## ABSTRACT

A study of catalytic metals and alkaline metal oxides leading to the development of a stable Ru-doped Ni Dual Function Material for CO<sub>2</sub> capture from flue gas and in-situ catalytic conversion to methane

Martha A. Arellano Treviño

Atmospheric CO<sub>2</sub> concentrations are at their highest level on record. Scientific evidence has demonstrated a direct correlation between the rise of CO<sub>2</sub> levels and an increase of the global median temperature (~1°C higher than compared to the pre-industrial revolution times) due to the greenhouse gas effect. The change in climate due to this rapid increase of CO<sub>2</sub> levels is already negatively affecting our ecosystem and lives, with unpredictable consequences in the future.

The main source of anthropogenic CO<sub>2</sub> emissions is attributed to the combustion of fossil fuels for energy production and transportation. Global indicators signal that carbon-intensive fuels will continue to be utilized as a main energy source despite the rising implementation of renewable energy sources. In order to curb CO<sub>2</sub> emissions, several carbon dioxide capture, utilization and sequestration (CCUS) technologies have been suggested. The current state-of-the-art CO<sub>2</sub> capture technology utilizes toxic and corrosive aqueous amine solutions that capture CO<sub>2</sub> at room temperature but require heating above the water boiling point temperatures to separate CO<sub>2</sub> from the amine solution; the latter of which is to be recycled. Once the CO<sub>2</sub> is purified, it is necessary to transport it to its sequestration site or an upgrading processing plant. These are complicated schemes that involve many energy-intensive and costly processes.

To address the shortcomings of these technologies, we propose a Dual Function Material (DFM) that both captures CO<sub>2</sub> and catalytically converts it to methane *in-situ*. The DFM consists

of a catalytic metal intimately in contact with an alkaline metal oxide supported on a high surface area carrier. The process operates within the flue gas at 320°C for both CO<sub>2</sub> capture and methane generation upon the addition of renewable H<sub>2</sub>. The catalyst is required to methanate the adsorbed CO<sub>2</sub> after the capture step is carried out in an O<sub>2</sub> and steam-containing flue gas. Ruthenium, rhodium, and nickel are known CO<sub>2</sub> methanation catalysts, provided they are in the reduced state. All three were compared for performance under DFM flue gas conditions. Ni is a preferred methanation catalyst based on price and activity; however, its inability to be reduced to its active state after experiencing O<sub>2</sub>-containing flue gas during the capture step was an outcome determined in this thesis. The performance of a variety of alkaline adsorbents (“Na<sub>2</sub>O”, CaO, “K<sub>2</sub>O” and MgO) and carriers (Al<sub>2</sub>O<sub>3</sub>, CeO<sub>2</sub>, CeO<sub>2</sub>/ZrO<sub>2</sub> (CZO), Na-Zeolite-X (Na-X-Z), H-Mordenite Zeolite (H-M-Z), SiC, SiO<sub>2</sub> and ZrO<sub>2</sub>-Y) were also studied. Selection of the best materials was based on CO<sub>2</sub> capture capacity, net methane production and hydrogenation rates that were evaluated with thermogravimetric analysis and in fixed bed reactor tests.

Rh and Ru DFMs were effective methanation catalysts with Ru being superior based on capture capacity, hydrogenation rate and price. Ru remained active towards methanation even after exposure to O<sub>2</sub> and steam-containing simulated flue gas. Alkaline adsorbents, in combination with reduced Ru, were tested for adsorption and methanation. Ru – “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> DFMs showed the highest rates for methanation although CaO is also a reasonable candidate with slightly lower methanation kinetics. To date, we have demonstrated that  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> is the most suitable carrier for DFM application relative to other materials studied.

The Ni-containing DFM, pre-reduced at 650°C, was highly active for CO<sub>2</sub> methanation. However, the hydrogenation with 15% H<sub>2</sub>/N<sub>2</sub> is completely inactive after exposure to O<sub>2</sub> and steam, in a flue gas simulation, during the CO<sub>2</sub> capture step at 320°C. This thesis reports that small

amounts of precious metal ( $\leq 1\%$  Pt, Pd or Ru) enhance the reduction (at  $320^\circ\text{C}$ ) and activation of Ni-containing DFM towards methanation even after  $\text{O}_2$  exposure in a flue gas. While ruthenium is most effective, Pt and Pd all enhance reduction of oxidized Ni.

Another objective of this thesis was to investigate whether a portion of the Ru, at its current loading of 5%, could be replaced with less expensive Ni while maintaining its performance. The findings show that the main advantage of the presence of Ni is a small increase in  $\text{CO}_2$  adsorption and increase in methane produced, at the expense of a lower methanation rate. Extended cyclic aging studies corroborate the stable performance of 1% Ru, 10% Ni, 6.1% “ $\text{Na}_2\text{O}$ ”/ $\text{Al}_2\text{O}_3$ .

Characterization methods were used to monitor physical and chemical changes that may have occurred during aging studies. Measurements of the BET surface area,  $\text{H}_2$  chemisorption, XRD pattern, TEM images and STEM-EDS mapping were utilized to study and compare the structural and chemical changes between fresh and aged Ru doped Ni DFM samples. While similar BET surface areas were observed for the fresh and aged samples, some redispersion of the Ru and Ni sites was confirmed via  $\text{H}_2$  uptake and the observed decreases in Ru and Ni cluster size in the aged sample in comparison to the fresh. XRD patterns confirm an almost complete disappearance of the  $\text{NiO}_x$  and  $\text{RuO}_x$  species and the appearance of catalytically active  $\text{Ru}^0$  and  $\text{Ni}^0$  peaks on the aged sample compared to the fresh one. Further details of these methods, findings and conclusions are described in this thesis.

## Acknowledgements

I would like to express my heartfelt appreciation to my PhD advisor and life mentor Prof. Robert Farrauto. His work ethic and passion for catalysis have been my guiding star during all these years. Ever since he gave me the opportunity to work in his research group, his unconditional support through the ups and downs of my PhD gave me the confidence I needed to give the best of me and succeed in this journey.

I give my sincere thanks to my committee members Prof. Jinguang Chen, Prof. Alissa Park, Prof. Ngai Yin Yip, and Dr. Michel Deeba for their time and help with my research throughout the years. I would also like to thank Prof. Edward Leonard for his career and life counsel during the past 8 years. I appreciate the opportunity he gave me when I was still an undergrad to come to Columbia for the first time and do an internship in his lab. This chance changed my life for the best and I will forever be in debt with him.

Many thanks to my sponsors. The Mexican Science and Technology Council (CONACYT), the Fulbright Scholarship and AngloAmerican Platinum for their generous financial support on my graduate studies.

Ever since I came to Columbia, I've had the opportunity to work with some wonderful people. I would like to especially thank Dr. Melis Duyar for her friendship and guidance during my PhD. She's been an inspiration for me, and it's been an honor to continue working on the advancement of the DFM project that she started. I would also like to acknowledge the former PhD students in our group: Dr. Ashley Wang, Dr. Angela Zheng, and Dr. Emi Leung for their friendship, mentorship and companionship throughout my PhD journey. I would like to thank all the former and present students that have collaborated with me, especially: Chae Jeong-Potter, Nisarg Kanani, Malia Libby, Nicky He, Amanda Huang, Brandong Xie, Rees Chang, Arvind

Ramachandran, Xiaoxuan Teng and Laura Proaño. Thank you all for sharing my passion for this project, for your hard work, creativity, friendship and for your time and dedication.

Many thanks to my Columbia friends, specially to Ricardo Esparza, my best friend for the past 3 years. Thanks to Ken Sinclair, James Doss-Gollin, Yash Amonkar, Anas Alkhani, Atishu Jain, Elaine Gomez, and Constantine Spanos for all the shared moments, the happy and stressful ones, for all the plans, the drinks, and the many experiences lived together.

I would also like to thank my lifelong friends, specially my best friend Marifer Loya, that has been my constant for 22 years, for always being there for me, my biggest cheerleader and warmest friend. To my college friends Mariana Moreno and Jared Martínez, for their constant support. My dearest friends Ángel García, Lauren Oliver, Mariana Basilio, Rianna and Alex Leighton, that have made my experience in NYC an unforgettable one.

A special thanks to Adam Atia, for being there for me during the arduous last year of my PhD, specially the last couple of months of thesis writing. For keeping me sane, focused and motivated. For his kind heart, for being my emotional support and for his infinite patience.

Finally, I would like to dedicate this thesis to my family. My sister Karla Arellano, who has been my biggest fan, my mother Martha Treviño, who is the voice inside my head and my father Carlos Arellano who is my biggest champion. Everything I do is to make them proud and if I have been able to come this far, it is because of their love.

*To my family. My sister, Karla and my parents, Carlos and Martha*

# Chapter 1: Introduction

## 1.1. Motivation

Despite the rise in renewable power generation, the world's primary energy source is still based on combusting fossil fuels. According to the 2017 Global Energy and CO<sub>2</sub> Status report by the International Energy Agency (IEA) the global energy demand increased 2.1% in 2017 and almost three quarters (75%) of the rise was contributed by fossil fuels and a historically high 25% was provided by renewable sources. Global CO<sub>2</sub> emissions saw an overall increase of 1.4% but many countries like the United States saw a decline due to higher deployment of renewable energy sources and greater industrial conservation and efficiency. Of the fossil fuels, natural gas demand grew by 3% due to its availability and relatively low cost of supply. While most of it is used in the power sector, there is an increasing demand for its use in the industrial and construction sectors [1]. It is clear fossil fuels will continue to be used for combustion for the foreseeable future with the consequential generation of large amounts of CO<sub>2</sub>.

According to the Intergovernmental Panel on Climate Change (IPCC) [2], sustained greenhouse gas emissions have caused impacts on the atmospheric and oceans systems. The increase of greenhouse gas emissions, linked with fossil fuel usage, will likely cause severe, long lasting and irreversible effects on the environment, ecosystems and humankind. It is, therefore, necessary to implement immediate actions to continuously limit and reverse greenhouse gas emissions to minimize any further exacerbation of climate change. Different scenarios have been modeled to estimate the costs of implementing low-carbon technologies to reach CO<sub>2</sub> atmospheric concentration targets for this century (2015 – 2100), and in all scenarios, carbon capture, utilization and storage (CCUS) technologies will play a crucial role in curbing greenhouse gas emissions at

the lowest mitigation costs. Several companies in countries such as Switzerland and Canada have emerged to provide solutions for CO<sub>2</sub> abatement through different CCUS schemes. For example, Inventys in British Columbia, Canada, offers services for CO<sub>2</sub> capture from stationary applications [3]. Carbon Engineering, also in Canada, and Climeworks in Switzerland both develop technology for direct air capture and utilization [4,5].

Current state-of-the-art CO<sub>2</sub> capture technology relies on toxic chemicals such as liquid amines, the most well-known being monoethanolamine (MEA), to scrub carbon dioxide from flue gas streams. Water is added to amine adsorbents due to their excessive corrosiveness and viscosity. Therefore, the process requires a large heat input, associated with the volatilization of water required to separate the CO<sub>2</sub> and the amine solution (MEA) the latter of which is recycled [6]. Direct air capture has several disadvantages as the source of CO<sub>2</sub> is very diluted (~400 ppm in air); the reactor bed needs to be large and requires an energy penalty to compress air into the system and maximize adsorption. These technologies face the disadvantage of low operating temperatures (25 – 120°C) where kinetics for CO<sub>2</sub> conversion to useful products are very slow, even in the presence of catalysts. Furthermore, a temperature swing is necessary to bring the captured CO<sub>2</sub> to higher temperatures for desorption and further processing (>200°C) [7–12].

Utilization of CO<sub>2</sub> as a reactant to generate useful products is an attractive approach that can offset the cost of capture if the resultant product has a significant market. It is important to clarify that the process would have to rely on H<sub>2</sub> generated from renewable energy sources (solar, wind, hydroelectric, geothermal, etc.) in order to approach carbon neutrality and sustainability.

Renewable energies like solar and wind are intermittent. Excess electrical energy must be stored during non-productive utilization periods. One way to use this excess renewable energy is to produce hydrogen via water electrolysis for future use. Even though renewable energy costs

have significantly dropped, the price of renewable hydrogen is still too high compared to large-scale industrial hydrogen production (from fossil fuels) [13]. An economic model developed by Glenk and Reichelstein [14] predicts that power-to-gas technologies will generate price competitive renewable H<sub>2</sub> in the next ten years. The model also predicts that policy incentives can make renewable hydrogen economically competitive as early as 2023 in places like Texas and Germany.

How can the increasing energy demand be satisfied in a sustainable and practical way, but also acknowledging that fossil fuels will likely continue to be the main source of energy in the foreseeable future? Furthermore, how can potential solutions achieve this with simple, energy-efficient processes and cost-effective materials? The objective of this thesis is to answer these questions by presenting the advances in the Dual Function Materials (DFM), initially developed by our research group in 2014 [15].

The Dual Function Material (DFM) is a dispersed alkaline CO<sub>2</sub> adsorbent, with a methanation catalyst both of which are supported on a high surface area carrier. DFM both captures CO<sub>2</sub> and catalytically converts it to methane (CH<sub>4</sub>) in a single reactor at the same temperature. Taking for example an air-fired natural gas power plant, DFM would be placed downstream of the pollution abatement technology. In the first step, CO<sub>2</sub> would be captured by the dispersed alkaline oxide on alumina producing a CO<sub>2</sub>-free flue gas vented to the atmosphere. Once the material is saturated, in a second step (offline) renewable hydrogen is introduced to convert the adsorbed CO<sub>2</sub> to methane which is recycled to the power plant inlet, reducing CO<sub>2</sub> emissions and approaching carbon neutrality. Alternatively, the methane produced can be safely and cheaply stored and distributed to many locations through the natural gas pipeline network.

The uniqueness of this material lies in the synergistic relationship between its two components. Dispersed alkaline oxides behave very differently from their bulk material counterparts [16] since reactive chemisorbed CO<sub>2</sub> occurs rather than bulk carbonate formation. Heat released by the exothermic methanation reaction drives the endothermic CO<sub>2</sub> desorption from the adsorption sites to the catalyst sites via the spillover mechanism [17] to complete methanation of all the adsorbed CO<sub>2</sub> at the same moderate temperatures of 250 – 350°C. This technology does not require additional energy input as it uses the sensible heat of the flue gas. We envision the implementation of the DFM with at least two parallel swing reactors where H<sub>2</sub> is added to the CO<sub>2</sub> saturated reactor while a parallel reactor continues to capture CO<sub>2</sub> allowing continuous operation. In order to be functional in a real industrial application, the CO<sub>2</sub> capture and hydrogenation steps should have similar rates for continuous operation. Aging studies have demonstrated stable performance for over 50 cycles of CO<sub>2</sub> capture and hydrogenation [18].

Our previous published work explored the 5%Ru, 10%CaO/Al<sub>2</sub>O<sub>3</sub> and 5%Ru, 6.1%“Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> systems for maximum CO<sub>2</sub> capture and methanation capacity [15,19] and also established the stability of the systems in cycle tests in a simulated flue gas [18,20]. We also reported the CO<sub>2</sub> capture capacity of different dispersed alkali adsorbents (CaO/Al<sub>2</sub>O<sub>3</sub>, reduced Na<sub>2</sub>CO<sub>3</sub>/Al<sub>2</sub>O<sub>3</sub>, reduced K<sub>2</sub>CO<sub>3</sub>/Al<sub>2</sub>O<sub>3</sub> and MgO/Al<sub>2</sub>O<sub>3</sub>) [21]. One of the aims of this thesis is to better understand the CO<sub>2</sub> capture mechanism of these adsorbents as well as the kinetics of the CO<sub>2</sub> methanation when in direct proximity to a methanation catalyst, with a specific focus on Ru. Previously, all DFM studies were carried out for samples dispersed on Al<sub>2</sub>O<sub>3</sub>. Thus, we explored alternative candidate carrier materials for the DFM application: CeO<sub>2</sub> (HSA: high surface area and LSA: low surface area), CZO, Na-Zeolite-X (Na-X-Z), H-Mordenite Zeolite (H-M-Z), SiC, SiO<sub>2</sub> and ZrO<sub>2</sub>-Y with the initial objective of studying and understanding the metal/adsorbent/carrier

interactions for CO<sub>2</sub> capture and methanation over different supports in search of alternatives to Al<sub>2</sub>O<sub>3</sub> that might enhance the DFM process.

In previous studies, we presented the performance of different precious metals (Ru, Rh, Pt and Pd) as well as base metal catalysts (Ni and Co) tested at stoichiometric conditions for methanation activity (4:1 H<sub>2</sub> to CO<sub>2</sub> ratio) over a temperature range of 250 – 350°C [21]. The methanation activity of the metals in descendent order was Ru > Rh > Ni. From an economical point of view, the screening of these metals offers relevant information since we can compare the catalytic activity of expensive Rh (\$114.11 USD/g)\*, moderately priced Ru (\$7.99 USD/g)\* and inexpensive Ni (\$0.01 USD/g)\*. Ni is clearly the most preferred metal from an economical point of view provided it has acceptable performance.

Even though Pt and Pd were not good methanation catalysts by themselves, previous studies demonstrated that doping Ni catalysts with small amounts of these precious metals could boost nickel's methanation activity to compete with that of Ru [22]. Lowering the precious metal loading by substituting with a more economical catalyst like Ni, would mean substantial reduction of the DFM costs, provided the new alternative could retain activity and stability in simulated O<sub>2</sub>-containing CO<sub>2</sub> capture conditions.

This thesis presents a detailed study of methanation kinetics displayed by Ru, Rh and Ni catalysts in concert with dispersed alkaline adsorbents supported on a variety of carriers for cyclic CO<sub>2</sub> capture and catalytic methanation. We also present the feasibility studies of precious metal doped Ni bimetallic catalysts for CO<sub>2</sub> capture and methanation at simulated flue gas conditions. Cyclic aging studies and characterization of the fresh and aged samples demonstrated stability of

---

\* Price as of 7/14/19

the bimetallic system and the possibility of reducing the amount of precious metal loading while increasing CO<sub>2</sub> capture capacity and methane production.

## **1.2. Thesis structure**

This thesis presents the evaluation of catalytic metals (Ru, Rh and Ni) and adsorbents (CaO, “Na<sub>2</sub>O”, “K<sub>2</sub>O” and MgO) intimately dispersed on high surface area Al<sub>2</sub>O<sub>3</sub> and other carriers. CO<sub>2</sub> capture capacity and hydrogenation kinetics of the adsorbed CO<sub>2</sub> were studied as the variables of interest. We also present the enhanced reducibility of NiO at lower temperatures by doping small amounts of precious metals (Ru, Pt or Pd) on Ni DFMs for application in O<sub>2</sub>-containing CO<sub>2</sub> capture processes and subsequent methanation. The results presented will demonstrate the stable performance of a Platinum Group Metal (PGM)-promoted Ni-containing DFM when exposed to simulated flue gas conditions for over 20 cycles of aging. Characterization of the fresh and aged sample confirm the stability of the catalytic system.

Chapter 2 presents a comprehensive literature review that provides the scientific foundation of the rise of CO<sub>2</sub> levels in the atmosphere due to anthropogenic activity as well as its correlation to global warming. It also presents a study of the known CO<sub>2</sub> capture, storage and utilization technologies, their main advantages and shortcomings. This chapter also contains a short review of the current status of the hydrogen production utilizing renewable powered sources. Finally, this chapter explains in detail the DFM concept, the newly discovered improvement in performance and initial scale up feasibility is presented.

The experimental methodology of the work presented is detailed in chapter 3. A description of the material synthesis, experimental setup and process conditions are provided. Also presented is a description of the equipment utilized, data acquisition and analysis methods.

Chapter 4 presents the study of the proposed metal/adsorbent/carrier combinations for DFM by comparing their respective CO<sub>2</sub> capture capacity, methanation kinetics and overall methane production. A difference between CO<sub>2</sub> removal via a catalyzed methanation reaction vs a non-catalyzed desorption is shown using thermogravimetric analysis (TGA). Fixed or packed bed reactor tests and TGA are used to highlight the influence of different catalysts (Ru, Rh and Ni), adsorbents (“Na<sub>2</sub>O”, CaO, “K<sub>2</sub>O” and MgO) supported over different carriers (Al<sub>2</sub>O<sub>3</sub>, CeO<sub>2</sub>, CZO, Na-Zeolite-X (Na-X-Z), H-Mordenite Zeolite (H-M-Z), SiC, SiO<sub>2</sub> and ZrO<sub>2</sub>-Y). Standard characterization of all fresh materials is provided by measuring BET surface area and metal dispersion measurement is conducted with H<sub>2</sub> chemisorption at room temperature.

Chapter 5 presents the feasibility studies on various precious metals (Ru, Pt or Pd) in combination with Ni DFM catalysts. Fixed bed reactor tests present the limitations of Ni-only DFMs for O<sub>2</sub>-containing flue gas conditions. TGA is performed on Ru or Pt-doped Ni/Al<sub>2</sub>O<sub>3</sub> catalysts for isothermal reduction conditions at 320°C where enhanced NiO reducibility at lower temperatures is demonstrated due to the promoting effect of the precious metals. Fixed bed tests corroborate the promoting effect of Pt or Ru-doped Ni DFMs with Ru showing the greatest promotion consistent with TGA tests. Cyclic aging tests demonstrate stable performance of the Ru, Ni DFM using a simulated O<sub>2</sub> and steam-containing flue gas for the CO<sub>2</sub> capture step. Fresh and aged samples are characterized via TEM, XRD, H<sub>2</sub> chemisorption at 100°C and BET surface area measurements.

Chapter 6 presents the main conclusions from this thesis as well as the proposed future work to address the areas of opportunity to achieve commercialization of the DFM technology as well as other possible applications.

## **Chapter 2: Background and literature review**

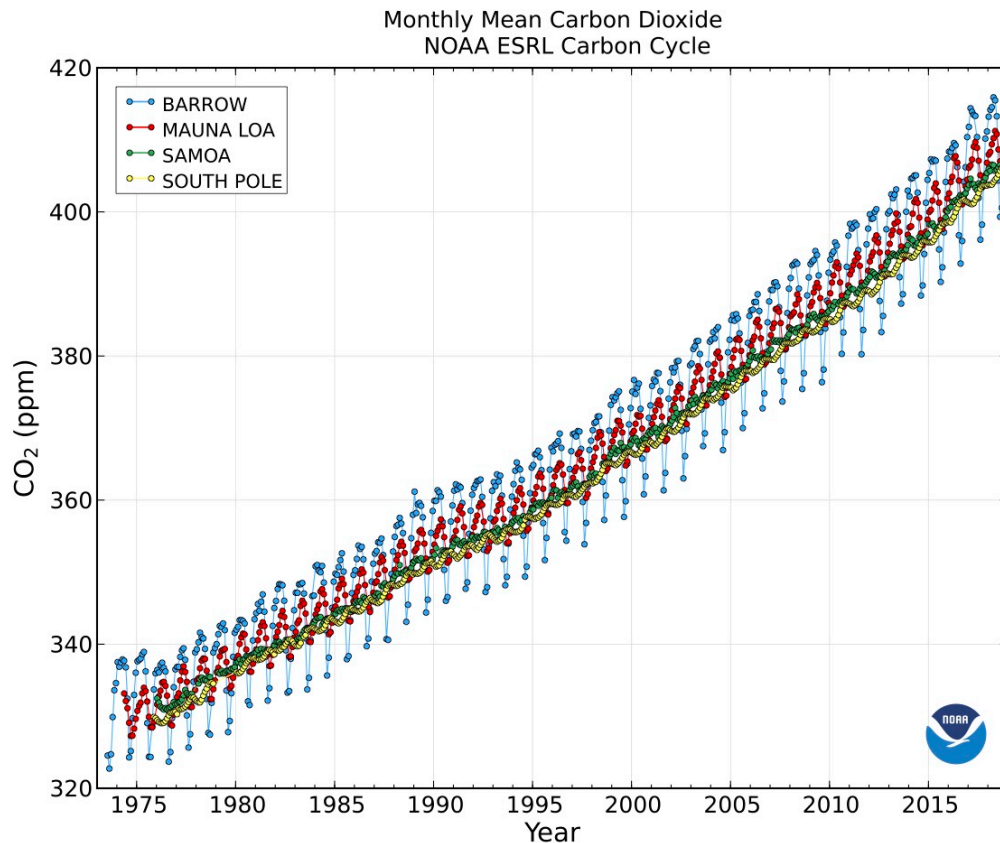

### **2.1. Rise of anthropogenic CO<sub>2</sub> emissions and correlation with climate change**

The most recent Intergovernmental Panel on Climate Change (IPCC) report agrees that “*Climate change represents an urgent and potentially irreversible threat to human societies and the planet*” [23]. It also states that the mean global temperature has risen by 1°C since the industrial revolution (early 20<sup>th</sup> century), with some parts of the planet (like the north and south poles) seeing even a higher increase in their mean temperature. The report’s goal is present the current political strategies and technologies available to curb climate change. The report includes models of different scenarios where we can reach the goal of limiting the mean global temperature rise to 1.5°C higher than that of pre-industrial times as well as scenarios of possible consequences to our environment if we fail to do so. The IPCC states that the effects of climate change are currently affecting biodiversity and life in all its forms around the world with devastating consequences, specially to island nations that are in great danger by the rise of the sea level and extreme weather conditions that can be attributed to this phenomenon.

There is a strong evidence that there is a direct correlation between the rising CO<sub>2</sub> concentration in the atmosphere and the rise of the mean global temperature. A study by Chen, et al. shows that CO<sub>2</sub> emissions contribute to about ~50% of the global temperature increase between the decades of 1990-2010, which corroborates this hypothesis [24]. The increase of the global temperature can be attributed by the strengthening of the greenhouse gas effect by the increase of the concentration of CO<sub>2</sub> in the atmosphere. The greenhouse gas effect is a natural and beneficial physical phenomenon that permits life on earth, without it, the surface temperature of our planet would be too cold to support a biodiverse ecosystem. Our atmosphere consists of a mixture of

gases, some of which are able to adsorb some of the infrared radiation that we receive from the sun, by this mechanism, the concentration of these “greenhouse” gases play a crucial role in the regulation of the temperature of our planet. In the late 1950s, Dr. Charles Keeling started measuring the concentration of these greenhouse gases from our atmosphere from the Mauna Loa Observatory in Hawaii. Soon after, other observatories around the world also started taking similar measurements. **Figure 2.1** presents the data collected over the years from several of these observatories which show an unequivocal increase of the concentration of CO<sub>2</sub>, which is considered a greenhouse gas. Even though the CO<sub>2</sub> concentration is relatively small (411.5 ppm as of April 2019 [25]), it’s been demonstrated that its radiative forcing impact is greater than the other greenhouse gases and for that reason it’s been studied the most [26] .

The carbon cycle describes the natural mechanisms in which CO<sub>2</sub> concentrations are regulated in our planet. The main carbon reservoirs are the oceans, land and atmosphere where CO<sub>2</sub> can be found in diverse forms as part of the biomass, carbonaceous and fossil sediments as well as in its gas and ionic form. All of these carbon forms are in a delicate equilibrium that has been disrupted by anthropogenic activities since the industrial revolution where fossil sediments started to be utilized as fuels for power generation and for other human related activities. These fossil sediments have been burned at a rate faster than the natural carbon cycle mechanisms can assimilate them, therefore a net accumulation of carbon species in the atmosphere is observed.

**Figure 2.1.** Monthly mean atmospheric CO<sub>2</sub> concentration in ppm determined from continuous monitoring programs at Barrow, Mauna Loa, Samoa and South Pole observatories [27].

## **2.2. CO<sub>2</sub> capture, sequestration and utilization technologies, their application and limitations**

CO<sub>2</sub> capture technologies have been studied and developed in the past. Some motivations to separate CO<sub>2</sub> from a gas mixture are for purification of products when CO<sub>2</sub> is a byproduct or for sorption enhanced reactions (SER) methods for production of hydrogen via equilibrium-controlled reactions like integrated steam reforming of methane with water gas shift [28,29] taking advantage of Le Chatelier's principle. Capturing CO<sub>2</sub> in steam reforming (endothermic) allows operation at lower temperatures while for water gas shift (exothermic) adsorbing CO<sub>2</sub> allows operating at

higher temperatures where enhanced kinetics translates into reduction of reactor sizes. These are industrial driven reasons that allow cost reduction and improved quality control of the processes. However, recently the main motivation for capturing CO<sub>2</sub> from flue gas or post conversion industrial applications is to abate greenhouse gas emissions.

As mentioned previously, some of the major sources of anthropogenic CO<sub>2</sub> are the energy sector that rely on burning fossil fuels to produce electricity, the oil refineries, cement industry (decomposition of CaCO<sub>3</sub>), iron and steel industry, biogas purification via fermentation, diverse chemicals (ammonia, ethylene oxide, methanol, pharmaceuticals, etc.) production industries and transportation sector. These industries either utilize or produce CO<sub>2</sub> and therefore, are the perfect candidates to integrate some form of CO<sub>2</sub> separation technology [30]. CO<sub>2</sub> capture efforts can be classified in five major groups: oxy-fuel combustion, chemical looping process, direct air capture, pre-conversion capture and post-conversion capture.

Oxy-fuel combustion technology utilizes pure oxygen for combustion, which makes the process highly efficient with CO<sub>2</sub> and water as the only products. One of its advantages is that the flue gas has very high CO<sub>2</sub> concentration which is desired because it translates to a smaller reactor bed volume due to enhanced efficiency of capture. The main disadvantages rely on the high cost of cryogenic oxygen purification necessary for the combustion and the high percentage of CO<sub>2</sub> and vapor products is very corrosive.

Chemical looping combustion is a novel technology that utilizes metal oxides as oxygen carriers instead of using air or pure oxygen for combustion. In this process the metal oxide is reduced, providing oxygen that when in contact with fuel, combusts to produce energy, CO<sub>2</sub> and water. The reduced metal is then exposed to air to be re-oxidized and utilized again in a cycle of oxidation/reduction [31]. This technology has similar advantages as oxy-fuel combustion because

it produces very concentrated CO<sub>2</sub> flue gas that is easy to purify by simple water condensation. Chemical looping combustion overcomes the high cost of cryogenic oxygen purification and its main disadvantage is integrity of materials during recycle and that it's still in the early development stages.

Direct air capture is the process of capturing CO<sub>2</sub> from the atmosphere for subsequent purification and sequestration or future use instead of using (liberating) already sequestered CO<sub>2</sub> in form of fossil fuels, biomass or natural CO<sub>2</sub> reservoirs [32,33]. This is a relatively new concept that has gained more interest worldwide as the technology has been demonstrated in the laboratory, pilot plants and industrial scale [4,5,34]. The advantage of this technology relies on the future environmental benefit it will provide to remove CO<sub>2</sub> from the atmosphere that would otherwise take a very long time to be sequestered by natural means. The disadvantages of the process are the technical difficulties to adsorb such diluted amounts of CO<sub>2</sub> (~400 ppm) from air (which also has other contaminants that may have a negative impact on the adsorption efficiency) that require large reactor beds and an energy penalty to compress the air into the system to maximize the capture efficiency. Moreover, the regeneration of the adsorbents presents another disadvantage point since it relies on energy intensive temperature swing [13,34–37] since CO<sub>2</sub> capture is favored at a low temperature while separation from the adsorbent requires a higher temperature, not to mention that once the CO<sub>2</sub> is purified it has to be compressed and transported to a point of sequestration or reuse facility which is another drawback.

Pre-conversion capture occurs when CO<sub>2</sub> is an undesired intermediate byproduct of a larger desired reaction [30,31]. A clear example is the ammonia synthesis process. For this reaction, large amounts of hydrogen are needed. The H<sub>2</sub> is most widely provided via the integration of steam reforming of methane and water gas shift. CO<sub>2</sub> and H<sub>2</sub> are the main products of the integrated

process but hydrogen must be purified before reacting with the atmospheric N<sub>2</sub> in air to catalytically produce ammonia [38]. The most widely used method for CO<sub>2</sub> separation is the use of liquid absorbents like monoethanolamine (MEA). The amine scrubbing technology was developed in the early 20<sup>th</sup> century which makes it one of the most developed, tested and robust technologies for CO<sub>2</sub> capture. The technology is very well known and consists of a low vapor pressure aqueous amine solution that is put in contact with a CO<sub>2</sub> rich gas mixture at room temperature. The CO<sub>2</sub> forms a complex with the amine functional group that can be regenerated by a water vapor stripper unit which produces pure CO<sub>2</sub> that can be compressed and transported to a sequestration point or to be used as a reactant in a chemical process [6,39,40]. The main advantage of this technology is that it's already widely used and known but its disadvantages include the handling of corrosive, highly degradable amine solutions, the high energy penalty of the temperature swing necessary for decomposing the CO<sub>2</sub>-amine complex and volatilization of the large amount of water present to minimize corrosion and provide fluidity and the compression and transportation of the pure CO<sub>2</sub>.

Finally, post-conversion capture (also known as post-combustion capture when talking about energy production via burning fossil fuels in power plants) is the process of removing CO<sub>2</sub> from the final products of an industrial application like cement production, biogas purification, oil refining, ethylene production, etc. The same as pre-conversion capture, aqueous MEA is the most widely used solvent for post-conversion capture but many other technologies like membrane separation, hydrate-based separation, pressure swing adsorption, cryogenic separation and solid sorbents are also used [30,31,39,41–43].

Of the technologies mentioned before, solid sorbents are of particular interest. They can be categorized into low temperature (< 100°C) physisorbents, mid temperature (200 – 500°C)

chemisorbents and high temperature ( $> 500^{\circ}\text{C}$ ) bulk adsorbents [29].  $\text{CO}_2$  adsorption is an exothermic event that is thermodynamically favored at lower temperatures, physisorbents rely on the Van der Waals forces that exist between the porous sorbents' surface walls and the  $\text{CO}_2$  molecules. These adsorbents also exploit the interaction between the strong quadrupole moment of  $\text{CO}_2$  molecules and the polar and ionic adsorbent sites [29,44]. Examples of low temperature physisorbents include zeolites, metalorganic framework compounds and activated carbons. These sorbents may be enhanced by modification with amine functional groups or other alkaline sites. The main advantages of physisorbents are their fast adsorption kinetics and high capture capacity. Desorption of  $\text{CO}_2$  during regeneration is carried via temperature or pressure/vacuum swing cycles. The main disadvantages of these products are that their capture capacity rapidly decreases at temperatures higher than  $100^{\circ}\text{C}$  and also that they are not resistant to moisture, since water preferentially adsorbs on their surface over  $\text{CO}_2$  so the feed gas should be a dry mixture [45].

Alternatively, there are high temperature bulk adsorbents that can reversibly adsorb  $\text{CO}_2$  at high temperatures. Some of the most common bulk adsorbents are alkaline metal oxides like  $\text{CaO}$ ,  $\text{MgO}$ ,  $\text{BaO}$ ,  $\text{Li}_2\text{O}$ , etc as well as natural and man-made hydrotalcite materials (Mg-Al structures with different levels of carbonation and hydroxylation that determine their basicity and therefore, capture capacity) [45–47]. These materials have been used in their pure form or in combinations or promoted by different materials (like potassium, sodium, iron, gallium or zirconium, etc.) [48,49] to provide better cyclic stability and thermal resistance to sintering, which are some of the main problems that face these materials by working at high temperatures.  $\text{CO}_2$  capture at high temperatures has been shown to promote endothermic equilibrium-dominated reactions like integrated methane steam reforming coupled with exothermic water gas shift and integrated gasification combined cycle (IGCC) [50]. The capture capacity of bulk adsorbents is very high

with initial fast kinetics of CO<sub>2</sub> capture on the surface of the material, followed by a slow mass transfer limited reaction to carbonate the core of the particles. Both the adsorption and desorption of CO<sub>2</sub> are favored at high temperatures close to the carbonate decomposition temperatures (> 500°C) [45,48].

Finally, we present the mid temperature CO<sub>2</sub> chemisorbents that can reversibly adsorb CO<sub>2</sub> at temperatures ranging between 200 – 500 °C. Their CO<sub>2</sub> capture capacity is not as high as that of physisorbents or bulk adsorbents but they overcome some of the disadvantages of both since they can be designed for high CO<sub>2</sub> selectivity over water, N<sub>2</sub>, H<sub>2</sub> and other gases with excellent cyclic stability since they don't suffer from sintering due to exposure to extremely high temperatures [30,31,45]. These chemisorbents would be ideal candidates to remove CO<sub>2</sub> from flue gas or post-conversion applications since they preferentially adsorb CO<sub>2</sub> without pre-treating the feed to a specific temperature, pressure or moisture condition. Some examples of these materials are CaO and Na<sub>2</sub>CO<sub>3</sub> promoted Al<sub>2</sub>O<sub>3</sub> [16,51,52]. It has been reported that dispersed CaO and Na<sub>2</sub>CO<sub>3</sub> on Al<sub>2</sub>O<sub>3</sub> changes the adsorption mechanism compared to the bulk materials. In the case of CaO/Al<sub>2</sub>O<sub>3</sub>, at moderate temperatures, CO<sub>2</sub> chemisorbs onto the CaO sites without forming the strong carbonate bonds that appear in the bulk CaO. The weakly bound chemisorbed CO<sub>2</sub> can be adsorbed and desorbed at the same temperature (about 300°C) just by purging the system with N<sub>2</sub> or another inert CO<sub>2</sub>-free gas mixture, eliminating the need for temperature swing or vacuum/pressure swing. Spectroscopic data shows no sign of carbonate bands forming on the surface of the CaO/Al<sub>2</sub>O<sub>3</sub> material which explains the low temperature of desorption compared to the >700°C needed to decompose bulk CaCO<sub>3</sub> bonds [16]. In the case of Na<sub>2</sub>CO<sub>3</sub> doped Al<sub>2</sub>O<sub>3</sub>, several studies confirm that by dispersing Na<sub>2</sub>CO<sub>3</sub> on Al<sub>2</sub>O<sub>3</sub>, the Na<sub>2</sub>CO<sub>3</sub> decomposition is initiated at much lower temperatures (as low as 150°C) both in air and inert atmospheres [53] relative to

the decomposition of bulk  $\text{Na}_2\text{CO}_3$  ( $>600^\circ\text{C}$ ). The final composition of the material has been described as a sodium aluminate species that we designate “ $\text{Na}_2\text{O}$ ”/ $\text{Al}_2\text{O}_3$ . Infrared studies report that  $\text{CO}_2$  adsorbs into these  $\text{Al—O---Na}^+$  sites as a combination of weakly bound monodentate and bidentate carbonates without forming strong carbonate bonds [17,54]. The weakly bound monodentate and bidentate carbonates are similarly decomposed at moderate temperatures (200 – 400°C) just by purging the system with a  $\text{CO}_2$ -free gas mixture [21].

Once the  $\text{CO}_2$  is captured and purified it is necessary to establish a practical, safe and economic way to transport it. There are several ways to do this, from onshore/offshore pipelines, pressurized tanks that can be transported by land and sea, etc. All of these mediums have their own advantages, limitations, risks and costs associated to them. Most of the previously suggested transportation mediums work best by transporting  $\text{CO}_2$  in its supercritical form, which is achieved at temperatures above  $32.1^\circ\text{C}$  and pressure above 72.9 atmospheres. This supercritical state also requires ultra-pure  $\text{CO}_2$  with moisture levels or other contaminants below 500 ppm to ensure that the  $\text{CO}_2$  remains in the supercritical one phase state. A dry composition is essential not only to maintain a single-phase during transportation but also to avoid corrosion of the pipelines (that are mostly made of carbon steel) and the pressurized containers [31].

There are several  $\text{CO}_2$  storage or sequestration options available. Most of them make use of available and suitable geological sites. The most widely used and mature technology is the use of  $\text{CO}_2$  for enhanced oil recovery (EOR). This technology consists of injecting supercritical  $\text{CO}_2$  into the oil/fossil fuel reservoirs to facilitate their extraction [30,31]. The reason  $\text{CO}_2$  works well for this process is that at its supercritical form it can be miscible with the oil and gas in the reservoirs decreasing their viscosity making the extraction more favorable. Enhanced oil recovery

is a well-known technology that has been practiced since the 1970s, but it mostly uses CO<sub>2</sub> extracted from natural reservoirs, which is undesirable from an environmental point of view.

Another CO<sub>2</sub> sequestration idea being explored more recently (early 2000s) are unmineable coal beds. This is a way to recover trapped methane (natural gas) that exist naturally in these coal beds by injecting CO<sub>2</sub> in a similar way as EOR. This technology is already in practice in China, the USA, Canada and Japan's coal sediments [55–57]. These beds are excellent storage points, the same as old oil sediments, since they have very low permeability and therefore, have a low chance of CO<sub>2</sub> leaks. Saline aquifers also offer great potential for CO<sub>2</sub> sequestration. This technology is not as widely explored as EOR and coal bed injection, but there are several projects that are exploring the option in the North Sea, Canada and USA principally. This technology consists of injecting CO<sub>2</sub> in the deep aquifers that carry high salinity brine that has no use. The CO<sub>2</sub> can be diluted in these deep reservoirs where they would undergo a carbonation process trapping the CO<sub>2</sub> in the sediment instead of remaining in the aqueous solution [58]. It is important to mention that all of these sequestration technologies present a risk of leakage, however minor, which could defeat the purpose of removing CO<sub>2</sub> from the atmosphere.

CO<sub>2</sub> sequestration has many technical and logistical disadvantages, and even though it represents the only way to permanently remove CO<sub>2</sub> from the atmosphere, there's still not enough infrastructure and economic and policy incentives to make this technology viable. It is necessary to find more alternatives to make CO<sub>2</sub> capture more attractive, one of them is the idea to utilize CO<sub>2</sub> directly or as a building block to produce higher value products that can offset the costs associated to implementing CO<sub>2</sub> capture technologies.

CO<sub>2</sub> can be utilized by itself for many applications. To mention some, the EOR technology that has discussed previously, in the food industry to carbonate beverages, to preserve and package

foods, to extract flavors and scents, to decaffeinate coffee and as a refrigerant [30,59]. It can also be utilized in the chemical production industry as needed in the production of several commodity chemicals like urea, methanol and salicylic acid [60]. For all the previously mentioned applications, it is needed to have a pure CO<sub>2</sub> stream free of impurities, however, it is possible to utilize CO<sub>2</sub> present in flue gas to grow microalgae for biofuel production where both CO<sub>2</sub> and N<sub>2</sub> are nutrients for the microalgae. The benefit of this technology is that unlike biofuels made from crops, it doesn't pose a competition or threat to food demand. The main disadvantage resides in the large energy requirement of harvesting the algae and the need of big reactors for its large-scale production [61,62]. Another promising way to utilize and sequester CO<sub>2</sub> is to utilize it as a building block in the high-volume production of polymers. Polymers are long chains of carbon and other functional groups that are produced in massive quantities worldwide. They are very difficult to decompose so once the carbon is utilized for their production it can be fixated for centuries or thousands of years [63].

These CO<sub>2</sub> utilization processes would have to rely on energy generated from sustainable and near-zero carbon footprint renewable energy sources. Renewable energy sources like solar and wind are intermittent; therefore, excess electrical energy must be stored during non-productive times. Water electrolysis produces hydrogen which can be stored conveniently for further use. The concept of chemical energy storage has gained more popularity as a means to produce “clean” fuels using captured CO<sub>2</sub>.

### **2.3. CO<sub>2</sub> catalytic upgrade**

There are several technologies under investigation to convert CO<sub>2</sub> to useful products such as photochemical [64,65] and electrochemical [66,67] processes that are being widely studied

since they can offer a renewable energy source. However, their application appears to be limited due to their low conversions, poor product selectivity, lack of widespread infrastructure and therefore, have not yet been proved to be economically or technically feasible for scale up [60]. Another way to convert CO<sub>2</sub> to chemicals and fuels is via the catalytic conversion that offers the advantage of a more mature technology with well-established processes, scalability and well-known reactor design principles. There are many fuels that can be produced via CO<sub>2</sub> catalytic upgrade, for example, syngas (CO + H<sub>2</sub>) production by CH<sub>4</sub> and CO<sub>2</sub> catalytic dry reforming. The syngas can be upgraded via Fischer-Tropsch process to higher value products and fuels. Other fuels that can be directly produced using CO<sub>2</sub> include methanol [68], formic acid [67] and methane [69] to mention a few.

Methane production using renewable hydrogen presents an attractive solution for energy storage. Even though H<sub>2</sub> is an energy carrier it has its drawbacks: it is highly flammable and difficult to transport. Currently there's a pilot plant in Germany, built by Audi that uses H<sub>2</sub> from renewable sources in combination with landfill gas rich in CO<sub>2</sub> to produce methane (CH<sub>4</sub>) via catalytic hydrogenation. Methane can be integrated into the existing natural gas grid making it readily available to many [70,71]. CO<sub>2</sub> methanation is a highly exothermic reaction favored at lower temperatures with the right catalyst providing rapid kinetics in the low temperature regime of about 250 – 350°C and 1 atm. Even though conversion kinetics are faster at higher temperatures, competing reactions like reverse water gas shift become more thermodynamically favorable at T > 400°C with the production of undesired species like CO [69].

CO<sub>2</sub> methanation via the Sabatier reaction is a well know commercial technology that has been widely reported in the literature [7,9,9,11,46,72–74] and used for many years. Earlier studies

showed that Ru, Rh and Ni were the best methanation catalysts [21] consistent with the literature [8,9,78–83,10,46,65,69,74–77].

Differences in activity and stability have been reported for methanation catalysts supported on different carriers. Ceria has been studied over the years as a promising carrier for methanation catalysts demonstrating good activity, stability and promoting effect for both ruthenium and nickel catalysts [84–89]. Ceria – zirconia (CZO:  $\text{CeO}_2 - \text{ZrO}_2$ ) as a carrier known for its good thermal stability, oxygen storage capacity and promoting effect on metal dispersion [90].  $\text{ZrO}_2$  was also considered since it has shown to be a promising carrier regarding activity and stability when impregnated with catalytic metals [84–86]. Zeolites are also viable candidates since they have high internal surface areas and can be ion-exchanged with alkaline cations as possible  $\text{CO}_2$  adsorbents [91–95]. Recent studies shown that different  $\text{TiO}_2$  phases (rutile and anatase) demonstrate different catalytic activities with Ru dispersed on rutile  $\text{TiO}_2$  being the better catalyst at low temperatures [96,97]. Silica ( $\text{SiO}_2$ ) was also studied as a reference for a high surface area inert carrier [80,98–101].

## **2.4. Dual Function Materials (DFM) for $\text{CO}_2$ capture and catalytic conversion**

Anticipating the market need for  $\text{CO}_2$  capture and conversion to useful products (utilizing renewable hydrogen) we present Dual Function Materials (DFM) as an alternative to current carbon capture utilization and sequestration (CCUS) processes. DFM both captures  $\text{CO}_2$  and converts it to synthetic natural gas ( $\text{CH}_4$ ) at the site of its use. It is composed of an alkaline chemisorbent and catalyst both supported on the same high surface carrier [15]. **Figure 2.2** presents a schematic description of the dual function material in operation. Flue gas (from power plants, boilers, compressors, etc.) is first treated for pollution abatement removing CO, HC and

NO<sub>x</sub>. It then enters a packed bed reactor at 320°C, containing a DFM where on a first step CO<sub>2</sub> is selectively adsorbed on the alkaline adsorbent sites. On a second step, the adsorbed CO<sub>2</sub> is then hydrogenated also at 320°C with renewable H<sub>2</sub> to produce CH<sub>4</sub> and H<sub>2</sub>O. The heat released by the methanation reaction creates a synergistic effect that drives the CO<sub>2</sub> desorption from the alkaline adsorbent sites which spills over to catalytic sites to produce CH<sub>4</sub> (synthetic natural gas) + 2H<sub>2</sub>O after each cycle [17]. After drying and compressing, the CH<sub>4</sub> can be recycled to the inlet for re-combustion or can be distributed and transported to other locations through the natural gas pipeline network. At least two parallel reactors act in tandem for continuous capture and conversion. Aging studies have demonstrated stable performance for over 50 cycles of CO<sub>2</sub> capture and hydrogenation using a 5%Ru, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> DFM [18].

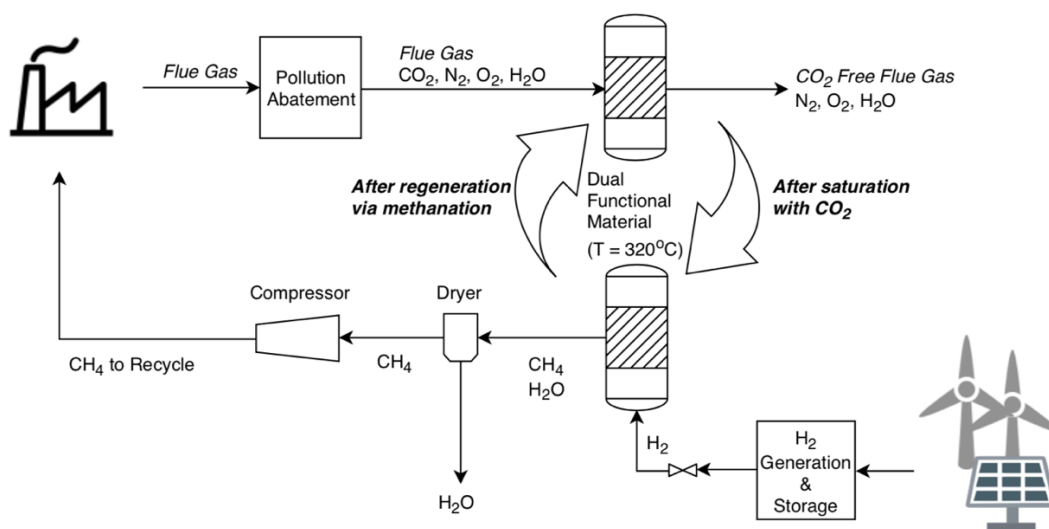

The main advantages of DFM over the other technologies presented in this chapter are:

1. Elimination of corrosive amines
2. Elimination of temperature and/or vacuum swing desorption
3. In-situ production of synthetic natural gas (CH<sub>4</sub>), which can be recycled for re-combustion. This decreases the volume of natural gas imported for the plant. Furthermore, the process approaches a carbon neutrality
4. Using excess renewable energy to produce synthetic natural gas (or methane) is a way to safely and cheaply store and distribute renewable fuels to many locations through the natural gas pipeline network.
5. No CO<sub>2</sub> purification or transportation is needed since the process is carried out at the site of CO<sub>2</sub> generation
6. The exhaust from a natural gas power plant provides the temperature required for the process (320°C) eliminating any the need for external heat input.

7. Ambient air containing ~400 ppm CO<sub>2</sub> is used for combustion and therefore its CO<sub>2</sub> is processed with the DFM technology eliminating stand-alone equipment for direct air capture.

The main drawbacks of DFM are:

1. The need for economical renewable H<sub>2</sub> and its infrastructure
2. Most likely, the excess H<sub>2</sub> required to ensure complete methanation will have to be separated from the natural gas produced to be reused
3. The DFM contains an expensive precious metal (Ru at ~ \$8/g) which can be leased and recycled
4. Parallel reactors are needed for continuous operation. It is conceivable to implement a rotating bed design with two chambers; one chamber being hydrogenated while the other is capturing CO<sub>2</sub>
5. Traces of NO<sub>x</sub> not removed during upstream SCR will likely have to be adsorbed prior to the flue gas entering DFM

**Figure 2.2.** Schematic description of the proposed DFM process flow diagram

Ruthenium has unique redox properties that allow it to rapidly reduce to its catalytically active state after exposure to an oxidizing environment (such as power plant flue gas) during the CO<sub>2</sub> capture step [16]. While Ni is the most widely used methanation catalyst commercially, when exposed to an oxidizing environment during the CO<sub>2</sub> methanation, it dramatically and steadily loses activity over time [11]. Many research groups have studied Ni-containing DFMs but in all these studies the capture step is conducted in an O<sub>2</sub>-free environment [102–105]. Several precious metals like Pt, Pd and Ru are known to dissociate H<sub>2</sub> molecules [106,107], rendering them stronger reductants for NiO and CuO, lowering the oxide reduction temperature [8,22,101,108–111]. Success by promotion with small amounts of precious metals (Pt and Ru) would make Ni-containing DFMs suitable for O<sub>2</sub>-containing flue gas applications. This would mean a significant improvement in the DFM economics.

Previously, we reported the CO<sub>2</sub> capture capacity of different dispersed alkali adsorbents (CaO/Al<sub>2</sub>O<sub>3</sub>, reduced Na<sub>2</sub>CO<sub>3</sub>/Al<sub>2</sub>O<sub>3</sub>, reduced K<sub>2</sub>CO<sub>3</sub>/Al<sub>2</sub>O<sub>3</sub> and MgO/Al<sub>2</sub>O<sub>3</sub>) [21]. The dispersed

carbonates, in the presence of a catalyst, are hydrogenated (producing  $\text{CH}_4$ ) to what we assume are “ $\text{Na}_2\text{O}$ ”/ $\text{Al}_2\text{O}_3$  and “ $\text{K}_2\text{O}$ ”/ $\text{Al}_2\text{O}_3$ , respectively [6-8]. Quotation marks (“ ”) are used since their exact chemical composition has not yet been confirmed by XRD or other characterization methods. These dispersed adsorbents are acceptable for DFM applications since they reversibly chemisorb  $\text{CO}_2$  at moderate temperatures (200 – 400°C) allowing for catalytic methanation [21].

The selection of Ru, and the rejection of Ni alone for  $\text{O}_2$ -containing flue gas is a critical part of this thesis. A new bimetallic catalyst composed of Ni with Ru has been demonstrated for use in DFM in  $\text{O}_2$ -containing flue gas. The selection of reduced  $\text{Na}_2\text{CO}_3$  on  $\text{Al}_2\text{O}_3$  compared to other alkaline adsorbents and carriers is also a focal point of this thesis. Characterization of fresh and aged materials is also included for completeness.

## Chapter 3: Experimental Methodology

### 3.1. Material synthesis

#### 3.1.1. 5%Ru, Adsorbents/Al<sub>2</sub>O<sub>3</sub>

“Na<sub>2</sub>O”, CaO, “K<sub>2</sub>O” and MgO adsorbents were prepared by incipient wetness impregnation using aqueous precursor solutions of Na<sub>2</sub>CO<sub>3</sub> (Sigma Aldrich, USA), Ca(NO<sub>3</sub>)<sub>2</sub> (Sigma Aldrich, USA), K<sub>2</sub>CO<sub>3</sub> (Sigma Aldrich, USA) and Mg(NO<sub>3</sub>)<sub>2</sub> (Sigma Aldrich, USA) respectively impregnated on  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> (SBA-150, BASF, USA) powder. Adsorbents were then dried at 140 °C for 2h and calcined in air at 400°C for 4h. After calcination and H<sub>2</sub> reduction, the achieved loadings of adsorbents were 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>, 7.1% “K<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>, 10% CaO/Al<sub>2</sub>O<sub>3</sub> and 10%MgO/Al<sub>2</sub>O<sub>3</sub>. Quotation marks (“ ”) are used since their exact chemical composition has not yet been confirmed by XRD or other characterization methods.

Ruthenium (III) nitrosyl nitrate (Alfa Aesar, USA) was impregnated onto the adsorbents supported on  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> to achieve the desired metal loading (by weight) of 5%Ru. All materials were dried in air at 120 °C for 2h and calcined in air at 250°C for 2h. The pre-reduction step was performed in situ at 320°C with 10-15% H<sub>2</sub>/N<sub>2</sub> to generate the active catalytic metal and convert any remaining carbonates and nitrates to their respective oxides. Calcination temperatures were limited to 250°C to avoid formation of volatile RuO<sub>x</sub>.

### **3.1.2. Metal, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>**

Catalyst precursor salts were impregnated onto the 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> adsorbent, to achieve the desired metal loading (by weight) of 0.5%Rh and 10% Ni respectively. Samples were prepared using Rhodium (III) nitrate (BASF, USA) and Nickel (II) nitrate (Alfa Aesar, USA) respectively. All materials were dried in air at 120 °C for 2h and calcined in air at 500 °C for 2h. The pre-reduction step was performed in situ at 320°C with 10-15% H<sub>2</sub>/N<sub>2</sub> to generate the methanation active Rh catalytic metal and convert any remaining carbonates and nitrates to their respective oxides. However, for oxides of Ni it was necessary to pre-reduce at 650°C with 10-15% H<sub>2</sub> to generate methanation active Ni metal.

### **3.1.2. 5%Ru, 6.1% “Na<sub>2</sub>O”/Carriers**

Zirconium (IV) oxide-yttria stabilized (ZrO<sub>2</sub>-Y) (Sigma Aldrich, USA), Na-Zeolite-X (Na-Z-X) and H-Mordenite Zeolite (H-M-Z) (Riogen, NJ, USA), Silicon Carbide (SiC) (SiCat, Germany), CeO<sub>2</sub>/ZrO<sub>2</sub> (CZO) (BASF, NJ, USA), high surface area CeO<sub>2</sub> (CeO<sub>2</sub>-HSA) and low surface area CeO<sub>2</sub> (CeO<sub>2</sub>-LSA) provided by the University of Udine, Italy and Silica (SiO<sub>2</sub>) (Sigma Aldrich, USA) were impregnated via the incipient wetness method using aqueous precursor solutions of Na<sub>2</sub>CO<sub>3</sub> (Sigma Aldrich, USA) and Ruthenium (III) nitrosyl nitrate as previously explained (section 3.1.1.) to achieve 5%Ru, 6.1% “Na<sub>2</sub>O” loadings into the different carriers.

### **3.1.3. 10% Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> samples doped with Ru, Pd or Pt**

The 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> adsorbent was prepared by incipient wetness impregnation using an aqueous precursor solution of Na<sub>2</sub>CO<sub>3</sub> (Sigma Aldrich, USA) impregnated on  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> powder (Sasol, TH100, Germany) using the same conditions explained in section 3.1.1.

Nickel (II) nitrate (Alfa Aesar, USA) was impregnated via incipient wetness onto the 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> adsorbent. The material was dried at 120 °C for 2h and calcined in air at 500°C for 2h producing a 12.4% NiO loading, which is equivalent to 10% Ni after reduction in hydrogen. For the purpose of identifying samples, they were labeled using the weight loading percentages of the most reduced state of the metal (10%) even when a Ni/NiO<sub>x</sub> mixture is present in the sample after reduction in hydrogen at 320°C.

Finally, salts of Ruthenium (III) nitrosyl nitrate (Alfa Aesar, USA), Palladium (II) nitrate (BASF, Iselin, NJ) or a water-soluble amine Pt salt (BASF, Iselin, NJ) respectively were impregnated onto 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> to reach a final loading of x% wt. Ru, Pd and Pt (x = 0.1, 1). All catalysts were dried at 120 °C for 2h and calcined in air at 500°C for 2h except for the Ru samples calcined at 250°C for 2h to prevent the volatilization of RuO<sub>x</sub>. All samples were pre-reduced *in-situ* with 15%H<sub>2</sub>/N<sub>2</sub> for 2.5 h (pre-reduction temperatures for samples are indicated in section 3.3.2.)

## **3.2. Thermal Gravimetric Analysis (TGA) tests**

### **3.2.1. Hydrogenation kinetics and CO<sub>2</sub> capture capacity measurements**

50 mg of powder materials were placed in an alumina crucible and underwent a cycle of CO<sub>2</sub> adsorption/hydrogenation in a NETZSCH TG209 F1 Libra instrument. All samples received *in-situ* pre-reduction at 320°C in 13.26% H<sub>2</sub>/N<sub>2</sub> (Standard Ambient Temperature and Pressure (SATP): 60 ml/min) for 6h. CO<sub>2</sub> adsorption was conducted at 320°C with 6.66% CO<sub>2</sub>/N<sub>2</sub> (SATP: 60 ml/min) for 30 min. The weight increase represents the amount of CO<sub>2</sub> adsorbed. This was followed by a 10 min N<sub>2</sub> purge, and then a catalytic hydrogenation step using 13.26% H<sub>2</sub>/N<sub>2</sub>

(SATP: 60 ml/min) for 6 h at 320°C. The weight decrease (removal of adsorbed CO<sub>2</sub>) after the addition of H<sub>2</sub> gives a relative measure of weight loss associated with CO<sub>2</sub> converted to CH<sub>4</sub> or simply desorbed unreacted. Confirmation of the products was determined in fixed bed reactor tests using the Enerac analyzer.

The rate (slope) of CO<sub>2</sub> weight loss due to either hydrogenation or unreacted CO<sub>2</sub> desorption is calculated in mg/min after the first 5 min of 13.26% H<sub>2</sub>/N<sub>2</sub> exposure. The time necessary to hydrogenate/desorb all the captured CO<sub>2</sub> is also presented. The relative rate of desorption is calculated by dividing all the hydrogenation rates by the slowest rate presented in the table, therefore making it the reference rate = 1.

### **3.2.2. Oxidation and reducibility capacity measurement**

30 mg of powder 10%Ni/Al<sub>2</sub>O<sub>3</sub> was placed in an alumina crucible and underwent a cycle of oxidation/reduction using a NETZSCH TG209 F1 Libra instrument. The initial sample was pre-reduced at 650°C in 15% H<sub>2</sub>/N<sub>2</sub> (SATP: 60 ml/min) for 6h. The sample was exposed to 4.5% O<sub>2</sub>/N<sub>2</sub> (SATP: 60 ml/min) at 320°C simulating the flue gas capture for 20 min. The weight increase is the extent of oxidation. This was followed by a 10 min N<sub>2</sub> purge (SATP: 20 ml/min), followed by the addition of 15% H<sub>2</sub>/N<sub>2</sub> (SATP: 60 ml/min) for 6 h at 320°C. The weight decrease gives a relative measure of the extent of reduction of the oxidized sample.

### **3.2.3. Effect of Platinum Group Metal (PGM) doping on NiO<sub>x</sub> redox properties**

The tests were conducted using a 1%wt. loading of platinum group metals (Ru and Pt) impregnated on 10% Ni/Al<sub>2</sub>O<sub>3</sub>. 30 mg samples were placed in an alumina crucible and were heated to 320°C and 1 atm at a rate of 10 K/min in inert N<sub>2</sub> (SATP: 20 ml/min). They were then exposed

to a reducing environment with a 13.26% H<sub>2</sub>/N<sub>2</sub> stream (SATP: 60 ml/min). The weight loss was recorded after constant weight was achieved.

### **3.3 CO<sub>2</sub> capture and methanation with different compositions of DFMs**

#### **3.3.1. Screening of DFMS with different catalysts, adsorbents and carriers using the Quantachrome unit as a fixed bed reactor**

The basic Quantachrome equipment is designed for BET surface area measurements, quantification of dispersed metal availability by H<sub>2</sub> or CO chemisorption, and temperature programmed reduction and desorption (TPR/TPD). We have modified it as a reactor for CO<sub>2</sub> capture and subsequent catalytic hydrogenation.

The samples (100 mg of powder) were placed in a u-shaped quartz tube fixed bed ChemBET Pulsar TPR/TPD unit (Quantachrome) reactor to test for CO<sub>2</sub> capture, followed by methanation upon hydrogen introduction. Temperature was controlled by a heating mantle surrounding the u-shaped reactor cell. The samples were first reduced overnight (12 h) at 320°C in 10% H<sub>2</sub>/N<sub>2</sub> (SATP: 30 mL/min). This ensured that all the precursor salts decomposed to their reduced and active form. Only the Ru and Rh DFMs could be tested on the Quantachrome unit since the mantle that controls the temperature inside the reactor cell is limited to a maximum of 400°C. The NiO catalysts that require a pre-reduction temperature of > 500°C in H<sub>2</sub> [84–86] for complete reduction and therefore, had to be evaluated in a packed bed reactor.

Each sample was then exposed to a 10% CO<sub>2</sub>/N<sub>2</sub> mixture (SATP: 30 mL/min) at 320°C for 40 min for the CO<sub>2</sub> capture step. The methanation step followed, with 10% H<sub>2</sub> /N<sub>2</sub> (SATP: 30 mL/min) introduction for 1 h. Three consecutive cycles (CO<sub>2</sub> capture + N<sub>2</sub> purge + methanation)

were performed and the results averaged. Gas compositions at the exit of the reactor were monitored using an Enerac portable emissions analyzer, capable of continuously monitoring CO<sub>2</sub>, CH<sub>4</sub> and CO concentrations (1 second sampling time). The Enerac analyzes post combustion gas mixtures using an infrared detector as well as an electrochemical cell for O<sub>2</sub> detection. Its measurement accuracy is stated as 96%. No CO was detected in any tests. A blank test was performed with an empty reactor cell to record the carbon dioxide and methane baseline signals for accurate subsequent CO<sub>2</sub> and CH<sub>4</sub> measurements.

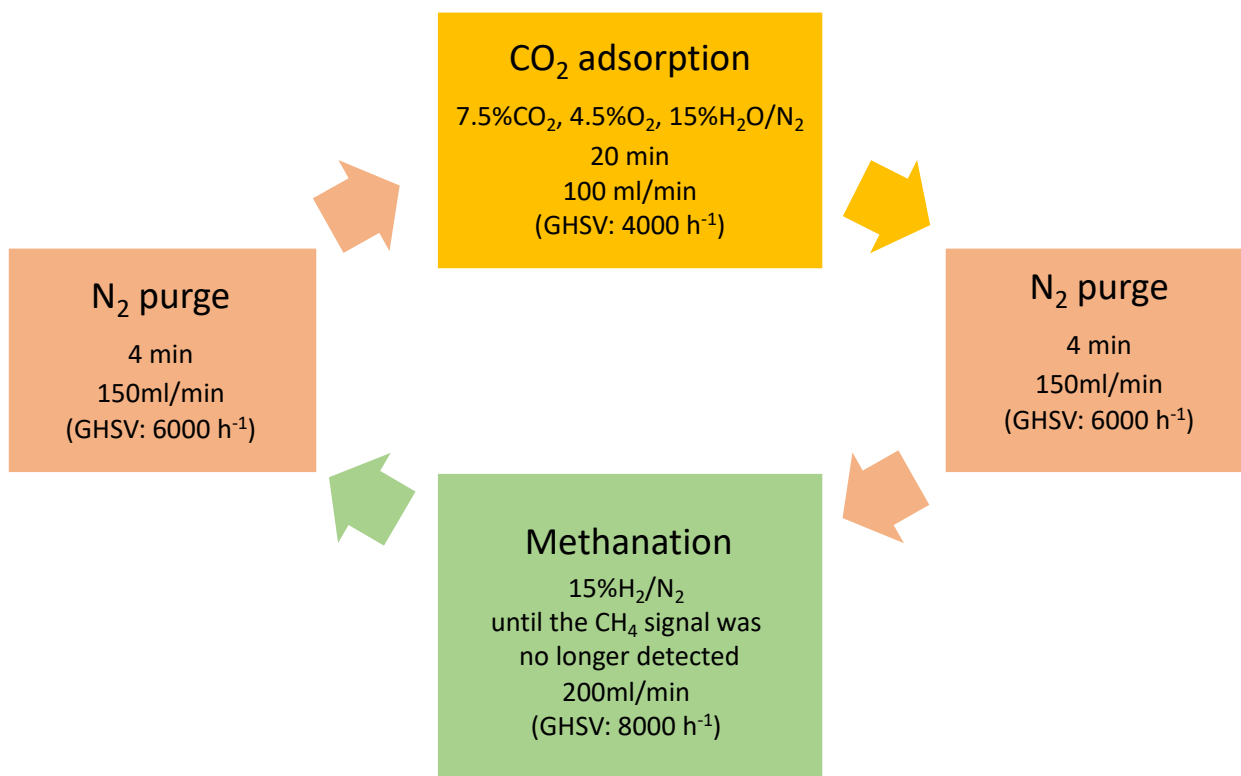

### **3.3.2. Packed bed reactor tests**

1 g of powdered samples was tested in a packed bed reactor made of a quartz (O.D.=12.75mm, I.D.=10.5 mm and length=500mm). A microthermal furnace (MTSC12.5R-.75 × 18-1Z, Mellen, USA) surrounded the reactor tube with temperature feedback control from a K-type thermocouple (Omega, USA) at the inlet of the catalytic bed. Compressed gases were mixed at designed flow rates with mass flow controllers (MKS Instruments, USA). Steam was introduced to the feed gases by injecting water with a syringe pump (Cole-Parmer, USA). The water was pre heated to 125°C inside the reactor feed tube wrapped with heating tape. The steam from the feed or from the water produced during methanation was condensed in an ice bath placed at the exit of the reactor. An Enerac 700 analyzed the dry gas composition of CH<sub>4</sub>, CO, CO<sub>2</sub> and O<sub>2</sub> every second. The Ru-containing samples were pre-reduced at 320°C and 1 atm for 150 min with 15%H<sub>2</sub>/N<sub>2</sub> at a total flow rate of SATP: 200 ml/min (Gas Hourly Space Velocity (GHSV): 8000 h<sup>-1</sup>). Pt and Pd-containing samples were pre-reduced at 500°C and 1 atm, at similar flow rate conditions. The 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> samples were reduced at 650°C and 1 atm, at similar flow rate conditions. After pre-reduction, the samples were tested for isothermal CO<sub>2</sub> adsorption

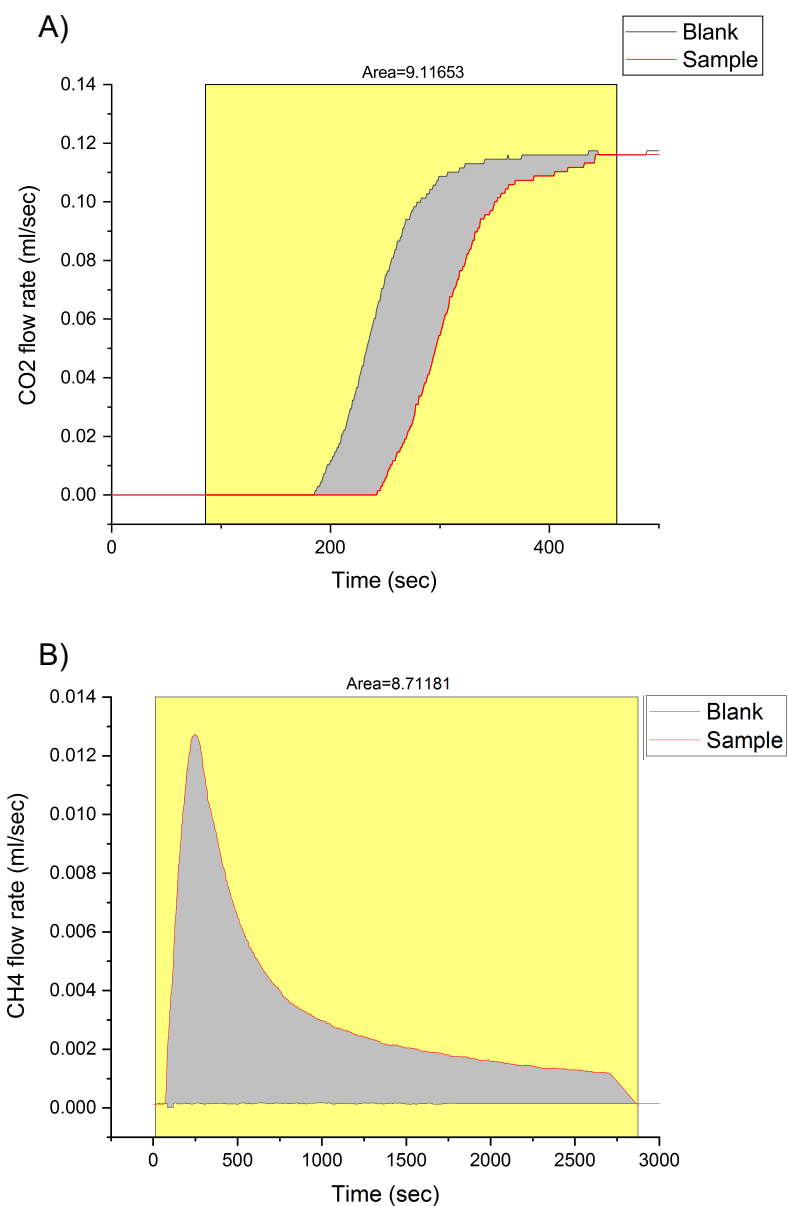

and methanation cycles at 320°C and 1 atm. The 320°C temperature was necessary to simulate the continuous operation of the DFM with O<sub>2</sub>-containing flue gas. **Figure 3.1** presents a schematic description of the reaction operation conditions.

The 4-min N<sub>2</sub> purge is needed both before and after CO<sub>2</sub> adsorption and methanation to avoid contact of possible explosive H<sub>2</sub> and O<sub>2</sub> in the catalytic bed. Each sample was tested for 3 consecutive cycles (1 cycle = CO<sub>2</sub> capture step + N<sub>2</sub> purge + methanation step+ N<sub>2</sub> purge).

A blank test was performed with an empty reactor cell to record the carbon dioxide and methane baseline signals for accurate subsequent CO<sub>2</sub> and CH<sub>4</sub> measurements. The CO<sub>2</sub> flow rate (in ml/sec) vs time (sec) during CO<sub>2</sub> capture and CH<sub>4</sub> flow rate (in ml/sec) vs time (sec) during hydrogenation are plotted and the area under the curves measured using the data analysis software Origin (OriginLab Corporation). The area under the curve gives the amount of methane produced and the CO<sub>2</sub> captured in ml. **Figure 3.2A** shows an example of a characteristic CO<sub>2</sub> signal recorded during CO<sub>2</sub> capture step and the blank profile used to calculate the CO<sub>2</sub> captured. The averaged (over 3 cycles) and normalized (using an empty reactor as a baseline) CO<sub>2</sub> signals and CH<sub>4</sub> peaks (see **Figure 3.2B**) were used to calculate the amount of CO<sub>2</sub> adsorbed and methane produced by the samples by subtracting the area of the blank to the area of the sample.

**Figure 3.1.** Schematic description of cyclic DFM operation. All steps conducted at 320°C and 1 atm. Volumetric flow rates corrected to Standard Ambient Temperature and Pressure (SATP: 25°C and 1 atm).

**Figure 3.2.** A) Characteristic CO<sub>2</sub> signal recorded during the CO<sub>2</sub> capture step in red compared to a Blank (empty cell) signal in black. The difference in areas represent the CO<sub>2</sub> captured by the sample (area in gray). B) Characteristic CH<sub>4</sub> peak recorded during the hydrogenation step in red compared to a Blank (empty cell) signal in black. Area under the peak curve in grey represent the CH<sub>4</sub> produced by the sample.

### 3.3.3. Cyclic aging tests in O<sub>2</sub>-containing simulated flue gas

The most promising DFM composition, based on CO<sub>2</sub> capture capacity and methane production rate (from packed bed reactor tests), was selected for 20 cycles of aging. The experimental procedure was described in section 3.3.2 The sample was pre-reduced at 320°C for 2.5 h with 15% H<sub>2</sub>/N<sub>2</sub> (GHSV: 8000 h<sup>-1</sup>) before the beginning of the first cycle. The schematic description of the cycles can be found in **Figure 3.1** with the only difference being that the methanation step time was fixed at 30 min.

## 3.5. Characterization

### 3.5.1. BET

A ChemBET Pulsar TPR/TPD unit (Quantachrome) was used to measure single-point BET surface area for fresh and spent DFM samples. First, the samples were degassed *in-situ* for 2 hours at 150°C and 1 atm to remove any moisture from the sample. Subsequently, the BET surface area was measured at 25°C and 1 atm. Three measurements were made for each sample.

### 3.5.2. H<sub>2</sub> chemisorption

H<sub>2</sub> chemisorption tests were performed using a ChemBET Pulsar TPR/TPD unit (Quantachrome). Ruthenium and rhodium metal dispersions were obtained at room temperature (25°C) after reduction *in situ* in 10% H<sub>2</sub>/N<sub>2</sub> at 320 °C (SATP: 30 ml/min) for 12 h. It was assumed that stoichiometry for relative chemisorption is one H atom per Ru or Rh site.

Fresh and aged (after 20 cycles) 1%Ru, 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> DFM powder samples were reduced *in-situ* in 10% H<sub>2</sub>/N<sub>2</sub> at 320 °C (SATP: 30 ml/min) for 12 h. H<sub>2</sub> adsorbed/g of material was obtained at 100°C.

### **3.5.3. X-ray diffraction (XRD)**

X-ray diffraction (XRD) patterns of the fresh and aged (after 20 cycles) 1%Ru, 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> DFM were performed using a PANalytical XPert3 Powder XRD. Patterns of  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> (Sasol, TH100, Germany) powder as well as 1%Ru 6.1% “Na<sub>2</sub>O” /Al<sub>2</sub>O<sub>3</sub> and 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> were also scanned for comparison. The XRD is equipped with Cu K- $\alpha$  radiation, and the diffraction data was obtained at  $2\theta = 20^\circ \sim 85^\circ$  with a step size of 0.01.

### **3.5.4. Transmission Electron Microscopy (TEM) and Energy-Dispersive X-Ray Spectroscopy (EDS)**

The transmission electron microscopy (TEM) image and energy-dispersive X-ray spectroscopy (EDS) mapping was conducted in a FEI Talos F200X TEM instrument operating at 200 kV. The scanning transmission electron microscope (STEM) EDS mapping was obtained with the size of the selected Condenser 2 aperture at 50  $\mu$ m and the spot size was 9. The EDS scans were acquired by Super X-EDS system.

The samples were prepared by depositing one droplet of the DFM colloidal suspension in isopropanol onto copper grids coated with a thin carbon film.

## **Chapter 4: Study of various catalytic metals/alkaline adsorbents/ carrier combinations for DFM: comparison of capture capacity and rates of reaction**

*The results presented in this chapter have been published in M.A. Arellano-Treviño, Z. He, M.C. Libby, R.J. Farrauto, Catalysts and adsorbents for CO<sub>2</sub> capture and conversion with dual function materials: Limitations of Ni-containing DFMs for flue gas applications, J. CO<sub>2</sub> Util. 31 (2019) 143–151.*

This chapter explores different catalytic metals (Ru, Rh or Ni) in combination with a variety of alkaline adsorbents (“Na<sub>2</sub>O”, CaO, K<sub>2</sub>O and MgO) as candidates for DFM application. Materials such as CeO<sub>2</sub> (HSA: high surface area and LSA: low surface area), CeO<sub>2</sub>/ZrO<sub>2</sub> (CZO), Na-Zeolite-X (Na-X-Z), H-Mordenite Zeolite (H-M-Z), SiC, SiO<sub>2</sub> and zirconium oxide-yttria stabilized (ZrO<sub>2</sub>-Y) were investigated as possible alternatives to alumina as a DFM carrier. All samples were tested in a fixed bed reactor to quantify the extent and rate of methane generation. Complementing fixed bed testing, thermogravimetric analysis (TGA) was used to evaluate the extent of CO<sub>2</sub> adsorption and rate of catalytic methanation.

### **4.1. Catalyzed vs. non catalyzed effect on CO<sub>2</sub> adsorption and hydrogenation/ CO<sub>2</sub> desorption rates.**

**Figure 4.1** presents the thermogravimetric and calorimetric profiles of the effect of catalyzed vs non-catalyzed CO<sub>2</sub> adsorption and catalytic hydrogenation or thermal CO<sub>2</sub> desorption rates (the experimental conditions are explained in detail in section 3.2.1). A weight gain is noted at the initiation of CO<sub>2</sub> adsorption on 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> (blue profile top half of **Figure 4.1**)

with an exothermic event (blue peak at t=0 lower profile in **Figure 4.1**). This is consistent with thermodynamics of adsorption processes and previous studies [19]. The amount of CO<sub>2</sub> adsorbed (blue profile in **Figure 4.1**) is less than when combined with reduced Ru which also adsorbs CO<sub>2</sub> (top red curve with the associated exotherm lower half of **Figure 4.1**).

Upon the addition of H<sub>2</sub>, the adsorbent alone (in blue) produces no CH<sub>4</sub> (verified by the lack of exotherm associated with hydrogenation and external product analysis) but shows a very slow weight loss indicative of the thermal desorption of chemisorbed CO<sub>2</sub>. The slow desorption (blue profile in **Figure 4.1**) is complete after 360 minutes. In contrast, the rate of hydrogenation to CH<sub>4</sub> (as noted by the weight loss for the Ru catalyzed DFM), was considerably faster and complete in 36 minutes (red profile in **Figure 4.1**) and corroborated by the exothermic peak and analysis in fixed bed reactor tests. The reaction produces 1 mol of CH<sub>4</sub> and 2 moles of H<sub>2</sub>O (1) leaving empty Ru sites free to accept CO<sub>2</sub> which spill over from the adsorbent to the Ru sites allowing for methanation. This postulated scheme is shown in equations 4.1, 4.2 and 4.3. Equation 4.3 is a repeat of equation 4.1. This mechanism has been furtherly corroborated by our *in-situ* DRIFTS studies. We report that CO<sub>2</sub> adsorbs onto Al—O---Na<sup>+</sup> (as bicarbonates and bidentate carbonates) with subsequent spill over to Ru sites for methanation upon the addition of H<sub>2</sub>. Formate species were found to be the main reaction intermediates in methanation [17].

**Figure 4.1.** CO<sub>2</sub> adsorption and catalytic hydrogenation or thermal CO<sub>2</sub> desorption rates. Bottom 2 profiles are the DSC signals while the two top profiles are the mass profiles for 5%Ru, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> (red) and 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> (blue). Adsorption feed gas was 6.6% CO<sub>2</sub>/N<sub>2</sub> with hydrogenation initiated upon exposure to 13.26% H<sub>2</sub>/N<sub>2</sub>, both at 320°C.

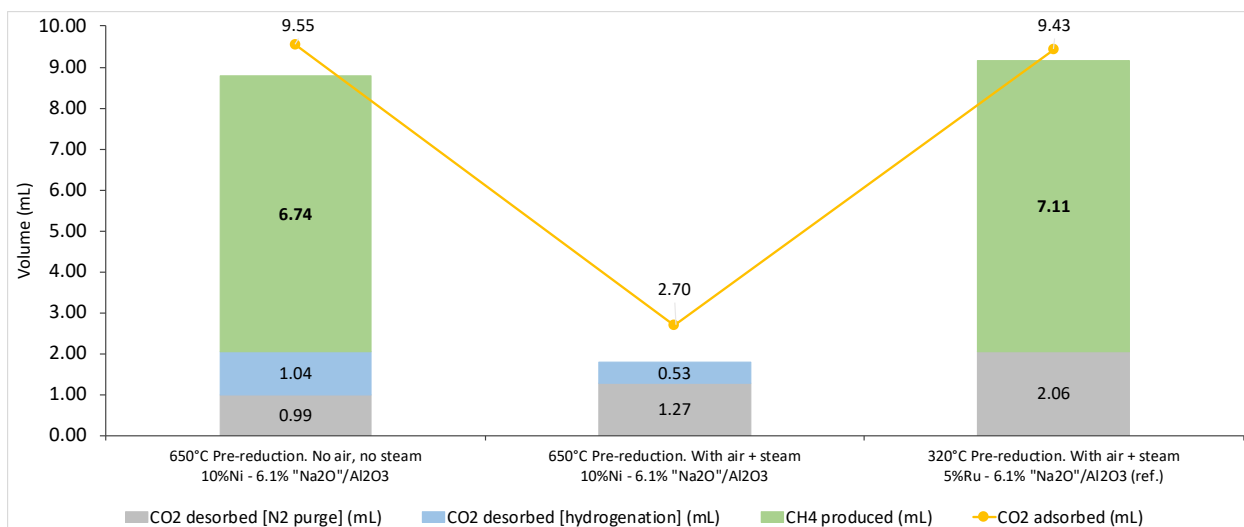

## 4.2. Limitations of Ni-based DFMs at simulated flue gas CO<sub>2</sub> capture and conversion

### 4.2.1. Packed bed reactor tests with Ni-containing DFMs at O<sub>2</sub>-free and O<sub>2</sub>-containing CO<sub>2</sub> capture conditions

Ni-based DFMs were tested with 7.5% CO<sub>2</sub>/N<sub>2</sub> and with a simulated flue gas composition (7.5% CO<sub>2</sub>/N<sub>2</sub> 4.5% O<sub>2</sub>, 15% H<sub>2</sub>O balance N<sub>2</sub>) for the CO<sub>2</sub> capture step. **Figure 4.2** and **Table 4.1** summarize the averaged performance (over 3 cycles) of the 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> samples. The first sample on the left, is Al<sub>2</sub>O<sub>3</sub> supported Ni<sup>0</sup> + adsorbent samples pre-treated at 650°C with 15% H<sub>2</sub>/N<sub>2</sub>. The CO<sub>2</sub> capture capacity is 9.55 mL under 7.5% CO<sub>2</sub>/N<sub>2</sub>. This high CO<sub>2</sub> capture capacity is attributed both to the “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> adsorbent and Ni being fully reduced at 650°C and active for CO<sub>2</sub> adsorption. Its hydrogenation generated 6.74 ml of CH<sub>4</sub>. He et al. have also reported the benefits of supporting Ni catalysts on high surface area carriers with basic sites [113]. In contrast the middle sample, also pre-reduced at 650°C, but exposed to O<sub>2</sub> and H<sub>2</sub>O during the capture step, adsorbed only 2.70 ml of CO<sub>2</sub>. However, no methane was formed due to the partial oxidation of the Ni during the capture step at 320°C. The final sample (extreme right of **Figure 4.2**) was 5%Ru, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> pre-reduced at 320°C and it was included as the reference material. It adsorbed 9.43 ml of CO<sub>2</sub>, after exposure to O<sub>2</sub> and steam at 320°C in the capture step. 7.11 ml of CH<sub>4</sub> were formed with a 75% conversion, (the difference due to CO<sub>2</sub> desorbed during the N<sub>2</sub> purge) and with no CO<sub>2</sub> detected after H<sub>2</sub> addition substantiating the role of Ru as the catalyst for DFM under simulated flue gas conditions. This latter result is to be directly compared to the Ni sample (reduced at 650°C) and exposed to O<sub>2</sub> and steam at 320°C (sample with 2.70 ml of CO<sub>2</sub> captured) with no methane production.

Reduced 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> only produces CH<sub>4</sub> when the capture step is carried out under O<sub>2</sub>-free conditions, but the moles of methane generated (276.2 mmol/kg, in **Table 4.1**) is about ½ that of 5%Ru, 6.1%“Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> DFM (614.4 mmol/kg) under similar O<sub>2</sub> free conditions (See **Table 4.2**). The conversion for the Ni based DFM reached only 71% (**Table 4.1**) compared to 96% for the Ru sample (See **Table 4.2**). The low carbon balance for the Ni-containing DFM (92%) can likely be attributed to CO<sub>2</sub> retained in the sample. It is possible that higher H<sub>2</sub> partial pressure may complete the reaction. Infrared studies of CO<sub>2</sub> adsorption on supported Ni catalysts have shown that inactive carbonate species can form on the Ni surface when Ni catalyzes a CO<sub>2</sub> reaction with surface oxygen species present in the carrier [114]. The formation of carbonate species on the surface of Ni DFMs can result in unreacted adsorbed CO<sub>2</sub> that cannot be hydrogenated at 320°C. It requires at least 800°C for decomposition[114]. Another explanation for the incomplete carbon balance is the formation of bulk NiO on the surface of the Ni catalyst by the adsorption of CO<sub>2</sub> in the absence of H<sub>2</sub> [115,116]. According to experiments performed by Mutz et al. these oxidized species can be partially reduced at T > 400°C, but not to the original reduced state (6% NiO remains in the surface even after 20 min of H<sub>2</sub> exposure) and the activity of the catalyst decreased over time, likely due to sintering.

In industrial processes Ni is a preferred catalyst because it is reduced at high temperature and is never exposed to O<sub>2</sub>. Furthermore, the process is operated close to stoichiometric conditions at high pressure [12]. We have shown that Ni is not viable under realistic flue gas conditions (O<sub>2</sub> present) for DFM at 320°C. We have reported that 15% H<sub>2</sub> is adequate to rapidly reduce the RuO<sub>x</sub>, formed from the O<sub>2</sub> present in the flue gas during CO<sub>2</sub> capture [18] substantiating that Ru is the best catalyst for the DFM application, although reductions in its metal loading is preferred.

**Figure 4.2.** Averaged CO<sub>2</sub> adsorption, desorption and CH<sub>4</sub> produced over 3 cycles on 10% Ni, 6.1%“Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> with and without O<sub>2</sub> present in the CO<sub>2</sub> feed. 5%Ru, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> included as reference. Ni samples were pre-reduced at 650°C while Ru samples at 320°C, both at 8000 h<sup>-1</sup> with 15% H<sub>2</sub>/N<sub>2</sub> for 2.5 h. Operation conditions: 20 min of CO<sub>2</sub> adsorption at 4000h<sup>-1</sup> of either 7.5% CO<sub>2</sub>/N<sub>2</sub> or 7.5% CO<sub>2</sub>, 4.5% O<sub>2</sub>, 15% H<sub>2</sub>O balance N<sub>2</sub>. Hydrogenation of adsorbed CO<sub>2</sub> at 8000 h<sup>-1</sup> with 15% H<sub>2</sub>/N<sub>2</sub> for 1 h. N<sub>2</sub> purge before and after CO<sub>2</sub> adsorption and methanation, 6000 h<sup>-1</sup> for 4 min. All adsorption and hydrogenation cycles performed at 320°C and 1 atm with 1 g of sample.

**Table 4.1.** Summary of fixed bed reactor tests on 10% Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>. 5%Ru, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> included as reference. Operational conditions described in **Figure 4.2**. Standard error of CO<sub>2</sub> adsorbed, CH<sub>4</sub> produced, CO<sub>2</sub> desorbed during hydrogenation and during N<sub>2</sub> purge in parenthesis.

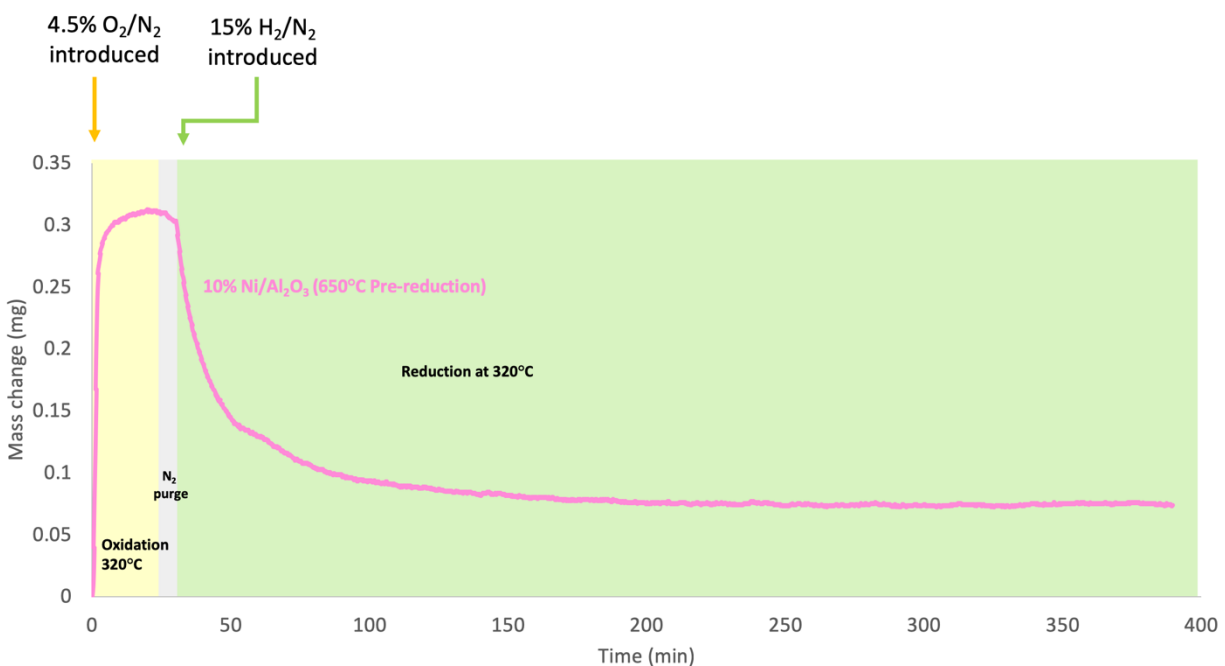

Row	Sample	Pre-reduction Temp (°C)	Air + Steam?	CO <sub>2</sub> adsorbed (mL)	CH <sub>4</sub> produced (mL)	CO <sub>2</sub> desorbed [hydrogenation] (mL)	CO <sub>2</sub> desorbed [N <sub>2</sub> purge] (mL)	mmol CO <sub>2</sub> /kg-DFM	mmol CH <sub>4</sub> /kg-DFM	Carbon balance (%)	Conv (%)
1	10%Ni, 6.1%“Na <sub>2</sub> O”/Al <sub>2</sub> O <sub>3</sub>	650	No	9.55 (±0.1)	6.74 (±0.05)	1.04 (±0.2)	0.99 (±0.2)	398.2	276.2	92%	71%
2		650	Yes	2.70 (±0.1)	0	0.53 (±0.04)	1.27 (±0.1)	112.6	0	67%	0%
3	5%Ru, 6.1% “Na <sub>2</sub> O”/Al <sub>2</sub> O <sub>3</sub>	320	Yes	9.43 (±0.2)	7.11 (±0.1)	0	2.06 (±0.01)	393.5	291.1	97%	75%

#### 4.2.2. Oxidation and reducibility of 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> samples

To better understand the oxidation and reducibility of the Ni-containing samples we studied the thermogravimetric profile of 10%Ni/Al<sub>2</sub>O<sub>3</sub> when exposed to 4.5% O<sub>2</sub>/N<sub>2</sub> (at 320°C) which is the typical oxygen concentration in flue gas from natural gas combustion. The exposure time was 20 min, followed by a 10 min N<sub>2</sub> purge (to avoid dangerous O<sub>2</sub> and H<sub>2</sub> mixture in the thermogravimetric chamber). 15% H<sub>2</sub>/N<sub>2</sub> was introduced to simulate the packed bed plug flow reactor conditions previously presented. **Figure 4.3** presents the thermogravimetric profile of 10%Ni/Al<sub>2</sub>O<sub>3</sub> where the reduced (at 650°C) sample is oxidized at 320°C when exposed to 4.5% O<sub>2</sub>/N<sub>2</sub>. Upon the introduction of hydrogen, it is not completely reduced as evidenced by the residual weight in the profile, after 6h of 15% H<sub>2</sub>/N<sub>2</sub> exposure at 320°C. This is consistent with the packed bed reactor test results (presented in previous section 4.2.1) that show no methane being

formed when the Ni-containing samples are exposed to O<sub>2</sub> as the Ni atoms cannot be rapidly reduced to an active metallic state under hydrogen exposure at 320°C. This has been previously reported in the literature [116].

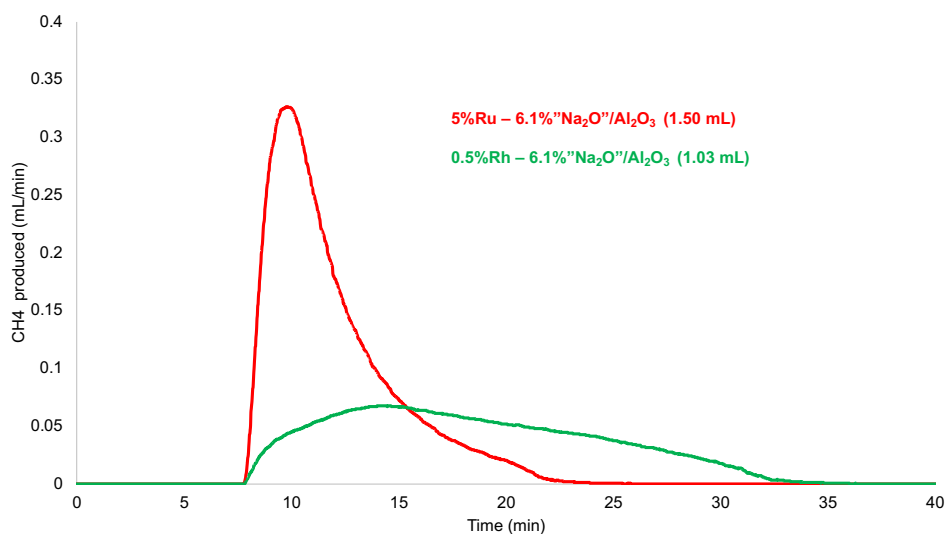

**Figure 4.3.** Oxidation (4.5% O<sub>2</sub>/N<sub>2</sub> exposure) and reducibility (upon exposure to 15% H<sub>2</sub>/N<sub>2</sub>) of 10%Ni/Al<sub>2</sub>O<sub>3</sub>. Thermogravimetric profiles at 320°C and 1 atm. Sample initially pre-reduced with 15% H<sub>2</sub>/N<sub>2</sub> at 650°C for 6h.

### **4.3. Influence of catalytic metals: Ru and Rh supported on 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>.**

#### **4.3.1. Fixed bed reactor tests (in Quantachrome) as a preliminary screening tool to quantify the methanation of the adsorbed CO<sub>2</sub> on Ru and Rh containing DFMs.**

The Ruthenium and Rhodium-based DFMs, were tested for 3 cycles of CO<sub>2</sub> adsorption and hydrogenation. The loading of 5%Ru and 0.5%Rh were chosen to compare similarly priced catalysts (Rh price was ~ 10x the price of Ru at the time of the study). **Figure 4.4** presents the averaged CH<sub>4</sub> signals. A fast and sharp methane peak is observed for the 5%Ru, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>. CH<sub>4</sub> detection occurs upon hydrogen exposure and all adsorbed CO<sub>2</sub> is methanated within 25 min. In contrast the 0.5% Rh, 6.1% “Na<sub>2</sub>O” DFM sample shows a broad methane signal with reaction proceeding for an additional 10 minutes compared to the Ru DFM. This demonstrates that the Ru DFMs have a faster rate of methanation than similarly priced Rh DMFs. The amount of adsorbed CO<sub>2</sub> is similar for both 5%Ru and 0.5%Rh samples (1.56 and 1.5 mL respectively) but the Ru DFM converts ~100% to methane (1.50 mL of CH<sub>4</sub>) while the Rh DFM converts only 69% of the adsorbed CO<sub>2</sub> to CH<sub>4</sub> (1.03 mL).

**Table 4.2** presents a summary of the CO<sub>2</sub> capture and methanation capacity (both expressed in mmol /kg of DFM) for the Ru and Rh supported on 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> DFMs. 0.5%Rh DFM showed a similar carbon capture capacity as 5%Ru but the methanation activity was poor with less CH<sub>4</sub> produced per kg of material (421.9 mmol of CH<sub>4</sub>/kg vs. 614.4 mmol of CH<sub>4</sub>/kg).

**Figure 4.4.** Averaged methane signal during hydrogenation step (SATP: 30 ml/min, 10% H<sub>2</sub>/N<sub>2</sub> at 320°C and 1 atm) for the 5%Ru and 0.5%Rh with 6.1% “Na<sub>2</sub>O” based DFMs

**Table 4.2.** Average methanation capacity of the adsorbed CO<sub>2</sub> on Ru and Rh DFMs supported on 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>. CO<sub>2</sub> adsorption for 30 min using SATP: 30 ml/min of 10%CO<sub>2</sub>/N<sub>2</sub> at 320°C. Hydrogenation of adsorbed CO<sub>2</sub> with SATP: 30 ml/min, 10% H<sub>2</sub>/N<sub>2</sub> for 1h at 320°C.

Standard error of CO<sub>2</sub> adsorbed and CH<sub>4</sub> produced in parenthesis.

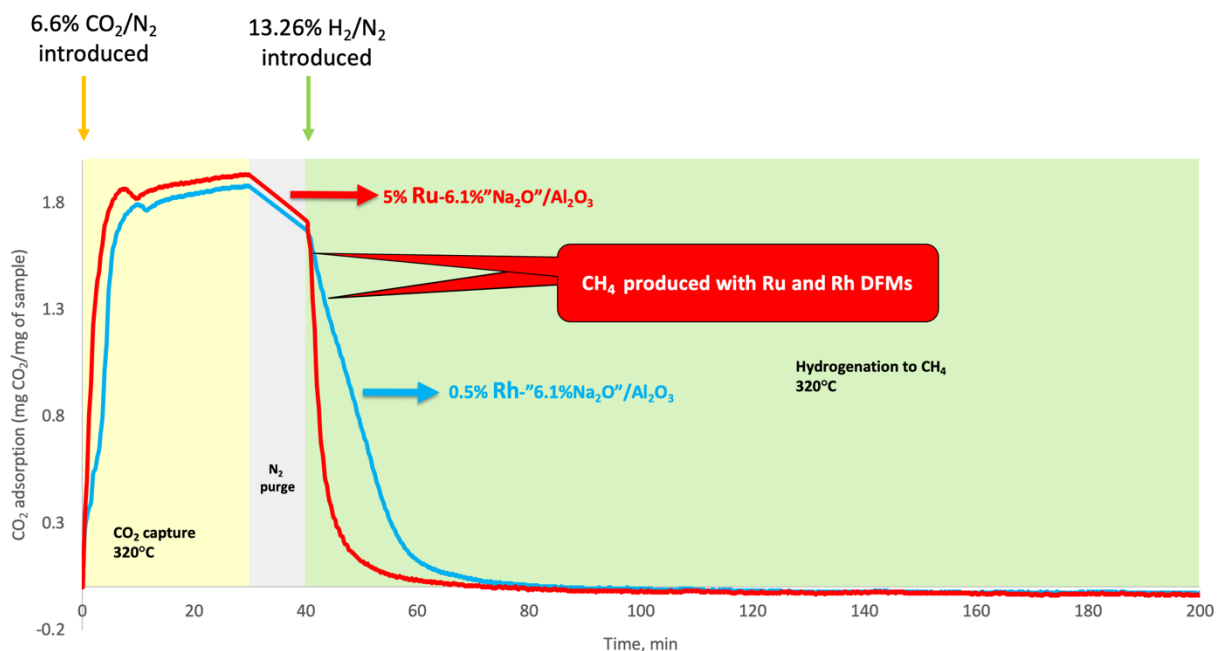

Row	Sample	CO <sub>2</sub> ads (ml)	CH <sub>4</sub> (ml)	CO <sub>2</sub> des (ml)	mmol CO <sub>2</sub> / kg-DFM	mmol CH <sub>4</sub> / kg-DFM	Conv. efficiency (%)	C. Bal. (%)
1	5%Ru, 6.1% "Na <sub>2</sub> O"/Al <sub>2</sub> O <sub>3</sub>	1.56 (±0.07)	1.50 (±0.01)	0	650.7	614.4	96%	96%
2	0.5%Rh, 6.1% "Na <sub>2</sub> O"/Al <sub>2</sub> O <sub>3</sub>	1.50 (±0.06)	1.03 (±0.02)	0	625.7	421.9	69%	69%

### 4.3.2. Thermal Gravimetric Analysis of Ru and Rh supported on 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>.

**Figure 4.5** reports TGA weight changes for 6.1% “Na<sub>2</sub>O” on Al<sub>2</sub>O<sub>3</sub>, in combination with 5%Ru (red), or 0.5%Rh (light blue). Ru and Rh containing-samples have about the same CO<sub>2</sub> adsorbed/kg (~ 380) but different weight loss rates indicative of the hydrogenation rates (Ru =0.1 and Rh = 0.04). **Table 4.3** summarizes all the data. The calculated rates of hydrogenation confirm the fixed bed reactor results that Ru catalyzes the fastest hydrogenation, likely due to the availability of more catalytic sites at a higher loading. We can also confirm that for the Rh DFM all the adsorbed CO<sub>2</sub> is removed (as CH<sub>4</sub> or unreacted CO<sub>2</sub>) upon hydrogen exposure.

The relative amount of CO<sub>2</sub> captured can be expressed as: 0.5%Rh ~ 5%Ru. This phenomenon can be explained by the known promoting effect alkaline metal oxides have on methanation activity [117,118] as well as the enhanced adsorption (multiple CO adsorbed per Rh sites may also apply to CO<sub>2</sub> adsorption) of highly dispersed Rh samples with metal loadings lower than 1% by weight [119]. We have also corroborated these findings with H<sub>2</sub> chemisorption data obtained at room temperature (See **Table 4.8**).

All samples were pre-reduced at 320°C for 6 h with 13.26% H<sub>2</sub>/N<sub>2</sub>. These pretreatment conditions are adequate to reduce Ru and Rh but not for DFMs with NiO since it is only reduced at higher temperatures (>500°C)[84–86]. The 320°C represents the temperature all catalytic metals will experience in repeated cycles during DFM operations. In conclusion, Ru is the preferred catalyst for its price, fast methanation kinetics and its unique redox chemistry that allows it to be rapidly reduced upon hydrogen exposure after being exposed to O<sub>2</sub>-containing simulated flue gas during the CO<sub>2</sub> capture step. Rhodium did not present any advantage over Ru and its high price makes it an unattractive candidate in a real industrial application.

**Figure 4.5.** Different catalysts (5%Ru-red and 0.5%Rh-blue) co dispersed with 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>. CO<sub>2</sub> capture (6.6% CO<sub>2</sub>/N<sub>2</sub> exposure) and hydrogenation of adsorbed CO<sub>2</sub> (upon exposure to 13.26% H<sub>2</sub>/N<sub>2</sub>) thermogravimetric profiles at 320°C and 1 atm.

**Table 4.3.** Thermogravimetric analysis data for Ru and Rh catalytic metals used for DFMs supported on 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>. All samples pre-reduced in situ at 320°C with 13.26% H<sub>2</sub>/N<sub>2</sub> for 6 h.

Row	Sample	CO <sub>2</sub> ads (mmol CO <sub>2</sub> /kg sample)	Rate of hydrogenation (mg/min)	Relative rate of hydrogenation	Time to complete hydrogenation (min)
1	5%Ru, 6.1% "Na <sub>2</sub> O"/Al <sub>2</sub> O <sub>3</sub>	381.4	-0.1031	2.4	36
2	0.5%Rh, 6.1% "Na <sub>2</sub> O"/Al <sub>2</sub> O <sub>3</sub>	382.8	-0.0434	1	48

#### **4.4. Influence of different alkaline adsorbents: “Na<sub>2</sub>O”, CaO, K<sub>2</sub>O and MgO with Ru supported on Al<sub>2</sub>O<sub>3</sub>.**

##### **4.4.1. Fixed bed reactor tests (in Quantachrome) as a preliminary screening tool to quantify the methanation of the adsorbed CO<sub>2</sub> on Ru and various adsorbents (Na<sub>2</sub>O, CaO, K<sub>2</sub>O and MgO) supported on Al<sub>2</sub>O<sub>3</sub>.**

We have chosen 5%Ru as our standard catalyst, based on the data presented in section 4.3. It was therefore used to test different adsorbents in DFM, the results of which are shown in **Figure 4.6**. The methane profile is similar for all samples with a sharp and rapid peak observed. Based on the amount of CO<sub>2</sub> adsorbed (**Table 4.4**) the best adsorbents were Al<sub>2</sub>O<sub>3</sub> dispersed “Na<sub>2</sub>O” and CaO followed by “K<sub>2</sub>O” and MgO. The carbon capture capacity of the calcium oxide system is higher than that of sodium-based adsorbents, but the same amount of methane was generated for both DFMs, so we can only conclude that both adsorbents perform similarly under the studied conditions. **Table 4.4** presents a summary of the data generated for the Al<sub>2</sub>O<sub>3</sub> supported DFMs with Ru/adsorbent variations. For all samples, ~ 91% of adsorbed CO<sub>2</sub> was converted to methane (with a carbon balance ~100%) with CaO and “Na<sub>2</sub>O” showing similar methanation performance.

**Figure 4.6.** Averaged methane signal during hydrogenation step (SATP: 30 ml/min, 10% H<sub>2</sub>/N<sub>2</sub> at 320°C and 1 atm) for 5%Ru on different adsorbents (10%CaO/Al<sub>2</sub>O<sub>3</sub> – green , 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>–red , 7.01% “K<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> – purple and 10%MgO/Al<sub>2</sub>O<sub>3</sub> – light blue) DFMs.

**Table 4.4.** Average methanation capacity of the adsorbed CO<sub>2</sub> on different Dual Function Materials supported on Al<sub>2</sub>O<sub>3</sub>. Standard error of CO<sub>2</sub> adsorbed and CH<sub>4</sub> produced in parenthesis.

Row	Sample	CO <sub>2</sub> ads (ml)	CH <sub>4</sub> (ml)	CO <sub>2</sub> des (ml)	mmol CO <sub>2</sub> / kg-DFM	mmol CH <sub>4</sub> / kg-DFM	Conv. efficiency (%)	C. Bal. (%)
1	5%Ru, 6.1% "Na <sub>2</sub> O"/Al <sub>2</sub> O <sub>3</sub>	1.56 (±0.07)	1.50 (±0.01)	0	650.7	614.4	96%	96%
2	5%Ru, 7.01% "K <sub>2</sub> O"/Al <sub>2</sub> O <sub>3</sub>	1.19 (±0.09)	1.14 (±0.03)	0	496.4	466.9	96%	96%
3	5%Ru, 10% CaO/Al <sub>2</sub> O <sub>3</sub>	1.63 (±0.05)	1.49 (±0.02)	0	681.5	610.3	91%	91%
4	5%Ru, 10% MgO/Al <sub>2</sub> O <sub>3</sub>	0.57 (±0.05)	0.52 (±0.05)	0	237.8	213.0	91%	91%

#### 4.4.2. Thermal Gravimetric Analysis of Ru and various adsorbents (Na<sub>2</sub>O, CaO, K<sub>2</sub>O and MgO) supported on Al<sub>2</sub>O<sub>3</sub>.

Figure 4.7 presents TGA data and Table 4.5 presents a summary comparing different alkaline adsorbents in combination with 5%Ru supported on Al<sub>2</sub>O<sub>3</sub>. The adsorbent with the highest CO<sub>2</sub> capture capacity is 10%CaO with 425.2 mmol of CO<sub>2</sub>/kg of DFM, however, its complete hydrogenation rate is much slower (335 min) than the Ru, “Na<sub>2</sub>O” (36 min) DFM. “K<sub>2</sub>O” also provides a reasonably high CO<sub>2</sub> capacity but its hydrogenation rate is lower (-0.086 mg/min) compared to the superior Ru, “Na<sub>2</sub>O” DFM (-0.103 mg/min). MgO is clearly the most inferior candidate and thus is not considered a viable adsorbent.

Fast hydrogenation can be attributed to weakly chemisorbed CO<sub>2</sub> on CaO (CO<sub>2</sub>-CaO) that can be easily spilled over to Ru sites to be converted to CH<sub>4</sub> while the slow hydrogenation can be attributed to the formation of more strongly bound CO<sub>2</sub>-CaO [16]. Both “Na<sub>2</sub>O” and “K<sub>2</sub>O” adsorbents are very similar in behavior, however, “Na<sub>2</sub>O” has a slightly better CO<sub>2</sub> adsorption capacity and better kinetics for hydrogenation, making it the preferred material. Infrared studies on CO<sub>2</sub> adsorption on “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> have shown that doping Al<sub>2</sub>O<sub>3</sub> with Na promotes the formation of ionic Al-O<sup>-</sup> sites allowing more hydroxyl sites to be accessed for CO<sub>2</sub> adsorption with “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> sorbents forming reversible bidentate and polydentate carbonates [53,54]. On the other hand, MgO showed the least CO<sub>2</sub> adsorption capacity with only 0.1540 mol of CO<sub>2</sub>/kg of sample. Infrared studies have shown that MgO/Al<sub>2</sub>O<sub>3</sub> is a more suitable adsorbent at lower temperatures (<150°C) since the major CO<sub>2</sub>-MgO/Al<sub>2</sub>O<sub>3</sub> bonds (bicarbonate and bidentate carbonates) are decomposed at temperatures as low as 300°C and only the unidentate carbonate sites remain active at temperatures higher than 300°C [120].

**Figure 4.7.** 5%Ru in combination with various adsorbents (10%CaO/Al<sub>2</sub>O<sub>3</sub> – blue, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> – red, 7.01% “K<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> – orange and 10%MgO/Al<sub>2</sub>O<sub>3</sub> – green) DFMs.

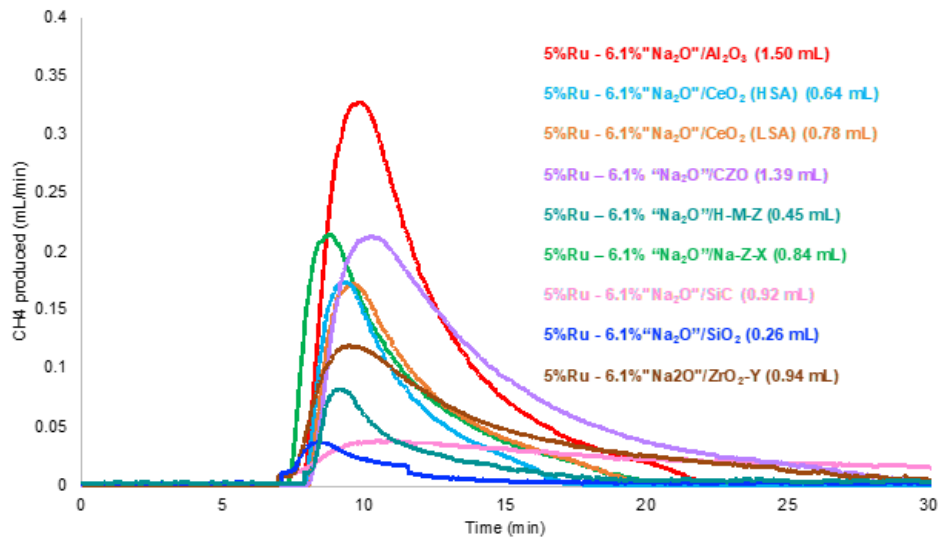

Thermogravimetric profiles at 320°C and 1 atm.

**Table 4.5.** Summary of thermogravimetric profiles of alkaline adsorbents with 5% Ru supported on Al<sub>2</sub>O<sub>3</sub>.

Row	Sample	CO <sub>2</sub> ads (mmol CO <sub>2</sub> / kg sample)	Rate of hydrogenation (mg/min)	Relative rate of hydrogenation	Time to complete hydrogenation (min)
1	5%Ru, 6.1% "Na <sub>2</sub> O"/Al <sub>2</sub> O <sub>3</sub>	381.4	-0.1031	2.74	36
2	5%Ru, 7.01% "K <sub>2</sub> O"/Al <sub>2</sub> O <sub>3</sub>	357.7	-0.0856	2.28	100
3	5%Ru, 10% CaO/Al <sub>2</sub> O <sub>3</sub>	425.2	-0.1300	3.48	335
4	5%Ru, 10% MgO/Al <sub>2</sub> O <sub>3</sub>	154	-0.0376	1	74

#### **4.5. Influence of carriers: 5%Ru, 6.1% “Na<sub>2</sub>O” DFM supported on Al<sub>2</sub>O<sub>3</sub>, CeO<sub>2</sub> (HSA and LSA), CZO, Na Zeolite X (Na-Z-X), H-Mordenite Zeolite (H-M-Z), SiC, SiO<sub>2</sub>, and ZrO<sub>2</sub>-Y.**

Alternative candidate carrier materials (other than Al<sub>2</sub>O<sub>3</sub>) for the DFM application have also been studied. Materials such as CeO<sub>2</sub> (HSA: high surface area and LSA: low surface area), CeO<sub>2</sub>/ZrO<sub>2</sub> (CZO), Na-Zeolite-X (Na-X-Z), H-Mordenite Zeolite (H-M-Z), SiC, SiO<sub>2</sub> and zirconium oxide-yttria stabilized (ZrO<sub>2</sub>-Y) were investigated as possible alternatives to alumina as a DFM carrier. Detailed results can be found in **Figure 4.8**, **Figure 4.9**, **Table 4.6** and **Table 4.7**. Even though CeO<sub>2</sub> and Ceria-Zirconia (CZO) carriers show promise they do not promote the rapid conversion of the adsorbed CO<sub>2</sub> to CH<sub>4</sub> when exposed to hydrogen. They also face the disadvantage that the CeO<sub>2</sub> component (Ce<sup>+4</sup>) can be reduced to Ce<sub>2</sub>O<sub>3</sub> (Ce<sup>+3</sup>) [121,122] which is an undesirable hydrogen consuming reaction.

**Figure 4.8.** CH<sub>4</sub> signal during hydrogenation step for 5%Ru, 6.1% “Na<sub>2</sub>O” supported on different carriers (Al<sub>2</sub>O<sub>3</sub>, CeO<sub>2</sub> (HAS and LSA), CZO, Na-X-Z, H-M-Z, SiC, SiO<sub>2</sub> and ZrO<sub>2</sub>-Y).

**Table 4.6.** Average methanation capacity of the adsorbed CO<sub>2</sub> on 5%Ru, 6.1% “Na<sub>2</sub>O” DFMs supported on different carriers.

## 4.6. Characterization

The fresh DFM samples and the pristine carriers were characterized by BET, the results can be found in **Table 4.9**. The 5%Ru and 0.5%Rh impregnated on 6.1% "Na<sub>2</sub>O"/Al<sub>2</sub>O<sub>3</sub> samples were also characterized via H<sub>2</sub> chemisorption at room temperature and the results presented in **Table 4.8** that show that the 0.5%Rh containing sample has a dispersion of 149.2% with an average crystallite size of 0.246 nm which are significantly smaller than the 5%Ru containing samples with a dispersion of 3.9% and an average crystallite size of 13.9 nm [18]. This is in accordance to Drault et al. reporting a highly dispersed Rh catalyst with a stoichiometry of H atom adsorption/metal atom higher than 1 [106].

**Table 4.8.** Ru and Rh dispersion and average crystallite size derived from H<sub>2</sub> chemisorption at room temperature (25°C) for fresh DFM samples. \*Obtained from Wang, et al. [18].

## **Chapter 5: Precious metal/Ni combinations as viable DFM catalysts in O<sub>2</sub>-containing flue gas due to enhanced nickel oxide reducibility**

*The results presented in this chapter have been published in M.A. Arellano-Treviño, N. Kanani, C.W. Jeong-Potter, R.J. Farrauto, Bimetallic catalysts for CO<sub>2</sub> capture and hydrogenation at simulated flue gas conditions, Chem. Eng. J. 375 (2019) 121953.*

In the previous chapter we demonstrated that Ni DFMs oxidize during O<sub>2</sub>-containing CO<sub>2</sub> capture conditions and are not able to reduce to catalytically active Ni<sup>0</sup> species when exposed to hydrogen at 320°C. In this chapter we report that small amounts of precious metal ( $\leq 1\%$  Pt, Pd or Ru) enhance the reduction and activation of Ni-containing DFMs towards methanation even after O<sub>2</sub> exposure in a flue gas. This was corroborated with thermal gravimetric analysis (TGA). In this study we attempt to replace some of the Ru in the DFM with less expensive Ni and demonstrate the advantages and disadvantages of this replacement. The PGM-doped Ni catalysts were tested at simulated flue gas conditions (O<sub>2</sub> and H<sub>2</sub>O present) for CO<sub>2</sub> capture in a packed bed reactor.

### **5.1. Thermal Gravimetric Analysis: Effect of Platinum Group Metal (PGM) doping on NiO<sub>x</sub> redox chemistry**

TGA tests were conducted to observe the reduction behavior of the PGM-doped DFM at 320°C compared to 10%Ni/Al<sub>2</sub>O<sub>3</sub> reference sample (green). The alkaline adsorbent was excluded to clearly observe the reduction of NiO promoted by PGMs. Removing the adsorbent provides a clearer depiction of the reduction behavior of the Ni DFMs promoted by the PGMs [53,54].

Samples of 1%Pt/Al<sub>2</sub>O<sub>3</sub> (dotted red) and 1%Ru/Al<sub>2</sub>O<sub>3</sub> (dotted blue) were also examined for a baseline comparison. **Figure 5.1** presents the results.

The 10% Ni/Al<sub>2</sub>O<sub>3</sub> (equivalent to 12.4%NiO/Al<sub>2</sub>O<sub>3</sub>) sample shows a small mass loss during the 5 hours of reduction at 320°C, equivalent to about 8% reduction. There is, however, rapid and significant mass loss observed in the 1%Pt, 10%Ni/Al<sub>2</sub>O<sub>3</sub> (red) and 1%Ru, 10%Ni/Al<sub>2</sub>O<sub>3</sub> (blue) DFM samples. The mass loss observed for the 1%Pt, 10%Ni/Al<sub>2</sub>O<sub>3</sub> and 1%Ru, 10%Ni/Al<sub>2</sub>O<sub>3</sub> samples include the reduction of PtO<sub>x</sub> and RuO<sub>x</sub>, which can be seen in the mass loss profiles of 1%Pt/Al<sub>2</sub>O<sub>3</sub> (dotted red) and 1%Ru/Al<sub>2</sub>O<sub>3</sub> (dotted blue), respectively; however, the additional and much more significant mass loss is attributed to reduction of NiO<sub>x</sub> to active metallic Ni. This is clear evidence that the reduction of NiO<sub>x</sub> is enhanced by the presence of PGMs such as Pt or Ru. In fact, the mass loss seen for the 1%Pt, 10%Ni/Al<sub>2</sub>O<sub>3</sub> sample is equivalent the full reduction of the PtO<sub>x</sub> species and 50.3% reduction of the NiO<sub>x</sub> species, which explains why this bimetallic pair produced methane in the packed powder reactor (see section 5.2.2.) while Pt alone did not [21]. The mass loss seen for the 1%Ru, 10%Ni/Al<sub>2</sub>O<sub>3</sub> sample is equivalent to the full reduction of the RuO<sub>x</sub> species and 70.3% reduction of the NiO<sub>x</sub> species present in the fresh sample, again explaining the enhanced adsorption and conversion activity of this DFM as will be discussed in the following section.

**Figure 5.1.** Thermal gravimetric analysis results for 30.0 mg samples of 10%Ni/Al<sub>2</sub>O<sub>3</sub> (green), 1%Pt/Al<sub>2</sub>O<sub>3</sub> (red), 1%Ru/Al<sub>2</sub>O<sub>3</sub> (blue), 1%Pt, 10%Ni/Al<sub>2</sub>O<sub>3</sub> (red), 1%Ru, 10%Ni/Al<sub>2</sub>O<sub>3</sub> (blue) reduced in 13.26% H<sub>2</sub>/N<sub>2</sub> for 5 hours at 320°C. It must be pointed out that supported Ni is present initially as the oxide and partially reduced during the reduction. Figure generated by

Chae Jeong-Potter.

## 5.2. Packed bed reactor tests with simulated flue gas conditions

### 5.2.1. PGM (Pt, Pd or Ru) doping ( $\leq 1\%$ ) to 10%Ni, 6.1% “Na<sub>2</sub>O” /Al<sub>2</sub>O<sub>3</sub> DFM

**Figure 5.2A** presents the detail of the 3 cycles of CO<sub>2</sub> adsorption (with O<sub>2</sub> and H<sub>2</sub>O present) and CH<sub>4</sub> produced along with CO<sub>2</sub> desorbed (CO<sub>2</sub> desorbed = CO<sub>2</sub> desorbed from N<sub>2</sub> purge + CO<sub>2</sub> desorbed during hydrogenation). In all results presented in section 5.2 and 5.3, the amount of CO<sub>2</sub> desorbed during the hydrogenation represented less than 5% of the total with most of the

contribution coming from the CO<sub>2</sub> desorbed during the N<sub>2</sub> purge. This is an experimental artifact of the reactor dead volume. **Table 5.1** summarizes the detail of each cycle as well as the average and provides conversion of CO<sub>2</sub> to CH<sub>4</sub> (calculated with equation 5.1). The conversion to CH<sub>4</sub> is calculated based on CO<sub>2</sub> retained on the sample after the purge.

$$Conversion = \frac{CH_4 \text{ produced}}{CO_2 \text{ adsorbed} - CO_2 \text{ desorbed during } N_2 \text{ purge}} \times 100\% \quad (5.1)$$

In **Figure 5.2A** we have included some of the previous results study where it was demonstrated that 10% Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> adsorbs very little CO<sub>2</sub> at simulated flue gas conditions (average of 0.11 mmol of CO<sub>2</sub> adsorbed) and produces no CH<sub>4</sub> when exposed to hydrogen [123]. These results are included as a reference to be compared to the PGM-promoted Ni samples which highlight the impact of a small loading of PGM (like Pt and Ru) on Ni-containing DFMs. It is clear from **Figure 5.1**, that one of the benefits of doping Ni with small amounts of precious metals is the lowering of the temperature for NiO<sub>x</sub> reduction. For the 0.1% Pt, Ni-containing DFMs, CO<sub>2</sub> capture (0.39 mmol of average CO<sub>2</sub> adsorbed) was due mainly to the “Na<sub>2</sub>O” present, which produced 0.16 mmol of CH<sub>4</sub> due to the enhanced reduction promoted by Pt. It should be noted that Pt alone does not produce CH<sub>4</sub> [21]. At a Pt loading of 1%wt. methanation activity is furtherly enhanced due to increased reduction of Ni (0.25 mmol of average CH<sub>4</sub> produced) with a slightly lower average CO<sub>2</sub> capture capacity (0.35 mmol of CO<sub>2</sub>/g) attributed to less “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> sites available at the expense of higher metal loading. By far, 0.1%Ru shows the greatest promotional effect for the reduction of NiO<sub>x</sub> with an average of 0.5 mmol of CO<sub>2</sub> adsorbed and 0.32 mmol of methane produced.

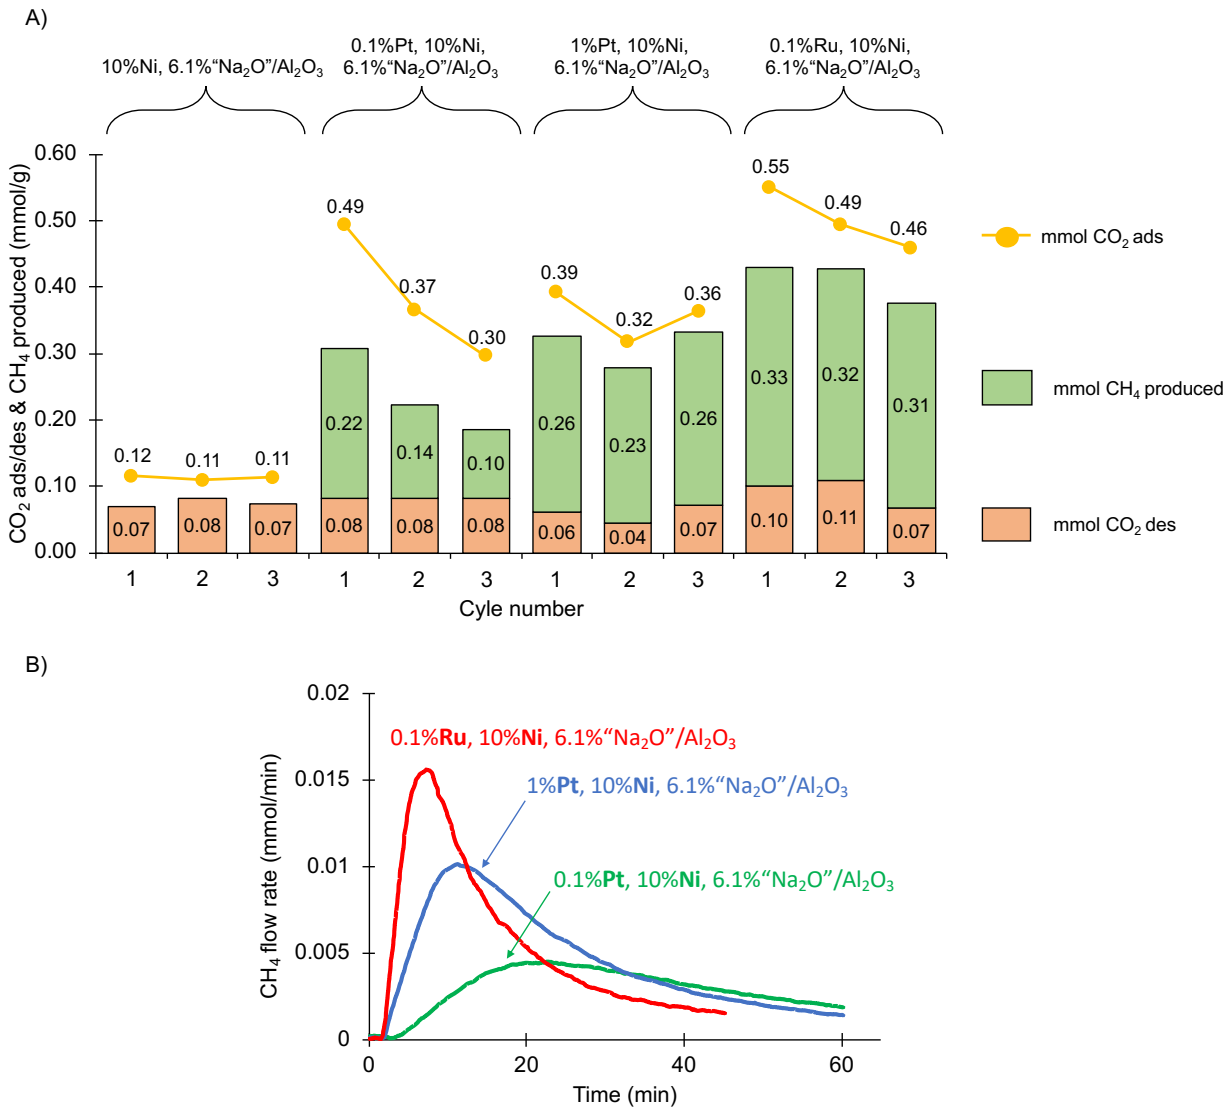

The conversion and carbon balances can be found in **Table 5.1**. The poor carbon balance values (for NiO<sub>x</sub> only, Pt, Ni and 0.1%Ru, Ni) can be explained by the low rate of methane formation presented in **Figure 5.2B**. Both Pt samples show slow rates of methane formation when compared to the 0.1%Ru, Ni system that presents the sharpest peak for CH<sub>4</sub> generation. However, the rates of methanation are not fast enough to hydrogenate all the adsorbed CO<sub>2</sub> (see rates in **Figure 5.3B** for comparison) resulting in unreacted adsorbed CO<sub>2</sub> remaining on the surface of the DFMs.

We can conclude that for the samples presented in **Figure 5.2B**, the CO<sub>2</sub> on the adsorbent sites are not fully desorbed at the end of the hydrogenation step and therefore the adsorbant is not active for CO<sub>2</sub> capture in the subsequent cycles. Overall, the 0.1%Ru, 10%Ni, 6,1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> sample has the highest average CO<sub>2</sub> capture capacity and methanation because Ru has the highest exothermic heat rate, enhancing CO<sub>2</sub> spillover (desorption) making more CO<sub>2</sub> adsorbent sites available for subsequent adsorption. Pt has a lower methanation and heat rate and therefore is not as effective as Ru. **Table 5.1** presents the detail of the cycles and a declining trend of CO<sub>2</sub> capture capacity can be appreciated for all the Pt-Ni systems and the 0.1%Ru-Ni system which corroborates this hypothesis.

*In-situ* infrared studies performed on the surface of Ru, “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> DFMs [17] indicate that CO<sub>2</sub> adsorption occurs mainly in Al—O—Na<sup>+</sup> adsorbent sites both as bicarbonates and bidentate carbonates while catalyst sites are oxidized in the presence of O<sub>2</sub>-containing flue gas. Upon the addition of hydrogen, the RuO<sub>x</sub> sites are rapidly reduced to metallic Ru. The CO<sub>2</sub> spills over to the Ru sites to be converted to CH<sub>4</sub> and water via formate species in an exothermic reaction that drives the spillover of more CO<sub>2</sub> to catalyst sites. In the case of PGM-promoted Ni DFMs we can speculate that PtO<sub>x</sub> and RuO<sub>x</sub> are rapidly reduced to their metallic state and aid the reduction

of NiO<sub>x</sub> at lower temperatures by splitting hydrogen atoms to readily reduce NiO<sub>x</sub> [106,107]. In the case of Ru, Ni DFMs, CO<sub>2</sub> would spill over to both Ni and Ru sites to be converted to CH<sub>4</sub> and water. In the case of Pt-Ni DFMs only Ni would methanate CO<sub>2</sub> since Pt is not active for this reaction [21].

The activity of the 0.1%Pd, Ni sample is also included in **Table 5.1** for reference. Pd-containing samples took longer times to complete hydrogenation (~90 min) and the rate of methane formation was the slowest of all the PGM-Ni systems. In addition to generally low CH<sub>4</sub> production, Pt-containing DFMs showed lower hydrogenation rates (as shown in **Figure 5.2B**). Neither high nor low Pt or Pd loading samples were very encouraging and because of their high cost and lower methanation rates, no priority for this application will be given relative to the superior performance of the Ru, Ni combination.

**Figure 5.2.** The positive influence of doping PGM (Ru and Pt) to promote 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> for use as a DFM when exposed to simulated flue gas. A) CO<sub>2</sub> adsorption, desorption and CH<sub>4</sub> produced over 3 cycles. B) Averaged CH<sub>4</sub> production peaks recorded during hydrogenation step. Operation conditions presented in **Figure 3.1**.

### 5.2.2. Effect of Ru doped Ni catalysts in CO<sub>2</sub> capture capacity and methanation rate of DFM

A higher loading of Ru was furtherly studied (1%Ru, 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>) both in the presence and absence of Ni in the DFMs composition. **Figure 5.3A** presents the results over 3 cycles of CO<sub>2</sub> capture + hydrogenation. 1%Ru, 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> appears to be the most promising combination having the highest CO<sub>2</sub> adsorption (average of 0.52 mmol of CO<sub>2</sub> ads) and average CH<sub>4</sub> production of 0.38 mmol for a hydrogenation duration of 30 mins. The 0.1%Ru, 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> also showed satisfactory results by producing an average of 0.32 mmol of CH<sub>4</sub> in 45 mins.

The Ru impregnated sample 1% Ru, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> showed the fastest methanation profile indicated by the sharp methane production rate (presented in **Figure 5.3B** as shown more clearly in the in insert). **Table 5.2** presents the slopes of the initial methanation rate where we confirm that the slope of the methane peak for this sample (4.4 ml/min<sup>2</sup>) is the steepest and ~176 times faster than the slowest sample (0.1%Ru, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>) used as a reference rate 1. However, its performance in terms of average CO<sub>2</sub> adsorption (0.41 mmol of CO<sub>2</sub> ads) and CH<sub>4</sub> produced (0.31 mmol of CH<sub>4</sub>) were lower compared to the 1%Ru-Ni system. The presence of 10% Ni with 1% Ru, showed a lower methanation rate (1.8 ml/min<sup>2</sup> from **Table 5.2**) with a broader peak shifted to longer times due to the lower methanation activity of Ni compared to Ru only. However, both the CO<sub>2</sub> adsorption and CH<sub>4</sub> produced were significantly higher than the Ni free system (see **Table 5.1**).

At lower Ru loadings (0.1%) the benefit of having Ni becomes even more evident. In **Figure 5.3B**, 0.1%Ru with no Ni (green) shows the lowest methanation rate (0.025 ml/min<sup>2</sup> from **Table 5.2**) while 0.1%Ru with 10%Ni (red) shows a 4 times higher rate of methane production (0.11 ml/min<sup>2</sup> from **Table 5.2**) . This is additional proof that Ni is contributing to methanation. It

is also appreciated from **Figure 5.3A** that in average, all the samples containing Ni in the Ru-Ni system adsorb more CO<sub>2</sub> and produce more methane under similar conditions compared to the Ni free Ru DFMs. For the 0.1%Ru-containing samples, it can be appreciated in **Table 5.1** that both samples have similar CO<sub>2</sub> capture capacities in cycle #1 and the 0.1%Ru, 10%Ni sample, having a better methanation and heat rate compared to the Ni-free sample was able to regenerate more CO<sub>2</sub> adsorbent sites after each cycle, which would explain its higher average CO<sub>2</sub> capture capacity and methane produced. However, for the sample with 1%Ru, 10%Ni, the CO<sub>2</sub> capture capacity is higher than the Ni-free sample starting with cycle #1. We hypothesize that the reason for the higher CO<sub>2</sub> capture capacity is likely explained by CO<sub>2</sub> adsorption on passivated NiO<sub>x</sub> sites [100,124].

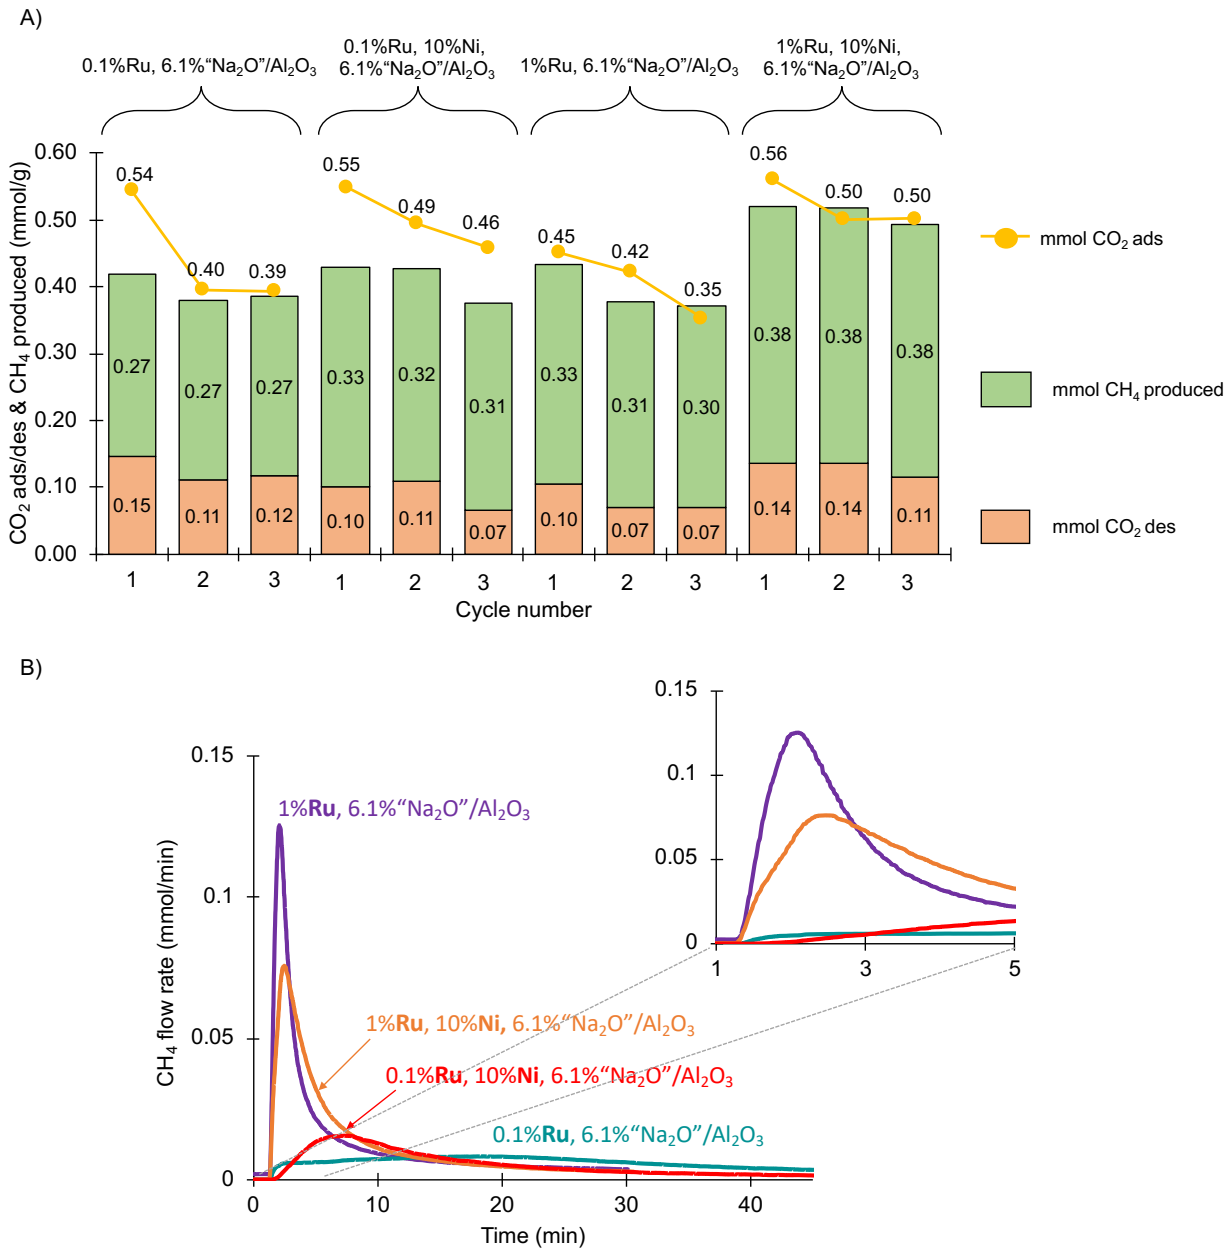

The 0.1%Ru, 10%Ni sample did not perform as well as 1%Ru, 10%Ni which is likely due to the low Ru loading that results in a slower rate of methanation. Nonetheless, 0.1%Ru, 10%Ni (and other Ru/Ni ratios) remains a promising alternative when considering economic cost trade-offs. With further material optimization and reactor design < 1% Ru loadings may be viable.

The Ru-containing Ni DFMs had average material balances close to or greater than 90% except for 0.1%Ru, 10%Ni at 82%. Conversion was close to or above 80% for the Ru DFMs (see **Table 5.1**). Overall, at higher Ru loadings, Ru-only samples showed a faster and sharper CH<sub>4</sub> formation peak. However, the Ru-Ni systems outperformed the others in terms of enhanced CO<sub>2</sub> adsorption (all Ni-containing samples adsorbed more CO<sub>2</sub>) but more extensive aging (>20 cycles) is necessary to ensure stability.

It is also important to mention that in all O<sub>2</sub>-containing CO<sub>2</sub> adsorption steps there was a small temperature rise (~10°C) observed in the catalyst bed in the first 5 seconds that rapidly stabilized. This temperature increase is associated with two exothermic events: adsorption of CO<sub>2</sub>

and oxidation of metallic sites. It is suspected that oxidation of nickel is the main contributor to the temperature rise. For the 1%Ru, 10%Ni sample this exotherm was more pronounced ( $\sim 80^{\circ}\text{C}$ ) as more Ni sites (from the previous hydrogenation step) were available for oxidation. This can become a more important issue as we scale up Ni-containing DFMs since it would be necessary to prevent dangerous hot spots in the packed bed associated with rapid Ni oxidation.

**Figure 5.3.** Effect of Ni on Ru-containing DFMs. A) CO<sub>2</sub> adsorption, desorption and CH<sub>4</sub> produced over 3 cycles for Ni-containing and Ni-absent DFMs with low (0.1%) and high (1%) Ru loading. B) Averaged CH<sub>4</sub> production rates recorded during the hydrogenation step. Same operational conditions as in **Figure 3.1**.

**Table 5.2.** Comparison of the slopes of the initial methanation rate peaks presented in **Figure 5.3B**. The slopes were calculated within the first 3 min of methanation. The relative rate is calculated by normalizing the slopes with the slowest rate stated as a reference of 1.

Sample	Initial methanation rate slope (ml/min <sup>2</sup> )	Relative rate
0.1% Ru, 6.1% "Na <sub>2</sub> O"/Al <sub>2</sub> O <sub>3</sub>	0.025	1
0.1% Ru, 10%Ni, 6.1% "Na <sub>2</sub> O"/Al <sub>2</sub> O <sub>3</sub>	0.11	4
1% Ru, 10%Ni, 6.1% "Na <sub>2</sub> O"/Al <sub>2</sub> O <sub>3</sub>	1.8	72
1% Ru, 6.1% "Na <sub>2</sub> O"/Al <sub>2</sub> O <sub>3</sub>	4.4	176

### 5.3. Cyclic aging studies in O<sub>2</sub> and H<sub>2</sub>O-containing simulated flue gas for the capture step using Ru doped Ni DFM

1% Ru, 10% Ni, 6.1% "Na<sub>2</sub>O"/Al<sub>2</sub>O<sub>3</sub> DFM was chosen for extended aging studies based on its good CO<sub>2</sub> capture capacity and CH<sub>4</sub> production. **Figure 5.4** shows the cyclic aging performed with 1 g of powdered sample. The results are presented as an average for every 4 cycles. The sample was aged for 20 cycles showing a stable performance. Both conversion and mass balances are close to 100% in all cycles with the performance improving slightly after the 4<sup>th</sup> cycle. **Table 5.3** presents the detailed information on the aging studies.

**Figure 5.4.** 20 cycle tests under simulated flue gas conditions on 1 g of powdered 1%Ru, 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> DFM. Operation conditions: 20 min of CO<sub>2</sub> adsorption (4000 h<sup>-1</sup>: 7.5%CO<sub>2</sub>, 4.5% O<sub>2</sub>, 15% H<sub>2</sub>O balance N<sub>2</sub>). Hydrogenation of adsorbed CO<sub>2</sub> (8000 h<sup>-1</sup>: 15% H<sub>2</sub>/N<sub>2</sub>) for 30 min. N<sub>2</sub> purge (6000 h<sup>-1</sup>) before and after CO<sub>2</sub> adsorption and methanation, for 4 min. All adsorption and hydrogenation cycles performed at 320°C and 1 atm.

We propose the following reactions during DFM process (all steps at 320°C):

1. Capture step in O<sub>2</sub>-containing flue gas: Both Ru and Ni are partially oxidized, CO<sub>2</sub> adsorbs on “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> and to a limited extent on NiO<sub>x</sub> sites:

2. Hydrogenation step. Reduction of Ru and Ni to their active metallic state. CO<sub>2</sub> spill over from “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> to Ru and Ni for methanation.

PGM promoted Ni-containing DFM is a promising technology for capturing and catalytically converting CO<sub>2</sub> to synthetic fuel in situ. We believe a scale-up of the process to 1 kg of DFM with detailed economics is worthy of pilot studies for possible future commercialization.

**Table 5.3.** Aging studies of 1 g of powder 1%Ru, 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> DFM. Results averaged every 4 cycles for a total of 20 cycles. Operational conditions presented in **Figure 5.4**.

Conversion calculated with equation 5.1. Standard error of CO<sub>2</sub> adsorbed/desorbed and CH<sub>4</sub> produced in parenthesis.

Cycle #	mmol CO <sub>2</sub> adsorbed/g	mmol CH <sub>4</sub> produced/g	mmol CO <sub>2</sub> desorbed/g	Conv (%)	Carbon balance (%)
1 - 4	0.56 (±3x10 <sup>-2</sup> )	0.39 (±2x10 <sup>-3</sup> )	0.13 (±2x10 <sup>-3</sup> )	90	92
5 - 8	0.52 (±2x10 <sup>-3</sup> )	0.41 (±1x10 <sup>-2</sup> )	0.13 (±1x10 <sup>-2</sup> )	106	104

## 5.4. Characterization

### 5.4.1. BET and H<sub>2</sub> chemisorption

The fresh and aged samples were characterized by BET and H<sub>2</sub> chemisorption (at 100°C) and the results presented in **Table 5.4**. The BET shows that the aged DFM had a slightly higher BET surface area after the 20 cycles but most importantly no sign of carrier sintering. A change in the Ru and Ni metal sites was evident from the H<sub>2</sub> chemisorption of the fresh (0.03 mmol H<sub>2</sub>/g) vs. the spent sample (0.05 mmol H<sub>2</sub>/g) consistent with the stability of the system after 20 cycles of aging. The results are consistent with previously published performance of the 5%Ru, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> system that demonstrates stable performance of the tableted DFM after 50 cycles in simulated flue gas conditions [18].

**Table 5.4.** BET surface area and metal dispersion together with average catalyst crystallite size derived from H<sub>2</sub> chemisorption at 100°C for both fresh and aged DFMs.

Sample	BET (m <sup>2</sup> /g)	mmol H <sub>2</sub> adsorbed/g
1%Ru, 10%Ni, 6.1% “Na <sub>2</sub> O”/Al <sub>2</sub> O <sub>3</sub> (fresh)	86	0.03
1%Ru, 10%Ni, 6.1% “Na <sub>2</sub> O”/Al <sub>2</sub> O <sub>3</sub> (aged 20 cycles)	99	0.05

### 5.4.2. XRD

X-ray diffraction patterns for fresh and aged 1%Ru, 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> DFMs are shown in **Figure 5.5**, the patterns of 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>, 1%Ru, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> and  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> were included for comparison. The representative peaks at 2 $\theta$  of 39.5°, 46° and 67°

associated with the carrier  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> (111),  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> (002) and  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> (022) respectively were retained for all samples.

In the fresh Ru-doped Ni DFM and 1%Ru, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O (reference) patterns, peaks located at  $2\theta$  of 27.7°, 34.7° and 53.7° are associated with RuO<sub>2</sub> (110), RuO<sub>2</sub> (011) and RuO<sub>2</sub> (121) respectively. RuO<sub>2</sub> species are formed mainly in the calcination step in air during the material preparation, it being the most stable oxidation state. Of the three identified peaks, two vanished in the aged bimetallic DFM pattern indicating only a minimal amount of RuO<sub>2</sub> is retained after exposure to H<sub>2</sub> for sufficient time. We suspect that some of the metallic Ru species are oxidized when in contact with air at room temperature.

Similarly, in the fresh Ru-doped Ni sample and 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O (reference) patterns, peaks located at  $2\theta$  of 37°, 42.9°, 62.4°, 74.8° and 78.8° are associated with NiO (111), NiO (002), NiO (022), NiO (113) and NiO (222), which are formed during the calcination step of the material synthesis process. Of the 5 NiO peaks identified, none were visible on the aged bimetallic sample. We hypothesize that the NiO crystals developed an (XRD invisible) amorphous pattern due to the redispersion (significant reduction in size) of the nickel sites after the extensive oxidation/reduction cycles. Also, there is evidence that some of the NiO was completely reduced to metallic Ni when exposed to hydrogen with the help of the promoting effect of Ru doping. We speculate that the broad peak shown in the aged Ru-doped Ni DFM pattern at  $2\theta$  of 44.5° corresponds to a mixture of Ru (011 at 44°) and Ni (111 at 44.7°) indicating the presence of both metallic Ru and Ni.

The decomposition of supported Na<sub>2</sub>CO<sub>3</sub> on Al<sub>2</sub>O<sub>3</sub> is speculated to generate 6.1%“Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>. Previous imaging from STEM-EDX mapping shows a very well dispersed Na adsorbent [18] so we conclude the corresponding X-ray diffraction pattern is amorphous.

Moreover, characteristic  $\text{Na}_2\text{O}$  peaks at  $2\theta$  of  $45.8^\circ$  and  $66.8^\circ$  corresponding to  $\text{Na}_2\text{O}$  (022) and  $\text{Na}_2\text{O}$  (004) are masked by  $\gamma\text{-Al}_2\text{O}_3$  (002) and  $\gamma\text{-Al}_2\text{O}_3$  (022) peaks respectively. However, a peak at  $2\theta$  of  $32^\circ$  associated with  $\text{Na}_2\text{O}$  (002) was observed in the aged Ru-doped Ni DFM and the fresh reference materials, yet it was not identified in the fresh Ru-doped Ni DFM.

**Figure 5.5.** X-ray diffraction patterns of fresh (red) and aged (black) 1%Ru, 10%Ni, 6.1% "Na<sub>2</sub>O"/Al<sub>2</sub>O<sub>3</sub> samples. 10%Ni, 6.1% "Na<sub>2</sub>O"/Al<sub>2</sub>O<sub>3</sub> (green), 1%Ru, 6.1% "Na<sub>2</sub>O"/Al<sub>2</sub>O<sub>3</sub> (blue) and  $\gamma\text{-Al}_2\text{O}_3$  (yellow) patterns included for comparison.

### 5.4.3. TEM-EDS

A detailed analysis of the microstructure and composition of both fresh and aged 1%Ru, 10%Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> surfaces were obtained via transmission electron microscopy (TEM). In order to differentiate the various elements present we used the scanning transmission electron microscope (STEM) energy-dispersive X-ray spectroscopy (EDS) mapping. **Figure 5.6A** presents the image taken from the fresh sample with the mapping of the Ru, Ni and Na species. We can see that the Ru-rich cluster (encircled in light blue) and the Ni-rich clusters (encircled in pink) are of similar size of about 58 nm and 53 nm respectively.

In **Figure 5.6B** we can see the aged sample’s surface with its respective EDS mapping. The Ni-rich areas appear to be more uniformly scattered throughout the sample with smaller clusters (when compared to their fresh counterpart) encircled in pink. Ru-rich clusters are similarly smaller (encircled in light blue). Both Ru and Ni clusters in the aged sample are of similar size of approximately 19 nm. The Ru and Ni cluster size decrease trend corroborates the H<sub>2</sub> chemisorption results presented in **Table 5.4** that show an increase in H<sub>2</sub> uptake that evidences some redispersion of the Ru and Ni sites after 20 oxidation/reduction cycles.

In neither the fresh nor aged sample we could see evidence of metal alloy formation. All other elemental components of the sample (Na, Al, O) show a very well dispersed EDS mapping for both fresh and aged samples.

**Figure 5.6.** STEM-EDS Mapping for A) the fresh and B) aged Ru-doped Ni DFM samples. Areas encircled in light blue are identified as a Ru-rich clusters and areas encircled in pink are identified as Ni-rich clusters with their respective estimated sizes.

## Chapter 6: Conclusions and future work

### 6.1. Thesis conclusion

Several alkaline adsorbents (“Na<sub>2</sub>O”, CaO, “K<sub>2</sub>O” and MgO) were dispersed on Al<sub>2</sub>O<sub>3</sub> and tested in combination with 5%Ru. Dispersed “Na<sub>2</sub>O” and CaO adsorbents showed the best adsorption capacity but “Na<sub>2</sub>O” in concert with Ru, showed the fastest complete conversion of the adsorbed CO<sub>2</sub> towards CH<sub>4</sub> making it the preferred combination. Even though several carriers show a high CO<sub>2</sub> capture capacity, they suffer from poor rates of hydrogenation to CH<sub>4</sub>. Al<sub>2</sub>O<sub>3</sub> appears to be a preferred DFM carrier when used to support Ru and “Na<sub>2</sub>O”.

Ruthenium, Rhodium and Nickel incorporated into the DFM (in combination with 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub>) have been evaluated in simulated O<sub>2</sub> and steam-containing flue gas for hydrogenation rate and quantity of methane production in the DFM process at 320°C and atmospheric pressure. 5% Ruthenium showed the fastest rate with the shortest time for complete methanation. Rhodium was second best for methanation, but its higher cost requires a reduction in metal loading that leads to fewer catalytic sites and lower reaction rates relative to Ru. The Nickel-containing catalysts need to be pre-treated at 650°C with 15%H<sub>2</sub> to reduce NiO to active Ni<sup>0</sup>. This produces a very active catalyst, however, methanation could not be achieved at 320°C after O<sub>2</sub> exposure in the capture step, consistent with the capture and conversion steps of DFM, making it unsuitable for the DFM application.

The presence of 1%wt. of Pt or Ru enhance the reduction of NiO<sub>x</sub> to metallic Ni (at 320°C) by 50% and 70%, respectively allowing methanation to occur with Ru being the most effective. 1% Ru, 10Ni, 6.1% “Na<sub>2</sub>O”/Al<sub>2</sub>O<sub>3</sub> DFM showed the best results in terms of CO<sub>2</sub> capture (0.52 mmol CO<sub>2</sub>/g) and CH<sub>4</sub> produced (0.38 mmol CH<sub>4</sub>/g) with proven cyclic stability over 20 cycles.

The presence of Ni in the 1%Ru-containing DFM enhances CO<sub>2</sub> adsorption (27% higher) but decreases the rate of methanation upon the addition of H<sub>2</sub> (60% slower).

Characterization shows a redispersion of the Ru and Ni catalyst sites as evidenced by higher H<sub>2</sub> uptake per gram of sample and smaller particle size in the aged Ru-doped Ni DFM compared to the fresh sample. XRD patterns confirm a disappearance of the NiO and RuO<sub>x</sub> peaks and the appearance of Ru<sup>0</sup> and Ni<sup>0</sup> characteristic peaks in the aged sample due to H<sub>2</sub> exposure during methanation. The possibility of replacing some Ru with Ni is worthy of additional studies for possible additional cost reduction.

## **6.2. Future work**

This thesis successfully demonstrated the feasibility of reducing the amount of precious metal loading in our DFMs from 5% to 1% by replacing some Ru with Ni, a more economical base metal catalyst, without sacrificing their CO<sub>2</sub> capture capacity or methane production. The further reduction of the precious metal loading is of vital importance to make DFM more economically attractive. However, there are still many areas of research opportunity to extensively demonstrate the scalability, flexibility and sustainability of DFM technology.

### **6.2.1. Ru-doped Ni DFM optimization, scalability and further characterization**

As discussed in chapter 5, we studied low (0.1%) and high (1%) Ru loadings in concert with 10%Ni as a candidate catalyst system for DFM. Both Ru and Ni loading studies need to be carried out to maximize CO<sub>2</sub> capture capacity and methane production rates.

Further characterization of the Ru-doped Ni system is also needed. *In-situ* FTIR/DRIFTS studies can help elucidate the CO<sub>2</sub> capture mechanism by identifying the intermediate species

involved that permit an enhanced capture capacity of the bimetallic DFM. It was shown that NiO formed during the capture step can enhance the CO<sub>2</sub> capture, by approx. 20%, and thus should be explored for possible reduction of Ru loadings lower than 1%. The intermediate species involved in the mechanism of NiO reduction at lower temperatures in the presence of Ru as well as the CO<sub>2</sub> spillover to active catalytic sites with the intermediate species for CO<sub>2</sub> methanation on the catalyst system could be studied with particular interest. It would also be of great value to study the oxidation state of the metal and any adsorbent, carrier interaction with the bimetallic DFM with the help of XPS.

There is also the challenge of scaling the Ru-doped Ni DFM from powder to pellet or tablet form. In past studies, our research group has tested different preparation methods to produce a uniformly distributed Ru and “Na<sub>2</sub>O” tablet. It would now be necessary to uniformly incorporate Ni in the tablet composition with special attention to the order of impregnation of the species, the precursors utilized, as well as the calcination and pre-reduction methodology. Different alumina tablet geometries (tables vs. hollow extrudates) can also be studied in order to enhance pore-diffusion limitations that impact catalyst and/or adsorbent effectiveness.

### **6.2.2. Assessment of DFM performance for alternative CO<sub>2</sub> sources and products**

To date, DFM has been studied mainly at simulated natural gas power plant flue gas conditions. It might be relevant to study the flexibility of our technology for other applications such as CO<sub>2</sub> streams from flue gas from cement plants and breweries or highly diluted sources such as direct air capture of CO<sub>2</sub> from atmospheric air. The goal is to prove the versatility of DFM to capture CO<sub>2</sub> from a wide spectrum of CO<sub>2</sub> concentrations and catalytic conversion to higher-value products like fuels.

The challenge of this task relies on finding the optimum operation conditions to maximize the CO<sub>2</sub> capture capacity while ensuring high conversion rates of DFM. Concentrated CO<sub>2</sub> streams offer the advantage of enhanced CO<sub>2</sub> capture kinetics, but the space velocity of the CO<sub>2</sub> capture step has to be adjusted to match the kinetics of conversion to ensure a continuous process. On the other hand, dilute CO<sub>2</sub> sources like simulated direct air capture conditions are more challenging. Since the kinetics for CO<sub>2</sub> capture are slower, mass transfer effects occur at low CO<sub>2</sub> concentrations. New reactor designs for enhanced turbulence will likely require a compressor system for the feed stream to drive the capture step. Air also contains a large percentage of oxygen (~21%) which can oxidize our catalyst system in a more permanent way than the current 4.5% O<sub>2</sub> in our simulated flue gas experiments.

There is also considerable value in investigating DFM for producing products of higher value than methane such as methanol or higher hydrocarbons. Higher hydrocarbons also require pressurized processes to meet thermodynamic limitations. Another application would be catalytic dry reforming of adsorbed CO<sub>2</sub> on DFM with CH<sub>4</sub> or reverse water gas shift for CO generation for synthesis gas.

### **6.2.3. Life cycle and economic analysis of DFM**

A detailed life cycle analysis of our technology is needed to corroborate the sustainability of our technology. An equally important economic analysis is also in need to assure DFM's viability and future implementation. A feasible supply of renewable H<sub>2</sub> is still a major unknown factor in the application of DFM to power plants.

The variables of interest for the life cycle analysis include the ecological and carbon footprint of all the processes involved in the DFM implementation, from the catalyst, adsorbent

and carrier production processes and the source of hydrogen (from either renewable power or industrial origin) to the end-use of the fuels or chemicals produced with DFM. A comparison of the carbon footprint of the DFM technology with other known CCUS technologies is also of relevance.

For the economic analysis, it is important to calculate and model the capital costs and operating costs associated with DFM implementation for different CO<sub>2</sub> capture scenarios, the price of the raw materials, the cost of reactants like renewable hydrogen vs the cost of industrial hydrogen and the power requirements for the operation of any heat exchangers, chillers and compressors needed. It is important to consider the different products that can be made using DFM and their market value and demand. The revenues of the sale and distribution of these products could offset any economic burden associated with the implementation of the new technology.

#### **6.2.4. DFM aging in actual flue gas**

The most important technical challenge for DFM is to demonstrate and confirm its life in a real natural gas-fueled power plant or other CO<sub>2</sub> generating sources. This is currently a topic of discussion with Susteon, a US based engineering company with whom we are exploring funding sources for a scale up skid mounted pilot plant that can be used at various CO<sub>2</sub> generating sites.
