Abstract. The spatial distribution of snow water equivalent (SWE) is modelled as a two parameter gamma distribution. The parameters of the distribution are dynamical in that they are functions of the number of accumulation and melting events and the temporal correlation of accumulation and melting events. The estimated spatial variability is compared to snow course observations from the alpine catchments Norefjell and Aursunden in Southern Norway. A fixed snow course at Norefjell was measured 26 times during the snow season and showed that the spatial coefficient of variation change during the snow season with a decreasing trend from the start of the accumulation period and a sharp increase in the melting period. The gamma distribution with dynamical parameters reproduced the observed spatial statistical features of SWE well both at Norefjell and Aursunden. Also the shape of simulated spatial distribution of SWE agreed well with the observed at Norefjell. The temporal correlation tends to be positive for both accumulation and melting events. However, at the start of melting, a better fit between modelled and observed spatial standard deviation of SWE is obtained by using negative correlation between SWE and melt.

1 Introduction

A major cause of severe flooding in Norway is the combination of intense snowmelt and heavy precipitation. In order to forecast these events, we need reliable forecasts of precipitation and temperature and a good estimate of the snow reservoir and its coverage in the catchment at the time of the forecast. The dynamics of runoff due to snowmelt, and thus the water balance in the melting season, is very dependent on the evolution of snow free areas, which again is closely linked

to the spatial distribution of snow water equivalent (SWE) (Pomeroy et al., 2004; Luce et al., 1998; Buttle and McDonnell, 1987). The shape of the distribution is important in order to describe the development of snow free areas in spring. A skewed distribution with high frequencies of small values of SWE would produce more snow free areas in response to uniformly distributed melt than would a more normal distribution of SWE where the highest frequencies are found for higher values of SWE. Increased production of snow free areas for skewed distributions will occur in cases where the spatial distribution of daily melt is inversely correlated to the distribution of SWE as reported by Faria et al. (2000).

Positively skewed distributions like the exponential (Gao and Sorooshian, 1994) and gamma (Onof et al., 1998; Mackay et al., 2001) have often been favoured for describing the spatial distribution of daily precipitation. As the accumulated SWE is the sum of such positively skewed and correlated variables, one would expect the distribution of SWE to be subject to the central limit theorem (Feller, 1971, p. 258) and being less skewed than the distribution of the individual snowfall events. The normal distribution has often been found to be a good model for describing SWE at its seasonal maximum (Marchand and Killingtveit, 1999, 2002; Alfnes et al., 2004), which indicates that the spatial distribution of SWE evolves from a rather skewed distribution at the beginning of the snow season towards a less skewed, (even normal) distribution at its seasonal maximum. The Swedish HBV model (Bergström, 1992; Sælthun, 1996) is used operationally for flood forecasting at the Norwegian Water Resources and Energy Directorate (NVE) and has been supplemented with a snow routine developed for use in Norway which accounts for the development of the snow reservoir and the snow coverage at different altitude levels (Killingtveit and Sælthun, 1995). This routine is developed under the assumptions that precipitation as snow is log-normally distributed in space with a fixed coefficient of variation. Donald et al. (1995) presented a snow accumulation

Correspondence to: T. Skaugen
(ths@nve.no)

model where, once the snow coverage was 100%, the spatial variability of SWE remained constant. These static ways of representing the spatial distribution of SWE are thus in conflict with the central limit theorem, reported observations (Alfnes et al., 2004; Pomeroy et al., 2004) and observations presented in this paper.

Skaugen et al. (2004) put forward a formulation for the spatial distribution of snow, using the fact that when individual snowfall events are gamma distributed, the distribution of accumulated snowfall events is also gamma distributed with parameters derived from the parameterisation of individual snowfall events and the number of accumulations. This model is constrained by assumptions of independence in time, but takes into account that the statistical features of the spatial distribution of SWE change during the season, as demonstrated from observations. The dynamical aspect of the shape of the spatial distribution of SWE is a feature that has to be included in the modelling of SWE in order to simulate realistic snow distributions

Observed differences for spatial distributions of SWE at the peak of accumulations has been addressed to landscape and meteorological features such as vegetation type, topography and wind (Erickson et al., 2005; Bruland et al., 2004; Alfnes et al., 2004; Marchand and Killingtveit, 2004; Erxleben et al., 2002; Shook and Gray, 1997). According to Liston (2004), three mechanisms effective on different spatial scales influence the snowdepth. Snow-canopy interactions in forested regions are important at one to hundreds of meters, snow redistribution by wind on tens to hundreds of metres and orographic influences of precipitation being active on one to a few kilometres. The latter spatial scale is the relevant scale for this study and for describing the spatial distribution of SWE in lumped hydrological models such as the operational HBV model. It is the objective of this study to demonstrate that the spatial distribution of SWE can be adequately modelled as the summation of correlated (in time) daily precipitation (snowfall) fields. The sources of variability at smaller scales, like snow-canopy interactions and wind drift are, in this study, not taken into account.

We want to develop dynamical expressions for the spatial variability of SWE both for the accumulation and the melting season. We further want to use this information to assign analytical expressions for the spatial distribution of SWE. The proposed methodology will be validated against time series of the spatial distribution of SWE measured at alpine locations in Southern-Norway.

The next section presents the derivation of expressions for the spatial moments of SWE, where temporal correlation is taken into account. The moments are then used for estimating the parameters of the spatial distribution of SWE. The third section presents a snow monitoring campaign specially designed for studying the spatial distribution of SWE throughout the snow season. In the fourth section the modelled moments and distributions are tested against observed

data and discussed, whereas conclusions are found in the final section.

2 Modelling accumulation and melt of snow as sums of correlated gamma distributed stochastic fields

When modelling the spatial distribution of SWE, we have to take into account the history of accumulation and melting events up to the time of interest. In Skaugen et al. (2004) this was carried out by modelling the spatial distribution of SWE as sums of independent, identically distributed stochastic fields of the two parameter gamma distribution. Here, the spatial distribution of SWE is also modelled within the framework of the two parameter gamma distribution, but, through a simple procedure, the effect of temporal correlation is introduced.

Let us assume that every snow fall event can be described as a collection of gamma distributed stochastic unit fields of snowfall, y . The stochastic unit fields of snowfall y is distributed in space according to a two-parameter gamma distribution, $y=G(\nu_0, \alpha_0)$, with probability density function (PDF):

$$f_{\alpha_0, \nu_0}(y) = \frac{1}{\Gamma(\nu_0)} \alpha_0^{\nu_0} y^{\nu_0-1} e^{-\alpha_0 y} \quad \alpha_0, \nu_0, y > 0 \quad (1)$$

where α_0 and ν_0 are parameters. The mean equals $E(y)=\nu_0/\alpha_0$ and the variance equals $\text{Var}(y)=\nu_0/\alpha_0^2$. The stochastic unit fields are hereafter, for practical purposes, denoted units. The choice of distribution is motivated partly from studies reporting the gamma distribution as a suitable choice of spatial distribution for precipitation (Onof et al., 1998; Mackay et al., 2001) and SWE (Kutchment and Gelfan, 1996) and partly because of the practical mathematical features of the gamma distribution and the flexibility needed for representing the observed changes in the shape of the spatial distribution during the snow season. We want to describe the moments of the accumulated snow reservoir $z(t)$, accumulated at time t , $z(t)=\sum_{i=1}^{n(t)} y_i$, where n is the number of units y accumulated up to the time t . The mean of $z(t)$ is

$$E(z(t)) = \sum_{i=1}^n E(y_i) = n \frac{\nu_0}{\alpha_0}, \quad (2)$$

whereas for the variance of $z(t)$ we have to take into account the temporal correlation of y and we have to consider the covariance matrix of $z(t)$ (see Haan, 1977, p. 56):

$$\text{Var}(z(t)) = \sum_{i=1}^{n(t)} \text{Var}(y_i) + 2 \sum_{i < j} \text{Cov}(y_i, y_j) \quad (3)$$

In the following, we assume that the covariance between the units can be described as a constant fraction c of the variance,

Var(y), of the individual y 's, $Cov(y_i, y_j) = c \text{Var}(y) = c \frac{v_0}{\alpha_0^2}$.
The variance of $z(t)$ becomes:

$$\text{Var}(z(t)) = n \frac{v_0}{\alpha_0^2} + n(n-1)c \frac{v_0}{\alpha_0^2} = n \frac{v_0}{\alpha_0^2} (1 + (n-1)c) \quad (4)$$

We note that $c = \frac{Cov(y_i, y_j)}{\text{Var}(y)}$ is the correlation coefficient, given that y_i and y_j are identically distributed. This correlation function should be a decreasing function with time, but is here represented with its temporal average over all the n units.

We want the spatial distribution of accumulated snow $z(t)$ at all times to be simple mathematically tractable distribution function, with which we easily can simulate and perform other exploratory analyses. We thus state that $z(t)$ is distributed as a gamma distribution with parameters $n v_n$ and α_n . In order to formulate the moments of the sum of the gamma distributed variables in this manner, the n elements of the sum have to be independent, and identically gamma distributed variables with parameters v_n and α_n (see Feller, 1971, p. 47). Let us denote these independent variables as Y_i . The mean and variance of $z(t)$ modelled as a sum of independent variables, Y are:

$$E(z(t)) = n \frac{v_n}{\alpha_n} \quad (5)$$

and

$$\text{Var}(z(t)) = n \frac{v_n}{\alpha_n^2} \quad (6)$$

From the mean and variance of $z(t)$ modelled as a sum of dependent variables, y , we can determine expressions for v_n and α_n by the mean and variance of $z(t)$ modelled as a sum of independent variables, Y . From the equating of Eqs. (2) and (5), $n \frac{v_0}{\alpha_0} = n \frac{v_n}{\alpha_n}$ and Eqs. (4) and (6), $n \frac{v_0}{\alpha_0^2} (1 + (n-1)c) = n \frac{v_n}{\alpha_n^2}$ we can solve for v_n and α_n and get:

$$\alpha_n = \frac{\alpha_0}{1 + (n-1)c} \quad (7)$$

and

$$v_n = \frac{v_0}{1 + (n-1)c} \quad (8)$$

We note that the ratios $\frac{v_n}{\alpha_n}$ and $\frac{v_0}{\alpha_0}$ are equal, which mean that the mean of the process is unaffected by the correlation.

2.1 Adding correlated variables to a sum of independent variables

Let us say at time t' an additional snowfall of u units of y , have fallen on $z(t)$ giving us the snow reservoir $z(t')$,

$$z(t') = Y_1 + Y_2 + \dots + Y_n + y_1 + y_2 + \dots + y_u \quad (9)$$

The mean can be estimated straightforwardly as the sum of the individual means:

$$E(z(t')) = \sum_{i=1}^n E(Y_i) + \sum_{i=1}^u E(y_i) = n \frac{v_n}{\alpha_n} + u \frac{v_0}{\alpha_0} \quad (10)$$

For the variance of $z(t')$ we must again consider the covariance matrix of $\text{Var}(z(t'))$ and $\text{Var}(z(t'))$ is the sum of all the elements of the covariance matrix. Given that the Y 's are uncorrelated, the covariance elements describing the covariance between the Y 's are zero and we get the following expression for the variance $z(t')$:

$$\begin{aligned} \text{Var}(z(t')) &= \sum_{j=1}^n \text{Var}(Y_j) + 2 \sum_{j=1}^n \sum_{i=1}^u \text{Cov}(Y_j, y_i) \\ &+ \sum_{i=1}^u \text{Var}(y_i) + 2 \sum_{i=1}^{u-1} \sum_{k=i+1}^u \text{Cov}(y_i, y_k) \end{aligned} \quad (11)$$

We assume also here that $\text{Cov}(Y, y)$ can be approximated by $\text{Cov}(Y, y) = c \text{Var}(y) = c \frac{v_0}{\alpha_0^2}$, and Eq. (11) can be written as:

$$\text{Var}(z(t')) = n \frac{v_n}{\alpha_n^2} + u \frac{v_0}{\alpha_0^2} + 2nuc \frac{v_0}{\alpha_0^2} + u(u-1)c \frac{v_0}{\alpha_0^2} \quad (12)$$

From Eqs. (10) and (12), we can develop expressions for the parameters of the distributions of $z(t')$ modelled as a sum of $n+u$ independent gamma distributed events with moments $E(z(t')) = n \frac{v_{n+u}}{\alpha_{n+u}}$ and $\text{Var}(z(t')) = n \frac{v_{n+u}}{\alpha_{n+u}^2}$:

$$\alpha_{n+u} = \frac{(n+u) \frac{v_n}{\alpha_n}}{n \frac{v_n}{\alpha_n^2} + \frac{v_0}{\alpha_0^2} (u + 2nuc + u(u-1)c)} \quad (13)$$

and

$$v_{n+u} = \frac{(n+u) (\frac{v_n}{\alpha_n})^2}{n \frac{v_n}{\alpha_n^2} + \frac{v_0}{\alpha_0^2} (u + 2nuc + u(u-1)c)} \quad (14)$$

2.2 Melting events

We can, in a similar way as above, develop the moments for the accumulated SWE after a melting event. Let us say at time t' a melting event takes place and u units of y , are melted from $z(t)$ giving us the snow reservoir $z(t')$,

$$z(t') = Y_1 + Y_2 + \dots + Y_n - y_1 - y_2 - \dots - y_u \quad (15)$$

We make here the assumption that the spatial distribution of a unit melt is identical to that of a unit snowfall. It is difficult to have strong assumptions on the spatial distribution of snow melt, other than that the ultimate melting event is necessarily identically distributed as the ultimate SWE. Essery and Pomeroy (2004) assumed a log-normal distribution of snowmelt from log-normally distributed SWE, a distribution of melt which is similar in shape to the gamma distribution. This issue is further discussed in Sect. 4.

The mean can, as above, be estimated straightforwardly as the sum of the individual means:

$$E(z(t')) = \sum_{i=1}^n E(Y_i) - \sum_{i=1}^u E(y_i) = n \frac{v_n}{\alpha_n} - u \frac{v_0}{\alpha_0} \quad (16)$$

Fig. 1. Locations of snow monitoring campaigns at Norefjell and Aursunden, Southern Norway.

and we have the following expression for the variance of $z(t')$:

$$\begin{aligned} \text{Var}(z(t')) &= \sum_{j=1}^n \text{Var}(Y_j) - 2 \sum_{j=1}^n \sum_{i=1}^u \text{Cov}(Y_j, y_i) \\ &\quad + \sum_{i=1}^u \text{Var}(y_i) + 2 \sum_{i=1}^{u-1} \sum_{k=i+1}^u \text{Cov}(y_i, y_k) \end{aligned} \quad (17)$$

We get negative and positive covariance contributions from the melting event. The negative contributions come from when the melting event is correlated to the snow reservoir prior to the melting. A melting unit correlated with a melting unit gives a positive contribution. Also here we make the assumption that $\text{Cov}(Y, y)$ can be approximated by $\text{Cov}(Y, y) = c \text{Var}(y) = c \frac{v_0}{\alpha_0^2}$, and Eq. (17) can be written as:

$$\text{Var}(z(t')) = n \frac{v}{\alpha^2} + u \frac{v_0}{\alpha_0^2} - 2nuc \frac{v_0}{\alpha_0^2} + u(u-1)c \frac{v_0}{\alpha_0^2} \quad (18)$$

From Eqs. (16) and (18), we can develop expressions for the parameters of the distributions of $z(t')$ modelled as $n-u$ independent gamma distributed events:

$$\alpha_{n-u} = \frac{(n-u) \frac{v_n}{\alpha_n}}{n \frac{v_n}{\alpha_n^2} + \frac{v_0}{\alpha_0^2} (u - 2nuc + u(u-1)c)} \quad (19)$$

and

$$v_{n-u} = \frac{(n-u) \left(\frac{v_n}{\alpha_n}\right)^2}{n \frac{v_n}{\alpha_n^2} + \frac{v_0}{\alpha_0^2} (u - 2nuc + u(u-1)c)} \quad (20)$$

Fig. 2. Observed spatial mean (solid line), spatial standard deviation (long dashed line) and CV (short dashed line) of SWE at Norefjell.

3 Snow course data from Norefjell – Southern Norway

During the EU project Envisnow, monitoring of the spatial distribution of SWE during the snow season was performed at Norefjell (60°15' N, 9°30' E) located in southern Norway 110 km north-east of Oslo (see Fig. 1). The motivation for the monitoring campaign was to study the possible change in features of the spatial distribution of SWE trough the snow season. The snow monitoring campaign was carried out doing snow surveys every second week in the accumulation season and every week during the melting season. The route was fixed (by GPS) for the 2 km long snow course and snow depth was measured every 10 m. Snow density was measured twice during the snow course at locations of the mean snow depth. The snow course route is located at 1100 m a.s.l. and is above the tree line. 17 one-day campaigns between November 2002 and June 2003, and 9 campaigns between October 2003 and February 2004 were carried out. The latter part of the monitoring period also includes the start of the accumulation period, whereas the former started when there were already 200 mm of SWE present.

Figure 2 shows the time series of the mean, standard deviation and coefficient of variation (CV) of SWE for the snow course data. We can note that the CV (see October 2003) is relatively high at the start of the accumulation season, decreases during the accumulation season, and rises sharply during the melting season. As the mean SWE and the standard deviation both decrease during the melting season, the increasing CV implies that the rate of change (decrease) of the mean is much higher than for the standard deviation. This feature of the spatial standard deviation of SWE was also noted by Pomeroy et al. (2004), who found that the otherwise strong association between mean SWE and standard deviation was not evident during melt. During melt, the mean SWE declined whereas the standard deviation increased or remained constant.

Fig. 3. Spatial analysis of precipitation from five gauges in the Norefjell area. Spatial mean of precipitation versus the spatial standard deviation. The spatial standard deviation can be modelled as a linear function of the spatial mean.

4 Results and discussion

The dynamical parameters α and ν of the two parameter gamma distribution was calculated for each point of observation of mean SWE, taking into account accumulation and melting events by using the Eqs. (13) and (14), or (19) and (20), respectively. The mean areal SWE acts as input and, after the parameters c , α_0 and ν_0 have been assigned estimated values, the proposed method estimates the parameters of the spatial distribution of SWE modelled as a two parameter gamma distribution.

In order to estimate the parameters of the distribution of a stochastic unit field of snow fall, α_0 and ν_0 , an analysis of the spatial statistics of precipitation in the area was carried out using the daily rainfall fields measured for a year from four nearby stations (the snow course site is situated in the centre of a square defined by the four stations). The events analysed were screened so that at least one station (of the four) measured zero precipitation. This strategy was chosen so we could be sure of that the spatial distributions analysed were not bounded to the left by values higher than zero, which would not be consistent with our definition of a stochastic unit field as distributed as a two parameter gamma distribution. Figure 3 shows the scatter plot of observed spatial mean and spatial standard deviation ($R^2=0.93$), indicating a more or less a constant spatial coefficient of variation, $CV=1.35$. This feature is also observed by Barancourt et al. (1992) for spatial precipitation events in France. The very high observed correlation between spatial mean and standard deviation suggests that we can estimate the spatial standard deviation of the unit stochastic field to be 1.35 times the mean. Let us say that the spatial unit of snow fall has a spatial mean equal to the daily mean of positive precipitation (excluding zero events) of the closest precipitation station located 18 km south of the snow course site and 367 m a.s.l. This is equivalent to the procedure used when using point observation(s) to estimate the spatial mean as input in rainfall runoff models. For Norefjell this procedure gives us the estimates

Fig. 4. Observed (solid line) and estimated spatial standard deviation at Norefjell. Long dashed line represents estimates by the new model and short dashed line represents estimates by the snow routine of the HBV-model.

of spatial mean and standard deviation as $m=5.86$ mm and $s=7.91$ mm, respectively. The parameters were estimated through the relations $\alpha_0=m/s^2$ and $\nu_0=m^2/s^2$.

It can be argued that the estimate for the spatial variability of precipitation used here for estimating the parameters of the stochastic unit fields (α_0 and ν_0) is too large and cannot be representative for such a small spatial scale as that of the snow course (2 km). If such an overestimation was substantial, we would probably overestimate the spatial variance, as the covariance, in the accumulation phase, represents a positive contribution to the spatial variance (see Eq. 3). It is possible that the correlation coefficient c (which is a tuned parameter and not estimated from data) compensates for this, and that it should, in reality, be higher.

The correlation coefficient c was tuned in order to get an optimal fit of estimated spatial standard deviation of SWE. The optimality of the fit is measured by the Nash and Sutcliffe coefficient of efficiency R^2 (Nash and Sutcliffe, 1970). The estimated time series of standard deviation and CV of SWE is also compared to that estimated by the traditional snow routine of the HBV models which uses a lognormal distribution with a fixed CV (optimized by the R^2 criterion). Figure 4 shows observed and estimated (by the proposed model and by HBV) values of the spatial standard deviation of SWE and Fig. 5 shows observed and estimated CV. The R^2 value for the estimate of the spatial standard deviation was $R^2=0.87$ for the new model, and $R^2=0.32$ for the snow routine of the HBV model. The new model is thus a considerable improvement to the lognormal distribution with a fixed CV. The observed values do indeed show that the spatial distribution of SWE changes through the season, and the proposed model capture these changes well. Figure 6 shows the agreement between the gamma CDFs (1000 values are simulated) based on the estimated values of α and ν and the empirical CDFs from the observations for the dates 18 March 2003 and 28 May 2003, confirming that a representative model for the spatial distribution of SWE is developed.

Fig. 5. Observed (black triangles) and estimated CV at Norefjell. Open circles represent estimates by the new model and black circles represent estimates by the snow routine of the HBV-model (fixed CV value).

Fig. 6. Observed and simulated spatial CDF of SWE at near snow maximum (18 March, and late spring (28 May) at Norefjell. Solid lines are observed values (thick line at 18 March), and dashed lines are simulated (long dashed lines at 18 March).

Unfortunately no validation data from this site is available. However, when the sample of SWE was split and the method was calibrated for the 2002–2003 data and validated for the 2003–2004 data, very good results were obtained with $R^2=0.86$ for the calibration period and $R^2=0.90$ for the validation period.

In this study we have assumed identical distributions of stochastic unit fields of accumulation and of melt. Observed spatial fields of snowmelt are scarce but from a research site near Trondheim in central Norway, 4 snow pillows is located within 25 m^2 . For the month of April 2007 we could observe 17 daily melting events measured at the 4 snow pillows. It is, obviously, difficult to make inferences on the spatial distribution from four values covering such a tiny area, but Fig. 7 shows how the spatial CV decreases as the spatial mean increases. This behaviour of CV versus spatial mean is similar to what can be seen for the accumulation of SWE (see Fig. 2) and consistent with modelling melt as summations of temporally correlated spatial fields, of which each can well be gamma distributed. The spatial distribution of daily melt, measured on fixed time intervals is obviously non-stationary. The proposed method takes the non-stationarity of melt into

Fig. 7. Spatial CV of daily melt versus spatial mean of melt. The data are from four snowpillows covering an area of 25 in the Trondheim area during April 2007.

account in the way that different number of units (typically increasing in spring) give different spatial distributions of melt, thus mimicking a non-stationary process. The good agreement between simulated and observed CDF (Fig. 6), in late spring (28 May) shows that the assumption of identical distributions of the units of melt and accumulation is not critical in respect to the performance of the model.

The optimal values for c in the Norefjell data was $c=0.019$. Using different values of c for accumulation and melting events were tried and, for this location, improvements of R^2 were found. When using $c=0.016$ for accumulation events and $c=0.01$ for melt events, we obtained a $R^2=0.90$. Studies of temporal correlation of precipitation, both for a fixed coordinate system and from a coordinate system that moves with the storm, show a rapidly declining correlation function which approaches zero after approximately two hours (Zawadski, 1973). As the parameter c represents a temporal average over the total number of events, it is thus not strange that the values obtained in this study are small. The effect of correlation, however, is significant, in that we would otherwise have a steadily increasing spatial variance as both summation and subtraction increases the variance (Haan, 1977).

It is also interesting to note that the correlation between melting events and SWE turns out to be positive. Pomeroy et al. (2004) found positive correlation between SWE and melt on the catchment scale ($>10 \text{ km}^2$) and negative correlation for smaller scales. Positive correlation was explained by the presence of landscape classes (shrub tundra) receiving more snow due to redistribution processes and the possibility of increased melt rate for areas with exposed shrub due to reduced albedo and enhanced aerodynamic roughness. We investigated the effects of varying the sign of the correlation coefficient c in Eq. (17) for melting and for different phases of the melting process. A negative correlation between melt and pre-melt SWE resulted in a steadily increasing standard deviation during the melting period and was thus not consistent with the observations. Negative correlation at the beginning of the melting period and positive towards the end

Fig. 8. Observed and estimated spatial standard deviation of SWE at Norefjell. The standard deviation is modelled with negative correlation at the start of the melting period, and positive towards the end of the melting period.

improved the fit between modelled and observed standard deviation of SWE ($R^2=0.92$) (see Fig. 8) and we note that the increase in standard deviation seen at the start of the melting season (see Fig. 8 when the mean SWE starts to decrease) is now well estimated due to negative correlation. A possible reason for an initial negative correlation can be the smaller demand of energy needed by shallow snow packs to reach an isothermal state and the maximum amount of retainable melt water in the snow pack. Melting will thus take place earlier for these shallow snow packs. The positive correlation is harder to explain if one does not take into account dominating landscape classes that favour both accumulation and increased melt rate. Such landscape classes are not present at the Norefjell snow course, where there are some 30–40 m of low-growing willow thicket (<60 cm) and otherwise no vegetation besides grass. Maybe the positive correlation becomes appropriate only towards the end of the melting season, when the entire snow pack is mature and producing melt. At this stage, SWE starts to be a limiting factor and more melt water is generated from larger snow packs simply because more SWE is available for melting.

In order to investigate whether the method could be applied also to other locations than Norefjell, we tested if the spatial variability of SWE could be reproduced at an alpine catchments at Aursunden in the northern part of Southern Norway (see Fig. 1). Snow course measurements was carried out at Aursunden (930 m a.s.l.) three times during April and May in 2002 (see Alfnes et al., 2004). Again, the route was fixed by GPS for the 1 km long snow course and snow depth was measured every 10 m. The parameters α_0 and ν_0 were estimated in the same manner as above from a spatial analysis of precipitation measured at five nearby gauges (spatial daily mean, $m=3.31$ mm, and standard deviation, $s=4.15$ mm). The correlation coefficient was tuned to the values of observed spatial standard deviation. Also here the best fit was obtained with using different values of c for melting ($c=0.11$) and accumulation ($c=0.13$) events. Figure 9 shows the good

Fig. 9. Observed and estimated values of standard deviation and CV at Aursunden for the weeks 15, 18 21 in 2002. Observed values of standard deviation and CV are represented by solid line and black triangles. Estimated values of standard deviation and CV are represented by long dashed line and open circles.

agreement between observed and modelled spatial standard deviation and CV. The correlation coefficient and the spatial standard deviation of precipitation take on quite different values at Norefjell and Aursunden. Although the observations points are too few to make strong inferences it does seem reasonable that we find high temporal correlation together with relatively low spatial variability of precipitation.

5 Conclusions

A model for the spatial distribution of SWE has been put forward. At all times the spatial distribution of SWE can be expressed as a two parameter gamma distribution where the parameters are functions of the mean and variability of observed precipitation, the number of accumulation and melting events and of temporal correlation.

The observed time series of SWE confirms that the spatial distribution of SWE do change trough the snow season with initially high CV, which decreases during the accumulation season and increases in the melting season. These features, as well as the shape of spatial distributions of SWE, are well reproduced by the proposed model.

The new model clearly represents the spatial distribution of SWE more realistically than the log-normal distribution with a fixed CV which is traditionally used in the HBV model in the Nordic countries. The model provides good estimates of the spatial variability of SWE at two alpine locations in Southern Norway.

Analysis of the correlations between pre melt SWE and melt suggests that correlation is negative in the early stages of the melting process and positive at later stages. Positive correlation between SWE and melt at the end of the melting proved, within the model framework, to be necessary in order to model the decrease in spatial variability observed in the snow course data.

Acknowledgements. The efforts of my colleagues E. Alfnes, L. Andersen, H. C. Udnæs, L. E. Petterson and S. Beldring for collecting the validation data are gratefully acknowledged. Also the comments of the two anonymous referees and the editor are highly appreciated.

Edited by: A. Gelfan
