. There may be cases such as small forest fires or landslides where the damage to be expected can be directly computed, but as soon as events become large enough to affect the socio-economic network including loss of life, reliable estimates may become difficult. For this reason, risk assessment is mainly restricted to single scenarios, such as an earthquake of a given magnitude, while in general a large number of scenarios covering a wide range of event sizes is required. So it seems to be necessary to introduce assumptions on the dependence of the damage on the event size, $D(s)$. Simple assumptions and their implications are discussed in Sects. 3–6.

2 Power-law distributions in natural hazards

Most natural hazards do not only cover a wide range of event sizes, but also exhibit scale-invariant (also called fractal) statistics. Earthquakes are the most prominent example, although their fractal character may be hidden behind the logarithmic definition of earthquake magnitudes. As mentioned above, an increase of magnitude by one unit roughly

corresponds to an increase in released energy by a factor 30. Therefore, the relation for the number $N(m)$ of earthquakes per unit time interval with a magnitude greater than or equal to m found by Gutenberg and Richter (1954),

$$\log_{10} N(m) = A - Bm, \quad (5)$$

can be transformed into a statistical distribution of the released energies E :

$$N(E) \sim E^{-\frac{2B}{3}} \quad (6)$$

where $N(E)$ is the number of earthquakes per unit time interval with an energy release greater than or equal to E . The theory behind this transformation was introduced by Kanamori and Anderson (1975); brief reviews are given in almost all textbooks on seismology (e.g. Lay and Wallace, 1995; Aki and Richards, 2002) and in some books on fractals in earth sciences (e.g. Turcotte, 1997; Hergarten, 2002).

If we switch to a more general notation and denote arbitrary measures of event size by s , earthquakes follow a power-law size distribution

$$P(s) \sim s^{-b}. \quad (7)$$

If earthquake sizes are measured in terms of released energy, the power-law exponent is $b=2B/3$. The parameter B slightly varies from region to region, but is generally between about 0.8 and 1.2 (Frohlich and Davis, 1993), so that b falls into the range between about 0.5 and 0.8.

Power-law distributions were found in some other natural hazards, too. For landslides, a rather strong variation in the exponent b was found, but this variation could be neither attributed to the triggering mechanism (e.g. rainfall, snow melt or earthquakes), climate, type of landslide nor to the geological setting. A review was given, e.g. by Hergarten (2003); the values of the exponent b listed there are given in Fig. 1. It was concluded that most of the studies resulted in values of b between 1.0 and 1.6 if landslide size is measured in terms of affected area. However, the range may in fact be narrower because there is still some uncertainty about the effect of the method used for data analysis.

Rockfalls are a type of gravity-driven mass movements which strongly differs from most other types (e.g. slides in the strict sense or flows). Their size distributions have been addressed in several studies, too. Results are reviewed and discussed by Dussauge et al. (2002, 2003). Power-law distributions were mainly found with respect to the volume of displaced rock. Similar to landslides, a strong variation in the exponents was observed (from about 0.2 to 1.0), but part of this variation may be artificial as a result of different methods of analysis. As shown in Fig. 1, most of the values fall into the range between 0.4 and 0.7. However, these values are not directly comparable to those of landslides listed above since the former refer to areas, while the latter refer to volumes. It is mostly assumed that the volume of the displaced rock increases with the area to the power of $3/2$, so that the size distribution of rockfalls should be a power law with respect

to the area, too. As a result of this transformation, the exponents increase by a factor 3/2, so that range of exponents mentioned above turns into a range from 0.6 to about 1.0 with respect to areas. So the power-law exponents of rock-falls seem to be smaller than those of landslides; the consequences of this difference will be discussed later.

Forest fires are another example of power-law distributed natural hazards. Since the fractal properties of forest fires were recently discovered (Malamud et al., 1998), available statistics are smaller than for earthquakes and landslides. There is still a considerable uncertainty about the validity of power-law distributions in forest-fire statistics and concerning the exponents b of the distributions. The range of exponents reported so far is $0.31 \leq b \leq 0.49$ if the burnt area is the measure of event size.

3 Event size and damage

In some cases, the damage $D(s)$ may be a linear function of the event size s . This may be the case, e.g. for forest fires as long as they are not too large. Damage may then simply be determined by the amount of destroyed wood which is proportional to the burnt area. However, there are several aspects which make the damage function more complicated in general:

- For some natural hazards, such as earthquakes, events below a certain size do not cause any damage, so that $D(s)$ is zero there.
- In return, there may an event size leading to total destruction, so that $D(s)$ is constant above this event size.
- In the range between these sizes, $D(s)$ will probably grow stronger than linearly with the event size. This may result directly from properties of the process (e.g. because large landslides are more likely to achieve high velocities than small landslides), but also from the event's increasing consequences on economy and human life.
- The damage function may even be discontinuous, e.g. loss of life may introduce steps in $D(s)$. In some cases, these steps may be rather large, e.g. if a nuclear power plant is affected by an earthquake.

4 A simple damage model

Since estimating the damage function requires detailed knowledge on the process and on the goods and human beings exposed to danger, we now switch to one of the simplest models of damage, a power-law dependence

$$D(s) = \alpha s^\beta. \tag{8}$$

As mentioned above, β may be one in some cases, but will mostly be larger. However, there may be even situations

Fig. 1. Power-law exponents of the cumulative size distributions of some natural hazards. The tickmarks refer to the four forest-fire data sets analyzed by Malamud et al. (1998), the studies on landslides compiled by Hergarten (2003), the rockfall data analyzed and reviewed by Dussauge et al. (2002, 2003), and 38 earthquake catalogs from various geographic regions (Frohlich and Davis, 1993, Table 1, last column).

where β is smaller than unity, which means that the damage increases weaker than linearly with the event size. Imagine an important road crossing a forest, and that a certain economic damage occurs if this road cannot be used because the forest close to the road is burning. Let us, for simplicity, assume that forest-fire areas are circular shaped, and that fires occur at random locations. Under these assumptions, a fire of radius r causes damage if its center is located in a strip of width $2r$ (r each left and right of the road) around the road. Therefore, the probability that a randomly located fire causes damage increases linearly with the radius r , and thus with the square root of the area, so that $\beta=0.5$ in this case.

5 The role of the minimum and maximum event sizes

Before evaluating the risk formula (Eq. (4)), we must specify the power-law distribution (Eq. (7)) more precisely. It is well-known that a power-law distribution can only hold over a limited range of scales in reality, so that cutoff effects at large as well as at small event sizes occur. A discussion of cutoff effects in power-law distributions is given, e.g. by Hergarten (2002). In the simplest cutoff model, only events with sizes between a minimum size s_{\min} and a maximum size s_{\max} occur. The corresponding probability density function is

$$p(s) = \frac{b}{s_{\min}^{-b} - s_{\max}^{-b}} s^{-b-1} \tag{9}$$

(e.g. Hergarten, 2002). From this, we immediately obtain the total risk to

$$R = N \int_{s_{\min}}^{s_{\max}} \frac{b}{s_{\min}^{-b} - s_{\max}^{-b}} s^{-b-1} \alpha s^\beta ds = \frac{Nb\alpha}{\beta - b} \frac{s_{\max}^{\beta-b} - s_{\min}^{\beta-b}}{s_{\min}^{-b} - s_{\max}^{-b}}. \tag{10}$$

As long as the power-law distribution extends over some orders of magnitude, we can assume that s_{\max} is much larger

than s_{\min} . In this case, the behavior of Eq. (10) strongly depends on the difference $\beta - b$.

If $\beta > b$, the term $s_{\max}^{\beta-b}$ is much larger than $s_{\min}^{\beta-b}$, so that

$$\begin{aligned} R &\approx \frac{Nb\alpha}{\beta - b} \frac{s_{\max}^{\beta-b}}{s_{\min}^{-b} - s_{\max}^{-b}} \\ &= \frac{N}{\beta - b} s_{\max} p(s_{\max}) D(s_{\max}). \end{aligned} \quad (11)$$

Thus, the total risk is mainly determined by the largest events.

In the opposite case, $\beta < b$, the increase of the damage with event size is not sufficient to compensate the decrease in frequency of event occurrence. The term $s_{\max}^{\beta-b}$ becomes much smaller than $s_{\min}^{\beta-b}$, so that the total risk is

$$\begin{aligned} R &\approx \frac{Nb\alpha}{b - \beta} \frac{s_{\min}^{\beta-b}}{s_{\min}^{-b} - s_{\max}^{-b}} \\ &= \frac{N}{b - \beta} s_{\min} p(s_{\min}) D(s_{\min}). \end{aligned} \quad (12)$$

In this case, the risk mainly arises from the large number of small events, while large events are less important.

Equation (10) is only valid if $\beta \neq b$. In the special case $\beta = b$, the integral in Eq. (10) is computed to

$$\begin{aligned} R &= \frac{Nb\alpha}{s_{\min}^{-b} - s_{\max}^{-b}} \log \frac{s_{\max}}{s_{\min}} \\ &= s p(s) D(s) \log \frac{s_{\max}}{s_{\min}} \end{aligned} \quad (13)$$

for any arbitrary value of s between s_{\min} and s_{\max} . Thus, the risk can neither be expressed in terms of s_{\max} alone, nor in terms of s_{\min} alone. Both small and large events contribute to the total risk in this case.

The case $\beta = b$ looks like a theoretical case which is hardly achieved in reality. However, if the difference between s_{\max} and s_{\min} is only a few orders of magnitude and β comes close to b , both small and large events contribute to the total risk. As an example, we assume that the power law distribution extends over three orders of magnitude, i.e. $s_{\max} = 1000 s_{\min}$ and that $\beta - b = 0.1$. Then, $s_{\max}^{\beta-b} \approx 2 s_{\min}^{\beta-b}$ in Eq. (10), so that the risk is clearly not dominated by the large events alone. So there is a region between both regimes where large and small events contribute to the total risk.

6 Implications for earthquakes, forest fires, rockfalls, and landslides

As discussed in Sect. 2, the exponent b of the earthquake size distribution is in the range between 0.5 and 0.8 if event size is measured in terms of released energy. Although quantifying the damage caused by earthquakes of different sizes is difficult, it can be expected that the damage increases stronger than linearly with the released energy, so that the exponent β exceeds 1. Thus, the difference $\beta - b$ is always positive, and

the total risk resulting from earthquakes is dominated by the largest events.

It is noteworthy that the largest event is not the largest historically recorded event. It is the largest event that is possible or better, s_{\max} is the event size where the power law distribution breaks down. Especially in regions with a moderate seismic activity, this size may be much larger than the maximum size obtained from historical earthquake catalogs. Detailed information on geology, especially on the size of the largest faults in a region, is necessary in order to assess the maximum event size.

Things are similar in case of forest fires. The exponent b with respect to the area is rather small (between about 0.3 and 0.5), which means that large events play an important part in forest-fire statistics. As a result, the difference $\beta - b$ will be greater than 0.5 if damage is proportional to the burnt area, and will remain positive even in the case where the question is whether roads are blocked by the fire ($\beta = 0.5$). Thus, the total risk related to forest fires will be determined by the largest events. However, assessing the size of the largest events may be even more difficult than for earthquakes where much research on this topic has been done. None of the forest-fire data analyzed by Malamud et al. (1998) reveals a clear upper cutoff of the power-law; instead, statistics become small at large sizes. So the question is whether the power-law distribution may hold up to the sizes of the largest forested areas or whether there is a cutoff at some smaller size. The lack of information on the maximum event size may be a severe problem in risk assessment with respect to forest fires.

As mentioned above, the power-law exponents b of landslides and rockfalls apparently differ. With respect to areas, a range from 0.6 to 1.0 was given for rockfalls, and a range from 1.0 to 1.6 for landslides. If we assume the simplest damage model, i.e. that the damage is proportional to the affected area ($\beta = 1$), we obtain $\beta - b \in [0.0, 0.4]$ for rockfalls and $\beta - b \in [-0.6, 0.0]$ for landslides. So the difference in the exponents seems to be critical for risk assessment. In the simple, linear damage model, the total risk of rockfalls arises from the largest events, while the large number of small events makes the major contribution in the example of landslides.

However, it should be mentioned the these results are less unique than the results for earthquakes and forest fires. Firstly, the difference $\beta - b$ approaches zero at the borders of the ranges of b given above. Secondly, the result strongly depends on the assumptions on the damage model. If we, e.g. switch to the model where damage occurs if a road is blocked ($\beta = 0.5$), a large part of the rockfall data sets falls into the range where risk is dominated by the small events. However, this may be unrealistic because small rockfall deposits are not very likely to block a road and can easily be removed. So rockfalls in fact seem to belong to the class of natural hazards where risk is dominated by large events. In return, assuming a damage model where the damage increases stronger than linearly with the event size ($\beta > 1$), which is not unrealistic, probably brings landslides into this class, too.

7 Conclusions

Many natural hazards extend over several orders of magnitude in event size, and some of them even exhibit scale-invariant properties over a considerable range of scales. Assessing risk with regard to this phenomenon requires the determination of damage as a function of the event size, which may be difficult. However, some general results can be obtained from a simple, power-law damage model. It turns out that the overall risk is governed by either the largest or the smallest events. For earthquakes, forest fires, and rockfalls, the largest events are dominant. The results for landslides are non-unique; it depends on the assumptions of the damage model whether the largest or the smallest events are more important for the total risk.
